S. tigrina.—This is, perhaps, the best of the Stanhopeas. Its pseudo-bulbs are large, furrowed, and bear broad, massive, much-plaited, leathery, deep green leaves. Its racemes are many-flowered, and the individual blooms often measure from 7 inches to 8 inches across, and are powerfully perfumed. Sepals and petals spreading, the former much the broadest; ground colour yellow, heavily blotched and transversely barred with crimson-maroon. Lip rich orange at the base—in front creamy-yellow and white, and, together with the column, profusely dotted with rosy purple. It blooms during the late summer and autumn months.

S. Wardi.—The general appearance of this species is similar to that of insignis; raceme many-flowered and the flowers deliciously fragrant. Sepals and petals reflexed, rich deep golden-yellow, over which is scattered a profusion of crimson-purple dots. Lip paler, whitish in places, ornamented near the base on each side with two large velvety-purple spots, and freckled in front with purple. Its flowers are produced during the late summer months. Like S. tigrina, it is a native of Mexico. W. H. G.

Angræcum caudatum.—The genus Angræcum is peculiarly rich in species with flowers in which the spur is produced to an extraordinary length. A. sesquipedale is one of the most striking and best known of them. A. Scottianum is one of the rarest and most beautiful. A. Kotschyi and A. Ellisi have the prettiest little flowers with tails nearly 6 inches long; and in A. caudatum we have an equally remarkable species, the length of its flower-spur being second only to that of A. sesquipedale. It is a curious fact that all these long-spurred Angræcums are natives of Tropical Africa, the home of the ostrich and giraffe, or of Madagascar, where all sorts of strange animals and plants are said to abound. A. caudatum is now in flower at Kew, a healthy plant bearing a four-flowered spike, and by no means wanting in what is vulgarly known as beauty. In habit it is not unlike an Aerides, the leaves being strap-shaped, arched, and leathery. The raceme springs from near the base of the stem, and is zig-zag. The flowers are on pedicels 1 inch long, and when in bud, they look little, small, very long-tailed monkeys perched on the horizontal stalk. When expanded each flower has five long, narrow, reflexed green segments (sepals and petals), a pure white wavy-edged cuneate lip, the apex of which is produced into a long point, and a brown flexuous spur over 9 inches long, and as thick as whip-cord. The column is also brownish. This species is a native of Sierra Leone.—B.

Societies and Exhibitions.

CRYSTAL PALACE HARDY FRUIT SHOW.

October 6, 7, and 8.

A substantial prize list is sure to attract exhibitors to a London fruit or flower show from all parts of the country, and the Crystal Palace Company generally attracts a representative gathering of competitors to its shows, because it invariably offers good prizes. This week the annual show of hardy fruits and vegetables proved to be in no way inferior to its predecessors, and as the usual exhibition of Potatoes did not take place this year in conjunction with it, the fruit had undivided attention. Looking at the heavily-laden tables of Apples, one would scarcely suspect that the crop of these this year is generally a failure, and the high qualities, particularly that of size, seemed quite equal to the exhibits in the great Apple show at Chiswick two years ago. Exhibitors from all quarters of the country competed in the classes for Apples and Pears, and so numerous were they, that we roughly calculated that no fewer than 2000 dishes of these fruits were shown. Finer kitchen Apples could not be seen, but the coloration of the fruits this season is not so remarkable, and this, we believe, is the general observation throughout the country.

The principal and most coveted prizes were those offered for the best collections of Apples and Pears, the first prize in each class being £10. The finest collection of Apples was that shown by Messrs. Bunyard, Old Nurseries, Maidstone. This was a really grand display of fruit, such as would be difficult to beat in any season, however good the Apple crop may be. The collection numbered upwards of 130 dishes, representing as many varieties, and there was scarcely a poor dish among the whole number. The fruit was gathered chiefly from the vigorous cordons and pyramids which are such a speciality in this Kentish nursery. The kitchen Apples were of enormous size, and not a few would turn the scales on 17 ozs. or 18 ozs., particularly fruits of such weighty sorts as Warner's King, Lord Derby, Gloria Mundi, Loddington Seedling, Beauty of Kent, Lady Henniker, and Alexander. Other sorts, such as Peasgood's Nonsuch, though as much as 5 inches in diameter, were comparatively light. The collection comprised a selection of the leading kinds of both kitchen and dessert Apples. The display was rendered attractive by such high-coloured sorts as Worcester Pearmain, Early Strawberry, Duchess of Oldenburg, Alexander, Crimson Queening, Tom Putt, Cellini Pippin, and the golden and yellow fruits of Golden Noble, Lord Suffield, and Queen Caroline. Among the best dessert kinds shown were Kerry Pippin, Margil, Cox's Orange Pippin, Ribston Pippin, Golden Pippin, and American Mother Apple, and some very fine fruits of another American Apple called the Melon. The second prize of £6 was won by a Herefordshire grower, Mr. Watkins, of Withington, who had also a wonderfully fine collection, particularly remarkable for high colour. There were over a hundred dishes in the collection, and perhaps there were never exhibited finer fruits of such as Duchess of Oldenburg, Peasgood's Nonsuch, and Red Costard, a highly-coloured large, conical Apple not much known. The third and fourth collections came from Devonshire gardens, Mr. Sclater, of Heavitree, and Mr. Powell, of Powderham Castle. No fewer than ten exhibitors competed in this class.

The finest collection of Pears in the open class was that shown by Mr. Thomas's gardener (Mr. Butler) at Orchard Lane, Sittingbourne, who showed about 100 sorts, all good dishes, many particularly fine. The most prominent sorts either for large size or high colour were Pitmaston Duchess, Souvenir de Congrès, Durondeau, Duchesse d'Angoulême, Beurré Clairgeau, King Edward, Doyenné du Comice, Beurré de l'Assomption, and Conseiller de la Cour. Besides these were many other remarkable dishes, and a fine dish of Louise Bonne of Jersey was admired by everyone. A capital collection took the second prize. It was from Messrs. Rivers, of Sawbridgeworth. It contained some very large fruits, especially of Pitmaston Duchess, Magnate, and Princess, both new sorts. The other four collections

hown were good, but were not so numerous as the prize-winning lots. The finest twelve dishes of Pears in the amateurs' class was that from Mr. S. Ford, of Leonardslee, Horsham, which was excellent in every way. Large size and good colour was seen in each sort represented. The selection was King Edward, Durondeau, Uvedale's Saint Germain, Vicar of Winkfield, Beurré Clairgeau, Conseiller de la Cour, Marie Louise d'Uccle, Beurré Bosc, Duchesse d'Angoulême, Doyenné du Comice, and General Tottleben. The second best dozen Pears came from Preston Hall, Aylesford, Kent, and among them that fine-looking Pear, Brockworth Park, was shown in rare condition. There were also good dishes of those excellent Pears, Gansel's Bergamot, Beurré Superfin, Pitmaston Duchess, Beurré d'Amanlis, and Durondeau. The third collection came also from a Kentish garden, Bickley Park, Chislehurst.

The amateurs' class for Apples, twenty-four dishes and twelve dishes, were well represented, there being six collections of twenty-four sorts and nine of a dozen dishes. The judges had a good deal of difficulty in awarding the prizes in these classes, as some of the collections were so excellent. The first collection of two dozen sorts was that from Mr. Edwards, Shinghill, Hereford, who had a matchless collection. There were marvellous examples of the followiog sorts: Peasgood's Nonsuch, Bedfordshire Foundling, Potts' Seedling, Blenheim Orange, Lady Henniker, Wellington, Tower of Glamis, Cox's Pomona, Alfriston, Waltham Abbey, Gloria Mundi, Mère de Ménage, Emperor Alexander, and the Old and Red Costard. The second collection, from Mr. Ford, Horsham, was remarkable for large size and high colour, and scarcely, if at all, inferior was that from Mr. Waterman, who took the third prize. The best dozen dishes was that from Mr. Jones, Wallington Bridge, Carshalton. He had enormous fruits of Dutch Codlin, Blenheim Orange, Flower of Kent, Emperor Alexander, Wellington, Scarlet Nonpareil, and others, while the next best dozen, from Mr. Jacob, Petworth, was remarkable for the high colour of the fruits, the best dozen in this respect in the show. The sorts comprised the old Sussex Nanny, a capital dessert kind which should be more known; Lewis' Incomparable, Emperor Alexander, Cox's Orange Pippin, Cellini, Ribston Pippin, and Alfriston. There were large miscellaneous collections of fruits shown. Messrs. Veitch, Chelsea, showed a collection of 150 sorts of Apples and eighty sorts of Pears, all accurately named. Other collections were shown by Messrs. W. Paul and Son, Waltham Cross; Cheal, of Crawley; Paul, of Cheshunt; while the place was enlivened by a large display of Dahlias from Messrs. Cheal and Mr. Turner, and open-air Begonias from Messrs. Laing, Forest Hill.

Vegetables.—There were some half-a-dozen classes devoted to vegetables, including Pumpkins and Gourds. In the open classes there was one for the best exhibition of vegetables arranged for effect, £6, £4, and £3 being offered for prizes. There were three competitors, who each showed enormous quantities of vegetables arranged on slanting stages some 8 feet or 10 feet square, like the front of a greengrocer's shop. The "effect" was somewhat muddly, but the winner of the first prize did his best to display his produce to the best advantage, and it only needed a few Roses and Camellias carved out of Turnips and Beet to complete the show. We imagine that Mr. Waterman had examples, good examples, of every vegetable, salad, or herb that it is possible to get together from an October garden. He had, we should calculate, some fifty or sixty sorts in his group, and his fellow-exhibitors were not much behind him in point of numbers. In the amateurs' class for twelve dishes, there was a good display, eight collections being shown. The best, from Mr. Waite, Glenhurst, Esher, consisted of excellent dishes of Pragnell's Beet, Autumn Giant Cauliflower, New Intermediate Carrot, Prizetaker Leeks, Clarke's Red Celery, Perfection Tomato, Anglo White Spanish Onion, Wroxton Sprouts, Champion Runner Beans, Snowdrop Potato, and Student Parsnip. The second collection was unnamed, but a capital dish of Ne Plus Ultra Peas was noticeable; and in the third collection the best were May's Northaw Sprouts, Rousham Park Onion, Hackwood Park Tomato, and Moore's Cream Marrow. Among other collections conspicuous sorts were Sturdy and Ne Plus Ultra Peas, Perfection Tomato, Reading Russet Potato, Walker's Exhibition Sprouts, and Moore's Cream Marrow. There was a class for ornamental Gourds, in which two collections were shown. Mr. Osman, of Sutton, had the best, representing a full collection of all sorts, shapes, and sizes to be found among Gourds. The heaviest Gourd weighed 139 lbs, and was grown by Mr. Rodhourn, Croydon. The two next heaviest weighed respectively 119 lbs. and 101 lbs.

A list of prizes is given in our advertising columns.

GARDEN DESTROYERS.

THE WASPS AMONG THE IVY.

THE last few warm days—I am writing on October 4, and from East Anglia (see "A. R., p. 326)—have brought forth our old enemies in full force. Had the north-east wind lasted a little longer we should probably have been well rid of them for the season, but the returned warmth has endowed them with new life. It is fortunate the Ivy bloom was open to allure them from more valuable products, by its fulsome feast of not over-pure honey. The wasps for the nonce appear to prefer it to all else, and every bough and stem clad with Ivy in blossom is now filled with their presence and the loud hum and busy buzzing of their abnormal industry and activity. Scripture has it, "Go to the ant, thou sluggard; consider her ways and be wise;" but if there are any of the former about, they had better go to the Ivy-clad trees these warm October days, consider the wasps gathering honey, and learn to be busy and industrious. There is a reckless haste, a wild spirit about the wasps among the Ivy blossoms that is seldom or never reached on other feeding grounds. Whether they know that this is the last field of rich honey for the season, or whether the honey itself stimulates them to abnormal energy it may be difficult to discover, but of the fact there can be no doubt. The fact of their number and force is equally demonstrated by the abounding numbers found on Ivy at this late date, and after the quantity we have bottled off, and the fifty nests and occupants totally destroyed. On one tree, under which I stood a few minutes to-day, there must have been many thousand wasps; I was attracted by the sound from several yards off, and the whole tree and its immediate surroundings were more like a hive of bees on the swarm than aught else; only, that the bees were all wasps, or nearly so. The wasps among the Ivy are selfish monopolists, keeping all the sweets to themselves, and driving off by mere brute force of numbers all intruders on their preserve. I have often noted this on other occasions, and again to-day, that there seemed neither a honey nor a bumble bee among them. Someone has said that Ivy honey poisons wasps, which I doubt very much indeed. But it is "a consummation most devoutly to be wished," and might place us abreast on the list of privileges with those who are recording their experience from various quarters in such words as "few or no wasps."

D. T. F.

Sedums *v.* bees and butterflies.—It would be interesting to know to what variety of Sedum "D. T. F." refers when he says that bees and butterflies become stupified and poisoned while gathering honey from its flowers. We have often seen peacock butterflies basking on the bloom-heads of Sedum spectabile, but whenever we have approached them they very quickly took flight. Common hive bees, too, seem fond of the flowers of this Stonecrop, but in no case have we seen either bee or butterfly dead on or near it. In wet weather I have observed bees, as it were, drowned by the rain, but during this very fine autumn none are to be found in that state.—J. R. HALL, *Fox Warren*.

OBITUARY.

THE REV. CHARLES PIERPOINT PEACH.

THE REV. C. PIERPOINT PEACH, who died recently at his vicarage at Appleton, Yorkshire, was an enthusiastic and accomplished gardener. The innate love of the beautiful was developed in his case by his early surroundings, his father being a skilful cultivator of flowers and fruits in his pretty gardens and orchards at Holme Pierpoint, in Nottinghamshire, where he passed his childhood. He had a true appreciation of all the charming grace of trees and plants and flowers, but he paid special homage to the queen of the garden, the royal Rose, and was honoured accordingly with her smiles and honours. He was also most successful in his artistic arrangement of his summer garden, and none knew better than he how to cultivate and to group the varied tints of foliage and of flower. He communicated to others the happiness which he found in horticulture by his encouragement, personal, practical, and pecuniary, of cottage gardening, and by his establishment and institution of floral societies. Whether he appeared as patron, exhibitor, or judge, he was ever full of sympathy, energy, and zeal. In other departments of art the loving heart made the able hand, and in the restoration of two churches he executed an amount of carving, both in wood and stone, which will testify for centuries his clever and laborious handiwork.

"Charley Peach" had an extensive circle of friends, and was so highly esteemed by the clergy of the diocese in which he lived, that he was elected by them as their Proctor in Convocation.

In Mr. Peach and in Mr. Nethercote, of Moulton Grange, Northamptonshire, we gardeners have lost two of the most devoted, most genial, most highly gifted of our brotherhood.

Friend after friend departs.
Who hath not lost a friend?
There is no union here of hearts
Which hath not here an end.

An end *here*, but no end hereafter—no end in "Paradise Regained" S. R. H.

Names of plants.—*C. M. Owen.*—Clematis connata (syn., C. amplexicaulis, C. velutina, C. gracilis) as near as we can make out. It is a native of temperate Himalaya, and is a large woody climber; leaflets three to seven, ovate, coarsely serrate or lobed; flowers in many-flowered panicles, sepals pubescent ontside, tomentose inside, not ribbed, filaments hairy, achenes white, silky-pubescent. You will see if this description fits your plant. You might try layering or grafting on to the roots of some other kind, or on its own roots, if they are strong enough. So far as we know, the species is not known in gardens.——*D. D.*—Sarcanthus recurvus.——*Annette S. W.*—Menziesia polifolia alba; the pink flower is M. polifolia.——*Multum.*—Tricyrtis hirta.——*Penrhos, Carnarvon.*—For Diplacus, see Mimulus.——*Mr. Fox*—Chelone obliqua.——*J. S. Cattley.*—Mespilus grandiflora, also called M. Smithi.——*J. D. Manscaven.*—Yellow Sternbergia lutea, other is Fragaria indica.——*C. J. H.*—Apparently a species of Carya; we may be able to identify it by next week.——*T. H. Archer-Hind.*—Cyrtomium caryotidium.——*F., Brighton.*—1, Dictyogramma japonica; 2, Asplenium Colensoi; 3, Cyrtomium Fortunei; 4, Polystichum, specimen insufficient.——*A Mizen.*—Apparently Père Delaux.——*Miss Dennison.*—Rosa mollis, a true species.——*Mrs. Newbolt.*—Double-flowered variety of Rosa lucida, native of United States.——*H. Kruse.*—Cattleya Loddigesi.

Naming fruit.—*Readers who desire our help in naming fruit will kindly bear in mind that several specimens of different stages of colour and size of the same kind greatly assist in its determination. Local varieties should be named by local growers, and are often only known to them. We can only undertake to name four varieties at a time, and these only when the above condition is observed. Unpaid parcels not received.*

Names of fruits.—*H. J. R.*—Resembles Pomme de Neige or Snow Apple.——*Novice.*—Your Apple is not recognised; does not seem worth growing.——*Bodger.*—Beurré Diel.——*W. Ruse.*—1, Emperor Alexander; 2, Cox's Orange Pippin; 3, Keswick Codlin.——*R. E. Batten.*—1, Sweeney Nonpareil; 2, Brabant Bellefleur; 3, Roundway's Magnum Bonum.——*A Subscriber.*—1, Swan's Egg; 2, Bishop's Thumb.——*M. W.*—The large Pear is Beurré Bachelier; the small, Thompson's.——*W. C.*—1, Hampton's Bergamot; 2, Glou Morceau.——*T. A. Neil.*—White Buckland.——*Enquirer.*—Your Apple is not known—seems worthless.——*Igno.*—Beurre Charneuses; 2, Napoleon; 3, Van Mons Leon Leclerc; Apple, Braddick's Nonpareil——*A. Godfrey.*—Pear, apparently Williams' Bon Chretien, but too much decayed to identify clearly. Other fruits will be named next week.

WOODS & FORESTS.

THE MANAGEMENT OF WOODS.

"Yorkshireman's" remarks upon this subject are to the point. What the reason is that there are so few really competent foresters is a question requiring careful looking into. In the present day, when there is so much competition for almost any post, at the first sight it appears strange that few go in for the business of forester, except as a kind of appendage to some other branch of employment. This being the case, there is no room for wonder that much of what by courtesy is called forest management is done in a very slipshod fashion. Unsatisfactory as this is, there is little room for surprise that matters are in this position, and there is little reason to hope that any great alteration will take place in the immediate future. The real explanation of this I take to be in the fact that the prizes in the ranks of foresters are not sufficient to enlist men of more than moderate ability. When it is considered what the extent of knowledge is, both scientific and practical, required by an individual to be fairly classed as a competent forester, and, on the other hand, to what point of eminence it is possible to rise—that is, in the sense of gaining a competency—there is no room for surprise that more are not found in the field. To be anything beyond a mere woodman, the forester must possess, besides a good elementary education, a knowledge of geology and chemistry, and have considerable skill in drawing. He must be a botanist, an entomologist, and be able to apply his knowledge of these subjects in a practical manner, and be well up in the economic values of the products of which he has charge, and all for the pay of an ordinary mechanic.

From this point of view it is of little use to urge that many of the studies are in themselves recreations, as, however true it may be, when it is looked upon as the serious business of life, it assumes a very different aspect. It must not, however, be inferred from these remarks that I wish to imply that foresters as a class are badly treated by their employers, as on the whole I believe the reverse to be the case, but rather that the small chances of rising to any very high position whilst following the profession lie more in the fact that profits derivable from woodland is insufficient to admit of any great progressive increase of salary to permanent foresters.

If, then, this is the real truth about the matter—and it cannot be expected that men who see their way to more lucrative professions will qualify for such posts which from time to time become open—we are face to face with the question, whether our forests and woodlands are to remain in practically their present condition. If not, who can be got to undertake the higher branches of the work? To this the answer is, that owners themselves as a body must take a deeper interest in their woods. On the large estates where this would be impracticable the few competent foresters are in most cases found, as the salaries are naturally higher, and it is the smaller places which constitute the bulk where the imperfectly trained men are to be met with. As it has been urged, it is very improbable that these latter posts will ever be filled by men who have been very highly trained; therefore, if a change is to be effected, it must be by those who alone can give sufficient study to the subject, viz., the owners or prospective owners. If this was taken to heart, it would not be long before an appreciable difference would be seen, as to men who, from the nature of their position, will naturally have received a liberal education and be grounded in most of the subjects of which it would be necessary to have a knowledge, it would be much more easy to follow this up in a practical manner than it would be to the man who has to fight his way up from the ranks and acquire as he goes along the elementary knowledge which the other already possesses as a part of his ordinary education.—Forester.

—— I read with interest the remarks at page 327, but I cannot altogether agree with the writer. I admit that gardeners understand the rearing and nursing of young trees, but I fear that it would be a failure to attempt to put them in places which foresters ought to fill. Although a thorough gardener may possess practical or theoretical knowledge, I contend that he is unfit for a forester. A forester now-a-days ought to be a man not only possessing a knowledge of chemistry, geology, entomology, and botany, but he should possess a good knowledge of estate carpentering, land-surveying, valuing of timber trees and coppice woods, besides a thorough knowledge of saw-mill management. I do not think the man who has been brought up in a garden could grasp the subject of valuing, and other points, so soon as "Yorkshireman" imagines. Forestry is still in its infancy, but landowners are alive to the fact that their woodlands must be put under proper management. They want men who understand this, and be able to instruct practically how timber should be felled and converted. I believe a gardener would require a second apprenticeship before taking the place of a forester. Before long we shall have some young men ready to accept situations as practical and theoretical foresters. Your correspondent seems to treat the subject of valuing as of minor importance. I believe it to be of the greatest importance, as frequently we have found timber valued too high, and in some, and not a few, cases too low. Again, timber is grown for useful purposes and not for ornament only, and men are wanted who have been trained foresters and not gardeners.—Omega.

—— Much has been said and written lately about the management of woods, and also upon the establishment of a school of forestry in Britain, and many sensible suggestions have been made. Great Britain itself contains an ample forest area, with sufficient geological variation as well as of climate, that any school for the teaching of practical and scientific forestry could require. The vast extent of the royal forests and of private estates in this country affords an ample field for the study and practice of forestry in all its phases. Were the nucleus of such a school placed contiguous to some large forest, such as the New Forest, in Hampshire, a wide field would be at hand for immediate instruction, and easy excursions could be made into other parts of the country for observation, comparison, and study. There can be no doubt that a school of forestry at home is greatly required for the development of arboriculture as a science, and its intelligent practice as an art. The many examples of mismanaged woodlands scattered over the country strongly testify to the necessity for better instruction in their cultivation and management; and I hope landowners will bestir themselves to establish a school of forestry at home, which would be so much for their own advantage.—A. P.

THE AXE IN TREE-FELLING.

That the axe should be the favourite tool with woodmen is only natural, seeing that its use is a much more exhilarating occupation than the cramped position one is obliged to assume in working a saw in the operation of tree-felling. This renders it the more necessary that a proper supervision be exercised when felling is going on. In different districts the extent to which the axe is used varies, as well as it does amongst individuals. I have often had to keep a sharp eye to this when employing men in places with which I was unacquainted. This is especially so with plantations of Fir poles. In some counties the woodmen seem to be in the habit of using the axe alone for trees up to a size of 6 inches or 8 inches diameter. For very small poles to use the axe is certainly the most expeditious plan, and for anything under say 4 inches diameter at the butt there will not be enough loss of wood to give room for serious objection, but above 4 inches diameter I look upon it as a wasteful method if the trees are not sawn. Two or three blows from an axe of a man in advance will be enough to prepare these smaller trees for the men who follow with the saw, and if this double operation costs a trifle more than felling entirely by the axe, which is doubtful, it will be more than repaid by the saving in timber.

With regard to larger trees which no practical woodman in this country would ever attempt to fell with the axe alone, it is capable of being abused, both by being used too little or too much. When used too little upon trees to be felled by the saw, the trees are liable to become torn at the butt. This not unfrequently occurs. Ash and other woods of a nature susceptible of being easily split require the most care in this respect, as I have often seen a tree damaged to several times the cost of felling by the neglect of having a proper "fall;" or, in other words, owing to being insufficiently hewn on the side towards which it was intended to be thrown. On the other hand, I have seen trees hewn to such an extent before the saw was applied as to cause a serious loss through the waste of wood in chips. Properly balancing the extent to which the axe and the saw should be used in felling is a matter which requires more judgment than would on the moment appear, and, like many other operations, is a thing which can only be acquired by practice. Even this is not always enough, as particular systems of work seem to be handed down from generation to generation, and these are not unfrequently systems of doubtful merit. Generally, I take it, as I have said, that for anything above 4 inches diameter at the butt the saw as well as the axe should be used, and for larger timber, if waste is to be avoided, the swelling of the bole just above the ground-level should not be reduced by the axe to a smaller size than the normal part of the trunk just above the point where the hewing in preparation for the saw commences. There will be, of course, here and there a case where this rule must be departed from, as trees do not all grow upon a single model, but in nine cases out of ten it will hold good. The saw is a comparatively harmless tool, and the chief thing to be observed in using it in tree-felling is to keep it as near as possible to the ground.

D. J. Y.

UNSKILFUL TREE PRUNING.

I have been more than ever impressed by the effects of indiscriminate pruning on an Oak wood here. The trees in question seemed to be very fair specimens of hedgerow timber, perfectly clean in the bole for some 6 feet or 8 feet, at which point the branches began. In the felled trees the places from which these large branches had been removed appeared to be perfectly sound, but when the boles come to be cut into sections a very different scene is presented, and only those who have had to deal with it can understand the perplexity it causes to have from a single dead knot to 2 feet or 3 feet of virtually rotten wood situated in the centre of a scantling which is required for a particular purpose and must be of a given length or size. This is just what happened in the case of the Oak trees I have mentioned, and whilst perhaps nine-tenths of the whole bulk was good sound wood—very often of really superior quality—the trees had to be discarded, and a loss of timber of from 25 to 50 per cent. sustained, simply because some ill-advised individual had perhaps half a century ago tried his skill at removing branches from the then young trees. It is impossible to form a just estimate of the loss which annually accrues from this one cause alone, but from my own experience I well know it amounts to a large sum.

Most trees suffer more or less, but the Oak is peculiarly open to damage, and from the form which the decay generally takes it is more serious than with almost any other. In Ash, reckless pruning often develops very bad knots and bad wood, but in Elm, though knotty wood is of relatively much less value, it is not often that it is made entirely useless. In touching upon the damage to Oak I do not refer to shakes and the like which are inherent to the tree, but simply unsoundness, which is to a large degree preventable. Pruning off small branches carefully when the trees are very young will not, as a rule, cause any practical damage, but when the limbs assume any considerable size, such, for instance, that they cannot be readily removed by the knife, pruning will assuredly be detrimental. If from any cause the cutting away of any large branches becomes imperative, I would rather sacrifice the whole tree than mutilate it and let it stand. This may be looked upon as rather severe, but it is infinitely better than allowing it to grow on and produce worthless material. It may be argued that it is seldom that the loss, when unsound wood occurs quite in the centre of the tree, falls upon the seller, but I cannot believe that the majority of producers would counten-

ance what now is chiefly an unconscious fraud if they were fully alive to the means of prevention.

D. J. Y.

SEASONABLE WORK.

Covert Planting.

Now is the time to form new shrubberies for covert, and in cases where the soil is of a poor, hungry nature, a mixture of soft earth, peat bog, or well decomposed vegetable mould, mixed with the soil at the time of planting, will be useful. As a general rule, most evergreen shrubs luxuriate in well decomposed matter, so that such may be applied to poor thin soils of an opposite texture with great advantage, and will have a wonderful effect on the health and vigour of the plants so treated. Transplant and renovate old shrubberies where necessary by cutting off all dead and decayed wood, and such plants as are falling into an unhealthy condition should be examined, and a proper remedy applied to save them without delay. In nine cases out of ten the cause of failure will be found to be either poverty of soil, hard impervious subsoil, or want of thorough and efficient drainage, all of which causes the cultivator can combat by timely and judicious remedies properly applied and within the reach of every one. In forming coverts care should be taken to introduce a liberal quantity of berry-bearing shrubs in order to give a supply of food for game. Plant each species and variety on the class of soil (as far as possible) most conducive to their nature and requirements, which will be a great means of attaining success.

Where open spaces occur here and there in deciduous plantations a few common Silver Firs might be planted in such with advantage, using good-sized bushy plants prepared in the home nursery for that purpose. This tree thrives exceptionally well in such places, retains its side branches, and affords cover and shelter during winter when the deciduous trees are stripped of their foliage. The sites for the trees should be well prepared by trenching a circular piece of ground not less than 6 feet in diameter, and extracting all roots and dead timber in order to render the ground pure and clean for the reception of the trees. It is sometimes necessary to cut a narrow, deep, circular trench around the newly planted tree, and allow it to lie open for a few years in order to prevent the roots of the old trees in the vicinity from exhausting the soil at the root of the young tree; but as soon as the latter is established, the trench may then be filled up.

Where it is desirable to extend the present coverts by means of layering, such work should be done and finished without delay, and in order not to disturb the game, or at least as little as possible, the different groups should be gone over by rotation, as may be found most convenient to all interested. Brittle wood that is apt to break when cut by the knife may be twisted and the bark ruffled; then by fastening them firmly down with a hooked peg and covering them with a few inches of soil, they will be found to emit roots and answer the requirements necessary.

Tree Planting.

Push forward the preparation of ground for new plantations by draining, fencing, and opening pits of sufficient size for the trees to be planted, and in all cases where the subsoil consists of hard till, have such well broken up, which will not only be favourable to the young plants at the outset, but will also have a decided effect on the healthy development of the trees in after life. On exposed situations near the seaboard, barren Heather moors, and bleak peat bogs, a screen fence erected on the most exposed points of the plantation is a great aid in the way of procuring shelter for the young trees. Such a screen fence may be erected by planting a line of wooden posts along the line of fence about 6 feet apart; then by stretching four horizontal wires along the fence and attaching them securely to the posts, and warping branches through the former, a useful and efficient screen fence can be erected at small cost. In cases where it was not convenient to procure branches, Heather and Bog Myrtle warped through the wires answer the purpose admirably. In cases where the fence is not to be of a permanent natnre, the size of the wire used may be No. 6 gauge, which will be quite efficient for the purpose. The posts may be made from young trees, the thinnings of young plantations, tree tops, or other wood of little value; efficiency and economy should always be the forester's consideration.

Plant out Coniferæ and other ornamental trees and shrubs as standards on the lawn and elsewhere as may be wanted, and in lifting the plants use digging forks with steel prongs in preference to spades, which will lessen the risk of cutting and destroying the roots in the course of removal. When planting the trees, it is a matter of vital importance for their success in after life to have the roots spread out in a regular manner from the base of the stem. Carelessness in this respect is sure to be the forerunner of serious loss and disappointment, so that great care is necessary to see that the work is properly executed. Stake, tie, and fence the trees according to their requirements, and finish by giving a good mulching in order to prevent too sudden evaporation. Look over standard trees and see that their wants are attended to in the way of staking, tying, and fencing. Plant hedges of Thorn, Beech, Privet, &c., where they may be wanted, using stout, well-prepared plants with bushy roots.

Nursery.

If not already done, finish putting in Evergreen cuttings without delay. The planting of two-year seedling or bedded Scotch Fir and Larch into nursery rows may now be done advantageously; likewise plant in the same way other hardy species of young Coniferæ, as well as other well-rooted plants raised from cuttings, as they will soon take to the soil at this season, and will not be apt to be thrown out of the ground during winter by frost. Seedling Hollies, Berberries of sorts, Rhododendrons, &c., may all be treated in the same way. Collect tree seeds as they ripen, such as Horse and Spanish Chestnuts, Walnuts, and Oaks. These may be sown at once on well-prepared ground, not of too heavy a texture, in good condition, and free from weeds. The seeds of Beech, Maples, &c., had better be kept till sowing time in spring, as the plants are apt to suffer by spring frosts when the seeds are committed to the ground in autumn. Collect the cones of different species of Picea and other kinds that ripen their seeds in autumn; choose a fine day for the purpose, and store them away in a dry place till wanted in spring. Haws that have been kept in sand-pits for a season should now be sown on well prepared ground, choosing a fine dry day for the operation. All unoccupied ground should be dug up into rough ridges to keep it dry and admit the influence of frost during winter, but in cases where the soil has become exhausted, a dressing of well-decomposed manure mixed with the soil at the time of digging will be beneficial. Turn over and prepare compost-heaps to induce decomposition, so that the stuff may be ready for use when wanted.

Trees in Tredegar Park.—In this beautiful Monmouthshire park there are very fine trees, chiefly Oak, Elm, and Ash, but I think the most imposing are those in the old avenue of Sweet Chestnuts. It is thought that this avenue of trees at one time led to the ancient residence, Tredegar House, but years ago there was a new road constructed leading from Newport to Cardiff which divided the avenue. The trees are many in number, and even the smallest of them is no mean specimen. I give you dimensions of three of the Tredegar trees: No 1, circumference 19 feet; No. 2, 18 feet; No. 3, 15 feet 10 inches, 5 feet from the ground. They average from about 40 feet to 50 feet in height to the topmost twig, but in the bole they only average about 14 feet to where the first limb spreads. The situation is low, and the soil is a sandy, loamy clay. I know of no better timber for gates and posts than that of the Sweet Chestnut. A post which has been standing for the last forty years is perfectly sound. We have also sold it for chair-making and for many kinds of scantling; in fact, it is a most durable timber for almost any purpose. We have found Sweet Chestnut growing and doing well in many different soils and exposed situations. We once felled some very fine trees growing in a marly stony soil on red sandstone, the timber of which was very hard.—Young Forester.

AMERICAN PINE TIMBER.

Fir timber of coniferous trees coming from America is distinguished in the market from Baltic timber by being termed Pine instead of Fir. The different kinds imported are known as Yellow Pine, Red Pine, White Pine or Spruce, and Pitch Pine, according to the nature of the wood, and they are mostly classed as first, second, or third quality, without, however, any distinguishing marks. The chief ports for American Pine timber are Quebec and St. John, the best Yellow Pine being shipped from the former, and the best Spruce from the latter.

American Yellow Pine is the product of the Pinus Strobus, or Weymouth Pine, a very different tree from the Pinus sylvestris, or Scotch Fir, which supplies the Baltic yellow deals; moreover, the term "yellow" is only applied to this wood in our markets; in America it goes by the name of "White Pine." It can be purchased in balks up to 60 feet or 70 feet in length and 24 inches square; it is not so strong or durable as the American Red Pine, but is much lighter, and is, therefore, readily distinguished in the floating docks by the height it stands out of the water. It is not much used in large scantlings in England, but is largely purchased as planks and deals, for it is admirably suited for all kinds of joinery, being remarkably free from knots, and very easy to work.

American Red Pine is the wood of the Pinus mitis, which is called in America the "Yellow Pine," and very closely resembles the wood of the Scotch Fir, though it does not equal it in either strength or durability, nor does it grow so large as the Dantzic and Memel timber, though it is said to be slightly stiffer. Being very straight-grained and free from knots, it is valuable for joiners' work where a stronger wood than the Yellow Pine is required, but it is not so much used in England, in consequence of its being more expensive, in proportion to its quality and size, than Baltic Fir. American White Pine or Spruce is very similar to Baltic white timber, but, not being considered equal to it in durability or strength, does not command a large sale in our markets. It is the produce of two different trees, the Abies alba or White Spruce, and the Abies nigra or Black Spruce, so named from the colour of their bark, though the colour of the wood is in both cases white.

The Black Spruce timber is much better than the white, besides being more plentiful and growing to a larger size. Pitch Pine is the produce of the Pinus resinosa, and it comes from the United States of America, but chiefly from the ports of Georgia, Savannah, and Pensacola. It is, on account of its dark grain, coming much into use for treads of stairs, framing of doors, and other purposes, when varnish instead of paint is to be used. The wood is heavy, sticky, and is as difficult to work as Oak, but the great quantity of resin which it contains—though it clogs the plane, and so adds to the difficulty of working it—renders it very durable, especially when exposed to damp and water; but if cut from the trees which have been recently tapped for turpentine, the durability and strength of the timber is much reduced. The wood is very free from knots, since the tree runs up to a great height, only throwing out branches at the top.

Government tree planting.—Her Majesty's Commissioners of Woods and Forests propose carrying forward planting operations on the waste Crown lands in the Isle of Man on a large scale. Messrs. Dicksons, of Edinburgh, are to supply forest trees for this purpose.

Guides in the forest.—It is a fact that Mosses, owing to their love for the shade, invariably grow on the north side of the tree. Two other rules useful to persons who have lost their way in a forest are (1), the limbs of a tree are generally larger, while the bark is rougher and considerably thicker on the south or sunny side; (2) the shadow of the trees also form a most reliable guide. Early in the morning the shadows are very long and point west. In the middle of the forenoon they are as long as the trees that make them and all point north-west, and at twelve o'clock they are very short and point due north.

No. 718. SATURDAY, Oct. 16, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

MISDIRECTED TIDINESS IN GARDENS.

WE all know the melancholy story of "Ixion, the Scapegrace," who, for his delinquencies, was condemned to be tied and tortured on a wheel, and there are, I am sorry to say, a good many horticultural Ixions, especially in public parks and gardens, who at this season must perforce offer up some sacrifice by way of propitiating the false idol, Tidiness. Whether dead and bleaching stalks of Lily or Delphinium are less attractive than earth scraped bare, I need not now stop to inquire, since it is a question which every owner of a garden, or now and then a gardener, may settle for himself or herself, as the case may be. Of one thing I am perfectly assured, and that is that many bulbs, often rare and beautiful, and not a few herbaceous plants are far less hardy if their old flower-stems are torn away at this rainy season than they would be if the same were left until the genial days of spring. Just at this time, or a little later, is the harvest-time of the jobbing gardener, who wanders from door to door with rake and spade. His mission is to "do up the garden," a mission which he carries out with an earnestness worthy of a better cause. Of course, every owner of a garden may "do as he likes with his own," just as some people get their "old masters" cleaned and re-varnished now and then for state occasions; but anyone who knows something of the natural beauty and usefulness of bare stalks and stems, albeit bleached and bare, must shrink from contemplating the tearing, pruning, and delving which too often form the work amongst hardy flowers during October and November. Quibbler says, a garden "ought to be clean and tidy," and yet he is always complaining that this bulb or that, which cost him many shillings, has failed to appear in the spring. Only the other day I explained to him that if he pulls up an old flower-stalk from a Lily or other bulb, that he leaves a nice little earth-tube right down into that Lilium auratum vittatum for which he paid a guinea last spring. The heavy rains of autumn trickle down the hole, and the interest on his capital goes, even if now and then the principal does not also vanish. "Well, I'll drop dry sand in the hole, or I'll cut off the stalks at ground level," says he, and so the matter ends in a compromise. But I know one garden from which no dead stalks are ever removed in autumn. "There they stand, 'bleached and bare,'" says Quibbler, and I assent to his interpolation. But what happens? The autumnal leaves are whirled around those old stalks and stay there in light fleecy masses locked in among the uprising stems, and neither rain nor frost penetrates to the scaled bulb or tender root beneath the soil. You inspect the borders on a frosty morning, and every dead stem is covered with hoar-frost, and sparkles as brightly as if set with brilliants, while every rare bulb and root below is warmly and securely thatched with leaves. This is no new idea, no new-fangled notion, no theory, but practice as old as the hills, it having been Nature's plan of protection originated at and adopted since the beginning. My dear old friend Quibbler is irrepressible. He says that as dwelling-houses are not built so as to resemble the natural rocky caves or primitive dwellings which they now supersede, so also should the garden have a neat and tidy appearance, and should not resemble a wilderness or a jungle! If mere appearance was at the root of the matter, I should agree with my friend no doubt, but as a gardener I was taught to value mere appearance only as secondary to the real welfare of the plants under cultivation; and if real welfare is the primary point, then the leaving of old stems and scapes is not only natural, but beneficial. If there is to be any pruning, or digging, or clearing up generally, it may be done now, but this does not prove that it would not be better if deferred until the time of budding growth in spring. If it be true that "a living donkey is better than a dead lion," it is also possible that even bare stems and stalks may some day be considered to be more interesting than the area of bare soil exhibited during the winter season. I do not wish to press the point, but if it be true that "anything is better than nothing," then I urge that dead stems have a distinct use always, and at times some beauty that should, when practicable or not undesirable, be spared.

VERONICA.

INDOOR GARDEN.

EARLY CAMELLIAS.

CAMELLIAS are sometimes induced to bloom in October and November, but most people find them to be most useful when brought into flower in December. Chrysanthemums are our best October flowers, and where quantities of the best of these are grown, Camellias would not be appreciated. As soon, however, as Chrysanthemums cease to be gay, which is generally in December, Camellias should take their place, and their large showy flowers never fail to be attractive. Most people know how valuable they are at Christmas for decorations of all kinds. December is, however, still early for Camellias to flower in quantity; many of them, indeed, do not open their blooms until well into spring, but there is no time when they are more appreciated than during December and January, and all who possess a few plants should strive to have some of them in bloom at that time. Those who are well acquainted with Camellias know that it is difficult to force them into flower like many other plants; they have a decided objection to much fire-heat, and the flower-buds swell quicker in a cool atmosphere than in a hot one. Indeed, those on which the buds were formed in August or September, and which are now being kept close and warm with the view of having them in bloom early, will most likely drop many of their buds prematurely and others will fail to open well, but if kept in a temperature not exceeding 55° or 60° at most, and if air is admitted freely, it is astonishing how rapidly they will swell up. This is the kind of forcing which agrees with Camellias better than being kept in a warm, close place, and a bracing atmosphere will always develop their blooms better than a stagnant one. I do not think our Camellias were ever more promising as regards a display in December than they are at present, and they have seldom had so much fresh air in September and the fore part of October as they have had this autumn. I find that they will bear a temperature of 65°, provided they are not shut up in it, but when that happens the buds are certain to fall off before opening. It is also of the utmost importance that they be well watered at the root, the soil being kept in a constantly wet and sweet condition, as root dryness is ruinous to them. Where the plants are in pots and can be shifted about freely, it will be found that their flower-buds will swell rapidly in a vinery from which the fruit has been cut, but where there is a constant circulation of fresh air and a little fire-heat. The foliage of Camellias often becomes covered with a sooty-looking deposit, and when that is the case it should be sponged off before the plants begin to blossom, as nothing detracts so much from the appearance of Camellia blooms as dirty leaves, and it is impossible to clean them after the blossoms have opened without injury to the petals.

CAMBRIAN.

WINTER-FLOWERING PLANTS.

BEGONIAS.—Than these, few plants are more easily cultivated, and none are more free or continuous bloomers. No varieties with which I am acquainted are of any service during the winter in a greenhouse, but there are plenty available for ordinary plant stoves, or any house in which the night temperature does not often fall below 50 or that of the day below 60°. When we had fewer stove plants than we have now, Begonias were more extensively grown; they are easily increased, and a house completely filled with them presents an almost unique appearance in mid-winter. We treat Begonias more as annuals than perennials, as we find young plants, whether raised from cuttings or seed, to be better than old plants, unless exceptionally well cared for. Our Begonias are kept on shelves in forcing houses or in warm pits, and are introduced into the Melon and Cucumber houses according as these are cleared for their reception. We find the majority of flowering Begonias to delight in a rather dry atmosphere, many of the flowers either damping off or dropping badly when much moisture abounds in the house. Plenty of fire-heat and a good circulation of air are what they require, and, other conditions being favourable, they well repay for any extra trouble that may be taken with them. B. semperflorens is perhaps the most valuable winter-flowering variety we have. It produces a continuous supply of beautiful white blooms, and may be employed effectively in various ways. This and any of the coloured varieties of it, such as rosea and gigantea, are best raised from seed every season; seedlings grow more strongly, are more branching in habit, and produce much finer bunches of bloom than older plants. Seed germinates readily in heat, and seedlings raised in March or April can be grown to a large size by the present time. In many gardens we see this class of Begonia standing about in out-of-the-way corners and in a half starved condition, whereas if the old plants were divided and repotted in good peaty soil they would grow strongly and produce flowers fit to be seen. It is not yet too late to give a shift to small Begonias of any kind, and it is useless to attempt to cultivate them satisfactorily in small pots. B. Carrierei (white) is quite a gem among winter-flowering Begonias, and very attractive at all times. It is really too floriferous, the greatest difficulty being experienced in procuring cuttings suitable for growing into useful sized plants. Some of the newly rooted young tops will push up strongly from the base, but with us fully one half refuse to do this, and only a single naked flowering stem is the result. Next season the whole of our plants of this variety will be raised from seed, of which abundance will be found on old plants. Its habit is dwarf and neat, and it does well in 5-inch pots, for which shelves are the best position. Moonlight is also a pretty and neat white-flowering variety, but I prefer B. Carrierei. One of the latest additions to our list of small varieties is B. Martiana gracilis. This produces erect branchless stems and a never-failing succession of charming reddish pink blooms. Clusters of bulbils are formed at every joint, and these, sown like seeds, soon develop into little plants. During summer and autumn it is most suitable for greenhouse decoration, but requires a little heat in winter. B. Ingrami is the best of the coloured compact-growing varieties. Capital plants of it can be flowered in 6-inch pots, or it may be grown to a much larger size in larger pots. During the summer and early autumn months it may be grown in sunny pits, and in order to have bushy plants of it they must be pinched back occasionally. During winter it blooms abundantly in gentle heat; small plants of it are much liked for house decoration, and we also cut the flowering shoots freely for vases, more shoots following quickly in abundance each time the plants are cut over. B. fuchsioides succeeds under precisely

similar treatment, or it may be grown tall; liberal shifts encourage the formation of strong branching suckers. B. erecta multiflora, a strong upright-growing variety, is very serviceable during winter. It should not be stopped many times, the aim being to get a few strong branching leading shoots; these produce a long and abundant succession of reddish pink blooms. During summer the plants can be prepared in a warm greenhouse, and we have had them 2 feet in height and upwards, and one mass of flower at Christmas. B. nitida is a fine variety, and particularly well adapted for the background to a group of plants, or it may be mixed with other plants without being injured. It attains a height of 4 feet, and, being naturally branching, should not be stopped after three or four shoots are secured. We sometimes flower plants of it with a single stem in 6 inch pots and bushy plants in 10-inch pots, and if well attended to they produce extra large panicles of pink flowers continuously. B. odorata, or as it is also termed B. suaveolens, much resembles B. nitida in habit, but it is not such a strong grower; the flowers, too, are smaller, pure white, and sweet scented. This nitida, fuchsiodes, Ingrami, and erecta multiflora succeed admirably when planted out against walls or pillars, in plant stoves, or other moderately warm houses, and thus treated they afford abundant supplies of cut flowers for home use. If good fibrous loam is available this may be employed in composts for Begonias at the rate of two parts to one of either peat or good leaf soil, or a mixture of both, and to this should be added plenty of sharp sand and charcoal, if it can be had. The small black fly is the greatest enemy which Begonias have, and this, when firmly established in the flowers, is very difficult to exterminate. Gentle fumigations with Tobacco paper are the best remedy, though much may be done with Tobacco powder.

Euphorbia jacquiniæflora.—If cuttings of this brilliantly-flowered stove plant could be struck with greater certainty than they are, many more plants of it would be grown than is the case in most places. Sometimes they strike freely; at others, under precisely the same treatment few or none will grow. In one place that I held, we grew large quantities of this Euphorbia, and they were never out of the Pine stove beyond the time taken up in repotting them; short cuttings taken off with a heel were dibbled thinly into 4-inch pots filled with light loamy soil, and kept in a close propagating frame till rooted. As a rule, three or four cuttings were struck in each pot and these were not separated. They were first shifted into 6-inch pots, and before they were badly root-bound the strongest were placed in 9-inch pots. Only clean, well-drained pots were used for them, and the compost consisted of two parts turfy loam to one of peat, to which was added plenty of silver sand and mortar rubbish. In some few cases the plants were allowed to develop unchecked in any way, and grand wreaths of bloom they produced, but smaller sprays were more in demand, and these we secured in abundance by simply bringing the points of the leading shoots down to the base of the plants. The easy curves thus formed caused the partially matured growths to break at six or more joints, each break developing into a fairly strong flowering spray; the points of the twisted branches also flowered. This I found to be a better plan than frequent stopping, and we still adopt it. Strong old plants that have been cut back and repotted are frequently very serviceable, while those planted out in a shallow border and trained where they can receive plenty of heat, sun, and air are when in bloom wonderfully effective. They must all be very carefully watered, the roots being most delicate, and very little liquid manure is needed. When grown in a high temperature and fully exposed to light and sunshine, this Euphorbia forms short-jointed, stout growths, and if induced to push out back growths either by cutting in the flowering portion or by bending the shoots down to the pot any time during winter, they will also flower. If there is a dry corner in the house, this should be devoted to the Euphorbias, as they delight in a rather dry atmosphere. Their flowering sprays in a cut state are very beautiful and durable. The smaller ones are suitable for ladies to wear, while long lengths properly wired may be coiled round the base of candlesticks or stands on the dining-room table, and there are other ways in which they can be effectively employed where the decorations are principally on the cloth.

Cyclamen persicum.—In very few private places are Cyclamens to be seen in good condition, or at all approaching the grand plants of them that are sent to the London and other markets. As a rule, too many matters need looking after just when the Cyclamens are most in want of attention, and, in addition, few have proper facilities for their culture. Not liking to be beaten with them, I tried what I believe to be a new departure in regard to them. Many will agree with me that the seedlings are most frequently ruined when in a young state, or, say, while they are in 2½-inch pots. When set on dry shelves or other exposed spots in a warm house after they are potted from the seed-pans they soon come to a standstill, and the tiny corms harden, never again to properly expand. Sometimes they are safely carried over that stage, only to be spoilt later on in a hot and dry pit or frame. Those who will follow my advice may easily guard against either contingency. Supposing the seed to be sown at the present time, or, better still, early in December, it should not be placed in heat till the commencement of January, when it will have either germinated or swollen considerably. This ensures a stout first leaf, and from that time they should be kept growing almost without a check. Instead of potting off the seedlings they should be pricked out thinly in pans of good free soil, from which, before they begin to crowd each other, they should be transferred to boxes of similar soil, and still be kept growing in gentle heat. Some time in May or early in June a frame or frames should be placed on a shallow hotbed at the back of a north wall, putting in first some short partially decayed manure if need be in order to bring the surface soil near the glass. The compost which we use consists of two parts old soil from Cucumber beds, to which is added one part of good sifted leaf soil. When this has warmed sufficiently the Cyclamens are planted out about 6 inches apart each way and watered. The lights for a time are kept on closely, and at midday a little shade is applied when necessary. On clear days the bed is syringed in the morning and afternoon, or sometimes before opening and prior to closing when a little air is necessary to ensure sturdy growth. Early in September all are potted, using rather rich compost and sizes of pots according to the balls of soil about the roots when lifted. When potted they are returned to cool frames and kept close and well shaded for a few days, and at the present time they are placed in a warm greenhouse in which plenty of bloom is already open. All old plants worth preserving are planted out in frames at the same time as the young ones, and similarly treated, with this difference that much of the soil is removed from the roots, or the balls when we came to lift them would be found to be much too big. No drying off after flowering is attempted; this, when practised, as it very often is, causes many of the corms to become nearly or quite blind. After all our old and young plants were potted they filled a good sized four-light frame. Persian Cyclamens will flower in quite a cool greenhouse, but they must be very carefully watered, or they are liable to damp off wholesale. We like to give them plenty of room on light shelves at a good distance from the hot-water pipes, which are kept warm throughout the winter. They require to be kept carefully watered, and when the pots are well filled with roots, liquid manure is beneficial to them. When blooms are wanted they are pulled clean off the corms, this being a safer plan than cutting them off, as the portion of stem left is almost certain to rot quickly, and spread decay on all sides. If the plants are kept clear of the other occupants of the house, as they ought to be, they will not be much troubled with insect pests; and, besides, they are most effective in masses. W. I. M.

LANCE-LEAVED LILIES.

This is the best time for repotting Lilies belonging to this class. I always make it a rule to shake them out of their pots when we cut the stalks down after the leaves have turned yellow and the flowers have all dropped. We generally set the pots out of doors after the flowers are all cut or have fallen for a week or two. During that time they get very little water, and if the weather is very wet we turn the pots on their side; the soil is thereby kept moderately dry. When shaking them out we sort the bulbs into three different sizes; we put the largest into 12-inch pots, the next size into 7-inch and 8 inch pots (five bulbs in each), and the very small bulbs we plant out of doors, and cover them with litter to exclude frost. The soil which suits them best is half-rotted turf, thoroughly decayed hotbed manure, and sharp silver sand; and in potting, we only fill the pots three parts full, in order to allow for earthing up with good soil after the stems have got half grown and surface roots are making their appearance. If the soil is moist they will require no water until growth commences in spring. We store the pots and bulbs in any cool house or shed secure from frost, where they remain until growth is observed in spring. They are then set out in cold frames. The roots of these Lilies being very fleshy and brittle are easily injured if repotting is left until the spring; in fact, I would rather leave them altogether undisturbed than repot after the roots are in active growth. Failures often occur from over-coddling in winter, thereby exciting premature growth, and also from deferring potting until late in spring. J. G. H.

Double Tuberoses.—Let it not be thought that pearly double Tuberoses can be grown and enjoyed only by people who have warm houses at their command. Anyone who has an ordinary greenhouse can flower Tuberoses satisfactorily, as I have just proved by potting them in good soil as early in the year as possible, so long as frost cannot get to them to injure the bulbs. I potted some bulbs early in March, placing two large ones in a 6-inch pot, using a good, free and rather rich soil, and taking care to drain the pots well. They were some time before they started into growth, but when they did do so they grew very fast, and ultimately flowered, each pushing forth a spike on which there were from fifteen to twenty flowers. Finding that the heat of the greenhouse soon affected them, I cut the spikes when about six blooms on each were well expanded, and I am pleased to report that all the remaining buds gradually expanded. The plants were kept well watered all the summer, and they occupied the sunniest part of the greenhouse. I shall now plant them out under a warm wall, protect them during the winter, and see if they will do any good next summer. To have Tuberoses in bloom in May and June, they must be forced into flower in heat; without heat they will flower in September. They are as easily managed as a zonal Pelargonium or a Fuchsia.—R. D.

Gloriosa superba.—I was much pleased to see a favourable note of the free blooming of this fine old plant, so seldom seen or noticed, at Park Hill, Streatham, p. 331. No doubt the mode of treatment described there has proved successful, but the finest example of this plant ever seen by the writer was planted out in a compost consisting chiefly of light sandy loam in an old-fashioned plant stove. Here the roots were left undisturbed for years, the surface of the mass of tubers being simply top-dressed annually. The chief precaution needed was protection to the tender stems when breaking afresh in the spring, it being found that slugs and snails of all colours and sizes were remarkably fond of these sweet and tender morsels. A large piece of zinc bent into a circle, dropped over the rising shoots and le

into the soil 2 inches deep, was found a sufficient barrier to the ingress of such foes. The sinking of the lower ends into the earth was found to be very important, for when placed on the surface merely the slugs and snails learned to find their way under it; but being poor excavators, the 2 inch deep barrier baffled them. The stems were cut down after blooming, and for many years the bulbs never failed to send up a small forest of shootlets. The strongest of these, to the number of half a dozen or so, were selected to clothe a rafter, and about so many more part of the end of the house, and these grew with a health and vigour, and produced an amount of bloom that I have never seen equalled. The very form and crispness of the extremities of the curious long tubers seem to protest against their annual lifting.—Hortus.

HOUSING CHRYSANTHEMUMS.

Chrysanthemums for all purposes, except plants which are grown for providing a very late supply of flowers, will now be housed; after this date it would not be wise to allow them to remain out of doors without protection; frost may come at any time now, and when the buds are affected by it the flowers get so crippled that they never properly develop. It is useless to allow the plants to remain outside after the flowers begin to show colour in hopes of retarding them, as rains quickly spoil the blooms, causing the petals to rot. The plants, when housed, should have as light a position as possible, and be as near the glass as circumstances will admit. When first housed ventilate freely both night and day, and, in fact, continue the same system of ventilation (avoiding direct draughts) after the flowers are expanded. Plants grown for decorative purposes only where quantity of flowers is the primary object should be slightly disbudded—that is, if a few large-sized blooms are wished for; in such a case all the flower-buds formed at the sides of the branches should be removed, retaining only the central one. If four or five branches on each plant are treated in this manner, the loss of flower-buds will not be much felt, and blooms of large size will be obtained.

Chrysanthemums should be freely fed from this stage of their growth, giving them stimulants of some sort every time that water is required at the roots. Many growers think that as soon as the flowers commence to unfold stimulants should be withdrawn; but that is just the time when the greatest strain is put upon the plants, and feeding then with suitable material is one of the chief means whereby flowers both large in size and long in the florets can be obtained, and, what is more, their colours are clearer and better defined than when the use of liquid manure is stopped at this stage of their growth. Circumstances must be one's guide as to the kind of manure to be used, for I find there is nothing like a change of food; under this method of treatment the plants appear to acquire renewed vigour. Of liquid manures from the cow houses and stables I prefer the former; but where liquid manure cannot be had from tanks fed from such places, drainings from a heap of manure, through throwing clean water over it and allowing it to soak through the manure and collect in a pit at the side of the heap, form a good substitute. Sheep manure, gathered fresh from the fields and placed in a bag to prevent it from mixing with the water, forms a good fertiliser; and deer droppings, treated in the same way, also make excellent liquid manure if put in a tub or tank of water and soaked for, say, twelve hours. A safe guide is to use such liquid manure when about the colour of brown brandy. Liquids made as described should be given every time the plants require water for, say, a week; then give them a few doses of soot water as a change. Soot is almost indispensable to the growth of Chrysanthemums; applied in a liquid form, it soon changes the colour of the foliage from pale to dark green. Some add soot to the water, stirring it and pouring on the soil, but such applications choke up the passage-way for future waterings. The best method of making soot water is to place as much of it as may be required in a sack sufficiently close to prevent it from being washed out; the water soaking through it within the bag gets charged with its properties and becomes a valuable manure. Guano finds favour with some Chrysanthemum growers. It is easily prepared and is excellent; a 4-inch potful to thirty-six gallons of water is a safe quantity to use. Chrysanthemums should now be carefully examined for mildew. It affects the under sides of the leaves of some varieties more than others. The most efficacious way of cleansing the plants from it is to lay them on their sides, and syringe the leaves and stems thoroughly with water in which flowers of sulphur has been dissolved, or, where the plants are only slightly affected, dust the leaves with dry sulphur. I prefer the brown sort to that of the ordinary colour; it is not so conspicuous. E. Molyneux.

Swanmore Park, Bishop's Waltham.

NOTES OF THE WEEK.

Plumbago Larpentæ.—This old-fashioned plant is now very conspicuous in the borders at Hampton Court. It furnishes rich, deep blue flowers in autumn, and is on that account valuable. Although introduced many years ago, its merits have been sadly overlooked.

Anemone japonica alba.—This plant is just now very fine in the gardens at Hampton Court—much finer, indeed, than we ever remember to have seen it before. It is planted in large masses, which are most conspicuous as border ornaments.

White-flowered Chicory.—The other day I came across a white form of the common blue Chicory. This is the first I have ever found either in England or on the Continent. Is it rare?—G. Flemwell, *Sutton, Surrey.*

We do not think it is common, but we have ourselves found the same form in your neighbourhood.—Ed.

Ficus elastica variegata.—This will make a thoroughly good window plant. It has just the appearance of the old India-rubber plant, but the greater portion of its leaves is suffused with creamy white and yellow. We saw good examples of it the other day at Holloway.

Othonna crassifolia.—This is a good plant for baskets, window boxes, or front edgings in greenhouses. It is employed very effectively at Swanley as edgings in the Pelargonium houses, its drooping habit, dark green leaves, and yellow flowers associating well with the brilliant flowers of the Pelargoniums.

Solanum jasminoides floribundum.—Those who appreciate the old form of this useful climber will welcome this free-flowering variety of it which Mr. Williams is distributing. It is scarcely so robust as the normal form; but perhaps that is an advantage, as it flowers in the Holloway Nurseries freely, even in pots of the smallest size.

Oncidium dasytyle.—This pretty Oncid is useful as an autumn bloomer; there was quite a quantity of it in flower the other day in a cool house at Mr. Shuttleworth's, Clapham. Hitherto we had not observed much variation in this species, but here were to be seen numerous forms, some of which were richly coloured.

Leea amabilis.—This deserves a place amongst the most beautiful of small-growing ornamental foliaged plants. Its leaves, which are pinnate, have somewhat oval, deep olive-green segments and a central flaked band of silvery white. It is a plant which requires strong heat and moisture in order to bring out its brilliant colours. We recently saw it in fine condition at Mr. Williams' nursery, Holloway.

The great Vine at Hampton Court.—This grand old Vine is carrying a heavy crop this year, consisting of some 500 bunches, evenly distributed throughout the house, whilst in thinning out the crop in spring about 700 clusters were cut off. Many of the bunches are by no means large, and there are some signs of shanking; but, on the whole, the berries are of fair size, and promise to finish off well.

October flowers.—In order to show that hardy flowers are still plentiful, Mr. J. Stevens brings us from his garden at Grasmere, Byfleet, a gathering of many kinds now in full bloom. One would scarcely credit that so much variety could be found in bloom at this season, but the mild weather of late is no doubt responsible for it. In the gathering are Crown Anemones, Japanese Anemones, Phloxes, Pentstemons, shrubby Veronicas, hardy Fuchsias, shrubby Mallows, Hypericums, and a host of Composites, Sunflowers, Golden Rods, Michaelmas Daisies, and these, like the Asters, are particularly beautiful, and Mr. Stevens must possess a fine selection of sorts. The most beautiful and the most desirable to grow are those named A. Novæ-Angliæ roseus, A. diffusus horizontalis, A. turbinellus, A. Chapmanni, A. Novæ-Angliæ pulchellus, A. Tradescanti, A. ericoides, A. Amellus, A. Novi-Belgii formosus, and A. versicolor. This group of species represents all the beauty to be found in the multitude of Asters now grown in gardens.

Chiswick.—A mutual improvement society has just been started among the young gardeners employed in the Royal Horticultural Society's gardens at Chiswick, which may prove beneficial from an educational point of view. The society has the support of the superintendent of the gardens, Mr. A. F. Barron, who is its president. It is intended to read papers upon and discuss various subjects in connection with the theory and practice of horticulture; some of the subjects announced, however, seem to be somewhat remote from practical gardening. Let us hope that the young men will not, in pursuit of the substance, only catch the shadow.

Irish Anemones.—From the Hill of Howth, "St. Brigid" has sent us another gathering of her glorious Anemones from plants raised from seed sown in the open ground on the 1st of April of the present year. The flowers are sent to show how soon Anemone flowers are produced, the bed in which the plants are grown having begun to blossom in August, and it is now bright with flowers. The blooms are double, quite 3½ inches across, the colours being a glowing scarlet and imperial purple. Would that we could grow Crown Anemones like these in the neighbourhood of London!

Lagerstrœmia indica.—We have received from Mr. Bedford, gardener at Straffan House, Kildare, some shoots of this plant, which have been growing luxuriantly and flowering profusely. This plant is seldom seen in flower in our gardens, and yet it is very easily managed. It is usually treated as a stove plant, but it grows and flowers best in an intermediate house, where it forms a dense shrub, furnished with bright green leaves and lilac or mauve-coloured flowers of great beauty. In Ireland it lives out of doors, but does not flower, and in all probability it would both grow and flower out of doors in the south of England.

Primula purpurea.—We have received from the Rev. Wolley Dod a very fine example of this rare Primrose—that is to say, rare as regards being seen in flower in English gardens. In many instances the plant found in collections is not the true P. purpurea of Royle, but simply a variety of P. denticulata. Royle's plant is a robust grower, with leaves some 6 inches long, slightly serrate on the edges, deep green above, and farinose on the under side. The spike is also farinose, and likewise the foot-stalks and calyx. The flowers are numerous, rich deep purple, increasing in intensity towards the eye, which is blackish purple. This plant must take rank as one of the most beautiful amongst Primroses.

Double Begonias.—One of the most beautiful features at Kensington on Tuesday was a display of double Begonia blooms from Messrs. Cannell, of Swanley. They exhibited flowers of two dozen of the finest sorts, and these made a show of double Begonias such as had rarely if ever been seen at a show. Two of the sorts were certificated, but as all were first-rate we give the names of the selection. These were Blanche Duval, creamy white, tinged with rouge; Susanna Hachette, cherry-crimson; Rosette, flesh-pink; Felix Crousse, vivid scarlet; Virginalis, white double; Agnes Sorel, blush-pink; Louis d'Or, deep yellow; Miss Lucas, orange-scarlet; Mons. Duvivier, deep cerise-crimson; Octavie, best double white yet raised; Prince of Wales, scarlet-crimson; Mons. Arnoult, large rose-pink; Wm. Bealby, cherry-rose; Pavillon Jaune, orange-yellow; M. Trauffaut, bright orange-salmon; Mme. Marie, deep pink.

Aralia Chabrieri and **A. Reginæ.**—These are two extremely ornamental plants, and as they can be grown in small pots they are well adapted for general decorative purposes. Unlike the majority of Aralias, they do not become coarse in appearance as they increase in size. The first-named is a most distinct plant, with long, pendent, pinnate leaves, the segments of which are narrow and deep olive-green, with a crimson mid-rib. A. Reginæ has palmately divided leaves with pendent bright green segments.

Its leaves somewhat resemble in general outline those of A. Veitchi, but they are more closely set upon the stems, thus giving the plant when old a more massive appearance, without losing the graceful and elegant outline which is so conspicuous a feature of it in its young state. In Mr. Williams' nursery at Holloway we saw plants of both these kinds from 6 inches to as many feet in height, and in both instances their value as decorative subjects was most satisfactory.

Winter-flowering Carnations.—These are very fine at Swanley. Pride of Penshurst, although a somewhat old variety, must not be passed over lightly; it is one of the very best and freest winter-flowering kinds—in fact, it is almost a perpetual bloomer. It is now displaying its soft yellow flowers in great abundance at Mr. Cannell's. Miss Joliffe, soft pink, is also very free and good, with a dwarf habit. La Belle, pure white, flowers all the year round. Mrs. Wallington is a very attractive variety; and the pink, crimson, and blush-white forms of Souvenir de la Malmaison are indispensable where good winter blooms are in demand.

Ivy-leaf Pelargoniums—These are invaluable for baskets, window boxes, balconies, or bedding purposes. The double forms of them to be seen at Swanley are very attractive; the flower-trusses are large, and the colours rival those to be found in the zonal section, whilst, on account of their long flower-stems, they are valuable for cutting. Some of the gems of the collection are Madame Thibaut, large, even, deep pink; Madame Pages, lilac, upper petals feathered with maroon; Emile Lemoine, rich orange-scarlet; Dr. A. Chipault, deep salmon-pink; Alice Crousse, deep magenta; Jeanne d'Arc, white suffused with lavender; Gloire d'Orleans, crimson-magenta; Viscountess Cranbrook, white satiny rose; Madame E. Galle, pure white and very double; and Sarah Bernhardt, white, feathered with maroon.

Three elegant Maiden-hair Ferns.—Amongst the numerous species and varieties of Ferns grown in the Holloway Nurseries, Adiantum scutum Lathomi, A. elegans, and A. Williamsi are conspicuous, and all are distinct in their way. The first, whilst retaining the massive pinnæ of the type, has pendent fronds of a light and airy form. A. elegans, which is said to be a variety of colpodes, has somewhat the appearance of an elongated cuneatum; independent of its graceful appearance as a plant, the length of its fronds renders them extremely useful for arranging with cut flowers. A. Williamsi is a free-growing plant, with long and broad arching fronds, the segments of which are elegantly divided. They are brilliant green above, and, when young, clothed on the under-side with golden powder, which in some of the varieties may be found even on old plants. A greenhouse temperature suits this plant perfectly.

WHITE TRUMPET DAFFODILS.

I was very much interested in the remarks on Irish Daffodils in The Garden (p. 323), and especially in those relating to white Trumpet varieties. Doubtless there is confusion in the nomenclature of this lovely group. This, indeed, is admitted; and Mr. Hartland, "G. H. E.," and all other growers, I am sure, will do their best to clear up any disputed point and finally settle the question of the nomenclature of this group. How is it to be done? There is but one answer to this question. They must all be collected in one place and on neutral ground. The garden of the Royal Horticultural Society at Chiswick is the proper place in which to carry out a work of this kind, and doubtless a suitable space would be set apart for the purpose if immediate application was made. Mr. Barr has a very complete collection of white Trumpets, which he would probably be willing to send there; if he is willing to send his collection, I am sure Mr. Hartland, "G. H. E.," and others would follow his example. I have long held the opinion, that whenever any disputed point arises as to the correct nomenclature of any plants, the most satisfactory way by which to arrive at a correct decision is to send them to Chiswick. The whole question of this lamentable confusion may be settled there. Let a beginning be made with this section, and when this one has been finally disposed of, go on to others. It would be too much to take in the whole field in one year. Will those who can aid the solution of this question kindly state their opinions in regard to it? J. Douglas.

*** At one of the meetings of the Narcissus committee it was decided to invite all growers of white Trumpet Narcissi to send bulbs to be grown at Chiswick for comparison, and the secretary, Mr. Scrase-Dickins, has, we believe, made a personal appeal to growers upon this subject. We believe that Mr. Barr is ready to send bulbs of all his white Narcissi to Chiswick, but as the season is advancing it is desirable that no time should be lost in carrying out this matter. Other members of the committee should also send bulbs.—Ed.

TREE ROOTS IN FLOWER BORDERS.

"Querist" (p. 333) raises a different question from that of "H. R. C.:" the latter wanted a 3-feet shelter and proposed to form it with Yews. This proposal was condemned on various grounds. "Querist" wants a shelter 5 feet in height composed, if possible, of Yews or Hollies, his border being exposed on the north-east to gales from a mountain range on that side. To baulk the force of this a single row of Hollies or a thin hedge would be of little use. Clumps or a massive belt so posted as to break the force of the wind at some considerable distance, say 10 yards or 20 yards from the border, is really what are wanted. This, apart from keeping the plant border free from the larcenies of thousands of hungry shrub or tree roots, would be far more effective than a shrub hedge planted in the back of the border, as it is found in practice that shrubs planted in projecting curved lines to meet and slide off the wind are far more effective shelters than those that confront it with a straight line—such as thin hedges, or even a wall. Hence, were it practicable to plant a broadish belt, the out—or windward—side should not be straight, but curved. If "Querist" is so restricted for area as to be compelled to plant his shelter in his border, he should bank out the roots with a concrete wall 2 feet deep at the back of his border, and, of course, plant his hedge outside the barrier. This will check, at least for a good many years, the inroad of the roots; but, if possible, he should interpose a gravel or grass walk, or even wider and more irregular space between his shrub shelter and his flower border. It is quite a mistake to suppose that the efficacy of the shelter lies in its nearness to the plants protected. It is often very much the reverse, especially with living shelters, which differ from dead ones in this respect. Dead shelters, such as wooden fences, brick or stone walls, divert the course rather than break the force of the wind. The air in swift motion leaps over or aside of them, and seems at times to gain destructive force by its temporary diversion.

But living shelters, by the mobility and the depth their mass of leaflets and twiglets receive, retain and exhaust the force of the gale. Anyone may prove all this for himself by simply walking on the lee side of a wood or shrubbery during a March day with a nor'-easter keenly blowing. The wind on the exposed side almost curdles his breath, while it is nearly or quite nil on the sheltered side. Hence the advice given to plant clumps or belts instead of a straight hedge; if the latter is used, it would need to be 2 feet or even a yard thick to prove impervious to north-east winds tearing down with fierce swoop from a mountain range. Even a hedge of such abnormal thickness would need an outer buttressing with clumps or belts to make it effectual against strong blasts. As to moving Hollies 4 feet or 5 feet high in October or November, the risk of checks and losses in such an exposed position would be so great, that it would be safer to defer it till April. Yews might be planted at once with less risk than Hollies. If "Querist's" situation is very cold and exposed, perhaps Scotch Firs or some of the smaller Spruces would prove a better shelter than either. There are few better or cheaper hedges than a thick one of Beech or a double one of Larch and Privet. A massive Beech hedge may be carried up to any desired height, and as it has the property in hedge form of retaining most of its leaves throughout the winter, it almost equals in sheltering warmth such evergreen hedges as those formed of Yews and Hollies. A great deal may also be done to keep Beech or other roots out of flower borders by removing a surface spit in winter and running down a sharp spade to its full depth within a foot or less of the stems. But these and other expedients are, after all, but poor palliatives to the inevitable impoverishment and exhaustion of flower borders through the agency of shrub and tree roots placed in too close proximity to them. By using either of the latter plants named "Querist" may plant his shelters at once. Should he decide on using Beech, it would be wise to enquire whether it is greatly infested in the district with aphides in the spring or summer. Should this be the case, it had better not be planted. D. T. F.

Fungi (*J. W., Edinburgh*).—The fungus from the floor and on rope is the early condition of the dry rot fungus (Merulius lacrymans); the Agaric is Agaricus nidorosus or some close ally. Badly packed, rotten examples full of maggots are not easy to name with certainty.—W. G. S.

Decayed bulbs (*C. B. and G.*).—The decay arises from various causes, often from bruising and sweating. Fungi grow on the injured parts. A decayed bulb will not affect sound ones in the ground unless one actually touches the other.—S.

Grubs (*W. S.*).—Unfortunately, the grubs had escaped from the box before it reached me, so I am unable to say what they were. The Post Office staff treat small boxes very badly, and seem to delight in smashing them in the process of stamping. The address and postage stamp should be on the label which is attached; then there is no excuse for stamping the box.—G. S. S.

Rose insects (*J. T.*).—The insect infesting the shoots of your Rose bushes is one of the plant bugs. They are originally produced from eggs laid by the parent insects. When first hatched they much resemble the latter in general appearance, but they have no wings; they gradually become more developed, and at last become perfect insects. They really undergo transformations like most insects, but these changes are not so decidedly marked.—G. S. S.

Diseased Violets.—Can you tell me what is the matter with my double white Violets? About a fortnight ago the whole of the leaves seemed scalded; they show traces of red spider, but there is hardly a whole leaf left. They are planted in a cold frame, the lights of which have not been put on since last March. The curious thing is, that there are other three sorts of Violets in the same frame which do not seem to be the least affected.—J. B., *Barrelwell, Chester.*

*** Your Violets have evidently suffered from a bad attack of red spider. Syringe the plants with 4 ozs. sulphuret of lime, 2 ozs. of soft soap, well mixed together and added to 1 gallon of hot water; or 2 ozs. of soft soap, 2 ozs. of flowers of sulphur, boiled in 1 gallon of water; or an infusion of Gishurst compound.—G. S. S.

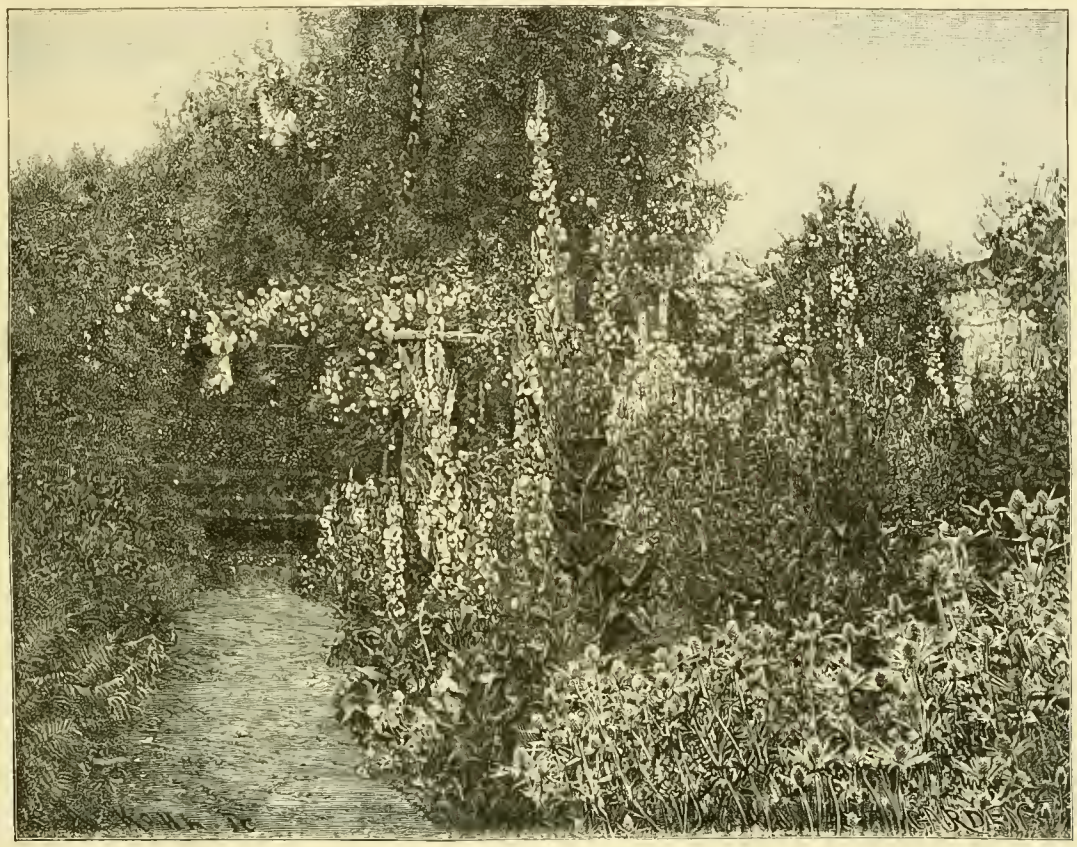
Insects on Melons (*Multum*).—The insects on your Melon plants are little creatures called chelifers. They are nearly allied to the scorpions, but have no tails or poison glands, as the latter have. They usually feed on mites and insects, and may often be seen attached to the legs of house flies, though whether they are parasitic on flies is uncertain. They are not considered to be vegetable feeders. The pieces of Melon leaves you forwarded with them were so dried up before they reached me, that I could not see whether they had attacked them in any way. I expect your Melons had been attacked by red spider, and that the chelifers had been feeding on them, but it is possible that in default of animal food they may attack the leaves of plants. Curtis, in his work on "Farm Insects," mentions that they have been found in some numbers among decaying Potatoes, and adds, "where probably they live upon mites."—G. S. S.

Market Chrysanthemums.—These just now consist of Madame Desgrange and La Vierge, both free blooming kinds, the latter being apparently the best. Both these kinds are invaluable at this season for harvest festival decorations. The winter bloomers are chiefly white, such as Elaine, Princess Teck, &c., and Jardin des Plantes, yellow—just about one dark kind being grown. Only distinctive and striking colours find favour; the merit of the light ones is that they keep true late into the winter, whilst the rich reds, chestnuts, and crimsons of the early season lose colour later.—A. D.

Flower Garden.

HARDY FLOWER BORDERS.

The grouping and massing of good plants is happily daily becoming better understood, to the great improvement of our gardens; it is one thing to have good plants and even plenty of them, and it is another to so use them as to get them to show their own beauty and to enhance that of their neighbours. What is needed is a true love of good flowers, a rigid exclusion of rubbish, and some taste—the more the better; indeed, the true gardener should be more than half an artist, painting living pictures with living flowers. The engraving shows one end of a straight flower border backed by a wall. The wall is clothed with Vines and other good climbers; at the end of the walk is a rustic seat under a bower of cluster Roses, supported on a framework of rough Oak posts and branches. The main group of flowers is of the fine Mullein, Verbascum phlomoides, the tallest 8 feet high; beyond are pale blue Delphiniums; behind are Globe Thistles, and in front a group of blue Eryngiums. Though in other parts of the border the tall plants are mainly kept towards the back, in this part they are allowed to come forward, making a pleasing variation in the general arrangement of the masses. The straight edge of the border is veiled by plants being encouraged to grow over its rough stone kerb, and, where they will do so, to root here and there into the path.



Flower border in July. Group of Mulleins (Verbascum) in the background, with Sea Holly (Eryngium). Engraved from a photograph for The Garden.

September Pansies at Windermere.—"It's the rain that does it!" was my first exclamation on reading your somewhat tantalising note on Mr. Rawson's admirably beautiful September Pansies. I hardly ever go north or west without catching the Pansy fever. Notwithstanding that I have had it many times, Pansies are so alluringly infectious, that I never go among them in their full beauty but I catch it again. The result is, that one more attempt is made to match the beauty and luxuriance of those splendid Pansies to the north and west of us. The result, writing broadly, is one more failure, and a little less of the Pansies or Violas for a time. But a trip to Manchester, Edinburgh, or even Birmingham renews the Pansy fever, with the old results, that seem to follow of necessity. The rainfall in East Anglia is too little; the midsummer sun's bright glare is too much for those sweet children of the cloud, the mist, and the rain. Special culture, partial shade, copious artificial waterings will do much to counteract an arid climate; but all these involve expense and extra labour that cannot always be spared even for sweet Pansies, and thus they suffer, pine, droop, and are not seldom burnt off in the arid east, while they are green as Leeks and clothed with beauty in the cloud-capped north and weeping west.—D. T. F.

MIXED WALL CLIMBERS.

As a fresh, bright-looking wall plant, pleasant to look upon all the year round, Ivy has no equal. It is vigorous in growth, and will thrive on all aspects, even on bleak north or eastern exposures almost as well as when facing the south or west, provided it has good rich ground to grow in. Though Ivy will live on scant fare, such as very few plants can exist at all upon, still, when subjected to semi-starvation, it makes little progress compared with what takes place when its roots have an unrestricted run in good soil. The common Virginian Creeper (Ampelopsis hederacea), as a strong, vigorous plant that will cover a large space in little time, is without a rival for elegance of habit, and the beautiful tints of the decaying leaves in autumn are not the least of its desirable properties. This plant will grow and look healthy under the disadvantages of little and indifferent soil, and also where the atmosphere is charged with smoke and dust that would be fatal to most things. Its only drawbacks are that it requires fastening to the wall, and that, being deciduous, it leaves the wall bare and cheerless in winter. A. Veitchi, like not a few other good plants, has been slow in making way, but it is now receiving the attention at the hands of those who require wall climbers that it deserves. It is amongst the freest of free growers, covering a large space in little time, and thriving on any aspect. It clings so tenaciously to anything on which the shoots can lay hold—bricks, stone, or wood alike—that no attention is required in the way of fastening it. The vivid crimson colour which its leaves put on in autumn is unequalled, and the leaves remain on the plant in their brilliant condition much longer than those of the old Virginian Creeper. On a northern aspect the colour of the leaves is paler than on the south, but they remain longer on the plant when facing northwards than under the sun's direct influence. All through the summer its pale green foliage, covering the wall as evenly as if the leaves had been placed there by hand, has a beautiful appearance, but it is wanting in the elegant drooping character of its shoots which the old kind possesses; as a matter of course, the wall on which it is grown is bare in winter, save for the presence of the long wiry shoots.

There are several kinds of evergreen plants that, although seldom used for the purpose, make good-looking coverings for walls of moderate height, say up to 18 feet or 20 feet. The different sorts of Japanese Euonymus, green and variegated, and Azara microphylla look well on walls. The Azara, although it has been some time in this country, is yet comparatively little known; the spreading fan form of its branches adapts it for covering walls. Its character of growth is like that of Cotoneaster microphylla, but it is a much quicker grower, and will cover a deal larger space. The branches, too, naturally assume such a spreading form, that they require few fastenings to the walls. There are few plants with leaves that possess a more pleasing shade of green than Euonymus, whilst those who like variegated foliage have choice in the different varieties of the yellow and the white variegated forms; but the green self-coloured sort looks best. In good soil the plants soon make headway, covering a considerable space in little time. In the use of these and all other plants for clothing a wall, care should be taken at the beginning to train the strongest shoots out horizontally, so as to furnish the bottom space at first; otherwise unsightly bare places will remain for years uncovered. It is particularly necessary to avoid these when plants like these Euonymuses, with an erect habit of growth, are used. The small-leaved E. radicans variegatus, as it is usually seen in the form of a low-spreading dense little bush, or as an edging, looks an unlikely subject for clothing a wall; but, so used, with a little attention in training the shoots at first, it soon makes a dense covering up to a height of 8 feet or 10 feet. But there is one thing that must not be lost sight of in using the different varieties of Euonymus, as well as the Azara, and that is, they are not sufficiently hardy in all parts of the kingdom to stand exceptionally severe winters, not even when they have the protection of a wall where the aspect is east or north.

So far these remarks have referred to the plants named when used singly, but to have wall climbers in the way that will produce the most elegant effect, several kinds require to be grown together in a manner

that will admit of their branches intermingling amongst each other with no more interference than is necessary, to prevent the stronger growers encroaching too much on the weaker ones. Roses, Clematises, Jasmines, Bignonias, Honeysuckles, Passifloras and the like are beautiful when seen singly or each with a space to itself on a wall; in this way they are usually grown, but so managed they are wanting in the elegant effect produced where they can scramble about loosely with a covering of Ivy behind them. So treated, flowering plants with a background of dense foliage produce an effect which is not obtainable when used by themselves. This may often be seen where an odd branch of a Rose or of a Honeysuckle outstretches the space allotted to it and rambles over something else. But that which thus occurs by accident can be done much more effectually when the necessary consideration is brought to bear on the planting. But in a mixed arrangement of this kind there is a difficulty that makes its appearance in a few years after the planting has been effected. Ivy is a gross-feeding plant, and pushes its hungry roots far and wide in all directions, soon exhausting the soil within its reach to an extent that reduces other plants associated with it to a state of starvation. When planting the first wall that I intended to clothe in this way I had some misgivings that this might occur, but supposed that the difficulty might be got over by subsequent applications of manure when the soil became poor. In this I was mistaken, for the more that was done in this way, the more persistently the roots of the Ivy laid hold of every particle of soil in the border, so that the Roses, Clematises, and Honeysuckles associated with it were not able to hold their own. The best means of avoiding this is to partition off stations for the blooming plants, so as to prevent the roots of the Ivy interfering with them. This is easily done by the use of thin concrete walls when the border is being prepared. This material is much more effectual than slates or stone slabs, between the divisions of which the roots of plants soon find their way. The concrete divisions need not be thicker than about 3 inches, as there is no pressure against them. In this way the flowering plants have the spaces allotted clear to themselves. Whatever plants are associated with Ivy in this manner should have the principal branches secured to the wall, but nothing more. The lateral shoots that spring from these ought to be no further interfered with than in keeping them thinly dispersed, allowing them to come as far away from the surface as they like.

In selecting the kinds of plants for growing in company with Ivy in the way indicated, it is obvious that they should be deciduous and of a somewhat thin, straggling habit. If close growers, unless the knife is freely used they get so dense, that they darken and weaken the Ivy so far that it is apt to suffer in hard winters. Roses, Clematises, Bignonia radicans, Jasminum nudiflorum, Glycine sinensis, Aristolochia Sipho, Passiflora cærulea, and its varieties are amongst the best things that can be used, in all cases having their shoots sufficiently far apart on the wall to begin with, and keeping them so afterwards. Not only is an arrangement of this kind infinitely better, so far as regards the appearance of the flowering plants when they are in bloom than when grown by themselves, but there is the advantage of having the wall covered effectually in winter; whereas when it is occupied by deciduous plants alone, when they are leafless it looks anything but inviting. T. B.

SHORT NOTES.—FLOWER.

Lilium auratum var. cruentum.—We send you a flower of a grand Lily out with us among our plants of L. auratum.—Alex. Wallace, *Colchester.*

*** The flower sent is an excellent form of auratum called cruentum, of which we gave an illustration in The Garden (Vol. XVI., p. 576).—Ed.

Lathyrus Drummondi.—In response to "J. C. B.'s" query with respect to the difficulty experienced in inducing the seeds of this Everlasting Pea to germinate, I can only say that hitherto I have been unable to obtain good seed. This year, however, the crop is heavy compared with that of previous years. Still, I must say that what seeds I have sown (and that has always been soon after they were ripe) have grown fairly well. This year I have already grown in a greenhouse a quantity in a pan, in which the soil is kept fairly moist.—A. D.

TUBEROUS BEGONIAS OUTDOORS.

Beautiful as these are in many places at all seasons from July to November in mild autumns, there are not a few sites and situations in which the midday sun's broad and full glare is rather too much for them in the summer months. In hot, dry sites they are most effective in a partially shaded as well as sheltered position. In writing thus I am well aware how brilliantly beautiful they are, and how bravely they withstand our climatal vicissitudes in the Forest Hill Nurseries of Mr. Laing and in many others around London. But here and elsewhere where I have seen them the leaves are apt to shrink from free development, and the flower-stems to fear rising boldly and far enough above them for the richest effects until the slanting rays and cooler nights of the autumntide come. I have not seen this so marked as this year. A row of seedlings on either side of an open walk across the kitchen garden appeared not to like themselves—to use a very expressive Suffolkism—until within the last month. During the long spell of north-east winds, too, they folded their leaves closely around them, and the flower-stems hugged the leaves too closely to reveal their beauty, but the warm days towards the end of September and the first week of October have quite transformed them. One can also see the foliage spread, the flower-stems rise, and the flowers open out to double or treble their summer-dried, cast-wind-parched dimensions. Stocks, Pansies, late flowering Roses (Teas and others) have now to play second decorative fiddle to the flaunting, flourishing Begonias. The latter are now so full of growth and beauty, that we intend to pot up the best before the frost makes a first meal of their tops. They will be placed in a cool greenhouse where they will bloom for a month or six weeks. As to commoner varieties, they will be left to take their chance till the frost mars their beauty, when the bulbs will be lifted and stored in a cold pit in cocoa fibre refuse for the winter. Some recommend drying the tubers in the sun or under glass before storing. They keep best stored as lifted, that is assuming they are lifted in dry weather. Of course, should they be soaking wet when lifted, partial drying is advisable. But these tubers suffer more from dry than wet rot. In fact, I do not remember losing any from the latter, though at first we lost many from over-drying the tubers in pots. But the point I wish to direct especial attention to now is the value of these Begonias as autumnal bloomers, and the superiority of the blooms in the late autumn over those of the summer months. By choosing sheltered and shaded sites most of this superiority may be realised all through the season.

Hortus.

Nicotiana affinis.—Is it usual for the roots of this to push up and grow the second season? This summer a quantity of young shoots came up from pieces of roots left in the beds last year. These I lifted, and used for enlarging my clumps of seedlings of this Tobacco in a herbaceous border. The blooms on the second year's plants are, I find, much finer and more abundant than those on the seedling plants, and they keep open all day, while those of the seedlings are closed.—A. Campbell, *Ashford, Cong, County Galway.*

Bedded-out Begonias.—Hundreds of dwarf, bushy plants of both single and double tuberous Begonias are growing out of doors at Twickenham, and blooming in the greatest profusion. They range from 6 inches to 9 inches in height, and are exceedingly sturdy plants. All, too, are from home-saved seed, and, still more, are in their respective sections perfectly true. The doubles seem to be almost even more floriferous than the singles, but all are of first-class quality. The flower-stalks are stout—a special desideratum in bedded-put Begonias. Without doubt these plants would have looked even more beautiful had they been planted on some green base, such as Sedum or Herniaria, and more thinly; or, better still, in clumps of half-a-dozen in rockwork recesses. The chief enemy of bedded-out Begonias seems to be cold nights, but those planted out early get fairly hardened, and if not too much exposed to early sunshine after frosty dews are less liable to suffer. Still the results, as seen at Twickenham, show that Begonias are far more satisfactory as bedding plants than is generally assumed to be the case.—A. D.

SINGLE DAHLIAS.

"Hortus" refers (p. 334) to the fragility of the flowers of the single Dahlia as a weakness which I had ignored, but it merely did not occur to me to draw any special attention to the point, as the objection seemed so much less serious than the dreary formality and heaviness of the double show Dahlia in a vase of flowers. Of course, the Cactus is more enduring than the single Dahlia, but if, as I pointed out, the blooms of the latter be cut before the central florets begin to develop, *i.e.*, before they scatter any pollen, they will last four days without shattering, and I have not succeeded in keeping the flowers of the former in water, in a state of beauty, for more than five or six days; while I certainly do not think I should like the task of emptying the vases in which they had remained for more than a fortnight. Neither the flower-stalks nor the water would be pleasant. But, granting that the single Dahlias are somewhat fugitive, is not a brief spell of beauty in our rooms preferable to the chronic ungainliness of the floral hemispheres which "Hortus" concurs in decrying? Besides, there is invariably an abundance of flowers ready within a day or two on the plants to replace the faded singles, which is not always the case with the double Dahlias; and, at any rate, there are other flowers less lasting than single Dahlias which are not denied wide popularity. Roses in July, for instance, seldom last more than a day unless the weather be damp and cool, and the majority of Hybrid Perpetuals have to be replaced every other day at the outside; they are thus less enduring than single Dahlias, but yet are desired. It is true, the Rose's fragrance counts for a great deal, and so does its colour; but in the latter respect the single Dahlia is even more brilliant and varied, and it is undoubtedly more graceful for arrangement in a flower-vase.

I wonder whether "Hortus" ever offered to decorate the drawing-room of one of his lady friends with typical double Dahlias, and, if so, whether he has yet forgotten the kind of reception that his proposal met with? One may guess that it might have been pretty sultry, for there seems to be an impression on the minds of many, if not a majority, of the fair sex that the veriest genetic connection represents the relation of earwig to Dahlia, if, indeed, the terms be not synonymous as far as the quilled show flower is concerned. But its own honest simplicity successfully guards the single bloom from being made the vehicle of the insect detested of women, which, if it should make an attempt to obtain carriage behind a ray-floret, is quickly detected and dislodged before reaching the house.

I rather sympathise with "Hortus's" liking for the less formal flowers—though I draw the line at quilled petals—as I have sundry times got much mocked by strict florists for owning to a certain sneaking fondness for loose, irregular blooms for use in very large vase arrangements several feet in height and for broad effects; but I cannot agree that they are the most decorative in the garden, as I have generally found that the "ragged" flowers are produced on weak stems and upon plants of straggling lanky habit.

When we succeed in getting Juarezi with the habit of some of our best singles—that is to say, holding its gorgeous flowers well above the foliage instead of their being half buried in it—I will heartily endorse all that "Hortus" says in favour of this beautiful and indispensable variety as a decorative garden plant, but even then the palm for grace and elegance in the cut state must be awarded to the single Dahlias, which we consequently continue to advocate and work at. I

may mention that I have succeeded in raising several distinct varieties of dwarf habit measuring not more than 9 inches to a foot in height from the surface of the soil to the top of the flower, which in spite of their diminutive stature are of very vigorous bushy growth and continue a mass of bloom throughout the summer; their flowers are about 2 inches in diameter and are carried on stiff, erect stems; one variety is of an intense dazzling scarlet colour, others dark shades of purple and maroon. Another series, running from 18 inches to 2 feet in height, include a yellow with a brown tip, a pretty pink, and a primrose colour. It is hoped that means may be found to exhibit these varieties next year in pots to show the habit of the plants, as it is thought that they may prove useful for bedding, and they will at least serve to show that single Dahlias need not be objected to as too tall or too short when they may be had of any height from 9 inches to 6 feet. A large bed or group planted with taller varieties at the back and graduated down to the dwarfs in front, from which all seed-pods were assiduously removed, would furnish a bank of bloom which, if not useful for cutting to those who do not care to re-arrange their vases oftener than once a fortnight, would certainly keep that part of the garden gay throughout late summer until destroyed by frost.

T. W. G.

NOTES ON HARDY PLANTS.

Corydalis ochroleuca.—One might grow many a less interesting and less beautiful plant than this. It is somewhat in the way of C. lutea, but it is rather taller and its habit is more erect. The foliage, too, is more glaucous, and the flowers not so yellow; in fact, they are a mixture of yellow, green, and white, and are produced in little clusters, nestling among the foliage. I suppose that there is something of a biennial character about this species: but, for all that, it is a plant capable of taking care of itself, I may say equally with C. lutea. Its usefulness consists mainly in its freshness and its habit of blooming successionally from spring until the end of the season. For dry, sunny rockwork it is a desirable plant.

Cyclamens.—Several varieties of these may be planted now with good results. For a long time C. coum used to rot with me from the top downwards. Those with a sunken circle around the crown, and others very flat and somewhat depressed, like the younger corms of C. coum, were especially liable to go off in this way, and also the very large ones, with, of course, a large upper surface, and often also somewhat depressed. What has been proved quite clearly to my mind is the fact that the loss of these corms is mainly caused through moisture lodging on them and rotting them. Such bulbs when planted should not be placed flat; they should be inclined a little to one side, bringing that part uppermost which brings the germ nearest the surface. By this method all lodgment of moisture will be avoided, and I do not remember since inserting the corms in this way that I have ever lost any by decay. It may not be desirable to transplant autumn-flowering kinds just now, but, for all that, if the roots have to be moved, I have no hesitation in saying that this is a better time to do it than in spring. For a whole year sometimes after transplantation Cyclamens will neither grow nor decay. They, however, both start and thrive best in a deeply prepared soil in which plenty of well-decayed leaf-mould has been worked. In fact, they want a body of soil almost elastic, incorporated with leaf-mould, peat, or something of that character. Just a little shade, too, seems to make them happy.

Campanula isophylla.—The white variety of this is so different from the type, both in habit, form and flower, and hardiness, that I have long suspected it to belong to a different class. It is not a common thing for the type to be more tender and less robust than a variety of it, yet it is so in this case, for the blue form or type will neither stand the amount of moisture in the land nor degree of cold which the white form will do. Moreover, the somewhat tree-like habit of the type is hardly represented at all in the white form, which is more in the way of garganica than isophylla.

Tropæolum tuberosum.—This is a free-growing species, but a sparse bloomer, *i.e.*, unless the tubers are planted in an exceptional way. It may, however, be had studded with hundreds of bright little orange-scarlet flowers from early in August until frosts set in. The best thing to do is to place the tubers in a dry, stony bank of very poor soil, and exposed to the greatest amount of sunshine possible. In such a place they will not only be pretty secure during winter, but they will reproduce themselves more than tenfold for another year. Either the roots should be 9 inches or 10 inches deep, or there should be a covering of ashes placed over them as soon as the tops are killed by frost.

Anemone vernalis.—This is one of the earliest flowering of alpine plants, but it may be said to be also one of the most difficult to establish, especially when plants of more than two years old are being dealt with. One can hardly reckon on older plants growing with certainty if set in the ordinary way. The chief thing to do is to set the crowns well above the surface. But in reference to this species, what I more particularly should like to mention is the fact that it is most easily raised from seed. A lady, who a year or two ago brought some fresh seeds of it from the Alps, sowed them in such material as she rightly supposed they would germinate in, and the result, after two seasons, has been the best plants of the kind I have ever seen either wild or under cultivation. She told me that the material in which she invariably found the plants wild was of a very stony character, especially on the surface. This seems to favour the plan of planting well above the surface, in order to keep the crowns from rotting during muggy winters. The chief difficulty lies in getting fresh seed.

Margyricarpus setosus.—This dwarf bush is reported to be but short-lived, lasting under cultivation only some three or four years. Where such is the case, I am of opinion that it has not been placed under proper conditions. The roots should be in dry, rubbly, or very poor soil of a vegetable character. Unless, too, the plant gets plenty of sunshine, the wood, which is thickly beset by the persistent chaff-like portion of the bristles, does not get sufficiently ripe.

Arabis lucida variegata.—This is anything but common, though one of the prettiest and best of the Arabises. So neat and shining are its pretty rosettes, and so durable are the distinct markings in its leaves, never fading even when they get old, that it may be relied on to be effective the whole year round. I find it to be frequently confounded with the variegated form of Arabis alpina, but the two are as different as it is possible for plants to be. That under notice seldom grows higher than 2 inches; it is quite stemless, and its growths form pretty rosettes. It does not, however, thrive in every garden, and in all it is difficult to keep through the winter. There should be plenty of lime put into the soil, *i.e.*, where lime does not naturally exist. Where the soil is calcareous, growth seems to stop much earlier in the autumn and the crowns become more thoroughly ripened, and so better capable of withstanding our wet winters. It is also a good plan to divide it severely in spring or early in autumn, young plants being much more vigorous than older ones. In all cases, however, lime should be used freely.

Veronica corymbosa variegata.—This is another dwarf plant with an abnormal colouring of yellow or creamy white on the edges of the foliage. The typical form of this Speedwell is neat in habit and valuable for its flowers, which are of good colour (rich deep purple) and continuously produced. The variegated form blooms equally freely, and the flowers afford a pleasing contrast to the two-coloured foliage. On rockwork this variety is one of the loveliest subjects with which I am acquainted. It rarely grows more than 9 inches or 10 inches high, and produces a goodly portion of barren shoots, which half creep on the surface, and thus render this Speedwell what may be termed a carpeting plant. It may be grown almost anywhere. The best plants are always those resulting from offsets taken in summer and well rooted before the winter sets in. Such plants have young growths more or less visible all winter.

Veronica incana.—This has the advantage of being well known and also justly appreciated. It is usually classed with plants that have variegated foliage, though, strictly speaking, it is not variegated, its white colour arising from its silky covering. In beds it is one of the most telling and enduring of plants, and it is equally effective on rockwork. Like most other Speedwells, it is not only kept in its best form when frequently divided, but, so far as I know, it is the only means of saving the plant from dying off in places, which old plants are apt to do. If the work of propagation is set about early in the year, fine plants may be had by the autumn: and these, if planted in rather stiff soil, to which this plant is somewhat partial, will lift with good balls, and may be employed for spring bedding. The advantages of this treatment are, that the plants are not liable to become uplifted by frost during winter, and that a very early crop of flowers may be expected in addition to the white foliage, the primary feature for spring bedding.

Primulas.—Such of these as are cultivated in pots will, no doubt, for the most part have been placed in shady or half-shady quarters, but keeping them there longer is not only a waste of the beneficial influences of sunlight, but the plants will hardly have justice done them. Fed up, as they are, much beyond what they would be in their wild state, they require all the more to be well ripened. If in plunging material lift them nearly out of it; there need be no fear that they will suffer from want of moisture; on the contrary, both roots and crowns will be benefited by being dried a little. I do not say it would be wise to leave them thus all winter. Doubtless during that season the roots would be kept in better health if the pots were plunged up to their rims, and not exposed to fitful sunshine, little as it may be.

Phyteuma campanuloides.—This may not be a very desirable border plant, owing to its straggling habit and somewhat weedy-looking foliage. But if its long slender spikes of purple-blue flowers could be seen in a cut state arranged with feathery Grasses and associated with just a morsel of white, it would commend itself for cultivation for that purpose alone. Its bloom-spike is not less than a foot or 15 inches in length in many instances, and the shorter lateral spikes, from 5 inches to 9 inches, can hardly be less useful. If one might be allowed to compare one flower with that of another and very different Order, the spikes of this Rampion may be said to much resemble a well-bloomed scape of Camassia esculenta, though the individual flowers are not so large. There is nothing special about the culture of Rampions, with the exception perhaps of comosum, with its hard, horn-like root: this kind and also the British ones require a deep rich loam for their long tap roots. In such a soil campanuloides grows quite 3 feet high. The flowers make their appearance in early summer and remain till frosts set in.

Planting dry bulbs.—By this I mean such bulbs as have suffered more or less from being out of the ground for a lengthened period; more injury is often done to such bulbs by inserting them directly out of paper bags into moist soils than one suspects. In the case of many Lilies, Sternbergias, Scillas, a few Narcissi, and even Tulips, we find the scales or wrappers often so much shrunken when too long out of the ground, that, to say the least, it is risky to set them in moist soil, which, of course, gets between the scales and induces decay which would never take place if the bulbs were fresh and plump. Death may not take

place the first season, because many can hardly be killed; but they send up weakly growths, and produce puny flowers. There is a remedy by means of which such bulbs may be restored to a proper state for planting. It consists in merely removing them from their dry quarters for five or six days before planting them, and in setting them out of doors on a moist bed of sand or Cocoa-nut fibre for that length of time. Thus treated the fractures in the bulbs will not only be found to close up, but the bulbs will become much heavier and plumper, and will soon begin to throw out roots. This practice I have followed in the case of dry bulbs for many years, and I am quite sure that bulbs so treated make a much more vigorous start either in the open ground or in pots than they otherwise would do.

Muhlenbeckia varians.—This is a better plant than M. complexa. For several weeks it has been in flower, if but sparsely. Such a thing has not happened in the case of M. complexa during nine years, though it has been grown in the hottest place I could find for it. M. varians is in stony clay, over which there is but an inch or two of mould. The situation is sunny and dry. It has been allowed to ramble into a young Rhododendron bush, and the upper twigs, most exposed, are those that produce flowers. I fear, however, that it is too late for us to see any berries, which are handsomer than the flowers. Grown under glass, either in a pot or otherwise, its fruiting is more certain. Apart, however, from either flowers or berries, both M. varians and M. complexa are very ornamental when planted on the dry parts of rockwork. Their habit is much more stunted than under glass. In fact, they become bushes, the twining habit only manifesting itself when the growth is rendered vigorous through the plants being placed in rich soil in moist positions. Even in dry situations they rarely get hardened in winter.

Rudbeckia (Echinacea) purpurea.—Mixed among yellow Rudbeckias this distinct form has a somewhat unique appearance. The reddish purple ray florets when newly opened are curiously contorted, a condition in which they remain for some days. When fully matured the blooms are as rich as they are distinct. I find this plant to be anything but a free grower, though I know it to be quite the opposite in some gardens, and it sometimes goes off suddenly and in an unaccountable way. I believe that the roots, which are as peculiar as the flower-heads, are partial to a sandy soil. They make very little fibre, and the healthiest growth is always made in porous soil. In the stiffer loams I never could succeed in making this plant grow at all. Even, too, when one is successful in getting good growth it is not at all certain that it will flower well. An exposed position in full sunshine seems essential to its well-doing.

Helenium autumnale.—This has been a mass of flowers ever since early in the summer, and still more and more are produced. They are not, too, smaller in size from having had so many predecessors on the same plant; on the contrary, they are quite as fine, and even more perfect as regards shape, and better in colour. The plant is now in what I consider its best form; but it may be interesting to state that the variety pumilum has long since ceased to flower and shows no inclination to follow the example of the type.

J. W.

Tritoma caulescens.—In common, I fancy, with most of your readers, I experienced no little surprise at the position given to this species in M. Victor Lebeuf's note on this genus. I have grown the plant since its first introduction, and it has very frequently produced its flower-spikes in the open ground. Invariably these have appeared in June, or early in July, according to the season. I am at a loss, therefore, to understand how it can flower in January and February in the latitude of Argenteuil. With regard to T. corallina, whatever difference exists between this variety and the T. Macowani disappears when it is perpetuated by seed. I have a considerable number of strong seedling plants, and I can affirm that no distinction is perceptible between them and T. Macowani either in colour, stature, or period of flowering. Apropos of the last-named species, I would remark that although M. Lebeuf puts it down as a June bloomer, it is in reality almost a perpetual flowerer; a strong clump will furnish spikes for two or three months, but the soil must be of fair depth and duly supplied with moisture. If the early spikes are allowed to mature seed, or even to bear it in any quantity, the further production of scapes will be considerably checked.—East Anglian.

TRANSPLANTING CHRISTMAS ROSES.

Like "J. C. B." (p. 313) I have learned the difficulties and dangers of autumnal planting through several failures and severe disappointment, and also the merits of spring planting by accident. Being a common plant, cultivators are prone to think that it may be moved at any time and in any manner. Thus it occurred that a lady who was very fond of Christmas Roses wished to grow them as winter or spring flowering plants among early flowering bulbs and other plants. There being a nicely furnished long-established border of Christmas Roses on the place, orders were given to lift these and plant them in the flower garden towards the end of October. This was done in a rough-and-ready fashion, and the results the first year were all that could be desired. In April they were moved back bodily, as near as may be, to their old quarters, and little more notice was taken of them till wanted again next autumn. It was then found that they had made few leaves, and that there were hardly any blooms, and the few there were refused to come up or expand. The plants made very little root, and not a few of them died. Disappointed and beaten in this almost my first dealings with Christmas Roses, it was needful to take means of increasing the stock. Plants were offered in a neighbouring market in full flower early in April, and these were purchased, divided into one-crown pieces, and planted in fresh and rather light soil. These formed roots, grew vigorously, threw up good crowns and several blooms in the winter of the first year. Since then, I have fought shy of disturbing Christmas Roses, though I quite agree that when transplanted in the spring, unless for a mere matter of one great display, then and there they should be divided into patches of single, two, or, at the most, three crowns. Those conversant with the semi-tuberous and fangy roots of Christmas Roses, and know how they bind themselves together in clustered and entwined masses, will easily see how impossible it is for them to form fresh roots in the centre of the mass. By pulling them asunder, which, when possible, is preferable to cutting, the roots and root-stock form new roots all round each one left, and hence their rapid growth if planted when the roots are in a state of activity. Planted in a dormant state, the larger roots seem to sulk and perish for lack of solidity and soil-hold. Clumps formed of a number of young plants are also far more floriferous than those formed by one, as the centre of the mass in old plants, for reasons already assigned, is mostly flowerless. Hortus.

Salpiglossis for beds and groups.—The Salpiglossis is a charming annual for beds and groups on borders for autumn decoration. The flowers are very bright and showy, and can be had in many colours, including crimson, yellow, and dark purple, all variously striped. By sowing in heat in spring, pricking the plants out early into pots singly, and growing them on for a time in a warm pit, they may be had in bloom by the end of June or beginning of July. They should be planted out when well hardened about the middle of May; in good soil they grow about 3 feet high. In habit they are light and graceful, and the flowers, taken off in sprays, are useful indoors for many purposes. Seeds may be saved now from the best marked flowers, gathering the pods and placing them on a sheet of paper in a cool airy room to ripen.—E. H.

HERBACEOUS BORDERS.

This season has undoubtedly been a good one for herbaceous plants. These in our case are in the kitchen garden on both sides of a well-made gravel walk 7 feet wide and 100 yards long, edged with ornamental tiles. Pyramidal fruit trees form the background, 8 feet from the edge of the walk; the trees are planted 9 feet apart, and between each tree we planted Hollyhocks, Pyrethrum uliginosum, tall varieties of Michaelmas Daisies, Helianthus multiflorus major, H. giganteus, Helenium autumnale, standard Roses, &c. These and the fruit trees form a suitable background for a herbaceous border. The fruit trees when in flower are in themselves an ornament, and they are not less so when laden with fruit. These borders this season look as well now as earlier in the year. They contain such plants as Gaillardia grandiflora, white and yellow summer-flowering Chrysanthemums, dwarf varieties of Michaelmas Daisies, such as Aster longifolius formosus, Amellus, salsuginosus, and multiflorus; Rudbeckia Newmanni, a striking plant just now, also the autumn-flowering Sedum spectabile, about which so much has lately been said concerning its attraction for butterflies and bees. The annual Chrysanthemums are very beautiful, and flower till frost sets in, *i.e.*, if the withered flowers are continually picked off them.

The white Anemone japonica is indispensable. If undisturbed, it flowers beautifully all through the autumn. We have one large plant of it which has stood where it is for years. It produces flower-stems 5 feet high, and the blooms individually are better than those on recently moved plants. Delphinium Cantab, Mrs. Miller, formosum, and ranunculoides all make grand border plants which also dislike disturbance. The varieties Cantab and Mrs. Miller, if cut down immediately their first flowers go off, will yield a good autumn supply of bloom if occasionally fed with sewage. The yellow Marguerite (Chrysanthemum Etoile d'Or) is a useful plant at this time of year. Plants of this that have done good service indoors in spring, if shaken out of their pots and the bottom roots pulled off, will make bushes 3 feet or 4 feet high by the autumn, and will furnish hundreds of flowers much richer in colour than those borne in spring. The hardy white Marguerite (Chrysanthemum maximum) is another grand border plant which, if fed with sewage occasionally, will yield large quantities of flowers that are most useful in a cut state. Amongst annual plants, Nicotiana affinis is one of the best. Plants of it from seed sown in heat in February and planted out like ordinary bedding material in rich soil produce by the end of the summer flower-heads over a yard through. Though the flowers are closed in the daytime, they open in the evening and early morning, and are very sweet-scented, chaste, and beautiful. The white and rosy-flowered lance-leaved Lilies likewise make beautiful border plants, which are now finely in flower, and they are quite hardy. The Queen Victoria variety of Lobelia cardinalis is also a handsome plant late in summer and autumn. In order to grow these successfully they must be planted in good rich soil and kept thoroughly moist at the roots. The best way to deal with the Lobelia is to take out about 1 foot square and 1 foot deep of soil from the border and fork in the bottom some good rotten manure. Then as the hole is filled add more manure mixed with the soil, leaving it a little below the surface. Plant four plants with a single plant of the variegated Veronica in the centre, and keep them well watered. A few clumps of this kind look extremely well.

Salvia patens in good light soil is one of the best late summer blue-flowering plants we have, and one which pays well for a little extra attention in the way of water and in supplying sewage occasionally. Tigridias, too, are strikingly beau-

tiful. They should be planted in sandy soil in the beginning of April where they can get plenty of sun; put five or six bulbs in a clump, with some silver sand under them, and then cover them with about 2 inches of light soil. Thus treated they flower well late in summer and autumn, especially the white variety, and though the individual flowers last only one day, they keep continually opening fresh blooms until frost puts an end to them. Nierembergia gracilis is a showy and conspicuous plant, and comes in well for filling up vacancies in herbaceous borders. Mignonette, too, is very useful for the same purpose. Fuchsia Riccartoni and corallina are also two conspicuous and graceful hardy shrubs suitable for plant borders. Single Dahlias likewise play an important part in making such borders gay, especially from this time on towards Christmas, *i.e.*, if frosts be merciful, and the later they flower the richer their colours are. Some advocate treating single Dahlias as annuals, but I dislike that plan where the border has to be kept trim. The best way is to mark a few of the best kinds that are not too rank in growth; select self colours, such as good yellows, crimsons, or whites (the best white with which I am acquainted being Duchess of Westminster), and then propagate these from cuttings annually. Double Zinnias, when planted in good soil well to the front of the border, prove to be very attractive. For the front line, about 6 inches from the edging tiles, we plant the variegated Grass (Dactylis glomerata elegantissima). This we divide in spring and plant pieces with two or three growths 1 foot apart; alternately with these we put Lobelias of the speciosa type close to the tiles. At the end of May we plant immediately behind the Grass scarlet and purple Verbenas and a few pink Pelargoniums. By the end of the season all these grow together—a charming mixture; the Verbenas falling among the white Grass, and the blue Lobelia peeping up here and there makes the whole very effective.

For filling up gaps at the end of the summer I sow a quantity of annuals very thinly in 3-inch pots in the early part of June, and plant them out without dividing them. Some very good annuals for this purpose are Alonsoa Warscewiczi, Calliopsis Drummondi, C. atrosanguinea, Nigellas (Love in a Mist), African Marigolds, and Mignonette. A few spare pot plants, such as small Fuchsias, are also very useful for this purpose. In my case I have generally in pots such plants as Lilium lancifolium, Montbretia Pottsi, Francoa ramosa, Madame Desgrange Chrysanthemums, &c., and these are plunged in the borders. I occasionally give our borders a thorough soaking with house sewage, and picking off withered flowers must have weekly attention. Many plants would flower more than double the time they do if this attention was given them.

Plants that die down below the surface should have something to mark their whereabouts, many good things being damaged and sometimes lost where this is not done. For my own purpose I use stout galvanised wire (three-sixteenths) cut into lengths of a foot for supports; one end is flattened, and a hole is punched through it for small zinc labels to be hung on it by means of galvanised wire. Before writing on such labels lightly cover them with the best white lead, then before the paint gets dry write the names on them with Wolff's pencils. Labels of this description will last good for years. Touch the ends of the stout wire inserted in the soil with boiled oil to prevent rusting; push them about half their length into the ground. We use such labels for naming and marking spaces for the plants, and with little or no disfigurement to the border.

Fox Warren. J. R. Hall.

Salvia patens.—"B." does good service by calling attention once more to the great merits of this old-fashioned plant, which is effective either as a bedding, ribbon, or border plant. Those who may be discouraged by its height—from 2 feet to 3 feet—may feel reassured by the fact that with a little humouring, for it is somewhat brittle, it may be pegged down. Those who wish, then, to keep it pretty close to the ground can give the shoots a slanting direction at planting. By carrying the main shoots along on or near to the earth and pinching out the points when they have reached a sufficient length, the shoots will break into laterals that will flower freely at heights varying from 1 foot to 2 feet. This considerably alters the general character of the plant, and, as many think, improves it by increasing the amount of bloom and rendering it more dwarf in habit. For mixed borders and bold groups, however, the natural loose and tall habit of this fine old Salvia is by far the most effective.—Hortus.

SAXIFRAGA SARMENTOSA.

Probably this pretty Saxifrage is best known as a basket plant hanging in windows. In this position its long pink threads hang straight down, some with tiny plants at the end, the threads growing longer and longer, vainly searching for

Mother of Thousands (Saxifraga sarmentosa). Engraved for The Garden from a photograph.

earth for the little plants to root into. It is properly a bank or rockwork plant, where its handsomely marbled leaves look well among rough mossy stones. It is hardy in our southern counties, but likes a sheltered place.

Anemone japonica in masses.—"Byfleet's" note on this subject (p. 312) is as timely as it is valuable. Two days before reading it I saw the finest masses of it I had ever met with in the fine old kitchen garden of the Duke of Grafton at Euston Park, near Thetford. Mr. Low, the duke's gardener, informed me that this beautiful autumnal Windflower was nearly a weed in the borders there. Certainly it is grown in enormous quantity in the mixed borders that abound in the kitchen garden. It is quite refreshing to meet with those cheerful relics of antiquity—the mixed borders, ever beautiful, fringing the quarters devoted to utility. The borders, too, may well rank among the most useful adjuncts of any garden. For all along them, gardeners in search of decorative leaves and flowers, and ladies and others who enjoy cutting old favourites for themselves, may come and cut again and again without greatly impairing the beauty of such well-filled mixed borders as abound in the kitchen gardens at Euston. Next to the Anemones, at the time of my visit, the single Sunflowers, Dahlias and autumnal Daisies were the most beautiful. But the greatest charm of such borders is that in all weathers and in all seasons there are always some pleasing objects of interest and beauty to be enjoyed or gathered. The major portion of the Anemones at Euston are white, which is by far the most useful. There are also many masses of the pink, but I did not see the red, nor have, so far as I can remember, ever met with such a red as that described by "Byfleet." All the reds I have ever seen have been pinks, varying in washiness of hue, but all comparatively worthless as contrasted with the white. But a really good bright red would be quite a different matter, and gladly welcomed to take equal or second rank with the white. Holders of good red strains of Anemone japonica would find it greatly to their interest to make them known.—Hortus.

NOTES ON POPULAR PLANTS.

Auriculas.—These will have been placed in their winter quarters, and the glass lights washed, repaired, and fresh painted. The glass is liable to become loose in summer, and unless made good and repainted, the leakage in wet weather injures the plants. Decayed leaves should be removed and the frames fumigated to destroy green-fly. As winter sets in, gradually withhold water, and when there is no rain the lights should be entirely removed. All alpine plants and their descendants naturally like plenty of air.

Carnations and Picotees will also have been placed in their winter quarters after having been potted. We began to take off layers in the last week in September. The largest plants are put singly in 3-inch pots, and the smaller ones two together in the same sized pots. The layers are well rooted this year and are stronger than usual. The weather has been warm and dry, conditions favourable to perfect development. They have, of course, received a sufficient supply of water. After repotting the lights are kept close or tilted a little at the back, more air being admitted by night than during the daytime. The young plants must on no account be allowed to flag; this they will do if exposed to bright sunshine or drying winds. During the last week in September the weather was excessively hot, but up to the present (October 9) not one plant has suffered. When the sun shone on the frames a mat was thrown over the lights, which were tilted about half-an-inch at the back, an attention which must be continued for a week or ten days; when the plants are established the lights should be removed altogether. Some varieties are very shy as regards forming roots, and if it be necessary to remove them from the parent plants before they are well rooted, they may be placed in a spent hot-bed; a brisk bottom heat would be injurious to them. Perpetual flowering varieties have been placed in a warm greenhouse; they are healthy plants in 5-inch and 6-inch pots. Larger plants might easily be had, but we prefer the smaller size, which when well managed flower freely from now until the first month in the new year, and intermix effectively with zonal Pelargoniums, Bouvardias, and other winter-flowering plants.

Dahlias have supplied us with an almost inexhaustible wealth of flowers this autumn. We have been cutting flowers from them almost constantly for harvest festivals and other purposes. There has been no frost to injure them in the least as yet, and the luxuriant growth made by the plants will have caused a corresponding root action; therefore the tubers may be expected to be of large size, and to keep better than usual this winter. For all sorts of decorative purposes small flowered double Dahlias (Pompons) are the best, and amongst Pompons the most useful in a cut state is Lady Blanche, a beautiful pure white variety.

Pinks.—These are doing well this year, but they ought now to be planted out in beds or borders. I like to plant them out in September, in order that they may get well established before frosts set in. Slugs and various kinds of grubs seem fond of Pinks, the leaves of which they eat mostly at night; it is, therefore, necessary to search for them with a good lamp. Rabbits, too, are very fond of them, and will take some pains to get at them. Frequent stirring of the surface soil is necessary during the winter. Now is a good time to lift from open borders plants of Pinks for forcing that have been in the open ground during the summer. Good clumps of these may be potted in 6-inch pots in good soil and be placed in frames, where they soon root into the good compost, and are ready when wanted to place in the forcing houses.

Gladiolus bulbs should now be dug up; this has been a good season for ripening them. When we get continued cold rains in autumn, the plants the following season decline and die at various stages of their growth. Some do not even appear above ground; others make good growth for a time and fail just before the flowers open. Seedlings grown in pots all through the season should now be shaken out of them, and the stems should be cut over close to the soil-line. Store them for the winter in dry sand in paper bags, and keep them in a cool airy room free from frost.

Pentstemons.—We are now putting in cuttings of these. They do well in boxes filled with sandy loam, and winter safely in cold frames. The treatment usually given to shrubby Calceolarias suits them remarkably well; they are almost, but not quite, hardy. Those who would like their plants to flower well late in autumn or early in winter should pick off all seed-pods as they form; if allowed to remain, they appropriate the sustenance that should go to the flowers.

Tulip planting time will soon be here; we have just gone over our stock of bulbs, and have had them all cleaned in preparation for planting; the bulbs are not large, but clean and healthy looking. We plant a few offsets with the flowering bulbs; these will not flower as a rule, but they make large leaves and form flowering bulbs for the year following. Preparation of the ground is an important part of Tulip culture. I have not, however, incurred much expense in this respect during these last few years, and we have had very satisfactory results. The ground is merely trenched and well manured. At planting time a drill is drawn as for Peas. A pinch of coarse sand is dropped where each bulb is to be planted, the bulb is pressed into the small mound of sand, the soil is drawn over the drill when all are planted, and no more trouble is taken with them. If some decayed turfy loam to fill up the drills is available, it would, however, be an advantage. When the plants appear above ground the surface of the bed is covered with decayed manure. We do not protect the beds in winter in any way. They may be planted at any time now and up to the middle of November, or even later. On examining some of the bulbs I find that they are swelling at the base, and if put into the ground would soon produce fibres.

J. Douglas.

Sunflower Miniature.—I fully agree with all that Miss Annette S. Wakefield, hailing from Uxbridge, says of this Sunflower. Entering a large garden the other day specially rich in autumnal Daisies and Sunflowers, the most brilliant of them all was the Miniature. The size of the bloom was not much larger than that of the herbaceous multiflorus, but it was even more brilliant and floriferous than that well-known species. It is not needful to add another word to the excellent description of the habit and character of the plant so truthfully given by Miss Wakefield. It is hoped the intermediate seedling referred to by that lady will yet seed with sufficient freedom to enable it to be widely distributed, as the more of these single Sunflowers we have the better.—Hortus.

—— With reference to my note on the above in a recent number of The Garden, I have received a communication from the Messrs. Sutton, of Reading, to the effect that my description must apply to Helianthus argyrophyllus, which is quite distinct from their Miniature Sunflower sent out by them in 1883. Accompanying this communication were specimens of the Helianthus in question, and also of their Miniature Sunflower. The former is identical with the new Miniature Sunflower sent out last spring by a leading firm of nurserymen. This has tolerably large, very woolly leaves; the habit is branching; it grows 8 feet high, and it does not bloom till late in the summer. Messrs. Sutton's Miniature is about 4 feet in height, and has small glossy green leaves. The flowers are good in form, apparently about half the size of those of argyrophyllus, and said to be produced freely and continuously through the summer. There could scarcely be a greater contrast than that afforded by these two Sunflowers. It is evident that Miss Wakefield, who differs from me in my estimate of the Miniature Sunflower, has grown Messrs. Sutton's variety. This seems certain, as she speaks of it as an old acquaintance; whereas the new Miniature—*alias* argyrophyllus—was distributed last spring for, I believe, the first time. Those, therefore, who wish to grow the true Miniature Sunflower must be careful from whence they obtain their seeds, or they will be likely to experience disappointment in meeting with, perhaps, an old acquaintance under a new name.—J. Cornhill.

Dahlia White Bedder.—In "A. D.'s" notice of bedding Dahlias (p. 336) I did not see this one mentioned, although I consider it to be the most effective of the whites. In point of habit it is almost perfection, the foliage being robust and of a rich green, the large pure white blooms standing up boldly above it. I went in early autumn, just when Dahlias were at their best, to see a large collection of them, and I thought White Bedder the most telling kind of all. It grows from 2½ feet to 3 feet in height, and is therefore well adapted for beds of moderate size. Wherever Dahlias are used for bedding this one should find a place.—J. C. B.

NOTES.

Lilium auratum.—This Lily is such a beautiful torment—that is to say, so capricious in its growth and so irritating in its tendency to die out on some soils—that I hope to be excused for again referring to its culture. A friend who had visited the Brook Lane Nurseries of Messrs. Davies at Ormskirk wrote to tell me that he had seen this Lily as raised there from seed in all stages and growing "like Grass," as he expressed it in his letter. I at once wrote to Messrs. Davies, who tell me they have no trouble whatever with auratums in their nursery. "They do grow like Grass in our light, sandy, and well-drained soil, but we have good hedges to screen them from the strong winds. We cannot boast of possessing many very large bulbs, for the simple reason that we sell them off too quickly and cannot give them time to grow big. We transplant them every two or three years and give them spent Hops and peat soil mixed with sand. Any well-rotted manure will answer. We raise them from seed in pans and plant them out as soon as they can be easily handled. We think full exposure to the sun is best for them, especially on damp or low-lying soils. Soil and climate have much to do with the successful culture of this bulb. You cannot grow them well in a heavy ill-drained soil; a peaty soil is most suitable, and they require plenty of sunshine to ripen up the bulbs and prevent decay." I hope this information will interest many besides myself who have only been partially successful in the culture of Lilium auratum. One thing seems certain, viz., that properly drained beds of light sandy peat, or peat, loam and sand will be necessary in most gardens where the soil is damp or heavy. Of course, I know how they grow and increase in Mr. M'Intosh's garden near Weybridge, where they occupy Rhododendron beds on a sloping lawn, but I shall try a bed of peat and sand specially prepared and well drained, and I propose to plant the bulbs in amongst the roots of dwarf Bamboos, as I am told they grow naturally in Japan.

Scarlet Lobelias.—We have no hardy flowers just now which can compete with these old herbaceous kinds of Lobelia in point of colour. There are many seedlings, from L. splendens, L. cardinalis, and L. ignea. One of the best is a form of L. splendens named Comet, which I saw the other day 4 feet or more in height, and bearing spikes of vivid scarlet broad-petalled flowers a foot or more in length. A very fine dark purple-leaved form of L. ignea named St. Clair is also far finer than the type, but if seedlings be reared from these flowers there is much variety observable in the progeny, a result not much to be wondered at, seeing that nearly all the Lobelias cross-fertilise each other with extreme facility. Like many other hardy flowers, these herbaceous Lobelias grow best when divided and replanted just as they begin to grow in the spring. They are not perfectly hardy on cold, wet, or retentive soils, but if lifted in autumn and potted, or if placed in boxes and protected in a cold frame all the winter, they are easily replanted during the following May. A good bed of Madame Castex Desgrange Chrysanthemum edged with Lobelia ignea is a sight worth seeing during chill October, and a mass of white Japan Anemone looks all the brighter if a clump of the Cardinal flower is planted near it for the sake of contrast.

Veronica Andersoni.—All the now numerous varieties of this Speedwell are tolerably hardy in nearly all seaside localities, and some are so distinct and striking when in flower, that the wonder is they are not more grown than they are everywhere by or near the shore. This plant is a hybrid raised at Edinburgh years ago by the late Mr. Anderson (who afterwards took the name of Anderson-Henry), and was the result of a cross by him effected between V. salicifolia and V. speciosa. The result is a shrub of considerable value, since in mild seashore places it continues fresh and floriferous all through the autumn and winter months. Some of the varieties have purple, crimson, blue, and lilac spikes of flowers and are far finer than the type. Even where they are not perfectly hardy in cold northern or midland places, it is easy to keep a few rooted cuttings in a pit or frame ready for planting out during the following spring. On light, dry soils they are now very fresh and pretty, especially at Bournemouth and elsewhere, in Hampshire, Somerset, Devon, Cornwall, Scilly, and in Ireland, as also in the Isle of Wight. The white variegated form of V. Andersoni makes a very useful decorative plant if grown in 6-inch pots, plunged outside in coal ashes, and watered regularly, with now and then a dose of weak manure water. Its bright oblong leaves of creamy whiteness show well by lamplight, and contrast well with Palms, Cyperus, and other Evergreens of similar habit.

Pampas Grass.—We ought to know a great deal more about Pampas Grass than we do. It is a very variable plant, and the varieties are by no means well defined. Some are tall and others short in habit; some are in flower early, while others hardly open ere the rains and frosts of early winter destroy all their grace and silvery sheen. Before purchasing Pampas Grass one ought to see the plants in flower, or one can never be sure of getting good forms. The dwarf rosy tinted form is distinct and pretty, but those who know it not must be satisfied with the merest suggestion of rose colouring, for if they imagine its rosiness to be anything approaching

that of, say, Spiræa palmata, or even S. venusta, they will be woefully deceived. Some kinds have a neater and more compact habit than others, and there is a difference in the strength of their culms, for while some sorts are easily broken down by rain and wind, others remain rigid and erect through the wildest storms. These distinctions, slight as they may be from a botanical point of view, practically mean a good deal in the garden, and it is the business of the gardener or amateur to select kinds best fitted for his purpose. There is a variety having a suffusion or a diffused stripe of yellow colouring down the leaves which gives a nice rich olive tone to the plant as seen in the mass. It is in some lists called golden variegated Pampas Grass, and, although a most satisfactory kind, it scarcely comes up to so definite a pseudonym. The only way to get good forms of Pampas Grass is to watch them when in flower and at once secure them.

Hypericum empetrifolium.—This pretty little sub-shrubby St. John's-wort is hardy during mild winters, but our plan is to save a rooted cutting or two in a pot in a cold frame. These are planted out during the month of May and grow away freely, and are now feathery masses of yellow flowers and bright green branchlets covered with narrow Flax-like leaves. I like it even better than H. Coris, which it somewhat resembles, but it is more erect in its growth. All the shrubby St. John's-worts are well worthy of general culture, and are easily increased from cuttings or slips of the young wood put in sandy soil, near the glass, in a cold frame. Young plants are most satisfactory, as when old the stems get gnarled and woody, and the flowers are neither so numerous nor so fine in size and substance as are those borne by healthy young specimens. I hope to try some of these Hypericums in pots another season, for, as it is, their latest buds and flowers are generally cut down by the first sharp frosts in November; whereas in a sunny greenhouse they would flower on for at least part of the winter season, and so be useful at a time when flowers are scarce. Has anyone tried the little creeping H. reptans as a basket-plant in a cool house? Outside, its golden blossoms are often a prey to snails and slugs, but in a basket they could dangle down near the eye, and one would have the satisfaction of knowing them to be safe from injury, while but few other basket-plants could be more graceful.

Nierembergia frutescens. — As a basket plant in a greenhouse or conservatory this Chilian plant is one of the most elegant I know, and has, moreover, the habit of flowering continuously. The pretty little cup-shaped flowers shade from lilac to white, and are borne quite jauntily on the tips of the numerous slender Flax-like shoots. It is hardy, or nearly so, in most localities, but is prettiest as grown indoors in the above way. Cuttings root quite freely in the spring, or indeed at almost any time, and if six or eight young-rooted bits are planted in a 12-inch basket, they soon cover it with a profusion of slender glaucous-leaved growths and dainty blossoms. One merit possessed by this little sub-shrubby species should not be overlooked, viz., that it is distinct in habit from nearly all other basket plants, its feathery spray-like growths being almost Asparagus-like in tenuity, and, as hung up near the glass, flowers are most freely produced. Like Ivy-leaved Pelargoniums, Harrison's Musk, some sorts of pendent-habited Fuchsias, and Begonias, this Nierembérgia grows and shows itself better in a basket than as grown in a pot. In some places it is used as a summer bedding plant, and grows and blooms freely as pegged down on the surface of the soil. Although long ago introduced to our gardens from South America, it is far less often met with in gardens than it really and truly deserves to be.

Pyrethrum uliginosum.—We have one or two white-flowered Asters and like them very much, but for size of flower and general effect we have nothing at all in that genus that can for a moment compare with this stately and floriferous Pyrethrum uliginosum. It carries on the Ox-eyed Daisy or Marguerite season into October and November, and its great white Daisy flowers contrast well in large dark vases along with the parti-coloured leaves of autumn. The increase and culture of this plant are of the easiest, our best plants being those divided and replanted every spring. It is just the plant to naturalise on the margins of wood walks or in plantations, where it soon becomes strong and vigorous in deep rich soil fed by the falling leaves year by year. It is quite robust enough to hold its own even when its roots have to compete with those of the surrounding shrubs and trees. In the kitchen garden belonging to the late Col. Fred. Burnaby at Somerby, near Oakham, in the fox-hunting country, I saw this plant years ago, long before it became popular as a hardy flower in gardens generally. An old herbaceous border ran the entire length of the garden backed by espalier fruit trees, which served to fence off the vegetables from the flowers—that is, it was intended that the wire fence and fruit trees should effect this purpose; but I remember this wandering Pyrethrum had crept under the fruit trees, and, at the time I saw it, was most rampant and most beautiful among the feathery red-fruited plumes of the Asparagus beds. It was a happy and suggestive union, even if an accidental one.

Helianthus lætiflorus.—Helianthus rigidus and several other perennial Sunflowers of that section were over weeks ago, but this H. lætiflorus is now quite fresh and beautiful. Its colour is so rich a yellow, that flowers of H. multiflorus simplex maximus near to it look almost primrose-coloured by contrast. This plant is a robust grower and increases rapidly. A friend sent me a morsel of its root ten months ago, and it is now 5 feet in height and bearing twenty or more of its vivid yellow semi-duplex flowers. This has been a very good season for all sorts and kinds of Sunflowers. H. orgyalis is now flowering well, a thing it very rarely does in this climate, and only the other day I saw H. tuberosus in blossom, which is even a yet more uncommon sight. The common annual Sunflowers have been good this year, but prettier than any is the pale primrose or sulphur-tinted kind, having a black disc which contrasts most forcibly with the ray florets. But, as a rule, it is the smaller-flowered kinds of the perennial race that are most useful for cut flowers and ornamental purposes generally. Some of them, such as H. rigidus, are dreadful ramblers, but by replanting the roots every spring they may be kept within bounds.

Rhus typhina.—No shrub I know dies off more brilliantly beautiful than does this feathery-leaved Sumach, which is just now a most effective combination of greenish red brightening into crimson and gold. A large mass of this plant backed up by evergreen Oaks is just now the most beautiful bit of colour in the whole place, and is much admired. It is a hardy shrub which grows very rapidly in deep rich soils, and it has the additional merit of being easily increased from root suckers or stolons, which are abundantly produced by old plants. Even when green and growing it has a distinct and effective foliage, and a few good groups of it on the margins of plantations, or beside woodland walks, or anywhere within sight of a country house would be always sightly objects, but at this season they would light up the landscape very prettily. I saw a bush of this Sumach the other day in a large bed along with Pampas Grass and Torch Lilies, and the effect, even at a considerable distance, was very beautiful. There is another species of Sumach which is often very lovely at this season on some soils where it is well established. I mean Rhus Cotinus, sometimes known as the Feather bush, its delicate hair-like inflorescence reminding one of Marabout feathers, shading from pale yellow to deep purple-red. Both these Sumachs deserve culture, and if well placed are very effective at this season.

Cotoneaster frigida.—Just at this moment we have no berry-bearing shrub or tree that can in any way compare with this crimson-fruited Cotoneaster. It forms a small tree 20 or more feet in height, and its topmost branches are now thickly set with its glowing berries, which shine bright and beautiful against the cloud-flecked sky. I know of no other berry-bearing tree which makes such a decided bit of colouring in the autumn landscape as does this Indian species, which is no novelty, having been introduced from Nepaul as long ago as 1824. All the species of Cotoneaster are fruiting well this season, and as a group they deserve more attention than they generally obtain. Some of the dwarf creeping species are very useful for covering masonry, or for creeping over moist mossy stones. One of the most rapid of growers is C. Simonsi, which makes a wall look cheerful during December and January if planted in company with Jasminum nudiflorum, or with any of the slender-growing small-leaved Ivies. One of the most distinct of all the species now in fruit is C. bacillaris, the leafy shoots or rods of which are now covered with axillary clusters of blackish purple berries in great abundance. It is so different from Cotoneasters generally, that at first sight one might be excused for not recognising it as a species of that genus. C. microphylla and its forms are often useful for covering walls or large rocky mounds; it is one of the very few shrubs which will grow downwards —a point well worth remembering.

Sundials in the garden.—It is a fancy of mine that every good garden should shelter that oldest of all chronometers, a sundial. I think it is Charles Lamb who says, "What a dead thing is a clock, with its ponderous machinery of lead and brass, its pert or solemn dulness of communication, when compared with the simple altar-like structure and the silent heart language of an old dial." The sundial was for centuries a garden guide, bearing witness to moderate labour and temperate refreshment. It was in a way the very epitome of all the Proverbs, the absolute ruler of all things done between the sun's rising and its setting. I can scarcely explain how it is, and that inability in itself is a testimony to its subtle interest, but the garden having a dial amongst its sweetest blossoms gives to me a greater pleasure than one where the figured plane with its gnomen is not hospitably entertained. I suppose the charm lies in the connection between the sunshine and the flowers, a union best seen during dull wintry days, when Aconites and Crocuses expand at the first breath of sunshine and shut again as clouds lower for rain. After all, Nature is greater than art, and so to-day, even in our mechanical era, we see children clustering round an old sundial just as bees swarm and hum among the blossoms of the garden. The interest of a sundial is perennial, as Lamb says it is Nature's own true measure for bird song, and also for the blossoming of beautiful plants. Veronica.

Michaelmas Daisies.—The more we see of these, the higher is our estimate of their fitness for the decoration of

our gardens in autumn. The best kinds are well worth placing in good positions, and they require very little attention, the chief thing being to divide them now and then. They grow up so quickly, that annual change of ground is the best treatment that can be given them. They should not, at any rate, remain more than two years in the same place.—R.

Rose Garden.

STAYING PROPERTIES OF ROSES.

"D. T. F." demurs to my statement of practical experience as to the best means of obtaining Rose-blooms that shall endure in a cut state, apparently because it does not dovetail into his speculation. Unfortunately, it has been the fate of many hypotheses, that have been founded on speculation rather than on the records of actual observation, that they have not been borne out by facts. Having grown Roses on soil of almost every conceivable consistency, the means shown by practical experience to be best adapted to the production of Rose-blooms that will "stand" well are summed up in the sentence of which "D. T. F." falls foul. It is true that a printer's error has made me talk about Roses journeying "to and from" shows, as if the same blooms were expected to come home and go out again like specimen plants, an achievement only occasionally effected with success by cut Roses; but beyond this, I am prepared to adhere to every point in the statement, and if "D. T. F." does consider it positive, I am glad that I succeeded in indicating my sense of conviction. If "D. T. F." would come down from speculation to facts and practical experience, we should be getting on; for instance, if he is convinced of the wrong-headedness of my practice, let him grow Roses on his "training" system, and bring up his blooms to one of the July shows in London; let him enter his Roses in one of the leading classes, and I will do the same; then let the judges say at four o'clock in the afternoon which flowers have stood the best. If "D. T. F.'s" flowers are placed first (say) three years in succession, then I will be delighted to "stand" him a lunch, and will admit that previously all rosarians must have been on the wrong tack, and will retire cheerfully to the contemplation of Roses growing strong and lusty as an athlete in their hungry wastes of sand.

There is one sentence of "D. T. F.'s" that I cannot get the "hang of": "As a rule, it will be found safer to thread one's way . . . . than to ride rough shod *through* the whole matter on the high level!" I give it up, but no doubt it elucidates quite a lot of truth. Oliver Wendell Holmes tells us that "the whole force of conversation depends on how much you can take for granted." If nothing can be taken for granted, discussion becomes impracticable, and, indeed, will be impossible with "D. T. F.," unless he will condescend to define the meaning of his terms. For instance, he objects to "assertions," and then cites as an example a purely conditional phrase; if the sentence quoted had been intended as an assertion, it would certainly not have contained the word "might." "D. T. F." himself writes, "We have not an atom of proof, direct or indirect, of any Roses having been starved to death." How is that for a man who finds fault with positive assertion? The rest of the remark conveys an intimation in many words that invisible signs cannot be seen, a proposition that may readily be granted, even if somewhat irrelevant.

The expression of a "bloom flushing" is new to me. If "D. T. F." will tell me what it means, I will tell him how I try to avoid it.

The rest of "D. T. F.'s" letter need not be discussed, as it is based entirely on a false assumption adopted by him to fit his own hypothesis; for, so far from the sandy soil being the most enriched with manure, the very contrary was the case. The heavier soil was well manured when trenched in the spring, and then received a liberal top-dressing when the trees were planted in the autumn, the mulch being forked in during the following March. The sandy soil was trenched and only slightly manured, not being at first intended for Roses, and this treatment was supplemented by a top-dressing of clay, as far as could be managed with limited means of carting, &c. The clay lay on the ground all the winter until the March winds dried it through, when it was thoroughly pulverised and incorporated with the native soil. The base of "D. T. F.'s" amazing contention, that "Roses grown on sandy soils are overfed out of their staying properties," therefore disappears.

It might be worth while to point out that, though "D. T. F." states that there are so many objections to the rule that strong growths carry first-rate flowers, he omits to enumerate a single one, were it not that further argument seems hopeless with one who does not distinguish between an active being with a free will and a passive subject of physical and chemical laws, or between the longevity of Rose trees and the endurance in water of cut blooms.

If "D. T. F." has come across anyone more conversant with the morphology and physiology of plants than Sachs and Prantl, or even Naegeli and Luerssen, we (I undertake to answer for my schoolfellows, whom, however, "D. T. F." also omits to specify) shall "positively be comparatively surprised," though superlatively interested, to learn his (the new botanist's) discoveries. But as "D. T. F." adverts to the scientific side of the question, let us briefly review the botanical facts that bear upon the point at issue. As I stated on p. 305, all that is necessary to keep a plant or part of a plant from flagging is a sufficient supply of water. The turgidity of a plant is dependent solely on its water supply, and when this is deficient the plant fades; but a faded plant may be restored to a state of turgidity by being supplied again with water, as anyone may prove for himself with an air-pump. Now the only way in which a growing plant can obtain water is through the roots, that is to say, it is entirely dependent for water upon the surrounding soil. Again, the whole food of a plant, except carbonic acid, is obtained through the same channel from the same source. Thus a copious supply of moisture in the soil is essential to the growth of a plant. The movement of water in plants is most noticeable at the period of most active growth, and though the movement of water effecting growth and nutrition is slower, the movement of water through the woody cells of the fibro-vascular bundles to supply the waste of transpiration and preserve the plant from a state of flaccidity is very rapid. These facts may serve to show that to grow Roses on moisture-retaining soil, and to supply them with abundant water in June, are not such unreasonable means of ensuring that the cut blooms shall continue in a state of turgidity as "D. T. F." would try to make out.

In conclusion, I cannot help thinking that if "D. T. F." had ever trained in an eight, he would not be so disposed to talk about the "moderate *regimen*" of an athlete; let him cater for a university crew for a week, and then see!

T. W. G.

THE EGYPTIAN PAPYRUS.

In your last issue "Veronica" asks what is meant by the byblus of Herodotus. Surely there can be no doubt but that it is the Papyrus! Not only is the name closely allied to the Greek *βύβλος*, but it has also given rise to the name of the town Byblus, in the delta of the Nile, in olden times so famed for the manufacture of paper from the Papyrus plant. Theophrastus (Hist. Pl., 4, 10) and Pliny (Nat. Hist., 13, 21-26) both tell us of the various uses to which this plant was applied, and, among other things, say the stem was used for making boats. From existing bas-reliefs we can see the ancient Egyptians of the fourth dynasty represented cutting down Papyrus leaves and binding the stalks together in the form of a boat. It is evidently to this custom that Isaiah refers when he speaks of "vessels of Bulrushes upon the waters" (xviii., 2). The Hebrew word here used is *gomè* (allied to the Coptic *gom*, a volume), and the same is applied to Moses' ark (Ex. ii., 3). It is, therefore, probable that Moses' ark was also made of the Papyrus. "Veronica" refers to the "paper reeds" of Isaiah; but this rendering of the Hebrew text is evidently wrong. In the preceding verse the word *gomè* is translated "reed," but here the word is *'aroth*, which literally means "green herbage," and not "paper-reed." The Papyrus plant, Theophrastus tells us, was a native of Syria, and, Pliny adds, it also grew in the Niger and Euphrates. In reference to Herodotus' remark that the roots were eaten, tubers of Cyperus esculentus (L.) have been found amongst the funeral repasts in some of the tombs of the twelfth dynasty (B.C. 2200-2400) in Upper Egypt. Several specimens are preserved in the Berlin Museum. Cyperus papyrus (L.) has also been found amongst other plants from the ancient tombs of Egypt (see Mr. Carruther's address to Biological Section, B. A., 1886). P. E. N.

Upper Norwood.

Garden Flora

PLATE 566.

SARRACENIAS.

(WITH A PLATE OF S. MOOREI AND S. POPEI.*)

The Side-saddle flowers of North America may be said to represent in the New World the Nepenthes of the Tropics of the Old World, and we know them both popularly as Pitcher plants, notwithstanding the wide difference between the two genera botanically. The cultivation of Nepenthes cannot be successfully managed without the aid of much artificial heat and the many other accessories to tropical plant culture, and it is no doubt owing to this fact that the many beautiful and truly wonderful Nepenthes now known are to be seen in only comparatively few gardens. But the Sarracenias do not require any more heat than is obtainable in an ordinary glass house, where fire-heat is used only in very cold weather, and we may therefore consider them as plants that may be grown in almost every garden of any size, where, according to Cowper, as well as the out-of-door garden there must be a greenhouse too. In Sarracenias we have a double attraction, viz., in the form of their pitcher-like leaves, which are often beautifully variegated, and in the large and handsome flowers which they produce very freely in the early summer months. These two characters are both exceedingly well shown in the accompanying plate, which ought to go far towards winning for Sarracenias a prominent place amongst popular greenhouse plants. It is unnecessary to go into the details of treatment for these plants, the pages of The Garden from its commencement up to recently containing frequent reference to the cultural requirements of Side-saddle flowers. The difficulty of making a plant known through a description in words is plain enough here, for it would be impossible to convey anything like a correct idea of the richness and beauty of colour and the singularity of form possessed by Sarracenias as shown in the plate. In the colours of the flowers and in the form and size of the pitchers there is very considerable variety amongst Sarracenias, and they are certainly amongst the most attractive of plants when grown in a corner or small house by themselves, as, for instance, at Kew, Glasnevin, and in several of the London nurseries. In our present remarks we intend more particularly to call attention to the hybrid kinds of Sarracenia which have been obtained by crossing the different species with each other, but before doing so it will be as well if the true species themselves are briefly referred to.

A few years ago an excellent synopsis of Sarracenias was prepared by Dr. M. T. Masters, and to this all admirers of these plants turn for

* Drawn in the Glasnevin Botanic Garden, Dublin.

the most recent historical information about them. There are six true species of Sarracenia known, all of them natives of the Atlantic States of North America. Darlingtonia californica, a closely allied monotypic genus, is, as the name denotes, a native of California, and the very remarkable, but as yet almost unknown, Heliamphora nutans, also a near ally to Sarracenia, is limited to the Roraima Mountain, in British Guiana. These three genera form the Natural Order Sarraceniaceæ, and all of them are in cultivation in English collections (Heliamphora is perhaps only in one collection as yet). Although frequently attempted, no one has succeeded in obtaining a cross between Sarracenia and Darlingtonia, and it is very likely that some functional barrier will prevent this from ever being accomplished. In the former the stigma is large, petal-like, and umbrella-shaped, and reflexed in such a manner as to completely conceal the stamens, much in the same way as those organs are hidden by the petaloid styles in Iris. In Darlingtonia the pistil is only slightly five-lobed and the stamens are exposed, whilst in Heliamphora the flowers are not unlike those of an ordinary Buttercup.

Specimen plant of Sarracenia flava.

S. PURPUREA is the best known, the longest cultivated, and the hardiest of the species; it has short horn-shaped, inflated pitchers of a deep blood colour when mature, the flap-like lid upright, so that rain easily falls into the pitchers. When well managed this sturdy plant forms a very attractive specimen. We have seen it grown in a 10 inch pot with at least thirty large crimson pitchers upon it, and in the spring these were accompanied by numerous large red-purple flowers.

S. DRUMMONDI has erect trumpet-shaped pitchers 2 feet or more long, the lid broad and wavy, the whole of the upper part being creamy white with a thick reticulation of reddish and green veins; the flowers are 4 inches in diameter and have dull red sepals, maroon-coloured petals, and the stigma, which is 3½ inches across, greenish red. It is still one of the most beautiful of all Sarracenias.

S. RUBRA.—In this the pitchers are erect, 1½ feet to 2 feet high, with a tail-pointed, inflexed lid, as in S. Moorei; they are green with deep red veins on the upper part, where, in autumn, they assume a uniform vinous colour. The flowers are 3 inches across and coloured reddish brown.

S. FLAVA.—This is the tallest-growing kind; we have seen pitchers of it which measured 3 feet 3 inches in length; they are erect, trumpet-shaped, green, the veins dark green (in some varieties red), and the lid, which is sometimes yellowish, is upright with the sides reflexed and the point tailed. The flowers, which are large, have a powerful odour, and are coloured a bright canary yellow. Some of the varieties of this, such as, for instance, ornata and atrosanguinea, are great improvements on the type, the former being very large and wide-mouthed in the pitcher; atrosanguinea, as the name implies, is remarkable for the deep red of its veins and lid.

S. PSITTACINA is a small plant with small horizontal pitchers, which have a broad wing like a knife-blade, a hood-like lid, and the apex of the pitcher so twisted as to give it the appearance of a parrot's head; hence the name. The almost transparent sides of the pitchers, with their numerous blotches of dark red, are pretty characters in this plant. It has only rarely been seen in flower in England.

S. VARIOLARIS is the least attractive kind, and it is not so easily kept in health as the others. It has pitchers 1 foot high, with a broad wing and a hood-like lid, and they are green with a little yellow mottling about the mouth. The flowers are large and pale primrose-coloured.

In several of the species we have considerable variation in the size and markings of the pitchers, but they all bear the stamp of their respective types, the descriptions of which about cover the characters of the varieties. We come now to the hybrid sorts. The last species introduced was S. psittacina, which Messrs. Veitch distributed in 1866, and from that time till 1874 no additions to the genus were made. In 1866 it was stated that seedling Sarracenias were unknown in this country. It remained for the late Dr. Moore, of Glasnevin, to not only succeed in raising plants from seeds, but also to obtain the first hybrid Sarracenia, which he exhibited in 1874, and which was named S. Mooreana. The parents of this beautiful plant were S. Drummondi and S. flava, and the characters of the two are blended in the offspring in the most perfect manner. The pitchers are large and richly veined, and the flowers are about 3 inches across, their colour being crimson, pink, and yellow. A flower and portion of the pitcher of this are shown in the plate.

S. POPEI.—This was obtained at Glasnevin through crossing S. flava with S. rubra. It is most remarkable because of its flowers, which are 4 inches across, and coloured rich velvety crimson, with yellow margins, and pink inside the petals. Mr. Pope, after whom this was named, is a foreman at Glasnevin, and has had the Sarracenias under his care for many years. A flower and pitcher of this hybrid are shown in the plate.

S. STEVENSI was obtained from S. purpurea crossed with S. flava, and originated at Trentham, under the care of Mr. Stevens. It is one of the finest of all Side-saddle flowers, growing into very large specimens, and holding its pitchers perfect much longer than any other kind. The pitchers are nearly 2 feet long, erect, broad, with a prominent wing, a large, almost round, lid, and they are coloured green with a reticulating nervation of brownish red. The flowers in this are also exceptional, being as much as 6 inches across, the sepals green with brown edges, the petals crimson outside, cream-coloured within, and the style, which is 3 inches across, bright green.

S. WILLIAMSI is an imported plant, and is supposed to have sprung from S. purpurea and S. flava in a wild state. The pitchers are shorter than in S. Stevensi, but similar to it in shape; whilst the flowers are 5 inches across and coloured reddish brown on the sepals, rosy lilac on the long petals, the large disc of the style being green. The contrast between these colours is peculiarly attractive.

S. PATERSONI was raised by Dr. Paterson, of Bridge of Allan, and is a cross between S. purpurea and S. flava. Except in the rich deep crimson colour of the upper part of the pitchers, there is little difference between this and S. Stevensi. It obtained a certificate from the Royal Horticultural Society at South Kensington about a year ago.

S. CHELSONI.—The parents of this were S. purpurea and S. rubra, and it was raised by the Messrs. Veitch in 1877. The pitchers are about 1 foot long, broad, as in S. purpurea, almost erect, and coloured a rich claret purple. The flowers are 4 inches across and purplish brown in colour. It is a handsome kind, and may be described as an elongated and improved S. purpurea.

S. MELANORHODA, also raised by Messrs. Veitch, was obtained from S. purpurea crossed with the fine hybrid Stevensi. In habit it is like S. purpurea, the pitchers being 6 inches long with a deep wing; colour rich blood-red.

S. FORMOSA, a hybrid from S. psittacina crossed with S. variolaris, has pitchers 6 inches high and coloured green, with reddish spots and veins. The pitcher is covered by the lid, as in S. psittacina, which it also approaches in the habit of the pitchers being almost horizontal.

S. COURTI was raised by Mr. Court, of Messrs. Veitch's establishment, and is a cross between S. purpurea and S. psittacina. It has decumbent pitchers, about 8 inches long, and coloured a rich deep crimson, and their form is intermediate between that of the two parents.

S. Swaniana, from S. purpurea and S. variolaris; S. Wrigleyana, from S. psittacina and S. Drummondi; S. Tolliana and S. Wilsoniana, from S. purpurea and S. flava; S. Mitchelliana, from S. Drummondi and S. purpurea; S. excellens, from S. Drummondi and S. variolaris; S. Maddisoniana, of the same parentage as S. formosa. These are hybrids, with characters partaking more or less of both parents, and which are all handsome in pitcher.

For descriptions of these, and also of several kinds not so well known, the reader may refer to THE GARDEN (Vol. XXVIII., p. 218). For cultural details for Sarracenias, see also THE GARDEN (Vol. XXIII., p. 341). B.

WORK DONE IN WEEK ENDING OCT. 12.

OCTOBER 6 AND 7.

STORMS of wind and rain on both these dates gave us the opportunity for which we had waited, namely, of arranging in something like neat order in the fruit room all Apples and Pears. We have plenty of space to lay them in single layers only; thus the work of examination to remove bad fruit is facilitated, and, what is better still, as they are laid so thinly, but very few decay prematurely, except from over-ripeness. The work of arrangement completed, all are neatly labelled, the floors cleaned, and the room ventilated freely in fine weather; but when the outside atmosphere is charged with moisture the ventilators are kept closely shut. Other work has been sponging plants, Dracænas, Palms, Crotons, and Gardenias, and washing the pots of Chrysanthemums, Bouvardias, Pelargoniums, Azaleas, Heaths, and Callas that have been put in houses and pits for the winter. Cut all the shoots of Peach trees in second house away from the trellis, and pruned the trees; the leaves are not quite all off, but this is of no consequence, as their work is completed, both wood and buds being thoroughly ripened. Still, for all that, we do not care to pull off the leaves much as we wish to see an end of them, that Chrysanthemums, &c., may have more light, which now that this moist weather has begun they need to

keep the opening buds free from injury by damp; necessarily, we have to over-crowd our houses to get in all the plants; hence the injunction to take special care to keep both foliage and buds as free of moisture as possible, and to water sparingly at the root whenever the outside atmosphere is charged with moisture. Stored away and sorted Onions into sizes, and arranged them on shelves in the order in which each sort is to be used. Gave potting, tool, and work sheds in general the thorough clear out they had long wanted.

October 8 and 9.

Very fine, and warm as midsummer—74° in the shade, and having, in this district, escaped the frost that occurred in some parts of the kingdom three weeks ago, the flower garden is still in the height of perfection. The rain of the past two days has made Pelargoniums look a little "weedy," but to most other flowers it has imparted freshness and to the plants new vigour. We have had a lot to do in the way of picking over of beds and sweeping up leaves, clipping grass verges and rolling walks, consequent on the storms of wind and rain of the last two days—a branch of work that at this season we sometimes feel disposed to shirk, but the resolution to do so does not last long—about a couple of days at most—and the "order of the broom" is again dispensed right and left, and wishes innumerable expressed at same time that the leaves would come down and be done with, but that is wrong, for what would then become of the beautiful autumnal tints of the trees that abound at the present time; they are more than magnificent, and the sight and enjoyment of them are worth far more than the little labour they cause in the way of sweeping up. Preparing stations for planting fruit trees, Peaches, Apricots, Plums, and Morello Cherries. Some old plants of each are to be replaced with young trees. Our soil being light, with an under stratum of gravel and sand, deep trenching is indispensable, and the gravel is taken out and the stiffest loam procurable substituted, and mixed with the light soil of the garden, together with a little chalk and a small percentage of crushed bones; this mixture is well pounded into the excavation made, and is then ready for the trees; obviously by reason of the gravelly nature of the ground, concrete bottoms or drainage is quite unnecessary; but in soils of a tenacious nature, drainage should always be the first consideration when fruit-tree planting is projected. Our rule is to plant as early in the autumn as possible, which virtually, if put in competition with spring planting, saves a year, as by the exercise of due care, trees that are transplanted now will bear well next year, but spring-planted trees cannot be warranted to bear till the following year, nor even to make the growth that autumn-planted trees make, apart from the question of fruiting, which I look upon as into the bargain. Therefore, plant as early as circumstances will admit, prepare the ground well, plant carefully, and not deeper than the trees have been in the nursery bed, and mulch thickly with good manure as soon as ever the plants are in. Got under cover the last of the Chrysanthemums; abundance of air will be given them in all weathers, short of actual frost, and any appearance of mildew checked by dustings of sulphur as soon as fungus is observed. Potted a few Deutzias, Rhododendrons, and Spiræas for forcing, and pruned a few Roses that have been grown in pots all the summer with the intention of forcing. The Tea section is the favourite class, and, what is a consideration, they always force better than any others, as they seem to revel in a moist heat. Shortened back all the laterals on Vines in the latest house, the better to allow the air to circulate freely about the fruit; artificial heat is always turned on at night, and, combined with ventilation, the fruit keeps perfectly; in fact, Gros Colmar and Lady Downes varieties are, as yet, scarcely fully ripe, so that, apart from the expulsion of moisture, heat is requisite for these kinds.

October 11 and 12.

We had another heavy storm of rain on the evening of the 10th, but finer and much colder weather has prevailed these two days, and precautionary steps have been taken to prevent damage of plants, &c., by frost. Except a few flower-garden plants, all that we care about now are in safe quarters, and the former we shall cover up with mats and canvas at night, for they are still in such good form that we wish to keep them out a little longer. We have lifted a very few of the rarer succulents, such as Echeveria Peacocki, E. farinosa, E. metallica, and the variegated variety of Sempervivum arboreum. Prepared cold pits for Strawberry plants; the earliest batch will be put under glass, but the great bulk we winter in pits formed with boards. The floor consists of a good foundation of cinder ashes, and the pots are plunged in the same, and in severe weather they are covered with straw, thatched hurdles, felting, or leaves—in fact, with anything to keep frost from the pots. Wet we do not mind, as the drainage is ample. Of course, if glass-covered pits were available, we should prefer to winter the plants in them rather than in the makeshift way necessity compels us to do. The latest potted plants still keep on growing, and runners and side crowns are kept persistently pinched off. The early plants being in small pots they quickly get full of roots; growth has stopped some time, and by way of giving them a short rest before putting them into forcing quarters—about the middle of next month—the supply of water will be lessened to the point of giving only just so much as shall ensure that no part of the ball shall get sufficiently dry as to make the leaves feel flabby. Perhaps I shall better express my meaning if I say that the soil should never be allowed to get anything like dust-dry, which condition I have from trials proved to be a more frequent cause of non-setting than any other of the many reasons that are advanced as the cause of failure in that direction. Took lights off late Peach house and gave the trees a thorough wash with a hose; the best part of the border is inside the house, and being able by removal of lights to, as it were, turn the border outside, is an immense gain when the labour of applying the quantity of water that such borders will absorb is taken into account. Soon as the border has got well saturated with rain, the lights will be replaced, and top-dressing of the border done as soon as the trees have had their annual dressing or painting over with a strong solution of soft soap and sulphur. Got all recently struck tender plants in stock-pots for next spring's supply of cuttings on to shelves in Pine pits; stagnation cripples them; they want plenty of heat to keep them gently on the move all winter long. I refer more particularly to Alternantheras, Coleus, Iresine, and Heliotropes; all others, or nearly all, will winter perfectly well in a greenhouse temperature, and many in a cooler temperature than that, so long as they are kept rather dry and free from cold currents of air, as these are the most prevalent cause of mildew. Weeded and pinched off runners from Violets in frames, also part of the flowers, in order to get increased vigour of plants. There was such a mass of flowers on very second-rate plants, that this seemed our only way of preventing premature exhaustion. Having a surplus lot of plants, we have planted them on a narrow border at the foot of a south wall, and, no doubt, if we are favoured with an open winter we shall get a good supply of flowers—in any case, they may be expected to flower well in the spring. Gathered all Pears, except the very latest kinds, such as Easter Beurré, Beurré Rance, Josephine de Malines, Ne Plus Meuris, and Directeur Alphand; these will be left till they really begin to drop from the trees; then the quality may be good. If gathered now they would only be fit for culinary use. Planted out more Lettuce on south borders, and pricked out the last of Cabbage and Cauliflowers to stand the winter. Earthing up Celery, preparing borders for fruit-tree planting by deep trenching. Pulled up Beetroots; they are stacked closely together in sand in a cool shed that is dry and impervious to frost. Salsafy and Scorzonera is conveniently stored in the same way. Carrots decay when thus stacked, and these we winter without any material between them. A month hence will be quite early enough to get these up. Parsnips we leave in the ground and dig up as required for use. The time to lift the lot is as soon as renewed growth starts in February. If left after that the roots quickly become tough and stringy, and therefore useless. Hants.

FRUITS UNDER GLASS.

The Orchard House.

In many places this structure will have been turned into a Chrysanthemum house, and the legitimate occupants will be standing out in the open air. The weather hitherto has been exceptionally good for ripening up the past season's growth, and as all forced trees have by this time recovered from the potting, the best thing will be their immediate disposal for the winter. In wet seasons we sometimes allow them to stand above ground for a few weeks to favour the hardening and ripening of the roots, but this first part of October has been so hot and dry, many will have found it necessary to plunge the pots to the rims to economise watering. Plums and Cherries, now bare of foliage, must be kept as cool as possible, and while guarding against dryness by burying the rims of the pots with old tan or decayed manure, no more water than is absolutely necessary must be given until the weather changes. Peaches, Nectarines, and choice Pears, on the other hand, will be benefited by the high temperature, as we rarely find them breaking into growth or their flower-buds getting too forward when they should be going to rest. If any late trees remain in their fruiting pots and a shift or shake out is thought desirable, there is no time like the present, as the sooner the roots are set free from old inert soil the sooner will they make a fresh start in the new. The foliage, it is true, may have fallen, but the trees will retain sufficient vitality to ensure the formation of fresh rootlets, and once started they will make steady progress for some weeks to come. Upon the same principle, trees of all kinds, intended for the orchard house, may now be lifted from the open quarters, potted firmly in good calcareous compost, and made safe for the winter. If of home-growth, and root-pruned last season, they will lift with wigs of roots which will preclude the possibility of anything beyond a wholesome check; and having been closely pinched throughout the summer many of them will be well furnished with flower-buds. It is gratifying to find in many places large trees in tubs and boxes which have braved many seasons and still going on in a satisfactory way. Many years ago it was considered good practice to pack stone fruit trees as close as they would stand under glass, and cut off the supply of water. Bud-dropping and premature old age naturally followed, and the system was voted a mistake. This state of affairs no longer exists, as the veriest tyro now knows his trees must be potted, tubbed, or renovated early in the autumn, and the soil in which they are grown kept moist throughout the winter. Moreover, he finds that turning into the open air all portable trees not only prolongs their lives, but also increases their health and vigour, and enables him to turn the orchard house into a gay greenhouse until after the turn of the year. Some trees there are too large for removal and too old to require pruning, as they make very short growths, and those if anything too thickly furnished with flower-buds, as every blossom sets. The proper course with these is the removal of a good quantity of the old compost round the insides of the tubs—if a foot or more in depth and 3 inches or 4 inches in width so much the better—and filling in with rather heavy loam enriched with bone-dust. The balls should be thoroughly moist when this is taken out, but the new compost should be dry, as firm ramming is one of the great secrets of success. The best time to perform this work is when the foliage begins to change colour, when watering to make the new as moist as the old will put the trees safe for the winter. When all the leaves have fallen and the

buds are firm and plump the judicious removal of some of the crowded spurs will insure a vigorous bloom and reduce the labour of thinning in the spring. The finest Noblesse Peaches, Stanwick Elruge, and Napier Nectarines which I gather are taken from trees in tubs which they have occupied for twelve years. They make very short wood, but this and the spurs require thinning out every autumn. They are trained in the ordinary way on a trellis in a span-roofed house and face the east. Stiff loam and bone-dust is their food, and they are well mulched with rotten manure as soon as the fruit is thinned.

Fruit room.—The gathering and storing of Apples and Pears is still in full force, and must be closely followed up until all the fruit is safe on the shelves. Although the season was late and the crops made but little progress until after midsummer, the fine rains following and preceding two hot periods brought about a most agreeable change, and fruit of all kinds on trained and untrained trees has finished up well. Indeed, many varieties of Pears and Apples are larger, brighter, and cleaner than we have seen them for several years past. The only drawback in many places is want of colour, but where they have been allowed to hang until quite ready for plucking, many varieties, notably of Apples, will yet finish off well in the fruit room. Crops, unfortunately, being partial, frequent advice to lay the fruit as thinly as space will allow may this year be carried out to the letter, but where the owner has the good fortune to hold a full stock, Pears of the best quality will pay for storing in rooms somewhat warmer than would be good for Apples. The fruit room, it is needless to say, should be kept scrupulously clean at all times, dry, cool, and airy, until the sweating process is over, when the ventilators may be partially closed to maintain an even temperature. Just now it ranges unusually high, 65° to 70° in the shade, and the ground being dry and warm, it is more favourable to the ripening of the trees than the keeping of the fruit, but this is a godsend of which no one will complain, as fruit-buds are abundant and promise well for another season. Having disposed of the best and longest keeping fruit on latticed shelves, through which the dry, cool air of the room can circulate, much space can be gained by folding extra fine specimens in tissue paper and placing them in air-tight earthenware pots, boxes, or drawers. The fruit selected for this mode of storage should be free from spot or blemish, quite dry and nicely coated with the varnish which sweating produces, before it is put away for the winter. Apples and Pears so managed will keep sound, crisp, and fresh much longer than others of their kind laid on open shelves, but the greatest care must be observed in their selection, otherwise the principle that one scabbed sheep soon affects the whole flock will find its parallel in the fruit room.

The Hardy Fruit Garden.

In recent papers I have pointed out the importance of carrying out all root and border work in the forcing houses before the leaves fall. This week we must look round and see what can be done for our hardy fruit trees. Wall trees of all kinds, with the exception of Apricots, in this district have acquitted themselves better than the tardy spring at one time led us to anticipate, and, as I have just observed, they look promising for another season. But this apparent security must not become a stumbling-block, otherwise trees just suspiciously strong this autumn, if left alone, may become unmanageable before we reach another. This is the more likely to happen, as the full crops which many trees have borne and the probable dryness of the subsoil have prevented them from forcing up a persistent growth of lateral; but the roots are there, and a wet winter may give them food for mischief next season. To counteract this, the regular system of root-lifting, so often advocated in The Garden, should now be in full force. Apricots and Peaches, the latter as the fruit is cleared, come first; then we have Cherries, Plums, and, last of all, Pears on walls. Pyramids and bushes may also be taken in hand, but wall trees, naturally the ripest, should always take precedence. If nothing more is needed, old mulching and inferior material should be removed from the wall paths, and if, as I suspect, any of the borders are too dry, the subsoil roots should be well moistened before they are covered up with new compost. Years ago it was the practice to make deep undrained borders as dry as possible by digging trenches round the trees and leaving them open often for weeks together in the autumn, but this is all changed, and the greatest danger the modern border-maker has to contend with is a dry stratum overlying a foot of drainage. Water in many places is plentiful enough; in others, thousands of gallons of the best which now runs away might be stored at trifling expense, as tanks open to the atmosphere are better than close ones; indeed, where the altitude favours natural gravitation there is nothing better than a well-puddled shallow pond for receiving the water intended for fruit tree borders. To the new beginner who has never reduced root-pruning to a system the labour appears formidable, but such is not the case—at least, where properly managed borders are attended to every year. To some new compost is an unsurmountable difficulty, but where there's a will there's a way, and poor indeed must be the locality which will not yield, when occasion requires, a few loads of fresh loam, burnt clay, and road scrapings.

Planting generally succeeds, or it may be carried on conjointly with root-pruning during the month of October and the early part of November. December and January are the worst months, as the roots, more or less injured, lie so long dormant in the cold soil and not unfrequently perish before spring. On very cold, tenacious soils spring-planting may perhaps be preferable to late autumn planting, but on these October is the month, as new roots are emitted at once and danger from spring drought is avoided. All these points should be well considered, and when a certain course has been decided upon despatch should be the order of the day. The ground at the present time is not only dry and workable, but it is unusually warm, and for these reasons, and for others to which I need not here allude, all who can should leave this root and border work in a finished state behind them.

Varieties.—Although all the best nurserymen have reduced their lists to an extent which renders the selection of inferior sorts of Apples and Pears an impossibility, and short lists of varieties which do well in different parts of the United Kingdom frequently find a place in the pages of The Garden, amateurs more than ever are constantly asking for information. This is an important step in the right direction, as it shows that growers both for private use and for profit are alive to the fact that they must put their shoulders to the wheel or be beaten out of the field by their colonial kinsmen. A few writers have thrown cold water on Apple and Pear growing, and the masses have been cajoled into the belief that American Apples are superior to the best we can grow in England; but I contend that our best samples are preferable, and the modern system of properly preparing the ground and planting Pears on the Quince and Apples on the Paradise stocks will enable the British fruit grower to keep his head above water. The great mistake which the majority make is the selection of too many varieties. All may be good in their way and in certain districts, but the autumn and early winter Pears and Apples are too numerous; moreover, they vary to an extent in different soils and localities which renders the giving a list which will suit all buyers a simple impossibility. Pears vary, perhaps, more than Apples, as we not unfrequently find early varieties worthless in the south and excellent in the north; while some late ones, as a rule, are good in the south and second-rate, or only fit for cooking, in the north. Early Apples, on the other hand, are improved by warmth, and for this reason varieties which succeed fairly well in the midlands or northern counties generally come extra fine on good soils in the south. Private growers in advanced fruit districts experience little, if any, difficulty in making selections, as they have only to look round and make themselves well acquainted with sorts which do well with their neighbours before they plant. This point settled, they should then purchase a few of the best in duplicate in preference to endless variety, as it is really astonishing how well a few suitable kinds will carry a family through the season. Commencing with first earlies, they might plant Irish Peach, Worcester Pearmain, and Kerry Pippin, Lord Suffield, Keswick Codlin, and Echlinville. For succession, Adams' and Golden Winter Pearmain, Cox's Orange Pippin, Golden Reinette, Ribston Pippin, Sykehouse Russet, Claygate Pearmain, and Court of Wick, Stirling Castle, Cellini, New Hawthornden, Golden Noble, Blenheim Orange and Flanders Pippin. For winter and spring use, Ashmead's Kernel, Court Pendu Plat, Golden Harvey, Mannington's Pearmain, Ord's Apple, and Sturmer Pippin; Alfriston, Brabant Bellefleur, Brownlee's Russet, Dumelow's Seedling, French Crab, Hanwell Souring, Northern Greening, Royal Pearmain, and Striped Beaufin. Of Pears, a still smaller number would suffice, as gathering at different times and storing in warm or cool rooms prolongs the season of different varieties, and enables the grower to dispense with all evanescent sorts which are hardly ripe one day and sleepy the next. Of sorts which come in before the end of October the name is legion. Many of them are remarkably fine, but they do not keep; consequently very few trees should be planted. The old Jargonelle is a household name, then we have Beurré de l'Assomption, Souvenir du Congrès, Williams' Bon Chrétien, Beurré d'Amanlis, Madame Treyve, and Fondante d'Automne. A more useful list includes Beurré Superfin, Beurré Hardy, Emile d'Heyst, Louise Bonne of Jersey, Marie Louise, Red Doyenné, Doyenné du Comice, Pitmaston Duchess, and Thompson's. For use from November onwards the following come in: Huyshe's Princess of Wales, Hacon's Incomparable, Winter Nelis, Glou Morceau, Josephine de Malines, Knight's Monarch, Jean de Witte, Zephirin Gregoire, and Van de Weyer Bates.

A Score of Good Late Apples.

Growers who are already well supplied, or possibly overdone, with early and mid-season Apples will not go far wrong in planting or grafting the following: Ashmead's Kernel, Baddow Pippin, Brownlee's Russet, Coe's Golden Drop, Cox's Redleaf Russet, Duke of Devonshire, Golden Harvey, Hambledon Deux Ans, Lord Burghley, Lemon Pippin, Lodgemore Nonpareil, Old Nonpareil, Northern Spy, Ord's Apple, Reinette Van Mons, Ross Nonpareil, Sturmer Pippin, Striped Beaufin, Winter Queening, Court Pendu Plat. If kept in a dark, cool, moderately dry fruit room these Apples will come into use from Christmas onwards, and give a supply up to the end of May. If I lived in an intermediate or cool district and wished to grow these varieties well I would erect rough wooden walls 6 feet or 8 feet high, and, worked on the Paradise stock, train them as oblique cordons. How seldom we meet with the Old Nonpareil and Margil in really good condition, and yet they are two of the finest flavoured dessert Apples grown. When worked on the Paradise stock they are marvels of fertility, and, being moderate growers, they need not be planted more than 18 inches apart. Add to these Cox's and Ribston Pippin, Golden Harvey, and Ashmead's Kernel, give them a south or west aspect, let the borders be narrow, properly drained, and well mulched, and the grower will produce six varieties fit to place before a king.

W. Coleman.

Eastnor Castle, Ledbury.

Wasps amongst Ivy.—If "D. T. F." (p. 352) will examine the wasps which congregate on the Ivy flowers, he will, I think, find them to consist almost entirely of males. There may be one or two workers and queens with them, but the bulk

will be found to be drones. Ivy flowers are a favourite resort of insects at this time of year.—A. R., *Windermere.*

Trees and Shrubs.

THUJOPSIS DOLABRATA A HEDGE TREE.

In his concluding remarks on this tree Mr. Webster says (p. 322) "If Mr. Coleman will tell where the hedges of Thujopsis dolabrata, to which he recently referred, are growing, he will answer a query which has been asked by more than one correspondent." If I wished to gain time or parry the question, I might do so by asking Mr. Webster in return where he saw my name appended to the statement that I had seen it growing as a hedge tree. But I will not do Mr. Webster, myself, or our guild an injustice by admitting the assumption that he for one moment thought I was "throwing the hatchet" or "drawing the long bow" in my recent defence of the hatchet-leaved Thujopsis. In my paper (p. 169), to which I beg to refer your readers, I stated that Thujopsis dolabrata was "alike useful in the pinetum, the flower garden, as a screen or hedge tree, and last, but not least, as a lawn specimen in the villa garden." My object, as all planters who have seen the Californian giants growing in small gardens will readily understand, was to draw the attention of villa owners to its adaptability to their requirements; but how this sentence can be converted into a statement that I had seen hedges of it I will leave others to decide. Many years ago I surprised a great nurseryman by asking him to quote two or three Conifers at prices that would enable me to use them as hedge trees. I had never seen them used in this way, but my experience justified the opinion that they would answer my purpose. I was not disappointed; and now miles upon miles of these hedges are in existence. On the same grounds, twenty years' experience with Thujopsis might have justified Mr. Webster's rendering of my remarks, but in this case it fortunately happens that I am supported by facts, and lest any of your readers should feel disposed to read between the lines of his paragraph, I beg to say I can look upon a hatchet-leaved hedge every day of my life. That hedge is within five minutes' walk of my house, and readers interested in Conifer hedges, Mr. Webster included, may reckon on a hearty welcome when opportunity favours their calling to see it. The "query" put forth by so many has never caught my eye, otherwise I should have answered it, as it has been, and always will be, my practice to give information in a plain, unvarnished way, and I have endeavoured to avoid useless discussion by confining myself to facts fully authenticated by my own experience.

William Coleman.

Eastnor Castle, Ledbury.

Acer Leopoldi is one of those variegated trees of which we should recommend the universal employment were it more vigorous. It is especially distinguished in early spring, when the leaves first appear, by a coppery-yellow tinge of incomparable richness and effect.

A good Weeping Poplar.—Poplars of late years are receiving attention, and already our list of weeping varieties numbers four or five distinct kinds. According to our idea of beauty, however, there is but one really first-class tree, and that one is among the finest of all the drooping plants; we allude to the P. grandidentata pendula.

Purple-leaved Barberry.—This is a variety of the common Barberry (Berberis vulgaris) which, in spring, has leaves of a vinous red colour, afterwards becoming brown by degrees, until, in autumn, they change to a purplish green. When the plant reaches a certain age it undergoes a change. The branches droop and become warped, and the leaves grow small and dull-coloured. Fortunately, it is easy to preserve this handsome shrub in a condition of perpetual youth, beauty, and freshness by cutting it back close to the ground every second year. The finest specimen I have seen of it is in the richly-stocked arboretum at Westdean Park, near Chichester, where, at the present time, the purple-leaved Barberry and the common variety are now in great beauty.—W. G.

The Weeping Sophora (S. japonica pendula).—There is no weeping tree with which I am acquainted that can equal this in beauty, but unfortunately it is of slow growth. Ten years ago I planted a tree here of this variety in a soil in which all kinds of Conifers and deciduous trees grow in the most luxuriant manner, but the Sophora makes but very indifferent growth. It would, therefore, be interesting to hear if there are any trees in the country that are making satisfactory progress; possibly our soil, which rests on red sandstone, is not quite suitable for the requirements of this tree, but all other Leguminous trees grow here freely.—J. C.

The Red Maple (Acer rubrum).—Why is not this beautiful deciduous tree more extensively planted? As an ornamental tree at all seasons few equal this in beauty; in spring its flowers render it especially striking; in summer its compact growth and fine foliage make it a very effective shade tree; whilst in autumn the brilliant golden-yellow of its decaying leaves attracts the attention of even the most casual observer. It is not such a rapid grower as the Silver-leaved Maple (Acer dasycarpum), but is neater in habit and much more handsome during early spring, its blossoms being deeper in colour and endure for a much longer time.—G.

Abies Alcoquiana.—This is a Spruce which for ornamental purposes is not surpassed by any of its congeners. Its habit of growth is free, and its colour a silvery glaucous hue, which in the case of the young shoots is very conspicuous; the plant, too, is thoroughly hardy, and not fastidious as to soil and situation. Where planted in company with some of the darker-leaved species such, for instance, as the Norway Spruce (Abies excelsa), the contrast is very striking. This Fir is a native of the mountainous parts of Japan, whence it was first introduced by the late Mr. John Gould Veitch.—A.

The Sea Buckthorn (Hippophaë rhamnoides).—If this will produce its bright orange-coloured berries, resembling somewhat those of a miniature Solanum, as freely in this country as it does in Switzerland, where I found it in great abundance, both in the Rhone valley and also in the Prättiqua, I should say it would be a good addition to our shrubberies. Small seedlings of it which I received by post from the Tyrol have grown with great rapidity, but as the tree is diœcious, as is the Aucuba, it remains yet to be proved whether I shall have any berries on those sent to me or not.—J. T. P.

The common Barberry.—This forms in suitable positions a striking object at this season, when heavily laden with bright scarlet fruit. It should occupy a slightly elevated spot, exposed on all sides, to permit the plant to assume its true character. It is one of the handsomest of our native shrubs, and deserves more attention than it gets at the hands of the modern planter. It has a chaste, elegant appearance when in flower in spring and even when leafless in winter plants of it are not unornamental. There are several varieties, though the only one with which I am acquainted that is at all common, besides the normal type, is the purple-leaved variety. The fruit of the common Barberry is sometimes used to make a preserve.—E. H.

The Red Horse Chestnut (Æsculus rubicunda).—This is one of the most handsome flowering trees that enliven our parks and gardens in spring. When in full bloom the effect of so many brightly coloured spikes of flowers is really grand, and forms a fine contrast to the lighter blossoms of the common kind. It is too well known to need any description, being commonly spoken of as the red-flowered Horse Chestnut to distinguish it from the common kind (Æ. Hippocastanum), from which it differs, besides the colour of the flowers, in being a much smaller tree and of a greater depth of green, while it is also somewhat later in opening its blossoms. As a lawn tree of a medium size it is unsurpassed, being admirably adapted for single specimens, from the circumstance that, so treated, it forms a dense tree of a beautiful regular outline, the ample foliage of which is very handsome, even when not in flower. As the red-flowered Horse Chestnut is generally propagated by grafting on the common kind, it comes into flower much sooner than it otherwise would if raised from seed. Individual plants vary a good deal in colour, no doubt owing to the tree having been propagated from seedlings, but it is the deep rich-coloured form that makes the finest display. There appears to be some doubt as to the origin of this tree. It is also known under the name of Æ. carnea. Of the common Horse Chestnut (Æ. Hippocastanum) there are several varieties, but the variegated forms, however beautiful they may look when in the propagator's hands or in the form of small plants under glass, are seldom satisfactory when planted out of doors, the sun and wind generally turning the variegated portions to a brownish hue. Besides the variegated there is also a cut-leaved form, while the double-flowered came with a high recommendation from America, which up to the present hardly seems to have been borne out in England, but probably as the plants become stronger and better established finer flowers will be produced.—A.

HARDINESS OF THE REDWOOD TREE.

Some say that the Californian Redwood, Sequoia (Taxodium) sempervirens, has not done well in this country, except in localities in which shelter from cutting winds is afforded. This is true, no doubt, to a certain extent, especially in the northern counties of England and Scotland, but it can hardly be applied to the southern and western counties of England; neither can it apply to Ireland, for there this tree grows most luxuriantly; the humid climate there and the deep soil, full of vegetable matter, are just what it delights in, and I think it is the place of all others to plant it exclusively with a view to produce timber, and where colossal butts of it may be anticipated in the future. My opinion of this tree is that it will prove to be the fastest producer of timber amongst all the Conifers, the Sequoia gigantea not excepted. The latter will probably grow to a greater height, as it is not so liable to lose its leading shoots by rough winds as the S. sempervirens is; but it is not likely to make so bulky a butt of timber, as its stem tapers more rapidly. I base my opinion on observation of several specimens growing in the south of England. I have seen several specimens of Redwood in perfect health and growing vigorously, and in the poor, green-sand soils in one plantation they are keeping pace with the Larch of the same age and time of planting. There is no doubt that this tree succeeds best and grows most rapidly in deep, moist soils, and when protected from rough winds, like all other fast-growing Conifers; but, at the same time, I maintain that in the south and west of England and Ireland it will thrive in almost any situation; on the other hand, I have seen it in the North Riding of Yorkshire present a miserable appearance, so battered and disfigured by storms, that one could scarcely recognise it, so greatly does difference of locality affect trees. The heart-wood of this Sequoia will, I think, prove valuable for furniture-making and for other constructive industries, where a richly-coloured, fine-grained wood is essential; it is also susceptible of high polish. I have in my possession a piece of the stem of this tree, about 6 inches in diameter; the heart-wood is of a reddish colour, close and fine-grained, while the sapwood is white, soft, and probably not durable, and of little value. G.

Ulmus Berardi.—This is a very remarkable and distinct variety of the common Elm (U. campestris), raised some years since by MM. Simon-Louis, of Metz. It forms a very bushy shrub with very slender branchlets, and in its foliage exactly resembles Comptonia asplenifolia. The leaves are of a very dark green, almost black, very small, and irregularly crenated, like those of Planera crenata, and usually stand erect on the branches, which they almost entirely hide from view. This variety is at present

not much known, but it cannot be too highly recommended as a singular, effective, and ornamental shrub.—G.

Pinus koraiensis.—This Japanese Pine appears to be the same as the P. parviflora, although the figures of the cones, published by Siebold, look very distinct, but the one is figured open and the other shut, which may be the explanation of this. I have lately seen P. koraiensis in cone, and the cone which that tree bears is identical with Siebold's figure of P. parviflora. Its leaf has a beautiful white silvery side, which gives it almost a variegated appearance, and as it seems hardy it will come in well with any of the dark Firs, such as the European Cembra or austriaca, or the Scotch Fir.—E.

A NEW HYBRID CRINUM.

(CRINUM POWELLI.)

To the list of hardy bulbous plants has lately been added this beautiful hybrid, raised by Mr. Powell, of Southborough, Tunbridge Wells, between the well-known hardy Crinum capense and C. Mooreanum. The hybrid is exactly intermediate between the two parents, the flowers being as large as those of Mooreanum, of an exquisite rosy pink colour and produced in clustered spikes, as is C. capense; it is, moreover, quite as hardy as the latter species. The following note respecting its origin has been sent to us by Mr. Powell:—

"This hybrid Crinum was raised from seed in Suffolk ten years ago, and having within the past two or three years become widely distributed in many districts both in England and Ireland, its complete hardiness may be said to have been thoroughly tested, and those who have grown it find it to increase in vigour and size yearly. All it wants is to be planted in a suitable spot, and if not meddled with, it will then take care of itself. It seems to grow twice as fast as C. Mooreanum in Kent, though Mooreanum, as seen out of doors at Glasnevin, is most satisfactory, both as regards foliage and bloom. I have tried Powelli in a pot, but could not get it to thrive, though in the same house Mooreanum succeeded well. The leaves of Powelli have great substance, and taper to a point; whereas those of Mooreanum are uniform in width and soft, and out of doors easily broken. They are not rigid and erect, like those of Powelli which they somewhat resemble in colour, being quite distinct from the glaucous green and prostrate leaves of C. capense. The flowers of Powelli vary in colour from pure white to deep rose, but bulbs of the white kind are very scarce as yet, and it does not develop many offsets. Strange to say, the white-flowered plants were obtained from C. capense roseum; while those from C. c. album (which was also used as a seed parent) had the deepest shades of rosy pink. The flower-stems of Powelli reach fully 5 feet in height when the bulbs are well established; the latter must be planted deep, with plenty of manure beneath them, but not in contact with the bulbs. This variety has never shown any signs of producing seed, but it has not been fertilised with any pollen except its own."

CLIPPING BOX EDGINGS.

THAT there is a right and a wrong way of doing things is a truism which applies equally to the annual trimming of Box edgings as to any other gardening operation. The condition of the Box bordering in many places is, however, a proof that this fact is not universally recognised. One often sees it wearing through the summer an aspect the very reverse of verdant, and in most cases this dingy appearance is due to the right moment not having been taken for cutting it in. Many of your readers will have remarked that the fresh green look of Box edging often suddenly gives place to a rusty, blighted appearance, from which it rarely recovers till the advent of the early autumn rains puts fresh circulation into the foliage. This is almost always due to the action of spring frost upon the tender budding foliage, and which seems to be about as susceptible to injury from this cause as that of any outdoor plant.

There is a natural tendency to push forward work by clipping Box edging early in the spring; this causes an early growth, which is just in the condition to be nipped by a sharp late May frost. The safeguard is to defer the cutting until the end of April, which just enables it to tide over the critical period. The new garb is not then put on till summer is on its way and frost is gone from us. Then comes a free, unchecked, healthy growth, which renders Box-lined garden paths cheerful and pleasant to the eye through times of heat and drought. But the clipping must not be too long deferred, or evil will come in another way—the young growths come away so tardily when hot, dry weather suddenly comes after clipping, that the appearance of the Box is the reverse of good for a couple of months or more; indeed, it sometimes fails to recover its true character before autumn. In brief, clip so that growth is just well commenced as the danger of frost is over, but sufficiently early to allow of the old wood breaking again before a scorching sun can act upon it. In some gardens it is not considered necessary to clip Box more than once in the year, but in many places two annual trimmings are regarded as imperative. I consider the early part of September to be the best time for the second cutting, as the wounds have good time to heal before the winter. To the skilled hand the clipping of Box edgings is an easy matter, but the inexperienced amateur generally finds it difficult to keep them even at top and of uniform thickness. So far as I am aware, nothing but practice will enable the operator to succeed in the first-mentioned detail, but the garden-line will enable a novice to keep an edging perfectly true and straight. After the top is cut, stretch a line along the centre of it from end to end, and by keeping the shears at an equal distance from the line on both sides the edging will be kept uniformly thick throughout. J. C. B.

New hybrid Crinum (C. Powelli) in the open border. Engraved for THE GARDEN from a photograph.

FRUIT GARDEN.

PLANTING WALL TREES.

THE holes for the reception of wall trees should always be dug to their proper width, and about 9 inches deep of soil taken out; upon the soil inside the hole may be spread 3 inches of well rotted manure (unless the ground is highly fertile); this should be well mixed up with the earth at the bottom of the hole. The roots of the tree having been previously pruned and prepared, should be carefully spread out upon the soil, the budded or grafted part of the tree to face the border, and the bole to be about 6 inches from the wall, allowing the head to incline towards it. If the plants have been grown previously in pots, it will be necessary to alter them from the manner in which they have hitherto grown, and I have noticed that planters spread them out fan-shaped. I have known trees turned out of pots and planted without much re-arrangement of the roots to fail and disappoint the cultivator. No roots should be allowed to point towards the wall, for if allowed to travel in that direction, on reaching the wall they turn up, and by forming an angle against the wall are generally injured, particularly so in the case of stone fruit trees. One who has large experience in planting trees against walls writes as follows: "When the roots are properly spread out, let about 3 inches thick of the soil that has been thrown out of the hole (and previously broken fine) be gently put upon them; upon this lay 1 inch of well-rotted cow manure, and, lastly, 2 inches more of soil. When this is done, let all be gently pressed down by the foot, always beginning at the extremities of the roots, so that the ends of them may thereby be kept in their proper positions. Then let the soil be levelled and raised so high that there is a mound of earth about 3 inches higher than the border to allow for settling. Always have the edge of the mound a little higher than the other part of it, so that it will hold the water which will be supplied; then let the tree be fastened to the wall."

It is scarcely necessary to bear witness to the value of mulching newly-planted trees. This prevents the water when poured upon the soil from running away, and it therefore sinks just where it is wanted. It also prevents the water from washing away the soil, and protects the roots both from drought and frost, as well as the earth from cracking under the influence of the sun. After the mulching is applied let a good watering be given if the weather is dry, as this assists the earth to settle close about the roots, and it is a far better practice than that of shaking the tree at the time of planting, which is so generally done in order to induce the soil to settle properly among the roots. The bad effects of such a practice is, that in raising up the tree the roots are drawn forward, and the soil then being light about them immediately closes up those spaces from which the ends of the roots are drawn, and when the tree is pressed down again, the tender roots cannot force themselves forward into the space they previously occupied, and are thus bent backward; in this way they remain, and very frequently the ends of the fibres afterwards point straight down and grow in that manner. But when water is applied, the desired end is attained equally as well as by shaking, and then the damage described is avoided. The water over the roots at this time also affords a portion of nourishment to the tree, which is very essential, because it has been deprived of a part of its natural support by removal.

If immediately following the planting of the tree dry weather sets in, the soil must be kept in a moist state. It is a good plan occasionally to remove a little of the mulch, and if the earth

under is found to be dry, some more water should be applied. The quantity applied must be regulated according to the state of the soil, taking care that it is not kept too wet, for if the roots are kept in a very wet state by frequent waterings, instead of being an advantage to the trees it rots the tender fibres of the roots. Unless, therefore, the soil becomes dry, the trees do not require water at the roots after planting until they begin to push into growth, and if necessary to be applied it will soon show its effects by the production of corresponding shoots at the top. It can be easily discovered when a tree is in too wet a state or too dry a one about the roots. For when too wet, if there be foliage upon the tree, it will turn yellow and the bark will shrivel, and if too dry the foliage will drop, and if no remedy be applied will fall away and the bark also shrivel, as in the other case. It is, however, on the whole, better to keep a tree too dry rather than too wet, particularly before it has pushed roots. It is very rare, if the trees are planted in autumn, that they will require more than one watering at the roots, but much will depend upon the dry character or otherwise of the weather, and especially during the spring when the time for growth arrives. As the roots of the trees extend themselves in the border great care must be taken that they are not injured by digging. The border ought not to be dug deeply, and it is best if it can be lightly forked over, and only shallow-rooting plants should be grown upon it.

What I have stated to be applicable to wall trees will also apply to a great extent to other trees, but I have been led to direct attention to this subject from having seen a good deal of the evils resulting from imperfect planting in suburban villa gardens. From this cause many trees die outright, or if they do not die, they become cankered and diseased and are absolutely useless for fruiting purposes. I write for the information of amateur planters who prefer to select and plant their own trees. R. D.

Old Peach trees.—The number of years during which Peach trees will continue in robust health and carry good crops of fairly good fruit is greater than is generally imagined. I cannot say exactly how long our old Peach trees have been planted, but certainly over thirty years, and during all that time they could hardly have been cleaner or in better health than at present. Many of their stems are from 18 inches to 24 inches in circumference, and in some cases they are mere shells. Here (in West Surrey) our soil is sandy loam, changing to sand at about 30 inches from the surface, and their cultural requirements may be summed up in a few words, viz., good spring protection, cleanliness during growth, early thinning of the wood in autumn, a good winter mulching, and a firm alley so far as is consistent with cropping the border. I find that the old trees will not bear heavy cropping, consequently we thin the fruits rather severely. They would average perhaps, taking them all through, about one fruit to the square foot. We are not at present rich as regards varieties. Amongst Peaches we have Early Crawford, Royal George, Noblesse, Bellegarde, Barrington, and the two Admirables, and amongst Nectarines Elruge, Hunt's Tawny, and Violet Hative. Younger trees and newer varieties are just coming into bearing; a curious old variety, Poole's Late Yellow, is rather a favourite. It grows to a great size and is a very firm Peach, having something of the consistency of an Apricot. I may say in reply to Mr. Gilbert that Admirable sets very well with me, and perfects every year a crop of very large fruit.—E. Burrell.

SHORT NOTES.—FRUIT.

Diseased Pear leaves (*Pansy*).—The leaves from your Pear trees are infested with a fungus namedRæstelia cancellata, said to be derived from another fungus which grows on Savin bushes. Perhaps you will tell us whether diseased Savin grows in the neighbourhood of your Pears. There is no known remedy. The diseased material should if possible be gathered and destroyed.—W. G. S.

Peaches at Ditton Park.—I have long known that Peaches succeed exceptionally well at Ditton Park, but it is odd to me that they are grown without protection when in bloom. "A. D.'s" remarks on the subject (p. 338) would lead one to infer that their success is mainly due to non-protection. I may, however, say in defence of the protecting system that without it we would not have a Peach crop once in ten years; whereas, with it we invariably secure all that we require. I have tried both ways, and therefore speak from experience as regards this matter.—Cambrian.

PALE PEACHES.

Mr. Coleman (p. 320) does well to add the above to complete his previous list of Peaches, and I hasten to welcome his four, pale-skinned Peaches, and all he says about them as about the strongest arguments that have yet been advanced in support of my views, not "that colour is a defect," but that an absurdly exaggerated importance has been attributed to it in the case of fruits grown to be eaten. Of course, on the show table there are money and victory in colour. So wide, deep, and general is the prejudice in its favour among jurors, that the writer has known Hamburghs but little sweeter than Sloes take first prizes in preference to others that were the very essence of sweetness and vinousness. "The colour carried it, sir," being mostly given and accepted as sufficient explanation. To such excess is this colour mania carried, that some jurors boast they never taste well coloured fruit. I was recently linked with such a juror, and on insisting on the test of taste being applied, there was quite a hubbub; the secretary and committee had to be consulted, but I carried my point, and the mere colourist was beaten in every instance, for I insisted in carrying the taste test through Peaches, Melons, Pears, and Apples as well as Grapes on that occasion. But to Mr. Coleman's most valuable testimony, and what it proves; he begins with an assumption, which is quite correct, that I will endorse his high praises of the Malta and other pale Peaches. I do this more readily, as I have grown the Malta for many years. Mr. Coleman says it is one of the most luscious Peaches he ever tasted, and there is no better grower or judge of Peaches than Mr. Coleman. He also adds the fruit is large, flesh greenish yellow, tender, juicy, and very rich. I can add that the tree is a free fruiter. And yet Mr. Coleman says he has never seen fruit of it on the exhibition table. Why, oh why, this exclusion of the most luscious Peach that even Mr. Coleman ever tasted from the mere chance even of winning honours on the exhibition table? The only reason is to be found in its colour, or want of it rather, as proved by experience, and further verified by the following descriptive notes: "Skin greenish yellow in the shade, blotched with purple next the sun, occasionally suffused with pink, especially so when grown under glass." I have inserted the word "occasionally" in Mr. Coleman's description, and so this pale-faced beauty retires, in order that the brilliantly coloured Georges, Violette Hâtives, &c., may sweep off cups and money prizes, though the Malta is faultless in size and form, and is one of the most luscious Peaches ever tasted by Mr. Coleman, or anyone else. Can it be needful to quote a stronger case against the red-tape absurdity of awarding prizes or determining quality by colour chiefly, or only? Since writing my last letter I have seen and tasted Grapes in several large vineries, and have passed through some houses in which the colouring has been ripened or faded out of Hamburghs. In no instance could I discover that any amount of flavour had been lost through the fading of their black rind. Were it so, then would the quality of the fruit rest in the rind, and not in the luscious flesh which it merely protects, and, it may be, adorns with its coat of richly varied, many coloured beauty. We all admit that beauty is but skin deep, neither less nor more; therefore, who can determine character by the colour of the skin? But that would be almost equally wise as setting up mere colour as a test of quality, and upholding it by all the influence of jurors, money prizes, and highest cultural honours, until any and every fruit that is out of the fashionable colour is relegated to obscurity or driven out of cultivation like the Malta Peach, untried and untasted. Pshaw! we had better set up our black and golden calf for Grapes, and our scarlet and pink ones for Peaches and Nectarines at once, and behead all writers and cultivators who will not forthwith bow down and worship these horticultural idols which our jurors and horticultural societies have set up.

Hortus.

COLOUR AND SIZE *V.* QUALITY.

It is pleasing to find "T. B." with his unique knowledge and experience placing his powerful influence on the rational side in this long-disputed matter (p. 338). "Chef" follows on the same page with the usual strong assertions of colourists to the effect that colour is an unfailing test of quality, and loftily dismisses other ideas and facts to the contrary, as "too absurd for criticism." Not content with running the colour-test of flavour rough-shod over all sorts of Grapes, "Chef" also runs it through Melons, Apples, Pears, Plums, Peaches, Nectarines, and maintains that each, in its way, is much better when lightly coloured. Any other view is but proof of wrong-thinking, which, though seemingly endowed with considerable vitality, must soon come to an end under the heavy sledge-hammer of "Chef's" sweeping assertions. "Chef" is, however, good enough to challenge me to test the matter by showing green and red against golden and black Grapes to prove that colour is no certain test of quality. But surely in vain is such a net set in sight of any bird after his record of the dispute of the judges over sour black and sweet red Grapes at the Manchester show. "Chef" was called in, and doubtless gave his verdict in favour of the black, because they were the finest, though not ripe. I believe I, too, had a voice in this very matter, and spoke in favour of the ripe, sweet Grapes, notwithstanding their lack of colour. But the mere fact of such a dispute being possible, or of the prize being awarded to fine black Grapes, albeit they were sour and unripe, shows how deeply jurors and societies have been bitten by the colour mania, and how impossible it would be for fruit deficient in colour to obtain first prizes from any existing authority.

Possibly "Chef's" extreme devotion to colour tests, and his running it through all our larger fruits, may destroy its tyranny over judges, and arouse our larger societies to the fact that it is little more than skin deep at the best, and is not seldom a mere Will-o'-the-wisp, to lead astray, as in the case of the unripe black Grapes at Manchester. "Chef's" red Grapes on the same Vine, but on a different limb from the black, proves nothing to the point, as no doubt they were partially starved or shanked into inferior quality, as is invariably the case with red bunches on Vines on which the normal crop is black. This case is on a level with the assertion that the greenish Muscats preferred to golden were watery. They were less hard in the flesh than golden Muscats often are, but the sap was so luscious and vinous as to be pronounced much better flavoured by connoisseurs who even so much preferred Grizzly Frontignans to Muscats, as to grow the latter in quantity as the best flavoured of all Grapes. But it is useless to reason further with your correspondent, who prefers unripe Hamburghs to ripe on account of their colour.

But if the highest coloured Grapes are the best, then should the Barbarossa, Gros Colmar, and Lady Downes be the sweetest of all black Grapes. The rage for size and colour has been largely fostered by lord mayors' dinners and other festive affairs. Huge Pears, totally unfit for eating, monster bunches of Grapes, sour as Sloes, big Apples, unripe Peaches—all look magnificent on the dinner-table, and in not a few cases they are piled up for mere effect, hired for the occasion, and removed afterwards, the eatable fruit being handed round.

Enormous quantities of fruit are also marketed and used in an unripe state. The size and colour regulate the price to a great extent, and the harder and less ripe such fruits as Peaches, Nectarines, and Plums are, the longer they keep saleable. It is difficult to prevent this. But there cannot be a doubt that the enormous extension of our culture of fruit for trade and commercial purposes has done much to impart a most exaggerated importance to its mere colour and size, and so lower its quality. The smaller and less

coloured varieties, however excellent, are driven out of cultivation, sat upon, and extinguished by the bigger coarser sorts, as "T. B." so pithily points out in the case of Grapes, Plums, Strawberries, and Pears. If "Chef" is disposed to doubt or deny all this, let him go to the first public dinner that comes in his way and try the fruits piled up for effect in the centre of the table. HORTUS.

CANTALOUP MELONS.

MR. CORNHILL (p. 308) is of opinion that Cantaloups "are scarcely known in this country," and to a certain extent he may be right, as they are now very rarely met with. In 1844 they were, however, extensively cultivated at Claremont by the late Mr. Charles McIntosh, and in his first edition of "The Practical Gardener" he enumerates four varieties, viz., the Montague Cantaloup, raised in 1815 by Mr. D. Anderson, gardener to Lord Montague; the Pine-apple Green-fleshed, Scarlet Rock, and Scarlet-fleshed, and adds, "but of these as well as the others (named), many very indifferent sub-varieties are in cultivation, in consequence of sufficient care not being paid to keep them from being impregnated while in flower by others of more indifferent properties"—an observation applicable to many Melons distributed at the present time. At a much later date when the Bourbon Princes were located at Claremont, Cantaloup Melons had to be grown extensively for them, as no other sort pleased them so well, but whether they brought or introduced their favourite sort from France I am unable to say. A few years ago I grew and fruited several Melons raised from Claremont-saved seeds, but the only recommendation pertaining to them was their free-bearing character under comparatively cool treatment. They succeeded admirably in frames with only sufficient bottom-heat to give them a good start, but no one could be persuaded to eat them. It may be if we had eaten them with pepper and salt they would have gone down better; but this was never tried; we were not then so well acquainted with French customs as we are now. The variety of Cantaloup which we cultivated produced very large fruits, which were scarlet-fleshed. They were ribbed, had a coarse blotched rind, mottled with green and white. Munro's Little Heath most nearly approaches the variety in question, both as regards constitution, shape, general appearance, and also quality; and the conclusion at which I arrived on growing it the first season after its distribution was that the Cantaloup must have been one of its parents. If ever Melons become as much appreciated in this country as in France, and which may yet happen, there will be a demand for such varieties as can easily be cultivated in frames, and the Cantaloups should be one of the progenitors of such a race. As a matter of fact, the majority of the Cantaloups which we ripened during the two seasons in which they were tried—once in the midlands and once in a more favoured southern county—were superior to many Melons staged at various horticultural exhibitions, and fully equal to many that receive prizes as being the "least worst" of the lot shown. W. I. M.

QUESTIONS.

5521.—**Transplanting Roses.**—I have a few scores of standard Roses which were budded this season. Would it be advisable to plant them out this autumn where I intend them to grow, or leave them where they are for another year? Some of them have made shoots 18 inches and 2 feet long.—J. H. O. M.

5522.—**Bees and rosy Sedums.**—Under this heading THE GARDEN of Oct. 2 contains an interesting letter, signed "D. T. F.," describing the fatal effects produced by the rosy Sedum on bees and butterflies which settle on its aromatic flowers. Might I ask your correspondent to kindly inform me whether the rosy Sedum to which he refers is the species commonly known as Sedum spectabile?—J. B., *Home House, Worthing.*

5523.—**Is copper wire hurtful to Roses?**—I have fastened some Acme labels on to my Roses with copper wire, and on a friend seeing them he remarked that it would kill them in consequence of the electricity in the wire coming in direct contact with the trees, as he had had painful experience on this point. Can any of your correspondents give further information in reference to this matter?—S. W., *Darlington.*

KITCHEN GARDEN.

THE EARTHING UP OF CELERY.

THOUGH differing from "W. S." on the one point of progressive or single earthing up for blanching, his general instructions for the culture of this useful vegetable are well nigh all that can be desired. There is, however, one point about the natural habit of the plant (see p. 295) which is rather misleading, viz., that Celery is naturally of a spreading habit. This is hardly borne out by observation and experience. The word naturally is doubtless capable of at least two interpretations. For example, it may mean in a state of nature. Now, in such a state Celery is found mostly in salt-water marshes and ditches. In these it is invariably crowded so much together as to render its spreading a physical impossibility. But possibly "W. S." alludes to the natural habit of the plant. But that plant is not the wild Celery, but the cultivated varieties, which through a long series of years have been selected for various cultural or culinary qualities, one of the most vital of which is the ability to grow up into a good stick. Hence it cannot be said of the most approved strains of cultivated Celery that their natural habit is to spread. Besides, trench planting, almost universal, still further curtails and controls any spreading tendency left in the improved garden strains, so that practically the spreading habit of cultivated Celery is no objection to its being left unearthed up till it is fully grown. In addition to all this, not a few of those who earth up only once for blanching advocate and practise the system of keeping the stems close to the hearts by loose tying, while all good cultivators of clean perfect sticks recommend early disbudding and the severe and timely removal of all suckers. All this favours one straight stick—the great point desiderated by the producers and purchasers of perfect Celery. As to the dressing of soot and lime recommended by "W. S.," the former should be sparingly used, if at all, and neither should be enclosed with the plants nor placed in their hearts during the process of blanching. Lime and soot dressings during growth may destroy slugs and worms, the latter being almost as injurious to Celery as the former, and stimulate growth. But blanched Celery is highly susceptible to taint or contamination from contact with such pungent substances as lime and soot. Nothing but sweet soil, free from rank manures, is capable of blanching and finishing Celery crisp as glass and sweet as a nut.

HORTUS.

WELL-FLAVOURED LETTUCES.

LAST spring a row of White Cos Lettuce was planted on a piece of ground which was about as poverty-stricken as garden ground could be. It had had no manure of any kind for several years and had been cropped with Strawberries for some time. When the plants were about 3 inches high the mould was drawn up on each side of them so as to form a trench. A tolerably liberal top-dressing of Clay's fertiliser was then given, which was well watered in. On another occasion they were again watered, and this was all the help they got. Although the season was dry, these Lettuces attained unusually large dimensions; they were good enough for any prize collection of vegetables, and had they been judged by flavour alone they would have been second to none in the kingdom. I can safely say that I never eat such crisp, well-flavoured Lettuces before. Everyone who eat them without exception said that these Lettuces were in flavour quite different from any they had ever tasted. For some time I could not understand it. I thought that I had accidentally procured an extra fine strain of the White Cos, but the enigma now seems plain to me. It was the absence of manure in conjunction with another manure of a forcing nature, and without its rankness, which gave them crispness and flavour. It has often been stated in THE GARDEN that Cabbages and Broccoli grown by market gardeners are inferior in flavour to those grown in private gardens, the large quantity of house manure used in their culture putting rankness as well as coarseness into them. I believe this to be true, and I advise your readers to experimentalise in this matter. I believe that Cabbages would be immensely improved in flavour by growing them in soil which had been manured for a previous crop, supplying the manurial deficiency by top-dressings well hoed in of some strong concentrated manure. This affair of the Lettuces in a great measure explains why our Coleworts are always so Marrow-like in flavour. We always plant them on a bit of ground which has been cropped with early Potatoes, or which has lain fallow through the summer. Oftentimes they get but a dressing of soot which helps to keep off the brown grub, but they are invariably first-class in quality, and I can give my neighbours no greater treat in mid-winter than a dish of Coleworts. BYFLEET.

FERNS.

GOLD AND SILVER FERNS.

FERNS of all kinds are favourites wherever plants are cultivated. True, we have many beautiful plants belonging to other Orders—plants with brilliant flowers and plants with beautifully marked and richly coloured foliage, all of which contribute to the beauty of our plant houses and the embellishment of our open-air gardens; but none of these can compete with the Fern family as regards grace and elegance of form. The rage which once existed for high-priced rarities in the way of Ferns has died more rapidly than that for Orchids. Still, that a lasting love for the grace and beauty of Ferns has taken deep root is evinced by the countless numbers of them disposed of annually in our public markets for window decoration, and also for grouping with various kinds of flowers. Ferns are capable of being grown in different ways to suit special purposes. Thus some display their beauties to the greatest advantage in hanging baskets, others as bracket plants. Some thrive best when planted in crevices of rocks, whilst the fronds of Maiden hairs (Adiantum) are looked upon in a cut state as quite indispensable adjuncts to coat flowers, houquets, and shoulder sprays. Gold and Silver Ferns are, however, not adapted for any of the purposes just enumerated; but when well grown they form the most *recherché* ornaments of a plant house. Used in that way, the extreme beauty of their fronds—which are, in most instances, deep green on the upper side and more or less densely powdered with a silver or gold on the underside—renders them favourites with Fern growers. In the genus Gymnogramma are some of the best of the Gold and Silver Ferns, but some may be met with in other genera deserving attention. Gymnogramma, as recognised by some authors, contains a very heterogenous set of plants, presenting totally different appearances and requiring different treatment; but the kinds here enumerated are all plants of similar aspect and habit, and all will readily submit to the same description of culture. They are plants which grow with remarkable freedom, and speedily make handsome specimens; indeed, they may be grown to almost any size desired. Gymnogrammas may be increased very readily from spores; therefore young plants are always obtainable to replace overgrown specimens, and young plants will be found to be more attractive in a general way than overgrown ones. As regards cultivation, a few particulars only are needed. We have found them to grow most rapidly, and to make the best fronds, when potted in good fibrous peat and sharp sand, without any other admixture; but cultivators who have but limited space at command will find smaller plants more suitable, and these can be secured by using a compost consisting of half yellow loam instead of wholly peat. In all cases and under all circumstances thorough drainage must be maintained, as Ferns require an abundant supply of water, and in the case of gold and silver ones it must be confined to the roots. Upon no account must the syringe be used for Gymnogrammas, or the farinose powder, with

which the undersides of the fronds are coated, and which constitutes their chief attraction, becomes smeared and dimmed. If the directions just given are followed, and the plants kept in a moist atmosphere and in the heat of an ordinary stove, the kinds enumerated below will produce a charming effect.

The fronds of the Gymnogrammas, which we here recommend as the best and most distinct, are, for the most part, decompound—that is to say, they are many times divided, the ultimate divisions being more or less broad. G. chrysophylla, from Jamaica and various other West Indian islands, has rather broad segments and intense deep green fronds, the under sides of which are heavily powdered with deep golden farina, through which, when fertile, the black sori protrudes. This is certainly the richest coloured form in this beautiful genus, but the plant is delicate, and we have always found it difficult to preserve through the winter months. Other forms with rich golden farina are G. Laucheana and its varieties. These are taller, more erect in growth, and more robust, whilst G. Laucheana grandiceps has tasseled fronds. G. sulphurea, from Jamaica, is a somewhat slender plant, but very elegant; its fronds are soft green above, and clothed beneath with a dense sulphur-coloured powder. G. triangularis, from California, is an outlying member of this family, and thoroughly distinct in aspect; its fronds are erect, triangular in outline, and leathery in texture, deep heavy green on the upper sides, and covered beneath, in most instances, with a dense deep golden-coloured powder, but in some varieties the colour becomes sulphur, and even white. This plant dislikes stove-heat, but thrives admirably in a greenhouse; indeed, in the southern counties it would succeed in the open fernery. G. calomelanos is widely distributed throughout Tropical America, and is usually a bold-growing plant of robust constitution; its fronds are deep green above and silvery white on the under side. G. tartarea is also a common plant in the Tropics of America, and varies much in different localities; its fronds, which are deep green above and French white beneath, are broader and less lanceolate than those of the preceding, and the bases of the stems are furnished with numerous black chaffy hairs. It is a robust plant, and extremely handsome. G. decomposita, from the South American Andes, is a robust, free-growing kind, with large fronds, the terminal segments of which are very finely cut; their upper side is a cheerful light green, and the powder on the under side varies from white to sulphur colour, and even golden. It requires less heat than most of the other kinds. G. pulchella, from Venezuela, is, as its name implies, a beautiful form, with broad, finely-divided fronds, which are brilliant green on the upper side and silvery white beneath; the colour of the farinose powder, however, changes in some plants to sulphur. G. peruviana argyrophylla is, in habit, very distinct; its fronds are arched, the pinnules or segments broad and obtuse, and clothed, both above and below, with a dense bluish white farina. C. Pearcei, from Peru, is an elegant and most distinct plant, with erect triangular fronds, the segments of which are as fine almost as in the case of Asparagus. The colour on both sides is vivid green, sparingly dusted below with silvery white. It is rather delicate, and, if subjected to a very high temperature, is apt to die out. G. Wetenhalliana is a charming plant for those who delight in crests and tassels; it is densely covered with a sulphureous powder. G. schizophylla and its variety gloriosa are both beautiful Ferns for small hanging baskets; their fronds, which are pendent, are very finely cut, but slightly farinose. G. trifoliata is a robust-growing Fern from Jamaica; it is erect, tall, and has trifoliate pinnæ, which are broad and bright green, the under surface being clothed with white or sulphur-yellow farina.

The Maiden-hairs contribute two species to this class of Ferns, viz., Adiantum sulphureum and A. scabrum, the latter powdered with white farina; both are natives of Chili, and have hitherto not been very successfully cultivated, the reason, we believe, being that in many instances they have been killed with kindness. They should be placed in a cold house; indeed, we are of opinion that they would thrive best on the open-air rockery in the south and west of England. Onychium auratum is a good Gold Fern not unlike the Japanese species, O. lucidum; but its fronds are longer, broader, and more elegantly cut than those of that kind; their segments are bright green above, while on the underside the sori and their coverings are bright golden yellow. Coming as it does from considerable elevations on the Himalayas, it requires a cool temperature. The genus Cheilanthes contains a few elegant members belonging to this category, and they require much the same treatment in a cultural point of view as that laid down for the Gymnogrammas. C. farinosa varies in height from 1 foot to 2 feet. The pinnæ, which are in opposite pairs, are notched on the edges, and stout and leathery in texture. They are deep green above and silvery white beneath. Other names for this plant are C. dealbata and C. argyrophylla. It seems to be widely distributed throughout India and the Indian islands. Another kind which much resembles it is C. pulveracea. It is, however, smaller and less leathery in texture, and the farinose powder on the under side is frequently scattered over the upper surface, a circumstance which adds materially to its beauty. It comes from Mexico. In C. argentea we have a veritable gem in miniature. It comes from Siberia and Japan, and must be kept in a cool house. It grows a few inches only in height, the slender stems being ebony black and polished, the fronds being triangular or pedate in outline. Above they are bright green, and beneath silvery white, bordered with a conspicuous and continuous line of black sori. Similar in appearance to argentea is C. chrysophylla. It is, however, much larger, and its fronds are more divided, and clothed below with a heavy golden farinose powder. It is a native of Northern India. Cincinalis flavens and C. nivea are two beautiful little Ferns, having jet-black stems and roundish pinnæ, reminding an ordinary observer of the Maiden-hair. The upper surface of their fronds is bright green, while the under side of the first named is golden, and of the last silvery white. Both come from the warm parts of South America.—*Field.*

Lycaste Skinneri; flowers pale rose (about half natural size).

Orchids.

COOL ORCHIDS.

LYCASTES.

These are for the most part plants of considerable beauty, and the length of time during which they keep in flower without injury to the plants when removed to the dwelling house adds considerably to their value. Even the flowers when cut and placed in water will last fresh and in good condition for weeks, especially if the ends of the stems are freshly cut occasionally and the water renewed. Lycastes produce pseudo-bulbs, bearing a pair or more of large, membranous-plaited leaves, which are persistent and deep green. The flower-stems rise from the base of the pseudo-bulbs after the growth is perfected, and each bears a single flower. The cultivation of Lycastes is by no means difficult, provided they are kept cool and moist and placed in a shady spot, but they will not thrive if subjected to full exposure to the rays of the sun and a high temperature. They should be potted in good rough fibrous peat and chopped Sphagnum Moss, with the addition of a few nodules of charcoal and a little sharp sand. It need scarcely be stated that for all Orchids the pots must be thoroughly drained, and especially is this needful in the case of Lycastes, as their roots require an abundant supply of water, and they are also much benefited by frequent sprinklings overhead with the syringe during the growing season; although much less water is necessary after growth is finished, at no time should it be entirely withheld, unless it may be necessary to retard their blooming. In that case the plants should be kept entirely dry and be removed into a cooler situation. L. Skinneri is at once the best and most variable of its race, scarcely two plants of it producing flowers alike either in shape or shade of colour. The sepals are very large and spreading, thick and fleshy in texture, waxy white, more or less pure, and tinged and shaded with pink, rose, or crimson in the different varieties. The petals are smaller than the sepals, curved upwards over the base of the lip, and rose or crimson. The base of the lip, is of the same colour, usually white in front blotched with rose or crimson. There are numerous named varieties of this species, the one called virginalis or alba being perhaps the rarest and most distinct. In this form the whole flower is pure waxy white, except the base of the lip, which is tinged with pale lemon. All the forms of this plant flower during winter and spring. The type comes from Guatemala. L. Barringtoniæ grandiflora has flowers similar in shape to those of L. Skinneri, but they are slightly smaller, measuring from 5 inches to 6 inches

across; they are pure white, more or less suffused with yellowish green. It blooms during the winter months. L. lasioglossa has flowers which measure about 5 inches across; they are spreading, and chocolate-brown in colour; the petals, which are small, are bright golden yellow. The lip, yellow, which is freckled with purple, is densely clothed with long silky hairs. This variety is a winter bloomer and comes from Guatemala. L. Harrisoniæ, a beautiful plant, has long been an inmate of our plant houses, and for years has suffered from neglect, refusing to die, even under the roughest treatment. It has, however, at last come to be appreciated. It is very distinct in appearance from the kinds previously named; the pseudo-bulbs are pale green, with a black top or neck, and bear a single, large, leathery, strongly-ribbed deep green leaf. The scape is sometimes two flowered, the individual blossoms measuring 3 inches or more across. The sepals and petals are thick and fleshy and pure waxy-white. The lip, which is rich purplish lilac, is furnished with short hairs. There is a variety of this plant called citrinus, in which the sepals and petals are pale yellow; and also another called alba, in which the flowers are wholly white. It blooms during early spring and summer. L. gigantea is, as its name implies, larger than the other species of the genus, *i.e.*, in growth rather than in size of flowers, although the latter are also large. The sepals and petals are brown, tinged with greenish yellow. The lip, which is flat and velvety, is deep crimson-maroon, broadly bordered with rich orange. It is a winter and spring bloomer and comes from Santa Martha. L. Deppei has olive-green sepals and petals, profusely spotted with orange and white. The lip is small and deep orange. This Mexican species, although not amongst the showiest of Lycastes, is nevertheless a most profuse bloomer, and its flowers are extremely useful in a cut state during the winter months. W. H. G.

SOCIETIES.

ROYAL HORTICULTURAL.

OCTOBER 12 AND 13.

A GREAT show of hardy fruits was the chief attraction on this occasion, and a finer display of Apples and Pears could not possibly elsewhere be found. The leading growers and exhibitors from all parts competed in the various classes, which throughout were represented by fruit of very high quality. There was but little room to spare in the large conservatory after the fruit had been staged; but, nevertheless, a great gathering of cut flowers, chiefly Dahlias of all kinds, was crowded round the margins. The floral committee had comparatively few novelties submitted to them. The following certificates were awarded.

First-class certificates to—

ANGRÆCUM CAUDATUM.—An extraordinary Orchid, imported from Sierra Leone over forty years ago, but still rare in gardens and seldom seen in flower. Like several other species of the genus, such as A. sesquipedale and Kotschyi, the flowers are remarkable for the length of their spurs, which in caudatum reach 8 inches or 9 inches in length. The flower measures about 4 inches across; the sepals and petals are narrow and of a dull olive-green colour. The lip is somewhat wedge-shaped and pointed, of firm texture and pure white, while the column is yellowish. The spur or tail is as thick as a quill, round and curly, and of a pale brown colour. The twisting of the spurs gives the flowers a most singular appearance. The plant bore eight expanded flowers and one bud, and the whole spike measured fully 2 feet in length. This number is unusual, for generally there are but four flowers on a spike; the leaves are deep green, arranged as in A. sesquipedale and others. The plant exhibited came from Baron Ferdinand de Rothschild's garden, at Waddesdon Manor, Aylesbury.

ADIANTUM CAPILLUS-VENERIS VAR. IMBRICATUM.—A very distinct and most beautiful variety of our native Maiden-hair Fern. It is somewhat similar to the Cornish variety named cornubiense, but the pinnæ are larger and deeply divided. The fronds are broad and dwarf, and form a dense mass of a beautiful fresh green. Exhibited by Mr. G. Masters, gardener to Col. C. Legh, High Legh Hall, Knutsford.

RHODODENDRON AMABILE AND LUTEO-ROSEUM.—Both new seedling varieties of the greenhouse Javanese Rhododendrons. The first has flowers of a soft pale pink tinge, the colour of the other being deep rose-pink with a suggestion of yellow on the petals. Both have large and perfectly shaped flowers produced in massive trusses. Exhibited by the raisers, Messrs. J. Veitch and Sons, Chelsea.

CHRYSANTHEMUM MONS. W. HOLMES.—A new Japanese variety. It has compact flowers after the style of Cullingfordi, which it resembles. The florets are dense and rather reflexed. The colour is a rich maroon-crimson with a pale yellowish gold tinge on the under surfaces of the florets. Shown by Mr. G. Stevens, Putney.

DAHLIA HELENA.—A single-flowered variety having small compact flowers, roundish florets slightly reflexed, and of good substance. The colour is a deep crimson, shaded with orange-yellow. From Messrs. Cheal, Lowfield Nurseries, Crawley.

BEGONIA MRS. PLUNKETT.—One of the finest Begonias of its colour yet raised; the flowers are 4 inches across, perfect globular rosettes of petals, which are of a delicate salmon-pink. From Messrs. Cannell.

DAHLIA ZEPHYR.—A single variety with medium-sized flowers. The florets are of a bright Indian red, broadly edged with orange. Very pretty and distinct from others. Shown by Mr. Turner, Royal Nurseries, Slough.

DAHLIA ANNIE HARVEY.—One of the so-called decorative sorts, having double flowers of medium size. The colour makes this sort remarkable, as it is the deepest yet raised. It may be described as a blackish crimson, flushed with scarlet. As a border variety it is a great acquisition. Exhibited by Messrs. Cannell, Swanley.

BEGONIA PAUL DE VICQ.—A lovely double-flowered sort, the colour being a soft cherry rose. The flowers are large, very double, and full. From Messrs. Cannell.

DAHLIA R. T. RAWLINGS.—A show variety, with perfectly formed flowers of a bright yellow. Shown by Messrs. Rawlings, Romford.

Other plants of interest shown comprised the following: Dendrobium Phalænopsis, a beautiful Australian species, reminding one of D. bigibbum, and of the same bright magenta-crimson colour. From Mr. Pollett, Fernside, Bickley. Cattleya Gaskelliana, a lovely white variety, still extremely rare; the flowers are pure white, except a dash of yellow on the lip. Seven flowers were shown by Mr. C. F. Partington, who also sent a spike of a good variety of Vanda cærulea bearing thirteen flowers. A cultural commendation was accorded to Mr. Partington's gardener. Messrs. Sander, St. Albans, showed a splendid variety of Cypripedium Spicerianum, named magnificum. It is remarkable for its unusually large flowers and the beautiful colouration of the dorsal sepal. Mr. Day showed an exceptionally fine variety of the pretty Odontoglossum Sanderianum, which may be known at a glance by the white lips of the flowers. Messrs. Veitch showed the new Amasonia punicea, whose bright crimson floral bracts are so attractive at this season. It is a valuable acquisition to stove plants. The same firm showed also some new Japanese Chrysanthemums, viz., Annie Clark, pale pink; Charlotte de Montcabrier, blush; and Bouquet Estival, deep rose-pink. Mr. G. Stevens also showed some new Japanese Chrysanthemums, those named Martha Harding, a bright yellow, and Miss Stevens, blush-pink, being the best. Mr. R. Marnock showed a branch of the Sea Buckthorn, Hippophaë rhamnoides, heavily laden with bright orange-yellow berries. It was cut from a bush growing at Rousdon. Mr. Penford, Barnfield, Weston, showed a new crested form of Pteris serrulata, named Westonensis. The fronds are slender and slight-tasseled. Some spikes of a beautiful dark form of Primula capitata were shown by Mr. G. F. Wilson, Heatherbank, Weybridge, which at this season seemed doubly welcome.

The majority of the other flowers exhibited consisted of Dahlias of all sections and other autumn hardy flowers, besides Roses, which both Messrs. W. Paul, of Waltham Cross, and Messrs. Paul, of Cheshunt, showed admirably. In the large collection from Waltham Cross, several well-known favourites were represented by really fine blooms, the Teas being particularly good. One of the most conspicuous was Perle d'Or, which is in the way of W. Allen Richardson, but paler, and, in our opinion, even more beautiful. Both the Pauls showed pot plants of the white Tea Rose, The Bride; hence it seems that they have a good opinion of it as a new Rose.

Dahlias were to be seen on every side, large and handsome show kinds, neat little Pompons, and elegant singles, the latter being by far the most abundant. We were pleased to see that the committee are taking a new course in certificating the single Dahlias. They do not, and rightly, select the big coarse flowers, but the medium-sized blooms, remarkable for good substance of petal, rich and decided colour, and slightly reflexed blooms, which latter point, as some think, adds to the beauty of the flower. One of the prettiest sorts on Tuesday we considered was that named Pink Paragon, from Messrs. Laing, of Forest Hill. The flower is good in all points and the colour most pleasing, the florets being pale pink edged with pure white. Mr. Turner's Pompons seemed to please the public most, as they have all the elegance of the singles combined with the beautiful symmetry of shape of the big show kinds.

Hardy Fruit Show.

The competitive classes on this occasion were specially limited to Apples and Pears, some sixteen classes being apportioned to the first and thirteen to the other. Generally the exhibits were of a remarkable kind; indeed, both Apples and Pears it seemed impossible to excel either in size, beauty, or average quality; whilst the competition throughout was remarkable, and fully displayed the popularity of hardy fruit shows.

APPLES.—The largest Apple class was one for fifty varieties, of which there were no fewer than seven collections, giving a total of three hundred and fifty dishes, all of fine quality. Messrs. Bunyard, Old Nurseries, Maidstone, worthily took first place, whilst Messrs. Sclater, of Exeter, and Mr. Watkins, Hereford, followed in that order. Thus the chief Apple counties were well represented. In these collections were fine samples of Warner's King, Lord Derby, Lady Henniker, Grenadier, New Hawthornden, Pott's Seedling, Lord Grosvenor, Washington, Stone's Pippin, Golden Noble, Peasgood's Nonsuch, Transparent Codlin, Alfriston, Lewis' Incomparable, Cox's Orange Pippin, Duchess of Oldenburg, Worcester Pearmain, Cox's Pomona, Emperor Alexander, and Red Costard—the latter half-dozen, from Hereford, having splendid colour. Mr. Bunyard's fine fruit were, it seems, gathered from ordinary nursery trees. The class for twelve dishes of culinary kinds brought grand samples, some, indeed, eclipsing anything before shown here. The dozen dishes from Linton gardens, Maidstone, included wonderful Gloria Mundi, Peasgood's Nonsuch, Loddington Seedling, Winter Hawthornden, Frogmore Prolific, and Stirling Castle, and were well worthy of the county and Mr. McKenzie, the gardener. Berks gave the second best lot, a beautiful, even collection, set up by Mr. Turton, Maiden Erleigh gardens, Reading, who had Echlinville Seedling, Pott's Seedling, Cellini Pippin, Waltham Abbey Seedling, Peasgood's Nonsuch, &c. Berks took third place, Mr. Ross, of Newbury, having fine samples. There were eight collections of twelve dishes, and no less than thirteen lots of six dishes, in which class again the fruit were exceptionally grand. Essex here came to the front, Mr. Smith, of Loughton, coming first; whilst Yalding and Margate gardens showed the second and third collections. Mère de Ménage, Striped Beaufin, Stirling Castle, Stone's Pippin, and Gloria Mundi were superb samples. Turning now to *dessert kinds*, no less than ten collections of twelves dishes were staged, affording much beauty and colour, especially in the earlier kinds. Very beautiful were Ribston, King, Cox's Orange, Strawberry, and Blenheim Pippins; also Evagil, Cornish Aromatic, Worcester Pearmain, and Mother Apple. Then no less than fourteen lots of six dishes of dessert kinds followed, the best coming from Beckenham, Kent, from Mr. Hoare's gardens; Sussex was next, and

Somerset third. Here was found the only dish of the old Nancy Apple, rich coloured and delicious; also good Ribstons, Blenheim, Duchess of Oldenburg, Cox's Orange Pippin, King of the Pippins, Worcester Pearmain, &c.

Single dish classes proved very interesting, and, on the whole, wonderful samples were shown. *Blenheim Pippin* came first with seventeen dishes, the best coming from Highworth, Wilts, and the next best lot from Petworth, Sussex, whilst all were good, though none showed special colour. Of that beautiful kind *Cox's Orange Pippin* there were no less than twenty-one dishes, the best, really unusually fine samples, coming from Shardeloes (Bucks), Maidstone and Mereworth (Kent). As evidence that the fine old dessert kind *Ribston Pippin* is not yet gone out of cultivation, no less than twenty-two dishes of very fine clean samples were shown, the best coming from Gaddesden Place, Herts, shown by Mr. Folkes; the next best—two lots—coming from Beckenham and Margate. Then, increasing in number, no less than twenty-four lots of that popular Apple *King of the Pippins* were shown. Here at last Middlesex had a turn, very grand samples coming from Mr. Wells, of Hounslow, and Mr. Chadwick, of Ealing, was third, whilst Mr. Bunyard took the second prize in Maidstone. Single dishes of culinary Apples began with *Wellington*—very good samples, the best coming from Carshalton, and the next best from Powderham Castle, Devon. *Mère de Ménage* was represented by four dishes only, the best, as usual, coming from Newbury, whilst the next lot was from Somerley Park, Kingwood. Then of nine dishes of Golden Noble, Mr. Powell had the best from Devon, the second lot coming from Sevenoaks, and the third dish from Exeter. All were handsome samples. *Warner's King* were very fine, and Mr. Turton's dish very clean and good, whilst the next best came from Mr. Bunyard's nursery. There were twelve dishes of these and seven lots of *Peasgood's Nonsuch*, probably the handsomest of kitchen Apples, really wonderful fruits coming from Mr Edwards, of Hereford, whilst Mr. Turton's dish, if a trifle smaller, was more richly coloured. Only four dishes of *Gloria Mundi* were staged, all fine; and but six lots of *Lane's Prince Albert*, the best again coming from Newbury.

Pears were shown in abundance, and really grand samples were shown, especially from Herts, as evidenced by the fact that in the class for fifty dishes there were five collections. Mr. Thomas, of Sittingbourne, came first, Mr. Davies, The Mote, Maidstone, and Mr. Bunyard being second and third. Amongst these collections, very fine, were Pitmaston Duchess, Souvenir du Congrès, Triomphe de Reine, Durandeau, Doyenné Boussoch, Beurré Hardy, Comte de Chambord, Beurré Clairgeau, Beurré Diel, Beurré Rance, Beurré d'Amanlis, &c. Then there were no less than fifteen collections of twelve dishes, Herts again coming first, with Mr. Thomas, and third with Mr. Waterman, of Maidstone, whilst Norfolk came second, through Mr. Allan, of Gunton Park, who is always strong with Pears. In this class were very beautiful samples of Beurré Bachelier, Doyenné du Comice, Hacon's Incomparable, Doyenné Boussoch, Marie Louise, Pitmaston Duchess, Beurré Hardy, Durandeau, British Queen, Gansel's Bergamot, and Souvenir du Congrès. Then there were eighteen lots of six dishes, Mr. Ware, of Tunbridge Wells, again taking the honours to Kent, as also did Mr. R. Smith, of Yalding, for the third place, whilst Mr. A. Smith took the second prize to Loughton, Essex. The first lot comprised beautiful samples of General Tottleben, Doyenné du Comice, Hacon's Incomparable, Beurré Bachelier, Beurré Diel, and Pitmaston Duchess.

Single dish classes of Pears began with *Doyenné du Comice*, of which there were twelve lots, the best coming from Tonbridge and Yalding. Twelve lots of Beurré Superfin were staged, the best coming from Devon, and fifteen dishes of the huge *Pitmaston Duchess* were placed, the finest coming from Sittingbourne, whilst the second and third lots were from Newbury, shown by Messrs. Howe and Ross. *Louise Bonne of Jersey* was represented by seventeen dishes, Mr. Thomas having for the first prize lot beautifully coloured fruits, Herts and Surrey taking the next places. Only six dishes of *Fondante d'Automne* were shown, but there were seventeen dishes of the better known *Beurré Diel*, the first prize dish coming from Kent, the second from Gunton Park, and the third all the way from Hampton Castle. Of the twelve lots of *Beurré Rance* the best came from Maidstone and Yalding. There were but six dishes of *Glou Morceau*, and twenty-four of that beautiful Pear, *Marie Louise*, Maidstone, Powderham Castle, and Hampton Castle taking the prizes. Finally, *Conseiller de la Cour* was represented by seven lots, Margate sending the best samples. A scrutiny of the list of awards will show that Kent has had nearly, if not quite, one half of the prizes awarded.

General collections of Apples and Pears were also a very strong feature, Messrs. Veitch, Chelsea, having some 120 dishes of Apples and about fifty kinds of Pears, all excellent samples of their nursery produce. Messrs. C. Lee, Hammersmith, staged 100 dishes of Apples, all fine fruits, from their Ealing nursery, and included all the best known kinds in cultivation. Messrs. Cheal, Crawley, Sussex, staged about fifty dishes of good samples of Apples and twenty dishes of Pears. Messrs. Paul, Cheshunt, had fifty dishes of Apples, including many rich in colour and fine. Messrs. Lane, Berkhampstead, staged a big collection of some eighty dishes of Apples, and Messrs. W. Paul and Sons, Waltham Cross, had a similar big collection of fine fruits. Very large and interesting collections were shown by the Horticultural Society of Montreal and from growers of Nova Scotia, the former collection specially including many kinds very rich in colour.

Fruit committee.—It was an unusually busy day for this committee, as a large number of exhibits was shown, and of which the following were the principal. A very fine fruit of the new, or rather still uncommon, Lord Carington Pine-apple was shown by Mr Miles, gardener at Wycombe Abbey. It weighed 7 lbs., and was handsomely shaped. The exhibitor well merited the cultural commendation accorded him. Mr. Howe, of Benham Park, showed a seedling Melon named Golden Ball. It is a cross between Hero of Lockinge and Benham Park. The committee desire to see it earlier in the season. Some very fine fruiting branches of the black Bullace were shown by Mr. Harwood, which looked like dense bunches of black Alicante Grapes, so productive were the branches. A large collection of open-air Grapes was shown by Mr. A. Horvath, of Hungary. The collection numbered about twenty sorts, nearly all of which have names strange to us here. There were, however, such familiar sorts as Muscat of Alexandria, Frontignans, Muscat Hamburghs, Chasselas Musque, and others, but very inferior to the same kinds grown here under glass. The flavour of some of the sorts shown was exquisite, notwithstanding their rather forbidding appearance. Mr. Thomas, of Sittingbourne, Kent, showed a large collection of Pears, and also a new Apple named St. Christopher, said to be a first-rate dessert sort. Mr. Jacobs exhibited some extraordinary Pears of various kinds. Among them were twelve fruits of Duchesse d'Angoulême weighing 228 ozs., twelve of Easter Beurré weighing 154 ozs., and a French Pumpkin weighing 187 lbs. Mr. Ford, of Leonardslee, showed his new Apple Ford's Seedling, a handsome-looking fruit. The committee wish to see it later. Mr. Laxton, Bedford, showed fruits of his new Pear Laxton's Bergamot, and another named Richard Thompson, both good-looking fruits. He also sent fruits of his Strawberry Noble in order to show how late it fruits out of doors. The richly coloured Dartmouth Crab was also shown by Mr. Laxton. It is a beautiful Apple, and a tree of it in fruit must be a great ornament. Among vegetables was a new Vegetable Marrow of large, oval shape. It came from Mr. Oxford, Chelford. Mr. Deverill, of Banbury, was awarded a cultural commendation for some wonderfully fine samples of his Rousham Park and Improved Wroxton Onions and Early Exhibition Carrots, while a new Runner Bean, also from him, named Ne Plus Ultra was referred to Chiswick. Mr. R. Dean had a dish of the somewhat rare Nanny Apple grown at Bedfont, and a dish of the fine golden Tomato Prince of Orange. Mr. Rivers, of Sawbridgeworth, showed as late Plums Monarch and Grand Duke, purple; St. Denys, red; and October, yellow—all capital samples. Mr. Laxton, of Girtford, had a collection of white seedling Potatoes, mostly flat or kidney shaped, and some good open air Tomatoes. A remarkable exhibit was a table of 50 feet long, backed by Tomato plants from the open ground in great variety and full of fruit, shown by Messrs. Sutton and Sons, Reading; whilst in fruit were baskets and clusters of all the best kinds, such as Reading Perfection, First Crop, Earliest of All, Chiswick Red, Golden Gage, a yellow cluster kind, and others—really a novel and singularly interesting collection.

Vegetables.

Special prizes.—The collection of eight kinds of vegetables staged in competition for the very liberal prizes offered by Messrs. Sutton and Sons brought a remarkable competition. Not only were eleven collections presented, but the quality was wonderfully even and good; indeed, better has rarely been shown at South Kensington. The samples shown included Autumn Giant Cauliflower, Matchless and New Intermediate Carrots, Rousham Park Onions, Sutton's Seedling, Abundance and Snowdrop Potatoes, Giant White and Leicester Red Celeries, Trophy and Perfection Tomatoes, Brussels Sprouts, Giant Leeks, &c. The prizes went to Messrs. Miles, Wycombe Abbey; Haines, Coleshill, Wilts; Meads, Shrivenham Park; Waite, Esher; and Pope, Highclere Castle—all first-class growers. A class for Sutton's Seedling Onion brought eleven lots—all fine samples, the best (very fine indeed) from Mr. Loder's garden, Wecdon. For the same firm's new Onions of 1886 capital samples were shown, Messrs. Haines, Allen (Hungerford), and Phillips (Meopham) taking the prizes. Messrs. Jas. Carter and Co., High Holborn, offered prizes for their Mont Blanc Cauliflower, the best coming from Mr. Waite. Eleven dishes of their Champion Runner Bean were staged, of which the best were from Mr. Waite also. Several lots of Tennis Ball Onions were also shown.

A list of awards is given in our advertising columns.

Obituary.

Many who knew Mr. Forsyth, gardener at Gunnersbury Park twenty years ago, will regret to learn that he died the other day by his own hand. Mr. Forsyth was one of the best gardeners of his day, and was particularly successful with Pine-apples and Grapes. He retired from the management of the gardens at Gunnersbury Park some sixteen years ago, and, on account of his long services, was allowed a pension by the Rothschild family. He was 73 years of age at the time of his death, which took place at Ealing last week.

The late Mr. Peach.—We are reminded that in the obituary notice of the Rev. C. P. Peach given in The Garden (p. 352) one interestiog fact is omitted, namely, that he was brother to the late Mrs. Miles (wife of the late Rev. Robert Miles, of Bingham), who used to send such artistic sketches of flowers to The Garden (so much appreciated by lovers of hardy flowers), and consequently uncle of Mr. Frank Miles the artist.

Names of plants.—*M. C.*—1, Pardanthus chinensis; 2, Athyrium filix-fœmina Frizelliæ.—*W. Hill (Rosera).*—1, specimen insufficient without fruiting frond; 2, Onychium lucidum; 3, Blechnum occidentale; 4, Asplenium laserpetifolium.—*R. C. Burr.*—Adiantum formosum.—*G. Fleuwell.*—Campanula strigosa, Stapelia variegata, some kind of Crassula.—*W. E.*—Yellow, Helianthus rigidus; white, Pyrethrum serotinum.—*Tahiti.*—Aster Novæ-Angliæ roseus.—*A. Chalmers.*—Cattleya Eldorado, true and a high coloured variety; Oncidium prætextum.—*J. J. Matthews.*—Broad-leaved variety of common Myrtle, sometimes called latifolia.—*B.*—White Dogwood (Cornus alba).—*C. J. H.*—Cannot name.

Names of fruits.—*Mrs. A.*—Simply a wild Crab, and utterly worthless.—*J. H.*—1, Beurre d'Amanlis; 2, Marie Louise; 3, Hessle; 4, Beurre Clairgeau.—*G. J. B.*—1, Marie Louise; 2, Beurre d'Amanlis; 3, Beurre Superfin; 4, Comte de Lamy.—*J. G. Flint.*—A fairly good example of Red Astrachan.—*H. E.*—Royal Somerset.—*Old Sub.*—Seckel.—*G. Thompson.*—Pear not known.—*J. G. R.*—1, Blenheim Orange; 2, Cox's Orange Pippin; 3, King of the Pippins; 4, Wellington.—*Devon.*—Appears to be Beurre de Capiaumont, but specimen poor.—*Scott.*—1, Beurre Rance; 2, Marie Louise; 3, Louise Bonne of Jersey. Plums smashed.—Others will be named next week.

WOODS & FORESTS.

EXTINCTION OF ASH AND SYCAMORE.

If "J." was as familiar with the nursery trade and planting as he appears to be with the timber trade, he would not write about the extinction of either of the above trees, for it is well known that both are now being planted more freely than ever they have been. Hitherto, or until a recent period, the Ash and Sycamore seem to have been left to perpetuate themselves, but now both are raised and sold in nurseries to an enormous extent, and in our woods of the future they are likely to be rather too abundant if anything. At present, I admit, both Ash and Sycamore of large size are comparatively scarce, Sycamores especially, and the price of both has been fairly maintained, while almost any quantity could be sold, but in the course of a generation or two there will be a good supply, as the two species are rapid growers. The present scarcity of Ash and Sycamore and some other trees is due to the want of foresight on the part of British foresters in the past and the needs of game preservers. There are estates in England and Scotland where woods of Ash and Sycamore would have been an invaluable legacy to present occupiers and their heirs, but the timber on which is almost useless, consisting, as it does, chiefly of young Oak and Spruce or inferior Larch.

We need not fear that "half a century must elapse" before a crop of Ash becomes useful. Not long since we knew of 20,000 feet of Ash being sold that was not more than thirty years old, the whole of the small poles going for shaft wood and such like purposes. You can sell Ash as thick as your arm, and find a ready market for stuff from 4 inches to 6 inches quarter-girth, and in good soil and sheltered ravines timber of those dimensions is soon grown. The great enemy to the Ash has been the rabbits. Probably they have destroyed four-fifths of the Ash planted in this country wherever they abound. The treatment the Ash, too, has received from foresters in the past is a sad commentary on their foresight and intelligence. While spending their breath on the advocacy of untried exotic species in the shape of Firs and the like, they have neglected the very trees which they knew they could rely on, and which produced timber of the most generally useful and indispensable description. Now and again some far-seeing writer has lifted his voice against the neglect of the Ash as a timber tree, but our enlightened Scotch and English foresters have gone on planting their rubbishy Spruce, and Scotch Fir, and other doubtful species of the same nature, and you might search far and wide for a plantation of useful Ash that has not sprung into existence by accident. Though scarcely a tool the woodman or the farmer used, nor any useful implement was made without Ash, and it was in common use in many ways besides, the idea of providing a supply of such a useful timber for the future never seems to have concerned planters, and you may read through yards of stupid essays read before sleepy arboricultural associations in which you will find no trace of a thought on the subject. If there be any body of cultivators who needs their wits sharpening it is the so-called British arboriculturist, with his pedantic notions and conceit and invulnerable ignorance which you see every day reflected among woodmen of all degrees and their work. It is just about one hundred years since Marshall wrote of the Ash, that "to enumerate its uses would require a separate volume; the farmer would find it difficult to carry on his business without it, and, indeed, the cooper and the coach-builder would be equally at a loss with the wheelwright should a scarcity of Ash take place, and we know of no species of timber so likely to be worn out in this country as the Ash." Marshall "was concerned to see," even in his time, "among the numerous plantations which have of late years been made, so few of this necessary tree," and thought it "more than probable that no tree would pay better for planting, not in single trees in hedgerows, but in close plantations," where it would grow tall and straight, producing timber of the best description. At the present time, and during all the depression in the timber trade, Ash has been in demand, and many foresters are now economising their supply and using it to help to sell other kinds of timber that has not such a good market. Nothing helps a sale better than a good bit of Ash in it, and the more Sycamore it contains at or above 11 inches quarter-girth the better also. Inasmuch as the timber of these two trees is in greater demand at present than any other class of English timber, it is not going too far to say that those who possess both in abundance on their estates are by far the wealthiest in that respect. YORKSHIREMAN.

PLANTING COVERTS.

I am about to turn some fields into game coverts. The land adjoins some old plantations in the park, and as the spot is within sight of the house, I should like to have the covert ornamental as well as being suitable for game shelter. Could you give me a list of plants other than those usually planted?—R. S. F.

*** There are various ways of making coverts of ornamental shrubs in parks, pleasure grounds, or in home woods that would be effectual for game shelter. Where something more than mere game protection is desired, we should then throw in groups of dwarf evergreen shrubs, so arranged as to produce a pleasing effect. Plants suitable for this purpose are plentiful, but the following are a few good kinds:—

Aucuba japonica	Ivy of sorts
Box, common	Juniperus sabina
Berberis stenophylla	Laurustinus
,, Darwini	Laurel, common
,, Aquifolium	Leycesteria formosa
Cotoneaster microphylla	Ligustrum ovalifolium
,, buxifolia	,, japonicum
,, Simonsi	Tamarix gallica
Holly, green and variegated kinds	Gorse, common and double
Hypericum calycinum	Yew, common

Then, among what are called American plants, there are such shrubs as Andromeda, Erica, Gaultheria Shallon, Kalmia, Ledum, Pernettya, Vaccinium, and Rhododendron. There is a wide field of evergreen shrubs, to which might be added a number of berry bearing plants, foremost among which I would name, for its delicious odour, the Sweet Brier, and numerous climbing Roses, and, above all, the Blackberries. The Snowberry (Symphoricarpus racemosus) is also grateful food for pheasants, though it is not a good covert plant—at least not for winter. One of the most useful plants that can be planted is the Jerusalem Artichoke, and pheasants are specially fond of this. The arrangement of these covert plants must depend upon the taste of the planter. For example, we would not plant a light foliaged plant under a light foliaged tree, neither a dark one near another heavy mass of Evergreens; but would so diversify the planting as to produce an agreeable whole with something of the picturesque about it. For example, the Aucubas and Golden Box and Hollies would give a fine mass of the palest green, or green and gold; while the Berberis would give dark green or, in the case of the most beautiful of all of them, B. Darwini, a very light tinge. Then of Cotoneaster, what can be so beautiful as C. microphylla when studded with its bright scarlet berries? G.

Foresters *v.* gardeners.—Few foresters, I think, will agree with "Y." that the valuing and disposing of timber can be learned in a very short time. On the contrary it requires years of constant practice and careful attention to become an adept at measuring and valuing timber. In these times of depression in all interests connected with land, it is an all-important qualification in a forester that he be able to measure timber correctly, either standing or felled, and have a practical acquaintance with its value. What can a man whose time has been spent in a garden know of the many details which go to make up the work of a forester? How can he tell when a man has done a day's work, say in felling timber, or in planting, or draining, &c.? Because he can manage the home nursery, therefore he is competent at once to manage economically a vast tract of woodlands! Strange reasoning this, and not worthy of the usual character of "Y.'s" writings. I am constrained to think that he does not really believe in the doctrine he preaches. —W. B. H.

THINNING OAK WOODS.

The time for thinning Oak woods, says Mr. Clutton, is when the underwood is cut. The greater part of the timber generally in the south is grown with underwood. The underwood is cut, on an average, once in ten years. At each cutting, trees which have attained a good size, and show symptoms of diminished growth, are felled, and open spaces are thus obtained for a fresh crop. The same opportunity is taken for thinning the young Tellars, and of saving such further young plants as have come up since the last cutting of the underwood, that is, ten years previously. In thinning Tellars and young trees, it is of the utmost importance that the leading trees should be left and the inferior ones cut. For the ultimate crop the trees should stand from 20 feet to 30 feet apart. The great aim of every forester should be to keep the trees thick enough to draw each other up to the height required, so as to have a clear stem of from 20 feet to 40 feet, as the case may be, and so to gradually thin them as not to abruptly admit the wind, and thus cause them to be checked in growth. Any checking of growth is speedily detected by the throwing out of a quantity of "bushy" boughs, as they are called, up to the age of from seventy to eighty years. If the trees have been properly managed the wood will require little further thinning until clearing, unless the timber is left for a longer period than 100 years for large shipbuildings. After a wood has been cleared of a natural crop of Oak, and the underwood has grown for a period of ten years, it will generally be found, at the next cutting, that a good crop of self-sown Oak Tellars is fairly scattered over the ground. The Tellars are usually marked with paint, and are excepted from sale. At this first cutting the young Oak trees will be about the same height as the underwood; and if the underwood is fairly good, the chances are that it will be unnecessary to thin the Tellars at all, more than by a woodman going round and chopping down with a hatchet any inferior trees. During the next five or six cuttings the real work of thinning must be executed.

The periodical cutting of underwood affects the growth of trees, as it affords the only opportunity of thinning woods; thus the thinnings are at longer intervals than perhaps is best for the growth of Oak timber. The custom in the wealds of Surrey, Sussex, and Kent is to cut the underwood at intervals of from eight to twelve years. Underwood is usually sold by auction in November, and in the following spring the Oak trees are inspected, and such thinning as is required is then done. If the timber only was considered, a shorter interval of, say, five or six years would be better, but as the underwood is an important portion of the profits, it is impossible to make the most of it until it becomes large enough for conversion into Hop-poles, hoops, &c. As to the age at which the timber causes injury to underwood, supposing there is a full plant of Tellars at any given fall, for the next two cuttings (say, for twenty years) there will be little difference found in the value of the underwood, which averages from £8 to £10 per acre. The next three cuttings will be reduced, on an average, about one-half, and afterwards the periodical cutting will be sold for a very small sum, viz., £1 to £1 10s. per acre, which will not pay for rates, fencing, and ditching.

Forest preservation in Canada.—The question of the best means of promoting tree planting and forest preservation in different parts of Canada is now exciting considerable interest throughout the Dominion. One proposal, having special reference to Ontario, is meeting with general favour. If this proposal were adopted, a farmer would be encouraged to reserve five,

ten, or fifteen acres of his land in forest by a Government enactment, freeing such portions of his property from taxation, but at the same time rendering him liable for all taxes whenever he ceases to preserve them.

THE MANAGEMENT OF WOODS.

"Omega" (p. 353) needs a word or two of reply. He thinks bred gardeners would be less fit to fill the forester's place than the present race of woodmen. This I take to be what he means. Very well. Our woods, by almost universal consent, are acknowledged to have been grossly mismanaged hitherto, and they have been managed by foresters. Who, then, is to blame? I admit that the landlords are so far to blame in not taking sufficient interest in their woods, but for the setting out, planting, and culture of the plantations the forester has been responsible in a great degree, and there are examples to show that this is true, for the woods on many estates reflect the woodman's management more than anything else, some being ill, some indifferently, and some fairly well managed, just according to the ability of the man. Gardeners are as much subject to the will and caprice of their employers as foresters, and more so, for they have, as a rule, more than one master to please. Yet they manage to leave their mark on the garden in almost all cases, and no one will dispute that their cultural successes are of a high order, far and away ahead of the forester. I do not wish to indulge in comparisons, but there can be no harm in trying to realise our position truly. "Omega" says a forester ought to be a man "not only possessing a knowledge of chemistry, geology, entomology, and botany, but a good knowledge of estate carpentering, land surveying, valuing, and a thorough knowledge of saw-mill management." Well, I content myself with denying that he needs much knowledge of the "ologies" and other sciences above stated; but, granted that he does, how many foresters in a hundred know anything about them? Not one per cent. probably; whereas gardeners worth the name almost all do know something of them, and have means of learning in their abundant experience and literature what they need to know.

As for carpentering, it is much more nearly allied to his department than any other on the estate, but, as a matter of fact, neither the gardener nor the forester need to possess a good knowledge of carpentering. The estate agent himself superintends all estate work of this kind where there is no clerk of works, and he gets on with exceedingly little knowledge of the subject. As to the saw-mill belonging to the woods, there are not many places where such a thing exists, and I find that there are always about a dozen handy labourers ready to take the whole thing in charge when a vacancy occurs. These two items are not worth mentioning. As "Omega" says, the felling and converting of timber and valuing are important matters to the proprietor, but there is nothing difficult or mysterious about them. The forester does not fell the timber himself, and he has only got to satisfy himself that the work is performed in a workman-like manner, and a glance will tell even a novice when that is done if he has once seen a tree properly felled. As to "converting" timber, the word is an exaggeration as applied to the conversion of timber on estates, which, in ninety-nine cases in a hundred means only sawing up rails, a few rough boards now and then, and making posts and stakes.

Valuing timber, too, is soon learned, but all woodmen are not experts at such work. Before timber can be sold, however, it must be grown, and it is in the laying out, selection of trees, and the culture of the plantations in which the forester has failed in the past, and which it is proposed to remedy by putting woods under men who understand tree culture. To this work the gardener brings a fund of experience and skill to which the forester is an entire stranger. He has never come in contact with plant life in the intimate manner the gardener has done, nor mastered the principles on which the latter proceeds, and which are as applicable to wooderaft as to gardening. It is here the mismanagement of our woods is seen, it must be remembered, and not in the disposing of the timber. Yorkshireman.

THE BLACK ITALIAN POPLAR.

This Poplar (Populus monilifera) is perhaps the most rapid growing tree we have in cultivation, and will produce in a given number of years more available timber than any other tree yet introduced. Since the commencement of the Larch disease, this Poplar has become very extensively cultivated, and its wood is now used for various agricultural purposes, as well as for railway wagons, &c. The wood of the Black Italian Poplar, as well as that produced by some of the other species, all being equally free-growing, is worthy of being experimented on for railway sleepers, so as to ascertain its duration when compared with the ordinary sleepers now in use; if prepared, and laid on broken metal, as sleepers generally are, it may last a very long time.

The Black Italian Poplar is admirably fitted for a fence in moist soils. Plants one year old, which are generally about 4 feet in height, will form a tolerably good hedge the first year. If the soil is dug over and manured several months previous to planting, strong cuttings may be inserted about a foot apart, and these will make shoots varying from 3 feet to 5 feet in height during the first season. At the end of the second year, during the month of November, the top of the fence should be regularly reduced with a hedge-bill to the height of 5 feet. This will strengthen the sides of the fence, and consequently increase the stability of the stems. A very good plan is to tie rods of wood to the young trees at 2 feet or 3 feet from the ground, until they have become sufficiently strong of themselves to resist the pressure of cattle. When properly attended to, by keeping them free from weeds, and trimming them regularly every autumn, these fences become highly useful and ornamental, and are at once amongst the cheapest and readiest of any that can be raised. The hedge should be wider at the base than at top, and should be trimmed wedge-shape. J. N.

Spring *v.* autumn planting.—From long and extensive experience in planting in different situations and soils, I am in favour of autumn planting of forest trees, and also evergreen shrubs unless in cold, bleak situations, when the latter are best deferred till spring or early summer. There may be situations where the soil is too wet to admit of early planting, but such is unfit for planting at any season till drained. There is an old saying which in practice I find to be correct, viz., "Plant a tree in autumn and command it to grow, but in spring you must coax it." Some are of opinion that severe frost will injure early planted trees; this I have proved to be a fallacy. In order to test it I left young trees with their roots uncovered during severe frost, and planted them when thawed, and I found that they sustained no injury. There is more risk from drought in spring planting than from frost in autumn or winter planting.—J.

Heart-rot or dry-rot in Larch.—The outward indications of fully-established heart-rot are—the tree becoming perceptibly thickened under about 2 feet from its base; the bark of both stem and branches assuming an unhealthy, dried, and more or less Moss or Lichen-covered appearance, the length and abundance of such covering being in proportion to the atmospheric dampness of the situation; and the stunted, decreasing growth of the annual shoots and foliage till the tree first becomes partly, and ultimately wholly dead. When cut down the internal appearances are—first unhealthy, darkish discolourations of portions of the red or heart-wood, which spread and change to dry rottenness, followed by hollow-heartedness, and finally by total decay; the decrease in the width of the annual wood-layers being proportionate to the increase of rottenness till arrested by death. These symptoms occur at all ages, but are most frequent between ten and thirty-five to forty years, and are attributable to occasional droughts, as well as to occasional over-saturation, to fungoid attacks on the roots, such as emanate from decaying remains in ground previously occupied by Scotch Fir, and to lopping off or otherwise destroying the roots—in fact, to anything that thoroughly checks or materially weakens the root action. The correctness of these remarks being assumed, it follows that the only prevention of dry-rot is to avoid planting Larch in places likely to produce it. The only remedial measures that can be adopted—for cure there is none—are cutting down the trees when it first appears, and re-planting the ground with other more suitable kinds.—W. G.

THE HEMLOCK SPRUCE AT HOME.

(ABIES CANADENSIS.)

One of the loveliest and most graceful of Canadian forest trees is a young Hemlock. As great a contrast does that elegant sapling, with its gay, tender green feathery sprays, bear in its beauty of form and colour to the parent tree, with its rugged stiff and unsightly trunk and ragged top, as the young child in its youthful grace and vigour bears to the old and wrinkled grandsire. The foliage of the young Hemlock in the months of June and July, when the spring shoots have been perfected, is especially beautiful; the tender vivid green of the young shoots at the end of the flat bending branches of the previous year appears more lively and refreshing to the eye in contrast to the older, dark, glossy, more sombre foliage which they serve to brighten and adorn. The Hemlock does not reach the lofty height of the White Pine, though in some situations it becomes a giant in size, with massive trunk and thick, bushy head; the bark is deeply rifted, dark on the outside, but of a deep brick-red within; the branches are flat, the small, oval, soft cones appear later in the summer on the ends of the shoots of the previous season. The timber of the Hemlock is very durable, tough, and somewhat stringy, loose-grained, but is said to resist wet; it is used for granary flooring, rail-ties, and some other purposes in outdoor work. The bark is used largely in tanning. The backwood settlers stack the Hemlock bark while clearing the forest land and carry it in during the sleighing season to the tanneries, receiving a certain value per cord in money or store goods.

Villages and towns now occupy the spots where only the dark forests of Pine and Hemlock, Maple and Beech once grew. The trees disappear indeed before the axe and fire from the site where Nature had placed them, but they reappear now as ornaments, planted by the hand of taste in the gardens, and as shade-trees on the streets of the towns and cities; and this is good, it speaks of taste and culture. The Hemlock, however, is less frequently seen about our dwellings, beautiful as it is, for it is tardy in growth and does not take kindly to cultivation. Its natural soil is dry, rocky, or gravelly land.—*Plant Life in Canada.*

Osier plantations.—The following is the method of planting an Osier bed which has been carried out by an experienced grower on some "warp" land near Stamford Bridge, Yorkshire. The land, which he has had on lease for twenty years, at a low rent is only 3 feet from the ordinary level of the river, and was when he took it a complete bog. However, by cutting a few deep ditches he dried it sufficiently to allow of its being ploughed, after which he let it to be trenched two spadings deep, the top spit to be placed in the bottom, at £6 per acre. Two years ago last March he planted cuttings 14 inches long, of the following varieties of Willow, viz., French, Black German, Spaniards, and Yellow Osiers. The rows of cuttings were 20 inches apart, and the cuttings were put in at a distance of 8 inches from each other in the rows. This is rather nearer than is usually done, but as the land was good, the planter thought it would be more profitable. The first summer he hoed over the ground at least twice to keep down the weeds; afterwards the Grass, &c., was cut out with a sickle, but it was anticipated that the Willows would in two years be able to overcome the undergrowth. The reason that cuttings of such a length as 14 inches were used is, that there had been no frost of sufficient keenness, during the previous winter, to temper the land.—W. H.

No. 779. SATURDAY, Oct. 23, 1886. Vol. XXX.

"This is an Art
Which does mend Natnre: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

ROSE GARDEN.

CLASSIFICATION OF GARDEN ROSES.

In attempting to handle this difficult subject, the very diverse requirements of a botanical classification of species and a convenient arrangement of garden varieties must be kept prominently in view. Mr. Baker, the best possible authority, gives the number of Rose species as sixty-two, a number which is more likely to be reduced than augmented, and of which it is quite possible that not more than twenty are answerable for the great bulk of the varieties now found in gardens. The contention of Rose reformers, however, appears to resolve itself into this: that the very various modes of classification adopted in their catalogues by different nurserymen are inconvenient; and that it is desirable that a uniform arrangement should be made use of in all lists. Apart from the possible comments of the trade-growers as to their perfectability to manage their own business, it may be pointed out that the variations of arrangement in catalogues are not more numerous than the differences of ability and knowledge in those who have gardens to furnish. For the amateur who sees a Rose which he admires, and merely wants to find its cost before ordering it, the simple dictionary of names of varieties with their prices attached is most convenient. The rosarian of wider experience or botanical tendency, on the other hand, demands a catalogue arranged on something like a scientific basis, in which varieties are grouped and classified under the head of the species from which they have sprung. But between these two extremes there is every imaginable class of constituent, to whom, naturally, every form of appeal is made.

What class of growers it is intended to benefit by the suggested alteration of terms is by no means evident. Anyone capable of understanding the somewhat ponderous expression annual blooming shrubs, would probably prefer the simpler term summer Roses that has done duty for so many years. Again, periodical blooming shrubs can hardly be considered a very great improvement on hybrid perpetual. The term perpetual has attained a fairly definite meaning in horticulture, and when a perpetual Rose or a perpetual Strawberry is spoken of, it is understood to mean that the plant flowers or fruits more or less a second time after the normal period of flowering or fruiting. When people speak of perpetual Roses they use the expression as the name of a group of widely-known Roses, which have, in common, the quality of blooming a second time—generally in autumn—to a greater or less extent.

But if the desirability of the suggested terms is open to question, far more so is the possibility of their introduction. When once a nomenclature has been adopted, and especially when its employment has become practically universal, it is pretty nearly hopeless to attempt to effect any substantial alteration. Many of the commonest expressions have long since lost their literal meaning, but are not, therefore, discarded as unintelligible; the fact that the sun does not in reality sink down when day is done was not a discovery of yesterday, yet the phrase "the sun is setting" still survives. "But," says "Hortus," "could perversion of words or misrepresentation of facts go further? Is it not a gross imposture?" Perhaps; but it answers. Sunset, if you will, is the unmeaning name of a common astronomical fact, and Hybrid Perpetual is the unmeaning, but perfectly well understood, name of a well-known group of Roses. There is an excellent old proverb about not throwing away dirty water until clean is forthcoming, which "Hortus" seems to have forgotten in suggesting the necessity of beginning a new arrangement by the abolition of existing Rose names, and really the objection to historical and geographical names is not so very obvious. Persian Yellow is a good enough name for the Rose sent home by Sir Henry Willock in 1837, and in all probability China Roses will be talked about to the end of time. What has been the result of the attempt to supplant the practical Fortune's Yellow by the more picturesque, but not a whit more descriptive name, Beauty of Glazenwood?

The proposed division of Roses into shrubs and climbers would but render confusion worse confounded, for, as "Hortus" points out, innumerable varieties may be equally well grown in either capacity, and the suggestion to supplement this admittedly doubtful classification by reference to such structural details as the prickles comes a little oddly from one so opposed to a botanical basis. The botanist may, perhaps, identify species by the form and position of hairs and prickles, but the gardener classifies his plants chiefly by their flowers, and it is hardly to be supposed that "Hortus" would seriously entertain the notion of putting Baroness Rothschild and Etienne Levet in different classes because one is thorny and the other smooth-wooded, or of separating Alfred Colomb and Marie Baumann because one has only large prickles, while those of the other are of all sizes.

Even the distinction most relied on by Mr. Hewett, namely, the number of times a Rose blooms during one season when considered without regard to the origin of the variety, is by no means dependable, for many varieties bloom more freely in autumn in some places and in some seasons than in others; and recent correspondence has shown that, whereas in certain localities Madame Gabriel Luizet has this year proved a most valuable autumnal bloomer, in other parts not a bloom has been seen since the July flowering. But if the period of a Rose's blooming is to be considered in connection with its race or origin, then Mr. Hewett's threefold division gives us nothing but our old friends the summer Roses, the Hybrid Perpetuals, and the Tea-scented Roses under new and not very attractive names. Concluding, therefore, that it will be impossible to get far away from the existing classification and nomenclature which Mr. Hewett considers so "sadly confused," and "Hortus" finds "uncertain and incomprehensible," it will be well to see how far a case is made out against present arrangements, and what amendments and simplifications it would be possible to effect.

Mr. Hewett's great difficulty seems to be to decide where to class certain recent Hybrid Teas and the Noisette Roses. Let the plan of the National Rose Society be followed of classing the former as Hybrid Perpetuals and the latter with the Teas, and almost the whole of Mr. Hewett's objections disappear. Just as Asia Minor is the general receptacle of the schoolboy for every place of whose exact geographical position he is uncertain, so the group of Hybrid Perpetuals may be made to include all Roses of such mixed origin as not to be referable to any distinct species, provided only they bloom more or less a second time during the season. Again, it might naturally be expected that a hybrid between a Tea and a Musk Rose when hybridised with a Tea would give seedlings very nearly resembling the general habit of the Tea, of whose blood it would have, so to speak, a double strain, and this appears to have been the case with the so-called Noisette Roses. The original Noisette (now believed to be entirely lost) came from a cross between a Tea and a Musk, and this hybrid, being again crossed with Teas, resulted in varieties such as Maréchal Niel, Caroline Kuster, Solfaterre, &c., so nearly of the character of the Teas as to justify their inclusion in the same group. By the way, Mr. Hewett makes a strange remark in asking whether "the yellow shades in our Tea Roses . . . are natural to the species canina;" whereas, of course, all our Tea Roses are derived from R. indica and its varieties. There are no yellow varieties of R. canina, nor does there appear to be any evidence of any cross with R. sulphurea having ever been effected.

"Hortus" says, "it seems physically impossible to make botanical species of Roses the basis of any practically useful nomenclature or classification that shall be understood by rosarians." The use of the term "rosarians" here makes this statement rather self-contradictory, for it is hardly to be believed that the rosarians who have carefully classified all the garden varieties under the heads of the species from which they have sprung have completed an arrangement practically useless and incomprehensible to themselves. But if "Hortus" means to say that beginners in the art of Rose-growing cannot use or understand the Rose catalogues that are arranged upon this botanical basis, the statement may be more or less true according to the way in which such novices approach their task. The catalogues of our large Rose growers are, as a rule, explicit enough for most people; but for beginners a further simplification might be desirable, and there is no doubt that all the varieties of Roses now grown in gardens might for practical purposes be included in the following four groups:—

1. SUMMER ROSES (Roses that never bloom more than once a year).—Provence and Moss, Damask, Gallica, Alba, &c., Hybrid China (so called), Climbers (Ayrshire, Evergreen, Banksian, Boursault). This would form a very brief part of the list, but few varieties being worth growing in an ordinary garden.
2. HYBRID PERPETUAL ROSES (Hybrid Roses which bloom to a greater or less extent more than once), including Hybrid Teas, Bourbons, &c.
3. TEA-SCENTED ROSES (varieties which have not widely departed from the type R. indica), including Noisettes and Chinas.
4. SINGLE AND SEMI-DOUBLE ROSES.—Species: Macartney, Rugosa, Musk, &c. This also would constitute but a short section.

In groups 2 and 3, which would, of course, constitute the bulk of the list, either some device might be employed to indicate the varieties best adapted for exhibition, or each group might be printed in two sections; the one to include the best varieties for exhibition, leading types of which would be, in group 2, A. K. Williams, Lady Mary Fitzwilliam, and Madame Isaac Pèreire; and in group 3, Catherine Mermet, Maréchal Niel, and Caroline Kuster; the other to include what are conventionally called garden Roses—that is, varieties with less perfect flowers, though well adapted in a mass to make an effective display in the garden—leading types of which would be in group 2, Anna Alexieff, Reine Marie Henriette, and Armosa; and in group 3, Madame Falcot, William Allen Richardson, and Cramoisie Superieure.

These four broad divisions form a purely garden arrangement, although originally founded on a

botanical basis, and, if convenient in catalogues, may also advantageously be maintained in a collection of growing plants. The summer Roses should be grown by themselves in the garden because many of them, such as the Mosses, Gallicas, &c., are exceedingly liable to mildew, which is a terribly infectious complaint. The Hybrid Perpetuals may well be grown all together, as none of them, whether called Hybrid Teas, Hybrid Noisettes (such as Boule de Neige), or Bourbons, are admissible in the classes devoted to Teas at Rose shows. The Tea-scented Roses, requiring in many districts a little extra careful treatment and protection, are much more conveniently managed when not mixed up with other kinds of Roses, especially also as they will thrive on lighter soil than that best adapted to Hybrid Perpetuals. The grouping of the single Roses by themselves might be considered unnecessary, seeing that they appeal, unfortunately, only to a limited public as yet; but that is all the more reason in reality for their separation, so that those who do not want them need not be bothered with their inclusion in other parts of the list, while their admirers may at the same time find them without trouble. Still, if the more decorative of these graceful single Rose types be grown more or less apart, or in the wild garden, anywhere where they can have room to grow as they like, the canopy of bloom under which the plants hide themselves from the summer sun cannot fail to win for them increasing admiration from all who see them.

T. W. G.

NOTES OF THE WEEK.

Chrysanthemums in Finsbury Park.—We have been requested to state that the annual display of Chrysanthemums in this park is now open to the public.

Anthuriums.—Of the forms of A. Andreanum that named Reine des Belges differs in the spathe, which is smooth, not wrinkled like the type, whilst the colour is a pleasing bright rose. A. Archiduc Joseph has also a smooth spathe, rosy peach in colour. A. ornatum, a very ornamental kind, has pinkish white spathes, and A. Dechardi, a compact-growing kind, has also white spathes and is almost a perpetual bloomer; all of these plants are now in bloom in the Maida Vale Nursery.

Tuberoses out of doors.—Having read "R. D.'s" remarks on double Tuberoses, I thought it might interest some to know that these flowers can be successfully grown out of doors. We have been cutting blooms here for the last six weeks from bulbs planted out about the first week in May. I enclose a spike, though the flowers are now getting spoiled, the nights being cold and foggy.—W. Thomas, *Aylesford.*

*** A very fine spike indeed of the best double form of Tuberose.—Ed.

Zonal Pelargoniums.—These are exceptionally fine just now at Swanley. Those who have not studied these plants could scarcely believe what great improvements have been made in them during the past few years. Anyone requiring a brilliant display of flowers either in the greenhouse or in a cut state from this time up to Christmas cannot afford to discard Pelargoniums. For this purpose there is absolutely nothing to equal them; beautiful even as are Chrysanthemums, they cannot approach zonal Pelargoniums in brilliancy. Amongst the finest singles adapted for pot culture may be mentioned Lord Rosebery, cerise-red; Lucy Mason, reddish salmon, suffused with orange; Lady Reed, pure white, with a large scarlet centre; Norah, soft blush; Imogen, pure salmon; Queen of the Belgians, large white, retaining its purity under any conditions; Aurore Boreale, light scarlet, tinged with salmon; Edith George, reddish pink, very fine; Nelly Thomas, bright scarlet, upper petals feathered with maroon; Queen Matilda, soft pink, base of upper petals pure white, dwarf, and very effective; Ajax, soft reddish scarlet; Swanley Gem, bright rosy salmon, with a white centre; Mr. H. Cannell, crimson and maroon, white eye; Lady Chesterfield, very deep salmon; and Lord Chesterfield, rich magenta, and trusses large. In the double section there are many fine varieties with broad, even petals, and as double as a Rose. Some of these are largely grown for market purposes, and are extremely valuable when cut, on account of their blooms lasting for a long period; the pips, when wired, are worked up into bouquets and button-holes. The following are the names of a few kinds which stand out conspicuously amongst thousands now in flower. First come the novelties of the season, and amongst these may be named Spade Guinea, orange-scarlet, suffused with yellow, very fine, and from which we may reasonably hope ere long to have a genuine yellow Pelargonium; Australian Gold, cerise-salmon, with a distinct yellow shade; and Blanche Perfecta, pure white. Amongst older varieties are Mr. H. Cannell, a useful sort for market purposes; B. K. Bliss, rich deep scarlet; Eteranthe, large in the truss, and pips large individually, flowers semi-double, rich scarlet; Belle Nancienne, white, edged with salmon, centre red; Sir G. Wolseley, mottled salmon, very fine; Mrs. Cordon, soft rosy cerise; The Lord Mayor, purple-pink; Magenta King, rich pure magenta; James Vick, deep salmon, shaded with pink; Charles Lalande, intense crimson; Le Cygne, pure white; and Madame Leon Dalloy, blush white—all very handsome.

Bromeliads in flower.—Among these beautiful plants which are largely grown at the Pine-apple Nursery, Maida Vale, are Caraguata cardinalis, with large scarlet spikes; Tillandsia Lindeni, rich blue; the old Æchmea fulgens, Billbergia thyrsoidea, Nidularium Meyendorfi and spectabile; whilst such kinds as Encholirion Saundersi, Tillandsia mosaica, and T. zonata and splendens are also conspicuous. The extreme beauty of this class of plants should render them more popular in English gardens than they have hitherto been.

Amaryllis Belladonna.—A border of this in front of one of the plant-houses at Gunnersbury Park, Ealing, presents a sight long to be remembered. The bulbs were put out a few years ago by Mr. Roberts; they were properly planted, and since then they have done amazingly well. The border is 30 feet or so in length, and about 21 inches in width, and it presents to view quite a forest of stout stems bearing very fine trusses of deep rose-coloured flowers. The border faces due south, and the east end of it is nearer the hot-water pipes than the other portions, the result being a succession of plants, those in the warm end coming much earlier into flower than those in the other. The bulbs were placed rather deep in the border, which consists of a rich, but rather light soil. There are many spots in gardens in warm, sunny positions that could be used for the growth of this really grand autumn-flowering plant.

Double Primulas.—These are quite a speciality in Messrs. Henderson's nursery, Maida Vale; they are just now coming into flower, and will continue in bloom throughout the great part of the winter. Apart from their utility and beauty as pot plants, few flowers are more popular for button-hole bouquets than are those of these double Primulas. Besides the old double white, we noticed a Fern-leaved form, with large, rich, crimson flowers, named Emperor; also King of the Purples, purplish crimson; Fairy, white, elegantly fringed; Princess of Wales, very large pure white; Maiden's Blush, white tinged with pink; and Water Nymph, Fern leaved, with white flowers. These are all first-rate sorts.

Begonia Mrs. Haworth-Booth.—Under this name we have received from Col. Haworth-Booth, of Hullbank, Hull, the finest single white Begonia of the tuberous rooted section we have yet seen. The flowers measure just upon 4 inches across, are of thick texture, and the petals are rounded in such a way as to make almost a circular flower. The whole flower is of snowy-whiteness, which is rendered all the more striking by being contrasted with the tassel of golden stamens. There are many white sorts of Begonia, but they have defects, some being flushed with pink; others, again, are defective in form, having petals of unequal size, but this seedling seems to be, as we have just said, the perfection of a first-rate white Begonia. The leaves are large and of fleshy texture, and we presume the habit of the plant is strong and dwarf. It was raised by Mr. Lawrie, the gardener at Hullbank.

Chrysanthemum La Vierge.—Some flowers of this beautiful early Chrysanthemum have been sent to us by Mr. Henderson, of Corstorphine, Midlothian, who states that the blooms were cut from plants lifted from the open ground and potted last month. The flowers are as fine as those of Elaine, and absolutely pure white. It is in every way superior to such kinds as Madame Desgrange for purposes for which pure white flowers are required.

Tercentenary of the introduction of the Potato into England.—it is proposed, says *Nature*, to hold a Tercentenary Potato Exhibition at the St. Stephen's Hall, Westminster, from Wednesday, December 1, to Saturday, December 4, and to appoint one of those days for a conference, when some of the unsettled questions relative to the history, &c., of the Potato may be discussed. The exhibition will consist of four sections:—(1) An historic and scientific collection, to include early works on botany, in which the Potato is figured; maps showing the European knowledge of the New World three hundred years ago, and the proximity of Potato-growing districts to the ports most frequented; early books on travels and voyages in which reference to the Potato occur; works and papers in which attempts to define the different species are made; illustrations of the species and varieties; contemporary references to the voyages of Hawkins, Drake, Greenville, and Raleigh. (2) Illustrations of Potato disease, and works on the subject. (Sections 1 and 2 will be arranged under the advice of a committee of scientific gentlemen who have consented to give their co-operation.) (3) Methods for storing, preserving, and using partly diseased Potatoes, &c. (4) A display of tubers of all the various varieties grown. (In this section, gold, silver, and bronze medals will be awarded. Each exhibit must be accompanied by a statement of date of planting, locality, nature of soil, &c.)

QUESTIONS.

5524.—**Preserving Filberts.**—What is the best way of preserving these and other nuts? I find that mine are shrivelling, though picked ripe and put in a dry place.—E. G.

5525.—**Moth traps.**—May I ask "G. S. S." to give me the correct name of the plant which acts as a moth trap? I should like to procure some.—Entomologist.

5526.—**Pistia Stratiotes.**—Will some reader of The Garden, who is a good grower of this aquatic, kindly give me some details as to its culture? I have a small plant or two floating in a Lily tank, but they seem to be dwindling away.—M. H.

5527.—**Too leafy Violets.**—How can I prevent Violets producing an over-quantity of leaves compared with the amount of flowers? Mine look green and healthy, throwing out quantities of leaves and runners, but the flowers are few. The soil is good, calcareous in subsoil and well manured.—Enquirer.

5528.—**Diseased Clematises.**—For these two or three years past, large-flowered Clematises in my garden at Weybridge have been so much diseased, that I am no longer going to attempt to grow them. It affects both Jackman's varieties and those raised by other growers, planted in different parts of the garden; the plants die off suddenly without any apparent reason. I should be glad to know if there are any large varieties proof against it, and if the disease is general.—Old Subscriber.

SHORT NOTES—VARIOUS.

5523.—**Label wires.**—Do not hang Acme labels by copper wire; galvanic action is set up between the zinc and the copper, and the zinc label very soon gets cut through and drops off. I speak from experience.—R. C. B.

Seedling Begonias (*G. H. M.*).—Very good blooms, but not superior to those of other sorts raised in nurseries in or near London. Your double sort is, we consider, the finest, but one with flowers very similar was shown at South Kensington the other day.

Anagallis cærulea and arvensis are identical, except in colour; therefore one is a variety of the other. A. indica from Nepaul is distinct. The large-flowered kinds from the Mediterranean require protection in winter. There is a white variety of A. Monelli.—S. A.

Fungus (*E. S and S.*).—The fungus which you send is not a truffle, though often mistaken for one. It is a kind of puff-ball named Scleroderma vulgare, and, if not poisonous, quite worthless for the table. It is, however, sometimes used for stuffing turkeys, sausages, &c., by the keepers of the commoner sorts of French-dining rooms in London. Its taste is by no means pleasant, but being black in colour it passes for truffle with some unfortunate diners.—W. G. S.

Flower Garden.

OX-EYE DAISIES.

There seems still to be a good deal of confusion prevalent about the synonyms and characters of several Ox-eye Daisies which are more or less common in English gardens and nurseries. The remarks I here make are founded upon the best botanical authorities, and upon an examination of specimens in the herbarium at Kew.

Chrysanthemum (Leucanthemum) maximum (De Candolle).—This is the plant figured on p. 333 of The Garden by the name of L. atratum. Plants of it came to me about five years ago named C. atratum, but, suspecting their genuineness, I sent them to Kew, and received a reply signed by the highest authority there saying, "Your Daisy is clearly Chrysanthemum maximum." Since that time I have distributed it largely under its true name. It grows 2 feet or 3 feet high or more, has a spreading habit upwards, but a close growth at the base, produces very large flowers in June and July, and is succeeded by

Chrysanthemum (Leucanthemum) latifolium (De Candolle).—This is the plant which is grown in many gardens and nurseries as C. maximum. It begins to flower just as the true C. maximum ends and grows twice as high, reaching in this garden a height of from 5 feet to 7 feet. In its native country (Portugal), I am told by those who have seen it, and have sent me seeds of it, that it grows to a height of 10 feet. The flowers are often as large as those of C. maximum, but the stalk is thicker, and the plant in every way coarser and inferior, but it has the merit of making a succession in the mixed border. Plants from the same lot of seed vary much in the form of the flower, the width and length of the rays, and the relative size of the disc; but there is a gap between latifolium and the nearest form of maximum to it which I have never seen bridged over. I first received this plant from the late Mr. Harpur Crewe by the name of C. lacustre, which is Brotero's name given by De Candolle as synonymous with his C. latifolium.

Chrysanthemum (Leucanthemum) atratum (De Candolle).—The characters of this plant do not agree exactly with those of any plant I have seen in cultivation in English gardens. The specimens, of which there are many, in Kew herbarium lead me to think it would be no acquisition, and in no respect superior as a garden plant to our common Ox-eye Daisy, C. vulgare, of which many botanists take it to be a mere variety. The leaves are narrow at the base, very obtuse at the apex, with three or five deep indentations. The name atratum, "blackened," refers to the outline of the back of the involucral bracts. In all the Ox-eye Daisies this is often marked with brown, but in C. atratum it is a distinct black line. In other respects the flower resembles that of C. vulgare, or of

C. montanum, a plant I had ten or twelve years ago from Ware's nursery, and, as far as I have been able to investigate it, it was correctly named. Generally speaking, it is hardly distinguishable from large forms of C. vulgare, and is hardly worth cultivating where C. vulgare is common. But either of these plants may be made to produce large flowers and tall stalks by high cultivation, or, by planting in rock without soil, to assume a neat and dwarf growth, not exceeding 3 inches or 4 inches high. Of these five species I have seen four in cultivation in England, C. atratum being the exception. There are many other white-flowered Chrysanthemums, but they are not so liable to be confused. I may add that the botanical character of the presence or absence of a pappus above the achene of the ray flowers, upon which some botanists depend for the distinction of these species, is thought by others to be less trustworthy. C. Wolley Dod.

Edge Hall.

P.S.—I hear from Mr. Loder, of Floore, that he had the Daisy lately figured in The Garden from me, and that I sent it as Chrysanthemum atratum. This is explained above.—C. W. D.

The Pyrenean Saxifrage (Saxifraga longifolia). Engraved from a photograph for The Garden.

THE PYRENEAN SAXIFRAGE.

(saxifraga longifolia)

The noblest of the silvery Saxifrages, and a most satisfactory plant in all stages. It is interesting to watch the gradual increase of the young rosette of stiff symmetrical foliage for two, or even three years, and finally the growth of the great flower-spike, when, after due ripening of the seed, the plant dies. Unlike other Saxifrages of this section, it makes no offsets, and young plants can only be got from seed. The plume of flower from which the engraving was taken was some 20 inches long, and nearly a foot wide at the base.

The white Mallow.—I have before me a vase filled with a bunch of the Malva moschata alba, with just a few flowers of a single dark red Gaillardia dropped in to give colour. This is, I take it, a rather uncommon bouquet, if it may be so termed, and yet a very pretty one. The Mallow flowers close up at night, and expand again in the morning; thus they are more enduring and escape that dust which settles so freely upon flowers after the gas is lighted. Unexpanded blooms at the time of cutting will open some two or three days later in water. I think, were this Mallow generally known and cultivated in gardens, it would be found of inestimable value for cutting purposes, and would be highly esteemed by ladies, as it is so pleasing and bright. Plants come freely from seed. They are perfectly hardy. During the winter the prettily cut foliage is very ornamental, and the plants will grow anywhere.—D.

Hybrid Gladioli.—Allow me to demur to a few of the opinions expressed by "Delta" (p. 336) in reference to the culture of Gladioli. I have been a grower of all the newer varieties I could procure for many years, and, therefore, am not unacquainted with their culture. In speaking of the natural advantages enjoyed by Mr. Burrell at Cambridge, "Delta" says the rainfall is 10 inches less than at Kelway's, in Somerset, that the soil is good loam, and that the autumns are dry, thus approximating comparatively to Fontainebleau. The climate in Cambridge, as a matter of fact, is considerably different from that of Fontainebleau; probably, so far as one could judge by visiting both in autumn, there is a difference of half-a-dozen degrees in temperature, and this tells vastly as regards the ripening process, which I look upon as one of the vital secrets of success. A southern aspect, too, tells vastly in the same direction. Take the same locality, plant Gladioli on a slope facing the south, and success is certain. Plant corresponding corms facing the north, where ripening from sun-heat is difficult or impossible, and failure and degeneration are equally assured. That is my experience, and I have grown spikes as fine as those I noticed in the magnificent stand of 120 varieties shown from Langport at the Royal Horticultural Society's show, at South Kensington, on the 24th of August last. As to moisture, I believe that Gladioli, especially in summer, are exceedingly fond of it. I have had as fine spikes as ever I saw within the past month, the majority of them being the rarer purples, pinks, and shades thereof, with the exception of Christopher Columbus, Cherub, Samuel Jennings, and James Macintosh—and yet rain, it raineth every day! As to soil, that of a rich sandy formation is by far the best. Sand I have found to be a great antidote to degeneration. I put a handful of clean river sand both above and below the corms; but where the soil naturally contains a large per-centage of it, there should, everything else being equal, be a distinct advantage. I manure heavily at the same time, and give frequent doses of liquid manure in summer.—W. J. Murphy, *Clonmel.*

Gaillardias.—Effective and fine as are many of the rich yellow and buff-coloured kinds, none are more useful than the deep red or reddish maroon forms, which seem to be rather scarce, perhaps from lack of selection. One of the darkest I have seen, and which has some semi-double features, as a few petals are thrown up in many of the blooms over the eye, is a seedling from the double Lorenziana, which in colour is quite a rich reddish

crimson, or perhaps chocolate. Not only do Gaillardias bloom over a long season and quite into the winter, but they are very easily propagated by cuttings, or may be raised from seed. Whilst the singles will perhaps prove the most acceptable for vase dressing, the doubles are very effective in beds or for common cut-flower uses.—A. D.

HELIANTHUS MULTIFLORUS SIMPLEX MAXIMUS.

With all due regard for "Veronica's" feelings, pray let me protest, and I am sure The Garden will join me, against this awful name. If Helianthus multiflorus really has garden varieties worth naming, let them have such names as Sunflower Dorothy, or Sunflower Mikado, instead of giving names offensive to science. To add simplex to the name of a flower is going out of one's way to make a long name, for it is only an abnormal departure from the type in the way of doubling—generally expressed by the letters fl.-pl., standing for flore-pleno, *i.e.*, with a double flower—which botanists ever think it necessary to note. But *apropos* of this H. multiflorus, Asa Gray tells us that the plant itself is a garden variety of H. decapetalus, though I have strong reasons for believing it to be a hybrid between H. annuus and H. decapetalus. However this may be, and wherever the original plant was produced, I believe that all the so called varieties of it are mere variations depending upon culture. With the same treatment all the single forms after a year or two produce in my garden flowers of the same size, about 5 inches across, more or less. Not a year passes that I have not plants of it producing single and double flowers on the same root, and I have seen the same thing in other gardens. What makes them revert from double to single, or become double, I have never been able to find out. The form of the double flowers varies much, the distinctive ray flowers being often absent, and the ligules of the disc differing in shape and size; but these differences, too, depend upon cultural conditions. I see no reason to doubt that every variety of H. multiflorus now in gardens might be from the increase of a single plant produced by an accidental cross and afterwards varied by cultivation. Has anyone ever found a fertile seed on H. multiflorus?

Edge Hall, Malpas. C. Wolley Dod.

Carnations from seed.—I have just had a communication from an old floricultural friend, an enthusiast in the matter of Carnations and Picotees, especially of the fancy varieties. He is especially interested in raising seedlings from Continental strains, in the hope of getting something new and distinct. "I have just received," he says, "for sowing next spring 500 seeds of fancy Carnations, 500 seeds of yellow-ground Picotees, 500 seeds of mixed varieties of Carnations, 500 seeds of mixed varieties of Picotees, 500 seeds of scarlet Grenadin, and 100 seeds of dwarf perpetual; in all 2000 seeds." What a garden of Carnations and Picotees they will make! What pleasure there will be in watching the expanding of the flowers even if hundreds of disappointments should be the result! It is only true enthusiasm that could carry through to the end such a trial as this.—R. D.

Varieties of Caucasian Scabious.—I have had sent me one of the most varied collections of this Scabious that ever came under my notice by Mr. Calthorpe, gardener to the Hon. Dudley Fortescue, Summerville, Dunmore East, with the following remark: "I wonder what the editor of The Garden would think of this strain for cutting purposes?" As the blooms were forwarded in a wooden box, they will hardly bear re-transmission to enable you to answer the query yourself, but you may permit me to refer to them. The blooms measure from 2 inches to 2½ inches across, and two-thirds of the thirty forwarded more or less differ from each other. Some are single; some double; some have a single row of guard florets around the margin; others are doubled; the colours range from pure white to perfect black, and there are numbers of intermediate shades of rose, purple, and crimson; others, again, have shades of blue and yellow, as in S. graminifolia; many have more than half-a-dozen shades of colour on one head alone. Remembering that this is one of the hardiest of all perennials, and that it succeeds with very limited attention, surely no garden should be without it, though all may not succeed in getting as good a strain as that at Summerville. —W. J. Murphy, *Clonmel.*

GRASS LAWNS.

The beauty of a lawn consists in the evenness of its surface, whether level or sloped, the absence of worm-casts, and of every kind of obnoxious plants, such as the Daisy, Plantain, Crowfoot, &c. A lawn should also be free from coarse Grasses, which greatly disfigure a smooth sward. Moss, too, is undesirable, although in the estimation of some it renders the turf soft and springy. To preserve a lawn in high keeping, considerable labour and attention are necessary, particularly during the summer months. In order to have a fine lawn, three things are necessary, viz., deep soil, proper kinds of Grasses, and frequent mowings and rollings. As regards deep soil, let it be borne in mind that verdure, the chief point of beauty in a lawn, has to be maintained through the summer when the weather is at times hot and dry, and, therefore, there must be depth of soil into which the Grass can strike root. It is reported that the roots of common Clover in trenched ground descend to a depth of 4 feet. One of the best lawns I ever saw was laid down upon soil—a good yellow loam of some depth—that had been deeply dug and then allowed to settle; on this was placed a layer of 2 inches of chalk broken fine, and the interstices between the chalk were filled up with the fine sweepings from a gravelled road. This was well beaten down until the surface was perfectly level, and then the turf—cut from a neighbouring common on which cattle grazed—was laid. This was the finest, softest, greenest, and most springy lawn I ever saw. A rich soil is not at all necessary, because that would cause the Grasses to grow rank; what is wanted is a short growth and soft herbage. Let the soil, therefore, be good, but not rich; depth and the capacity to retain moisture are the needful qualities. If the land be light and sandy, a mixture of a rather retentive loam should be added.

In selecting turf to make a lawn, that from a common or roadside, as free from weeds as possible, should be employed. Downs or common lands grazed by sheep supply excellent turf. If it has to be obtained from a distance, and if it has to be taken to some extent on trust, it should be stipulated that it comes as near as possible to the character just given. If seeds are to be used, the ground should be prepared and levelled in August, so that the seeds may be sown early in September. A lawn should not be laid down upon a piece of ground that requires draining; but if so, then it should be properly drained. Then let it be dug and made level, and rolled in order to make the surface as smooth as possible. As to the proper kinds of Grasses, I may remark that the following sorts are recommended as most suitable for producing a close, velvety turf:—

Crested Dog's-tail (Cynosurus cristatus)	Woodside Meadow Grass (Poa nemoralis)
Sheep's Fescue (Festuca ovina)	Yellow Trefoil (Medicago lupulina)
Fine-leaved Fescue (Festuca tenuifolia)	Bird's-foot Trefoil (Lotus corniculatus)
Dwarf Perennial Rye Grass (Lolium perenne)	Perennial White Clover (Trifolium repens perenne)
Smooth-stalked Meadow Grass (Poa pratensis)	Yellow Suckling (Trifolium minus)
Evergreen Meadow Grass (Poa sempervirens)	

These should be mixed in their proper proportions, and not less than three bushels of them will be required per statute acre, or one gallon to six rods or perches. Grasses best suited for lawns do not tiller (*i.e.*, put forth shoots from the roots) so much as some varieties which are valuable in a pasture do, and, therefore, the more thickly crowded, the finer will be the turf. Clovers do not wear so well as Grasses, and they have the additional objection of retaining moisture longer. On tennis grounds, therefore, it is advisable to sow Grasses only, unless the soil is liable to scorch in dry weather; in that case, it may be desirable to include Clover also, for Clover bears drought much longer than Grass. To secure an even plant, instead of sowing all the seed at once, let it be done twice. In the first sowing, travel up and down the land, and on the second occasion go across it at right angles. This will produce more uniform results than is possible from a single effort, no matter how skilful or practised the sower may be. As the seeds of fine Grasses are small and light, they are easily blown to some distance by a high wind; therefore choose a quiet time, if possible, and in sowing keep the hand low. When the task is accomplished, give another very careful raking, in order to cover as many seeds as possible. Finally, roll down, and if the work has been done well, there will be a surface as level as that of a billiard table. Sowing seeds may be done in the spring as well as in the autumn—from the middle of March to the end of April is the best time.

My third point is frequent mowing and rolling, say once a week or every ten days; without constant mowing a lawn will soon degenerate into a coarse meadow; while rolling will render it firmer, closer, shorter, and finer every time it is repeated. In the case of a lawn that has been sown as above directed, as soon as the young plants have attained a height of 2 inches or 3 inches, they should be carefully gone over with a scythe or mowing machine that is sharp enough to make a clean cut without bruising or uprooting the herbage. The scythe is preferable to the machine while the plant is in an early stage of growth. It is also necessary that the soil be kept in good condition, or as it is sometimes termed in "good heart," as it will, from various causes, become impoverished, and a close growth of Moss will be the result. There are some who, as has already been stated, like Moss on a lawn, contending that it makes it soft and elastic; but it is a sign of impoverishment, nevertheless; the beautiful verdure of the Grass is decidedly to be preferred. Lawns that have become impoverished and require renovation, if a fresh sowing is not required, will be greatly helped by having spread over them a thin layer of finely pulverised manure from an old hotbed; and it is best that this be applied late in the autumn when mowing has ceased; and prior to its being applied the garden-rake may be used to scratch over the surface, so that the manure may be the more readily incorporated with the soil. In about a fortnight after the manure has been applied the roller may be employed to make the surface level; but this should be done on a dry day, when the manure and earth do not stick to the roller. In selecting the manure for a surface dressing, it should be as free from the seeds of weeds as possible. A dressing of soot is of great advantage; when used with caution it produces a beautiful verdure, and it has this further recommendation, that it is free from weeds.

Where lawns require renovation, seeds should be sown, at the rate of one bushel per acre, either in spring or autumn. Before doing this, well rake the surface with a small-toothed rake, and do not be frightened at the apparent ruin which will result from this operation; the turf will speedily recover. Then sow, and either rake again or sift some fine soil over the surface, and afterwards carefully roll. On lawns that are in the main perfect there may, from a variety of causes, occur bare spots. In such cases the soil should be loosened with a rake, and a handful of seeds may be sown at any time from March till September.

Moss on lawns is generally, as has just been said, a sign of poverty in the soil, or that it requires draining. In removing the Moss, rake off

as much of it as possible; apply a top-dressing of quicklime mixed with rich compost in the winter, and sow more seed in spring, or top-dress with soot. Thus, by encouraging the growth of Grass, the Moss will be destroyed. Weeds on lawns, if numerous, should be dug up with an old knife—a tedious, but efficacious process. The holes so made may be filled up with finely-sifted soil, and the roller applied afterwards. A sure destroyer of weeds is "Bellicide," a new introduction that destroys weeds and fertilises the Grass at the same time; it should be applied in moist, not in dry weather. I have seen it applied, and am convinced it is an excellent and safe weed-destroyer.

The lawn should be swept and rolled before it is mown. Sweeping, when properly done with a Birch or Heath broom, is of great advantage, but when improperly swept with an old stubby broom positive harm is done. Rolling should be done only when the atmosphere is dry, otherwise worm-casts and loose leaves adhere to the roller and mar the efficiency of the operation. R.

THE FLOWER GARDEN IN WINTER.

Bare flower beds have a dreary look, and they are specially objectionable if immediately under the windows where they are seen daily. There are many ways of filling flower beds in winter, and any kind of vegetation is better than barrenness. The question really is one of ways and means, as if done well it will cost money in proportion to the costliness of the materials used. But there is no real necessity to employ costly materials. A few light-foliaged shrubs will be required for centres and occasional groups, foremost among which may be named the Lawson Cypress and its varieties. These, if taken care of and removed to the reserve garden as soon as their presence in the flower beds is no longer required, will last many years; the frequent removal will keep them small in size. The variegated Boxes, again, and the Aucubas and the Euonymus may be had in considerable variety, and would of themselves give warmth of tone and colouring if no other plants were used; and they may all be rooted from cuttings at home if desired, and this is the time to propagate them. The Boxes will strike very well in a shady border, but the Euonymuses, Aucubas, and Cypresses should be sheltered with glass. The tree Ivies are excellent for this work, especially when they have acquired age and size. I bought a collection about six years ago. There were in all seven varieties, including two with variegated foliage, and they are now very pretty little bushes loaded with flowers, and the foliage is of the darkest green. The variegated kinds have made less growth, but they also are full of blossom, and very pleasant to look upon. I should recommend these Ivies to the town gardener. The Barberries are handsome winter shrubs, but do not move well. Cryptomeria elegans has a pretty effect when young, and as a contrast Thuja Vervæneana would be serviceable, the latter having a pretty golden tint, and the Cryptomeria a deep-toned bronze. The Japanese Privets in a small state, especially the handsome variegated kinds, would be useful, as would also be some of the Japanese Cypresses, including Retinospora plumosa aurea, R. obtusa aurea nana and R. squarrosa. These last-named should only be taken on trial at first, as I do not think they will be serviceable everywhere. The Golden Yews both the golden Irish, and Taxus baccata elegantissima are pretty, and move well. Vinca elegantissima and Yuccas will also be very serviceable. Hollies, especially the variegated varieties, will be very valuable in large beds. Winter beds should not be wholly destitute of blossom. The Christmas Rose commences to bloom with us in November, especially the large variety of niger. This makes great clusters; both foliage and flowers are much larger than those of the type, and they lift without the least check. Clumps of the common white Pink have a pretty effect in winter; its tint of green is so distinct and lively. Winter Aconites, Snowdrops, Sternbergia lutea, Crocuses, and even Daffodils will come in sheltered places before the winter has left us, and Wallflowers, Pansies, Violets, Primroses, and Daisies are a host in themselves. The common hardy Heaths will grow anywhere in light soil, and large tufts are very interesting. Among low-growing hardy plants that are useful for winter effect are Golden Feather, Cineraria maritima, Cerastium tomentosum, Santolina incana, Festuca glauca, Stachys lanata, Arabis albida variegata, and various Saxifrages, Sedums, and Sempervivums.

E. H.

DAHLIAS IN OCTOBER.

It is not often that Dahlias of all sorts are so good late in September and up to the middle of October as they have been this season. Hundreds of bushels of blooms have recently been cut in various district for Harvest Thanksgivings, yet no amount of thinning out is long observable, the buds unfolding very rapidly even at this time of year. A fondness for Dahlias would appear to be reviving. When at Salisbury, on October 6, a party of us, all gardeners, spent some time among the Dahlias in the nurseries there, and came away more impressed than we went with the value of Dahlias for decorative purposes, either as plants in borders or in a cut state. Several acres of well-manured and trenched ground are here devoted to them, and every plant has abundance of room. Never before have I seen such grand foliage on Dahlias or such fine blooms. Every Dahlia catalogue contains a bewildering list of varieties in almost each section. The following notes and selections, therefore, made on the spot, may be of service to intending cultivators next season:—

Show varieties.—Of those distributed in 1886, one of the best is Richard Dean, deep purple, and an extra fine flower. Harry Keith, rosy purple, and Mrs. Alexander Campbell, pale yellow, are also very fine free-flowering sorts, and of good habit. Mrs. W. Slack, blush white edged with purple, will prove a useful sort either for exhibition or for decorative purposes; and the same may be said of Thomas Hobbs, purplish rose. Of those sent out in 1885, the best is Mrs. Langtry, cream colour edged with crimson—a truly beautiful flower, perfect in habit. Among the older sorts, the most striking are James Vick, purplish maroon, and a handsome flower; James Cocker, purple, and deservedly a favourite; Constancy, yellow ground edged with crimson-red, and very pretty; Buttercup, yellow tinged with red at the edges, a useful variety; Hon. Mrs. Percy Wyndham, yellow ground edged with rosy purple, a desirable sort; Georgina, creamy white and a large flower set on erect stems; Emily Edwards, blush white, fine in form and habit; James Stephen, orange-scarlet, a striking variety; Hope, rosy lilac, a reliable sort; Henry Walton, yellow ground edged with bright red and very handsome; Ethel Britton, blush white edged with purple, good in form; Herbert Turner, French white, very large and good; Joseph Ashby, orange, a good show flower; Imperial, deep purple, shaded lilac, one of the best in cultivation; Mrs. Gladstone, blush, remarkably handsome and good in every respect; Prince Arthur, clear yellow; Miss Cannell, creamy ground, edged with purplish crimson and very pretty; Joseph Green, bright crimson, finely formed; Lord Chelmsford, dark maroon, large and good; Mrs. Stancombe, rich yellow, handsome; Prince of Denmark, maroon, shaded with crimson, very fine; Rosetta, purple, a reliable sort; Thomas Goodwin, dark purple, most distinct and good; Royal Queen, creamy ground, edged with crimson, a fine large flower; Seraph, blush, noble erect flower; and Senator, deep purple, and good in every respect.

Fancy varieties.—Pelican, pure white, sent out in 1886, is extra good; and another novelty, Salamander, yellow, striped with red, will be found to be excellent; General Gordon, yellow, striped with scarlet, sent out in 1885, is perhaps the best in the section to which it belongs, being sturdy and very floriferous in habit, and with blooms large and full—altogether a most attractive variety. Among older sorts that can be recommended are Charles Wyatt, deep rose, flaked with crimson and purple, with occasional self blooms of purple and lilac; Gaiety, yellow, striped with red and beautifully tipped with the same colour, associated with various other combinations, as many as seven colours being discernible in some of the flowers, while others have only one colour (selfs), &c.; Adventure, Carnation-like, good; Chorister, fawn colour, striped with crimson, constant; George Barnes, lilac, striped with crimson, a very fine flower; Mrs. Saunders, yellow, tipped with white, one of the best; Mandarin, yellow, mottled with purplish crimson, reliable; John Forbes, fawn colour, striped with maroon, good in every respect; Fanny Sturt, red, tipped with white, very pretty; Henry Eckford, yellow, striped with scarlet, constant and good; James O'Brien, yellow, striped with crimson and red; Henry Glasscock, buff, striped and spotted with crimson, a fine show flower; Hugh Austin, orange-scarlet, striped with red; Hercules, yellow ground striped and speckled with crimson, an excellent sort; Madame Soubeyre, rosy lilac, striped with carmine, a fine variety; Miss Annie Melsome, yellow, white lip, exceptionally good; Professor Fawcett, dark lilac, striped with chocolate; Monsieur Chauvière, lilac striped, and spotted with dark crimson, one of the best; and Rebecca, lilac, striped with crimson.

Pompon, or bouquet Dahlias.—For general effect, and for affording a profusion of useful sized blooms, this class of Dahlias is pre-eminently serviceable. One variety not yet in commerce, and named Lælia, is destined to become popular, as it is singularly distinct and beautiful. Among those first distributed last season the most noteworthy are, Brilliant, deep crimson; Catherine, yellow; Darkness, very dark purple; Fashion, light orange; Profusion, crimson, tipped with white; and Rosalie, primrose, frequently edged with pink, all good in habit and very profuse bloomers. Nearly all the older sorts grown were in excellent condition, and the list will be rather lengthy accordingly. Brunette, red, frequently blotched and tipped with white, was very attractive, none more so, in fact; and several whites, such as Guiding Star, or White Aster Lady Blanche, and White Button, gave unmistakable proofs of their value for cutting. Other good sorts are Cupid, white, tipped, and suffused with rose, dwarf habit; E. F. Junker, a small amber flower; Dora, yellow and white; Favourite, dark maroon, with crimson edges, a fine flower; Flora Macdonald, primrose; Fortmeister Gschwina, dark crimson; Garnet, orange-scarlet, dwarf and very free; Gem, rich scarlet; Glowworm, yellow, edged with red; Hebe, blush-edged with rose; Hedwig Pollwiz, red, tipped with white; Isabel, bright orange-scarlet, very showy; Little Bobby, rich crimson; Little Dear, blush white, tipped with rose; Little Duchess, white, crimson edges, very pretty; Little Princess, white, tipped with rose; Little Wag, white, edged with purple; Mabel, lilac; Nemesis, maroon, sometimes tipped with white; Northern Light, rich scarlet; Prince of Liliputians, maroon; Rosetta, purplish magenta; Rougier Chauvière, light blush, one of the freest; Royalty, orange edged with crimson and quilled, good; Sappho, dark crimson; Sunshine, bright scarlet; The Khedive, rich crimson, suffused with white at the base of each petal, free flowering; and Wilhelm Nitsche, red, tipped with white.

Single Dahlias.—Of these there are innumerable varieties, and each season considerable numbers find their way to the rubbish heap, though as much may be said of the hundreds of seedlings of double varieties that are annually tried and found wanting. Paragon is still one of the best types of single Dahlias, and will outlive numbers of those that are extra large, flabby, and shapeless. Some of the best to be seen at Salisbury are Defiance, bright scarlet; Aurata, yellow; Acquisition, crimson, with scarlet bars at the edge of each petal; Evening Star, maroon; Fire King, rich crimson; Flavius, yellow, dwarf habit; Grandee, purple; Lucifer, good scarlet; Lutea, yellow; Lucy Ireland, magenta, suffused

with crimson, distinct and good; Magnificence, pale pink, of good form and habit; Paragon, dark velvety maroon; Picturata, rose; Purple Prince, very free; Red Gauntlet, crimson-scarlet; Stella Bianca, white; Terra-cotta, very distinct; Velvet Mantle, very rich crimson; Vesuvius, scarlet, dwarf habit; White Queen, the best white; and Yellow Queen, also good.

Other kinds.—The well-known Cactus Dahlia (Juarezi) was strikingly grand. Constance, also included in the list of Cactus or semi-Cactus varieties, is perhaps the most serviceable of all Dahlias. The blooms are beautifully white late in the autumn; in fact, it is usually at its best when frosts set in, and its blooms in a cut state never look out of place along with the choicest of flowers. Mrs. Tait somewhat resembles it; the petals of this variety, however, are much serrated; the newer Mrs. Hawkins, pale yellow, shading off to white, is also very beautiful. Other good semi-Cactus varieties are Cochineal, dark crimson, and scarlet and crimson Glare of the Garden, all of which are very profuse bloomers, and particularly to be recommended to those who require abundance of cut bloom. Of bedding Dahlias the best are George Thomson, pure white; Mont Blanc, white; Roustapand, yellow; and White Bedder; the first and last are especially good. W. I.

NOTES ON HARDY PLANTS.

Water Lilies (Nymphæa alba).—There are two varieties of this, the best of our native hardy aquatics. In the "English Flower Garden" one only, N. alba, is mentioned; but I have read elsewhere that there used to be a variety at Hampton Court with flowers as large again as those of the common sort. We have two sorts here, one of which I got from the late Mr. Speed, of Chatsworth, and which he called "candidissima;" this differs from the common kind in having larger flowers; otherwise the two plants are much alike. Both these Water Lilies are accommodating subjects, but they appreciate good culture, like other plants, and are affected by the depth of the water in which they grow. They will live and grow with just sufficient water to cover their roots; and I know one place where they are grown in a large outdoor cistern or reservoir, where their leaves stand erect like Docks, but they are stiffer and smaller than when floating and the flowers are few and small. When the plants get crowded they will throw their leaves out of the water even when 9 inches or 1 foot deep; hence the water should never be less than from 1 foot to 18 inches deep. Then the leaves and flowers are seen in their natural position and look better. Good loam and cow manure occasionally added to their bed improves the plants; and it is a good plan to lift and replant them now and then where practicable. I wonder these Nymphæas are not more extensively grown, seeing that their culture is so simple and that they grow so fast. They have not wonderful leaves, like the exotic Victoria Lily, but they are far more satisfactory subjects to grow, because they yield a profusion of magnificent flowers, unique in their way, and grand subjects for vases when set up by themselves.

Tritoma Uvaria.—This is a much more sensitive subject than it is generally thought to be. I have never seen such fine groups of it as there used to be in one or two places in East Lothian, where it had not been disturbed for several years, and consequently had got established. The soil there was dry and warm. In some parts of Yorkshire, on the other hand, it is not quite hardy, and only lives and does well on the most favourably exposed borders. I once thought it was a likely subject for naturalisation in woods and near lakes in parks, but unless the site is dry and warm it does not live. In gardens both Tritoma caulescens and Uvaria are the better for protection in the shape of dry litter or leaves tucked round the collars in winter, but not so as to smother the leaves or part of the plant. It is a subject that does best by itself. When planted in mixed borders, its trailing leaves, which are blown about by the wind, are rather a nuisance to its neighbours. The Tritoma and Cape Hyacinth appear to me to be about equally hardy.

Aster Amellus (Italian Starwort).—If I was reduced to the choice of one Michaelmas Daisy, I think I should stick to this one. The plant is neat, bushy, and green at this season; the pretty blue flowers are amongst the largest and showiest of their class, and they are excellent for cutting. One cannot get up much enthusiasm for these plants generally, but this is a really good useful variety. It has been in flower in our cool climate for a long time, and is still fresh in flower and foliage, notwithstanding the rain and cold. It soon makes good stools, and one divided as far as it will go will fill quite a large bed in a year or two. It needs no stakes nor tying, as here at least it does not grow above 15 inches high, or thereabouts, and makes a dense bush. I ought to state that I am speaking of a variety which I got for Amellus, but there is so much confusion in the names of hardy plants, that one cannot always depend upon getting them true. Only the other day I saw the most awful jumble of names attached to a collection sent from a London nursery, some of the plants not having the most remote resemblance to the species they were intended to represent. S. W.

The English Iris (Iris xiphioides). From a photograph.

Spring bedding.—Where a good display of spring flowers is desired, no time should now be lost in having plants for that purpose placed in their winter quarters. Owing to almost an entire absence of early frosts, summer-bedding plants in many places are still bright and gay; therefore they are allowed by many to exist undisturbed. But at any time now we may expect frost, and Pelargoniums and other summer-bedding plants will then have to be lifted in a hurry; beds and borders will have to be manured and dug in haste, and such plants as Aubrietias, Forget-me-nots, Polyanthuses, Violas, Wallflowers, &c., will have to be speedily planted. Therefore, should bad weather set in, such plants will have little or no chance of getting established before winter. Under such circumstances, should the winter be a hard one, they will suffer severely. Unless well rooted before winter, spring-blooming plants never repay any attention that may be bestowed on them. If Hyacinths, Tulips, and other spring bulbous plants are expected to look well, they, too, should be planted in October, which is much better than leaving that operation to be done later. Early planting gives the bulbs time to push out roots, and thereby enables them the better to withstand severe weather. Pelargoniums, moreover, and other soft-wooded plants that are wanted for another year should be lifted at once before they become crippled by frost.—B. O. Leach, *Albury Park.*

ENGLISH AND SPANISH IRISES.

English Iris (Iris xiphioides).—The large bulbous Iris of Spain and the Pyrenees, known as the English Iris, just follows the Spanish Iris in time of flowering. Though its range of colouring is not so great, it is still more effective as a garden plant from the large size of the flowers and the broad, finely waved lower petals. Its colours are pure white, splendid purple, and deepest violet-blue, with many shades of mauve. In some cases these colours are pure, but in many of the varieties they are splashed and flaked with markings a shade darker than the ground colour. All the varieties are beautiful, and worthy of a place in the garden.

Spanish Iris (Iris Xiphium).—Though June is the month most full of flowers, we could not, among the hosts of other garden beauties, spare the Spanish Irises—beautiful alike in their varied colourings and in their shape, which presents a remarkable combination of strength of structure and delicate grace of form. Their colours are nearly white, yellow and blue separately, and mixtures of these colours with shades of purple-bronze. One of the most beautiful is a clear yellow. The grand and well-named Thunderbolt is a near relation, whose mysterious lurid colouring makes one think of muttering thunder.

IRISH DAFFODILS.

Will "G. H. E." excuse me if I take exception to some of his criticisms on my little book? If "G. H. E." will tell me where in Ireland typical English pseudo-Narcissus is naturalised as in England, it will be knowledge hitherto unknown to me, quantity being in Ireland represented by various forms of princeps, as pseudo-Narcissus is in England. Then if princeps be naturalised from its native country (Italy) in Ireland, and not in England in the same proportion, it proves that the Emerald Isle has had an advantage as regards flowers as well as primitive civilisation. As to princeps being naturally hybridised, the late Mr. Nelson mentioned before his death that cross-fertilisation was not resorted to in this case. M. de Graaff's best seedlings, of which he has numbers, are wind-fertilised or chance hybrids; and the late Mr. Backhouse wrote in a contemporary, in 1865, that results were the same under artificial crosses and chance fertilisation. Double obvallaris.—I will send "G. H. E." what I believe to be correct blooms of this in spring. N. Ard-Righ.—There are three varieties of Irish spurius, of which I will send "G. H. E." flowers marked Nos. 1, 2, 3 in spring if spared. Now for a bit of history about this fine Irish introduction. A certain prominent member of the Daffodil committee got flowers from Ireland in 1884, also in the spring of 1885, probably for trial. I knew it to be named at the conference, but, being isolated, could not ascertain what it was called. Afterwards, in the autumn of 1885, when my book was printed, I was asked by a London firm to quote Yellow King by the thousand. This I would have done, but the request came too late, so I had to let the name of Golden Dragon stand, and see what else fitted Yellow or Irish King, so I fixed on Ard-Righ. Not one

in England has been imposed upon in regard to this matter; quite the contrary, for the bulb last year, as Yellow King, was priced at 2s. 6d. each, and may now be had for a fifth of the money. Of Narcissus nanus varieties, Haworth said we had seven or eight. There are certainly six varieties now planted at Temple Hill, including a pale canary-yellow.

White Daffodils and confusion.—Well, sir, if the consignment from Ireland was not put into the most admired disorder at the 14th of last April's sitting of the Daffodil committee I am a Dutchman, and there were some of these folks there too. The facts are these: A certain lady from Ireland had brought over a varied collection for naming. The committee, prior to attacking them, adjourned for luncheon, and when they got back to the "sitting," someone had been trying his "'prentice hand" and mixed the whole lot—whether purposely or not I cannot say. It was a hopeless case of confusion, and was about being abandoned when I ventured to separate them and put them into their original state. The question of names then cropped up. Taking the one most abundantly represented, I said to the chairman, "I know this Daffodil to be tortuosus tenuifolius; note its perfume, as of Oak timber, and foliage." It was arranged to drop the Latin. I was then asked for a name and suggested White Swan. This was objected to, but the chairman mentioned Leda. Therefore our Irish tortuosus tenuifolius got characterised there and then as Leda. I know typical tortuosus, having had it from Mr. Barr three years ago, and it is quite distinct. Here "G. H. E." and Mr. Barr are both in error. The one has been going by sight; the other by smell. If "G. H. E." got tortuosus tenuifolius from Ireland in 1885, he has got Leda.

Ard-Righ and Sir Watkin.—Let "G. H. E." select his finest flower of the former; cut the crown clean out, curtail it by half an inch, and lay it flat on paper with the crown inserted. If it does not resemble the big Welshman, my vision is like that of Sam Weller.

The doubling of Daffodils.—If "G. H. E." will read what has been said on this subject in the back pages of The Garden, he will see where it is alleged that double Lent Lilies were dug up in Devonshire and sent to the north of England, and are now, or have been, proved to grow into Telamonius plenus, my argument being that this is impossible, else we would have the single Lent Lily becoming a giant under like conditions.

Rip Van Winkle.—I often wish this and its patron had slept a little longer. We have scarlet Turban Ranunculuses, scarlet and yellow double Tulips; in Daffodils, double cernuus, common double Telamonius, and that most beautiful of all double forms, capax; all such will run to single flowers under certain conditions of soil and situation. I suppose the soil has something to do with it, but I can send "G. H. E." Master Rip with flowers as yellow and double as those of Kerria japonica, and that will be this coming spring if he writes for them. The secret with this Daffodil is to grow it on light turfy soil and in Grass. If in beds, let them be raised mounds, with seeds of Crested Dog's-tail shaken over them and well beaten down afterwards. The same rule applies to the typical and scarce double Lent Lily of Gerard; starve both, and both are beauties.

One word for Bishop Mann. I found this Daffodil where Leda could not possibly live, but would have died out, viz., in an old garden at Bishopstown, near Cork, and where the border was covered over with Laurels, Ivies, Mahonias, Hypericums, &c. I removed the bulbs, that had been planted for 150 years, to my residence some years since. This garden was the old palace grounds attached to the see at St. Fin Barrs, and Bishop Mann was the last resident and was very fond of flowers. The bulbs were growing in between huge roots of Beech trees at least 200 years old, and we had to use crowbar and pick-axe to get at them, and lost or mangled many. It is quite distinct from Leda, as alleged by "G. H. E.," very tall, most healthy, and the best white Daffodil known to me. W. B. H.

Temple Hill, Cork.

HARDY FLOWERS IN OCTOBER.

The merits of hardy flowers compared with such tender subjects as Pelargoniums, Calceolarias, and Lobelias are becoming more and more apparent. The fine masses of Dahlias, Marigolds, Pentstemons, Veronicas, Anemones, Rudbeckias, and old-fashioned Asters—better known as Michaelmas Daisies—which may be seen in many gardens during this month, form a striking contrast to the formal clipped lines of Golden Feather, Mentha Pulegium, Sedums, and other dwarf plants which are employed in the formation of carpet beds. I have not a word to say against carpet beds where suitable for the position; I can admire even their trimness and the skill displayed in

The Spanish Iris (I. Xiphium). Engraved from a photograph for The Garden.

arranging and blending their various colours, yet carpet beds in the flower garden proper are too artificial. Our garden flora is so rich, that even at this season we ought to have abundance of flowers to cut for indoor decoration. Perhaps the most conspicuous plants in bloom at this time of the year are Dahlias. The single varieties and the Pompons are the most useful for mixing with other flowers, while large double sorts are valuable for specimen glasses. Another useful class of plants, and one exceedingly valuable for cutting purposes, is the autumn-flowering Windflowers, or Anemones. We have three varieties, viz., A. japonica, which grows from 24 inches to 30 inches high and produces red-coloured flowers; A. japonica hybrida, 2 feet high, with rose-coloured flowers; and A. japonica alba, or, more properly speaking, Honorine Jobert, with pure white flowers. These Anemones bloom in great profusion throughout September and October. Of the three, the white is the best, and if there is only room for one sort, I should most certainly grow the white kind. These Anemones are all increased by root division, an operation which may be performed at any time during winter. So valuable are white Anemone flowers, that the plants are worthy of pot culture, or, in cold localities, of being covered with cold frames; by this means the flowers expand more freely, and, not being disfigured by wind or rain, they are of a purer white.

Next in importance as autumn-flowering plants come the perennial Asters, or Michaelmas Daisies. Of these, more than 200 varieties are known to botanists, but many of them are but little better than weeds; yet, by making a judicious selection, some grand forms may be had for autumn decoration. These Asters or Daisies need but little attention; they will thrive and bloom profusely in any light garden soil and produce an ample supply of flowers for cutting. They may be propagated by means of cuttings taken in spring, or by dividing the roots in winter. Six or eight good sorts will be found to be ample for most mixed borders. The best variety with which I am acquainted is A. formosus, which has fine large mauve-coloured flowers, quite equal to those of some of the best Cinerarias grown in our greenhouses. It grows about 2 feet high, and is a most profuse bloomer. A. grandiflorus grows from 3 feet to 4 feet high, and bears large flowers, the rays of which are purple. It is a most effective variety. A. alpinus is a dwarf plant, neat in habit, and very attractive. It is more suitable for a rockery than a herbaceous border. Others, such as Chapmanni, bright lavender; elegans, purple and white; versicolor, white and reddish-coloured; and ericoides, dwarf and white-flowered, are all good. The last is neat in habit and an abundant bloomer. Rudbeckia Newmanni is an effective autumn-blooming plant; it has yellow florets with a dark disc, and lasts long in good condition when cut. Then we have R. hirta and R. scorotina, both good October flowers, the former producing large, bright yellow flowers, with broad, spreading ray florets; the latter, flowers of a purplish red colour. Stenactis speciosa is also a fine autumn plant, which produces large showy pale purple Aster-like flowers with a yellow centre. The finest blooming plant in the garden just now is, however, Sedum spectabile, which has been in bloom for the last six weeks. It produces great heads of rose-coloured flowers, forming a solid mass of bloom, perfectly distinct from that of all other hardy plants.

Tritoma Uvaria and T. Rooperi are always welcome during this month; their fine spikes of bloom and warm colours are invaluable at this season. Senecio pulcher, known as Tyerman's Groundsel, is, where it does well, one of the finest autumn perennials in cultivation. It is perfectly hardy, and produces an abundance of golden-centred magenta-coloured flowers. Some few of the Veronicas have continued to bloom freely well into October; for instance, V. spicata, with its long elegant spikes of the most striking blue, and V. longifolia, 2 feet high, with dense, erect spikes of the richest deep blue, are two of the best plants on the hardy border. Erodium Manescavi is a showy, autumn-flowering plant, the foliage of which resembles that of an Oak-leaf Geranium, and its flowers are reddish purple. Helianthus multiflorus fl.-pl. is likewise a grand border plant, its fine yellow flowers being very welcome at this season. It is very showy and effective. Echinops ruthenicus is a singular Thistle-like plant, furnished with globular heads of rich blue flowers. In addition to the above we have stray plants of Tradescantia virginica rubra, Helenium pumilum, Statice latifolia, Pentstemons rather past their best, and Centranthus ruber. Some few annuals have been very fine during the early part of the month, especially Helichrysums and African Marigolds. Q. R. S.

Pleasley Vale, Mansfield, Notts.

White Trumpet Daffodils.—I have read Mr. Douglas's remarks (p. 358). Having a good many varieties of white Trumpet Daffodils, and being

also very anxious that some certainty may be arrived at as to their nomenclature (which I am afraid the Narcissus committee has as yet hardly achieved), I shall be very glad to send bulbs of what I think to be each variety of those I have to be grown on trial at Chiswick, but as it is so late in the season, all my bulbs being already planted, I would suggest that all growers of white Trumpet Daffodils should send a written promise to Mr. Scrase-Dickins undertaking to send bulbs to Chiswick not later than the 1st of August, 1887; if taken up now the bulbs would suffer and the flowers probably not show their wonted character from want of vigour caused by removal at a wrong time.—D. E. Wemyss, *Torrie House, Dunfermline.*

NOTES.

Flowers of October.—The chilly nights of mid-October, especially if accompanied by dripping skies and violent gales, make rather short work of the hardy flowers, but still there are plenty in good condition. Single Dahlias, especially the white kinds, are very useful; so also are Chrysanthemums, and especially the white Madame Castex Desgrange, which is undoubtedly one of the very best introductions of recent years. Michaelmas Daisies are yet useful for indoor vases, and there are even a few buds and blossoms on the big-leaved Magnolias by the walls. Senecio pulcher is at its best; so also are the latest buds of Souvenir de la Malmaison Rose. Sunflowers, Gaillardias, and different kinds of Coreopsis are still fresh and beautiful; also the shrubby Veronicas and Fuchsias of many kinds, the old white-petalled Madame Cornellissen being one of the best. The Belladonna Lily, where it does well, is hard to surpass amongst hardy blossoms at this season, and it forms a good companion for the great Colchicum speciosum, which is still opening its latest buds. Just as the last of the Roses are dying away the Wallflowers and Anemones and seedling Primroses are coming into flower, and as the leaves fall gradually from the deciduous trees we begin the more to appreciate the fresh green and golden-leaved Hollies, the bright-berried Cotoneasters, and the glossy Ivies on the old grey walls. So, too, amongst the dying Brake Fern the Bamboos stand up fresh and green and happy in the rain. The scarlet Schizostylis is sending up its budded wands, and its relatives, the Gladioli, linger on bright and beautiful, as if quite loath to go to rest for the winter, while Mignonette is never sweeter than thus late in the year.

Waste in gardens.—Professor Goldwin Smith tells us that, excepting the Americans, we are the most wasteful people in the whole world, and he further points out that the more perfect utilisation of our wasted products is one way in which we may meet foreign competition and depression of trade. When I read the above it occurred to me to ask if there is not much waste in our modern gardening. At any rate, of one thing I feel sure, and that is, that the more self-supporting a garden can be made, the better is it for the country, but more especially for the gardener. Of course, if the actual owner of a garden so wills it, he may keep up his garden purely for pleasure, just as he keeps his yacht or his hounds. On the other hand, if he so desires, he has as much right to sell part or the whole of the produce of his garden as he has to sell the young colts or shorthorns from his farm, or his pictures and books if he should tire of them. If labour is honourable, then trade is honourable, and any methods or means by which waste products can be utilised should be adopted in the garden. Young gardeners more especially should keep their eyes open, for the garden requirements of the next twenty years will be very different from those of the twenty years just passed. Even the rage for Orchids is but little compared with the ever-growing and wide-spread liking for all sorts of beautiful hardy flowers. These last may be grown by a cotter or in a farmer's garden, but they are being sought for and cherished everywhere throughout the length and breadth of this country. They have solved the cut-flower difficulty; they have done much towards making our gardens generally more interesting as well as more beautiful for nine months out of the twelve. The more extended culture of hardy flowers, together with the economical growth or disposal of glasshouse products seems to be the storm-warning of our present-day management in the garden.

Eryngium serra.—As distinct and handsome-foliaged plants some of the more stately of the exotic Sea Hollies could ill be spared. E. pandanifolium, E. yuccæfolium, and others are now largely used in some public gardens, but E. Serra is perhaps less often seen. It has broad foliage about 2 feet long and 2 inches in breadth, arranged in rosette fashion, from the centre of which rises a slender wand-like flower-stem 8 ft. or 10 feet in height, the upper portion of which is branched, and the branchlets tipped with greyish knob-like clusters of buds and flowers. It is a hardy, strong-growing species, the rosettes of which may be divided and replanted during the spring-time with success. As a class, we find nearly all the Eryngos, both native and foreign, handsome plants when well grown in the garden, one of the dwarfest, but by no means the least handsome, being our native Sea Holly (E. maritimum). If its roots be well planted amongst sea-sand and stones, it forms a pretty patch of colour every year. E. amethystinum, E. Oliverianum, E. giganteum, and E. campestre are other well-known kinds. Nearly all the species, if cut just before their flowers expand, dry well if hung up, and are useful for mixing with plumes of Pampas, or Arundo, and with the black-topped wands of the Typha and fruits of Physalis, or Honesty, for winter decoration.

Schizostylis coccinea.—One of the very best of all the hardy flowers of October and November is this near relative of the Gladioli, or Sword-flowers of the Cape. I saw some fine large clumps of it throwing up numerous flower-spikes in the flower garden at Powerscourt the other day, where soil and situation seem to suit it exactly, but, as a rule, this plant succeeds better and flowers stronger if the old clumps are divided and re-planted every spring. If planted out in rows or in beds in a sunny position and protected with frames or wicker hurdles and mats during sharp frosty nights, a supply of flowers may be had all through November, and even until Christmas or the new year. In some places the flowering clumps are dug up carefully, and are potted for greenhouse or conservatory decoration. On warm, rich soils near the sea this plant flowers nearly all winter without any protection, yielding a good supply of flowers on stems 2 feet or more in height. I do not recollect if this plant is much grown in Scilly or in Cornwall, but one would imagine it to be a likely and profitable crop in such a climate. It is most easy to propagate or increase, every little shoot transplanted in spring forming a plant which generally sends up a spike in the autumn. A good handful of its flowers, cut with long stalks and arranged either with its own foliage or with the leaves of Reineckia carnea, forms a pretty group in a slender vase or glass.

Pæonia corallina.—On the rocky side of the Steep Holme, a little island in the British Channel, this robust, broad-leaved Pæony finds a home, the only one of which it can boast as being its natural one in the British Islands. It exists here and there in gardens, but is by no means common, although a vigorous grower, and by no means difficult to increase by seeds or by division of the roots. It flowers in May, bears single, rosy purple blossoms among its bronzy green leafage, and it is just now again made beautiful by its brownish woolly capsules having burst open, thus revealing its blue-black seeds, the size of Peas, amongst numerous abortive ones which are of a bright red or scarlet hue. It is well worth a place in all gardens where distinct hardy plants are valued for its own sake, apart altogether from its interest as a reputed native plant. In De la Torre's "Tourists' Guide" it is said to be found in Upper Bavaria, Reichenhall, Styria, and also in Carniola, and he also mentions that it was united with P. officinalis by Linnæus. The P. officinalis of our gardens to-day is a different plant, and is the P. pelegrina of Miller. Now that all the Pæonies are becoming most popular in gardens, it would be a good thing if someone with means and leisure would produce a monograph with good figures. Mr. Barr and Mr. Ware have good collections, and in Continental gardens the varieties are very numerous. In the Salon every year we see pictures of these fine flowers in plenty, which is, in a way, an indication of their popularity abroad.

Rudbeckia Newmanni.—As Rudbeckia chrysolora this plant has been grown in some old gardens for many years. I only know of one dark-eyed, gold-rayed Composite which surpasses it, and that is Helianthella uniflora, as given to me by Mr. Archer-Hind. When well grown, we have but few, if any, late autumnal Daisy flowers which can equal this old favourite of other days. Like most of its Order, it enjoys fresh soil or change of place, viz., replanting every second spring at the farthest, and as so treated in good, deep loamy soil, it grows in masses a yard high, and is very brilliant as seen in the October's sunshine. A good handful of its flowering stems, cut rather long, so as to allow the flowers to spread out freely, makes a pretty picture in a deep vase or bit of old bronze. I saw a big pot filled with these flowers the other day, the long stems having been thrust down through a few flattish sprays of Mahonia leaves, just now changing from green to brownish crimson, and the effect was distinct and very good. Inula Hookeri is another good thing, having large pale yellow flowers, with a much-gashed or fimbriated series of ray-florets, but at present it does not seem very plentiful. Just as I write, a friend sends me a nice plant of "an Erigeron from India, bearing blue flowers almost as big as those of the perennial Sunflower." This would seem to be a good thing. What can it be? Perhaps a very good form of E. multiradiatus. At any rate, I shall take great care of it until it blooms, and may then have more to say concerning it from personal experience.

Single Hollyhocks.—Twenty years ago it was often said that the Hollyhock was the only garden or florist's flower capable of producing any appreciable effect in the garden landscape. About that period, or earlier, one often saw drawings and wood engravings showing groups of Hollyhocks nestling near the door of some country cottage, or by the beehives in the garden, with their tops level with the upper windows or touching the thatched eaves. If I remember rightly, Birket Foster used to draw lovely groups of them. At that time the flower was popular, and we used to admire the fine spikes or choice double blossoms—like satin rosettes they were—which the late Mr. Chater, of Saffron Walden, used to bring to the meetings of the Royal Horticultural Society at South Kensington.

Those were golden days for the enthusiast in Hollyhock culture; but alas! an enemy came in the shape of the Mallow fungus or rust (Puccinia Malvacearum), and these beautiful old blossoms vanished from our gardens as if by magic. Far and near the scourge spread until even the very staunchest lovers of the flower gave up its culture in despair. But we now see the Hollyhock creeping back again into public favour. At Glasnevin recently I saw some lovely single-flowered kinds, seedlings of 1885, and most lovely they were, varying from pure white and pale sulphur and buff to salmon-pink, rose, crimson-red, and in another garden I saw some with purplish black flowers. Seeds sown now in a cold frame would yield plants for next year's blooming, and seedlings, as we know by experience, best withstand the disease. We have no other Mallow or Althæa so easily grown or so beautiful as are the forms innumerable of A. rosea, and it is to be hoped that it will regain its former status in the garden, and especially do I plead for the culture of single-flowered kinds.

Cordyline australis.—In Southern England, near the sea, and in Scilly, and also in many parts of Ireland, this New Zealand Dracæna is perfectly hardy, and forms fine healthy plants 10 feet to 15 feet or more in height, and branched or unbranched, as the case may be. If it be accidentally wind-topped, or cut down by a more than ordinarily severe frost, the result is often a much-branched, tuft of young shoots instead of the more usual and natural single-stemmed individual. If reared from seeds sown as soon as ripe the plant is increased quickly; the young seedlings, if potted and kept in a cold frame in summer, and secured from frost during winter, soon become of a useful size for various decorative uses. When two years old they may be planted out permanently where they are intended to remain. On light sandy or peaty soils they are very handsome as grouped among Rhododendrons and hardy Ericas, amongst Furze or Broom, and under the shelter of high banks or sunny rocks. One result of raising this plant from seed is that the individuals vary, some being more dense and stubborn in habit and more hardy than others. Some have red veins (C. Veitchi), others green ones and broader, longer leaves, approaching C. Banksi in habit and coloration. In planting out the seedlings in order to establish them, the middle of May is the best time to select for the operation. Planted at that season, a whole summer's growth enables the plants to gain a deep and thorough root-anchorage before winter time, and a few shovelfuls of ashes or dry peat or bog-mould (called turf in Ireland) are generally sufficient to preserve the lower part of the stem and the roots alive, even if the tops are killed. After the first winter there is less risk, but out of a dozen or so some are sure to survive.

Tyerman's Groundsel.—On soils and in suitable climates this Senecio pulcher holds its own as a distinct Composite, and a free-flowering one to boot. On cold, clay soils it may not prove so effective, but here on a deep and rich sandy soil we have nothing like it amongst hardy flowers at this late season of the year. In some places its spikes appear so late that they are cut off by the first frost, but if the plants be carefully dug up and potted they will feel the check but little, and go on flowering all through November in a sunny greenhouse. Its flowers are most brilliant by artificial light, as arranged with white Pyrethrums, Asters, or Chrysanthemums. If a good stock of such a useful thing be desirable, now is the time to insert root cuttings. Drain and fill a seed-pan with sandy soil as if for ordinary cuttings; then dig up a plant or two of the Senecio and select the thickest of its white quill-like roots. These should be cut into inch-long lengths and inserted thick end uppermost into the sandy soil of the seed-pan. Let the tops of the cuttings be just level with the surface of the soil, so that when the whole is watered a small portion—say the eighth of an inch of the cutting—is bare and exposed to the light. Place the pan on a shelf near the light in a warm greenhouse or pit. The first symptoms of growth are shown by the ends of the cuttings turning green; then they split down one side, and from the crack a new shoot soon appears. The cuttings are ready for planting out next June.

Veronica.

Ferns.

Canadian Ferns suitable for England.

It frequently happens that Canadians are applied to, by their friends in the Old Country, for roots of our native Ferns, for cultivation in ferneries and conservatories, and it is not infrequently the case that these requests are not complied with, either from a lack of knowledge as to what species would be acceptable, or from the mistaken notion that because a Fern is exceedingly abundant here it must also be so in Great Britain. As a guide to those who may be anxious to delight the hearts of their Old Country friends by sending them living roots of Canadian Ferns, I append lists—first, of those which are not found growing indigenously in Great Britain at all; and secondly, of those which, although found there, are very rare, or which present differences in appearance from our forms, in consequence of which they would be acceptable to all Fern growers and collectors for comparison.

In the cultivation of Ferns there are one or two points which must always be borne in mind. First, it must be remembered that Ferns, unlike most other plants, shun the sunlight and court the shade and a moist atmosphere. Although some species may be occasionally found growing in open spots, it will generally be found that they are more luxuriant when in the shade and under the shelter of trees. Many Ferns will succeed well in flower-pots, but they require constant care and attention. One of the most important requirements of Ferns is perfect drainage; and this can only be attained at the risk of allowing the roots to become too dry, unless regularly watched. A liberal supply of drainage, in the shape of broken pots, pieces of old mortar, or bricks, should be placed in the bottom of the pot, and on the top of this a thin layer of Moss, to prevent the fine mould, which is necessary, from running down into the drainage. The mould should be light and finely sifted. A useful mixture for most Ferns is the following: Fibrous peat, leaf-mould, loam and white sand, in equal proportions. The roots bear transplanting better in the autumn than at any other time, but should not be forced to grow at once on arrival in Britain; they should be put by in a cool place until the next spring.

The facilities for the transmission of small parcels to Britain are now so great, that there is no excuse for our not sending large numbers of these lovely plants, many of which, although common with us, are, nevertheless, highly prized on the other side of the Atlantic.

Canadian Ferns not Wild in Great Britain.

Fairy Fern (Adiantum pedatum).—An exceedingly desirable species, of great beauty and easy culture; there is, perhaps, no species of the large family of Maiden-hairs, from all the different parts of the world, which surpasses our native species in grace and elegance.

Rock Brake (Pellæa gracilis).—This charming little species has yellow, fleshy root-stocks, which contain much oil, and it is doubtless this character which renders it capable of withstanding drought for a long time. Its natural habitat is in crevices and under overhanging ledges of limestone rocks, where it shoots out its delicate fronds in the month of June. At this time of the year the rocks in such localities as it frequents—on river banks and lake shores—are constantly wet from the snow water, which has not yet dried up in the woods; but is constantly trickling down over the surface of the rocks, and which, penetrating into the little cracks and crannies, gives the moisture which is necessary, with the warmth of spring, to quicken into life the lovely rock Ferns which grow there. After the end of July the fronds dry up and the plant again lies dormant until the next June. This Fern could be moved easily when in the dormant state, and should be cultivated with ease.

Cliff Brake (Pellæa atropurpurea).—A very attractive plant of small size, found in the crevices of dry rocks and cliffs; it should transplant easily, and, with care, would succeed in artificial rockwork where there was not too much moisture.

Chain Fern (Woodwardia virginica).—This would perhaps hardly succeed so well in cultivation as many of our other Ferns, as it is a vigorous growing, coarse plant, with large and long root-stocks, which grows in peat bogs and Tamarac swamps. Its fine appearance, however, makes it worthy of a trial.

Ebony Spleen-wort (Asplenium ebeneum).—Great care must be taken in the removal of this and all the Spleen-worts of the same class from their native rocks. These rock-loving Spleen-worts will, however, generally succeed well if their roots are taken up intact, and if they are planted in crevices of rockwork, or even in flower pots if well drained. On rockwork they should have an upper position, but should not be kept too dry. They generally succeed better if planted in a horizontal manner between two stones; when grown in pots, the soil should be a light sandy loam mixed with leaf-mould, and among this, about the roots, should be placed some pieces of old mortar or sandstone.

Narrow-leaved Spleen-wort (Asplenium angustifolium).—This is an exceedingly handsome Fern, well suited for conservatories. It requires good rich leaf-mould or peat and plenty of moisture, when the large, delicate, light green fronds would be produced in abundance and form a charming contrast with the darker hue of other Ferns. The name of this Fern is perhaps a little deceiving. Although narrow-leaved, it is one o our largest Spleen-worts, the fertile fronds frequently exceeding 2 feet in length.

Silvery Spleen-wort (Asplenium thelypteroides).—This is another of the large-fronded moisture-loving Spleen-worts. Its natural habitat is in the deep forest or in swampy woods. It is well fitted for conservatory and greenhouse culture, and, like the preceding, should have deep leaf-mould and plenty of moisture. The fronds are very handsome, of a deep green, and, as the name implies, the plant has much the appearance of the Marsh Fern (Aspidium Thelypteris) and grows much in the same manner, throwing up clumps or clusters of tall graceful fronds.

Walking Fern (Camptosorus rhizophyllus).—This is a particularly acceptable species, found on shaded limestone rocks. It is an Evergreen, is easy to cultivate, and has a very distinct appearance, quite different from any British Fern. It will transplant at any time of the year, and if given a shady corner with good leaf-mould, plenty of moisture, and sufficient room to spread out its fronds, will grow luxuriantly, and increase rapidly by taking root and making young plants at the tips of the fronds.

Broad Beech Fern (Phegopteris hexagonoptera).—This resemble the British Beech Fern

(Phegopteris polypodioides) very closely, but is a larger and handsomer plant with fronds of a delicate light green. It is easily cultivated, but must have good deep leaf-mould and shade.

Christmas Fern (Aspidium acrostichoides).—This is a dark handsome Fern, of a deep full green. A very desirable species, hardy and easy of culture, and has a very effective appearance among other more delicate Ferns. It is always to be obtained without difficulty in rocky woods, growing in clumps or small beds. It has somewhat the appearance of the Holly Fern, but is more showy.

New York Fern (Aspidium noveboracense).—A delicate and attractive species, not difficult of culture. Should have light soil and plenty of moisture; but must be well drained. This Fern is always acceptable, both from the delicacy of its foliage and its soft green colour.

Goldie's Shield Fern (Aspidium Goldieanum).—A large, rich, and handsome species, with dark foliage, that has lighter shades down the centres of the pinnæ, which give it a pretty, variegated appearance. It is of easy culture, and well suited for the back of a rockery. It succeeds better when supplied with a liberal allowance of peat and leaf-mould, but is very hardy, and will grow in almost any soil, with shade and moisture; it becomes stunted, and seldom produces fertile fronds unless provided with good soil, moisture, and shade. There is no Fern in Britain that has the same appearance as this, and this fact makes it a desirable species.

Marginal Shield Fern (Aspidium marginale).—A handsome Fern, but bearing too close a general resemblance to A. Filix-mas to make it a desirable species for transmission to Britain. A. Filix-mas, although so rare on this continent, like Scolopendrium vulgare, is one of the most abundant species all over Great Britain.

. Evergreen Wood Fern (Aspidium spinulosum var. intermedium).—This common variety of A. spinulosum, which is found everywhere in our woods, is not among these which grow in England. It is the A. americanum of Davenport, and is a graceful plant, which should be included in all collections of Ferns sent to Europe. It is hardy, very easy of culture, and easily obtained. The fronds are evergreen and of a bright colour.

Boot's Wood Fern (Aspidium spinulosum var. Bootii).—This is a much rarer Fern than the preceding, with thicker and less cut-up foliage, sometimes resembling A. cristatum as much as A. spinulosum in appearance, and much more like the British form of A. cristatum than the Canadian; it is considered, however, to be a variety of A. spinulosum. It requires a good depth of leaf-mould, shade, and a liberal supply of moisture.

Clinton's Crested Shield Fern (Aspidium cristatum var. Clintonianum).—This handsome Fern is quite unlike any European form of A. cristatum, and in some respects bears a much closer resemblance to our own A. Goldieanum. Its habitat is wet, swampy woods and in the deep forest, where it sometimes grows to a large size. It is a very desirable species for European collectors to compare with their own forms of A. cristatum.

Scented Shield Fern (Aspidium fragrans).—There are few of our native Ferns more attractive than this; the deep blue-green fronds hang in rich clusters from the crevices of rocks where it grows. It is considered one of our rare species, but is generally to be found in abundance where it occurs. The Lake Superior region seems to be the centre of its distribution; there it is most abundant, growing on trap rocks. The close compact growth of the plant and the abundance of the sori, with their lead-coloured indusia, give this Fern a very rich appearance, and its agreeable scent makes it still more a desirable species. It would probably be rather shy of cultivation, but might be treated in the same manner as the Rock Spleen-worts.

Trailing Fern (Cystopteris bulbifera).—No collection of Canadian Ferns would be complete without this common, but charming species. It is undoubtedly one of our most elegant Ferns; the slender, elongated fronds of light green, with their ruddy, semi-transparent stipes, render it most valuable for contrast. It is very easy of culture, and will flourish luxuriantly if planted on a wet wall or near a waterfall. It grows easily in a flower-pot in a conservatory, but cannot bear sunlight. It should have a light peaty soil and plenty of moisture, both in the atmosphere and at its roots. It would probably grow better if small pieces of rock were placed among and about its roots.

Oak-leaved Fern (Onoclea sensibilis).—There are few of our Ferns which are greater favourites in Europe than this common species. It has long been known there as a greenhouse plant, where it is prized as well for its graceful foliage as for the ease with which it can be cultivated. With light soil, shade, and moisture it grows well in Europe and increases rapidly, but seldom produces the fertile fronds so abundant here. It is always acceptable.

Ostrich Feather Fern (Onoclea Struthiopteris)—This stately plant is valuable for the back of a rockery. If supplied with a good depth of leaf-mould it grows easily and throws up its lofty plumes to the height of 3 feet or 4 feet or even more. There is no Fern which resembles it in Great Britain. It bears transplantation well, and will grow vigorously in a flower-pot in the house, when it becomes a useful and graceful ornament for a drawing room.

Northern Woodsia (Woodsia hyperborea).—All Woodsias are welcome additions to a European collection. Unluckily, however, all of our species, with the exception of W. ilvensis, are very rare. W. hyperborea is only found on high cliffs and near waterfalls. The culture should be the same as for the Rock Spleen-worts, the chief essential being perfect drainage, together with plenty of moisture and light soil.

Smooth Woodsia (Woodsia glabella).—This species is found in similar localities with the above, and should be cultivated under the same conditions.

Gossamer Fern (Dicksonia pilosiuscula).—This lovely scented Fern, with its delicate fronds of tender green, is a charming object as it grows in its native woods, where it is generally found on a cold, sandy loam. It is, however, rather shy of cultivation. The root-stocks are very wide-spreading, and in transplanting specimens, small and young plants should always be taken. A sandy loam, with about one-fourth leaf-mould, is the best soil for this Fern. Although difficult to grow, its beauty well repays any trouble expended upon it.

Interrupted Fern (Osmunda Claytoniana).—This Fern and the next are always welcome additions to European collections, not only for their own beauty, but because they are so different from the royal flowering Fern (Osmunda regalis), which is well known there. The Interrupted Fern is well suited for planting in fountains and on the borders of ornamental ponds, where its curious, graceful fronds are shown off to great advantage.

Cinnamon Fern (Osmunda cinnamomea).—This is another handsome Fern, generally found in slightly wetter places than the preceding, but it is hardier and may be grown under the same circumstances. The foliage is not so handsome, but it is always an acceptable plant and grows easily.

Rattlesnake Fern (Botrychium virginianum).—This is a great favourite with British collectors. It is very different from the European B. Lunaria, grows easily, is of convenient size and compact growth. Light soil, about half leaf-mould, is the best for this Fern. It succeeds well when single plants are grown separately in flower-pots.

Grape Fern (Botrychium simplex).—This rare Fern has more the appearance of B. Lunaria than any of our American representatives of the genus. It, like Botrychium matricariæfolium and B. lanceolatum, is difficult to cultivate, and the only way to succeed with these species is to remove a large quantity of the soil with them from their native haunts so as not to disturb the roots. When growing in turf in meadows this is not difficult, but when in the light leaf-mould of the forest it is not so easy.

Ternate Moonwort (Botrychium ternatum).—This is a very handsome, dark green, fleshy Fern, found in open grassy spaces near woodlands. It has thick fleshy roots, but is rather difficult to move unless a piece of sod is taken up with the plant. The fertile frond is large and conspicuous, and is a great ornament to the plant when the spores are mature. It is an Evergreen, and takes a rich bronze tinge of colour from the winter's frost.—*Mrs. Traill's "Canadian Plant Life."*

Garden Flora.

PLATE 567.

BIGNONIA PURPUREA.*

Amongst the numerous species of Bignonia, some have flowers possessed of great beauty, but it is often difficult to get the plants into flowering condition. The plant herewith figured belongs to the few which are pre-eminently useful garden plants. It is a free grower; its habit is such as gardeners like in climbing plants, and it never fails to flower profusely under ordinary stove treatment. In an account of the garden kinds of Bignonia, given in The Garden (Vol. XXVI., p. 521), and accompanied by a plate of the grand greenhouse kind named B. Cherere, it is stated that B. purpurea is closely related to B. speciosa, a statement confirmed by the representation here given, in which the resemblance is apparent enough. Where the one thrives the other may be grown; but although the two are much alike in general characters, they differ in a point of much importance, viz., the time of flowering. B. speciosa produces its numerous masses of pale purple or lilac flowers early in spring, whilst B. purpurea flowers about August and September, when the large specimen of it in the Palm house at Kew is usually a perfect curtain of bloom. It has a climbing habit, the old shoots pushing from their axils numerous long string-like pendent branches, which ought not to be tied up, but allowed to hang naturally. Its leaves, which are opposite, are produced in pairs 6 inches apart, and are composed of two obliquely ovate leaflets and a terminal one, which, however, is almost always modified into a long hooked or spiral tendril, whose purpose is to enable the plant to climb. Its flowers are borne in short axillary panicles at every node on the lowest yard or so of each shoot; they number about six in each panicle, so that in the case of well-managed plants about a dozen flowers cluster round each pair of leaves. The flower-tube is 1½ inches long, widening upwards; the limb, which is composed of five rounded segments, with a sinus in the apex of each, spreads to a width of 2 inches. Its colour, as will be seen, is purplish lilac, with a few lines of red running down the tube, the inside of which is almost pure white.

The cultivation of B. purpurea is of the easiest description. It should be planted out in a bed or border of rich loamy soil, and kept well watered all summer. The only point to be specially observed is that of pruning, which should be done after the flowering is over, and after that, except perhaps a little thinning out of the new growth, no further pruning should be done. During winter very little water should be given, but absolute drought must be avoided. For draping pillars, or even for forming curtains or

* Drawn in the Royal Gardens, Kew, in August, 1885.

BIGNONIA PURPUREA.

screens against unsightly walls, this Bignonia is one of the most useful of stove climbers. It may be readily propagated by means of cuttings made of the ripened shoots. B.

WORK DONE IN WEEK ENDING OCT. 19.

October 13 to 19.

The sudden change to wet and boisterous weather has at one stroke sounded the death-knell of open-air flower gardening for this year. Every plant was looking so well, and flowering just as freely as at any time during the summer, that our regret at such an ending is very great; but regrets do not mend matters, and, though not with a very good grace, we have again to bow to the inevitable and set about repairing the damage by starting in earnest to put the beds in winter dress, but as yet little progress can be made in that direction by reason of the weather, which continues wet and stormy. All the hardy plants, such as Sedums, Saxifrages, Herniaria, Pyrethrum (Gold Feather), Veronica incana, Yuccas, Phormiums, and small evergreen shrubs that have formed part of the summer arrangement remain as before, and the tender plants are replaced by other small shrubs, mainly supplemented with Hyacinths and Tulips, these being planted with dibbers on a groundwork of Sedums, &c., that remain as during the summer. The following are a few of the best shrubs for this purpose. I name them in order of preference: Retinosporas (various kinds), Cupressus Lawsoniana erecta viridis (fine for dot plants), Thujopsis borealis, Euonymuses (all the kinds), Cotoneasters, Mahonia Aquifolium, Golden Yews, variegated Box, variegated Periwinkle, variegated Ivy, Aucuba variegata, Portugal Laurel, variegated Hollies, Laurustinus, Andromedas, and small Rhododendrons. The lifting of the bulk of herbaceous plants for the trenching and renewal of soil and re-arrangement of plants being contemplated, such clumps and roots as are not well known when stemless are being labelled, and their heights and spread of growth marked in addition to the name as an aid to us when the plants are being arranged in the borders. Except trenching, it has not been possible to do any kitchen garden work, or, in fact, open-air work of any description, other than cleaning up the *débris* on lawns, walks, and roads that the severe gales of the 14th, 15th, and 16th inst. scattered in every direction. The few Apples and Pears we had not harvested were nearly all blown down, and are only fit for immediate use. What few remain we shall gather the first dry day. Fruit rooms have again been overhauled and made to look their best, and during this damp weather the ventilators are kept quite close. Grapes hanging on the Vines have required almost daily examination to cut out bad berries; all the laterals were cut off the Vines long ago for the better admission of light and air, and a little artificial warmth is constantly kept up to ensure the internal air being lighter than that outside. Vineries from which the Grapes have been used are now filled with flowering plants—Chrysanthemums mainly—and to prevent the flowers damping we have, contrary to our wish, been obliged to have recourse to slight warmth in the pipes, of course, accompanied with as full an amount of air as is possible in such wet weather. As might be expected, under such weather-conditions, the foliage of some of the weaker-growing varieties of Chrysanthemums is falling a prey to mildew, and repeated dustings of sulphur have to be applied to keep the parasite in check. Much time is now taken up in finding space for and arranging bedding and stock plants for the winter, our aim always being to get all we can into heated structures, to save the labour of covering up of frames and pits in severe weather. Preparation is now being made for potting and otherwise housing all old plants that are to be saved from the flower garden. Fuchsias, tuberous Begonias, and Cannas we pack closely together in cocoa fibre in a frost-proof cellar. Herbaceous Lobelias and fibrous-rooted Begonias are planted closely together in boxes, and afforded room in Peach or other fruit houses from which frost is excluded. In anticipation of frost, autumn-struck Pelargoniums are being got into frost-proof quarters in frames that in mild weather can be thrown fully open.

Hants.

FRUITS UNDER GLASS.

Melons.

We are still cutting good fruit of Golden Perfection, Highcross Hybrid, and Reading Hero, but, having plenty of Pears, a clearance of the Melons will be a relief, as Cucumbers are now pressing for space. A few there are who are obliged to have very late Melons, and as some sorts do much better than others, a note for another year's guidance may not be out of place. The three just named are good setters, swell and ripen quickly, and are perhaps as good flavoured as any I have yet met with. For all-the-year-round use, where high flavour is the test of merit, I have found Golden Perfection the best; Highcross Hybrid comes next, but its pale, smooth skin is against it, for with me, no matter how large or well the fruits are grown, it rarely puts on the slightest resemblance of netting. Reading Hero, on the other hand, lays on its beautiful bread lines irrespective of size or quantity of fruit which individual plants are allowed to carry. Moreover, it keeps sound and perfect in a dry, moderately warm room or vinery for a considerable time after it is cut and fit for table. Like the old Golden Gem, this is a most excellent market grower's Melon, as it can be got in very early; its size can be regulated by thinning as every fruit sets, and the rich golden colour which the masses cannot resist will always sell it. From these remarks it must not be inferred that the flavour is deficient, as I look upon it as the best all-round white-fleshed Melon of recent introduction. Some of the scarlet or orange-fleshed varieties, too, are very good autumn Melons, but, never so rich as the greens, they fall off rapidly when sun-heat becomes weak and fitful. The well-known Blenheim Orange, when grown as Mr. Crump, the raiser, still grows it, is a host, and a very handsome host, in itself, but it must have plenty of light and heat, and these he is able to give by plunging the pots in tan and training the vines under a very steep, lightly-timbered roof. Another good and handsome Melon is Sutton's Invincible. Read's Scarlet still holds its own, and for rich flavour Turner's Scarlet Gem has not yet been beaten. All these varieties are good for early or late forcing, and will give satisfaction wherever they are properly grown. For early or late use the roots should be entirely under control; hence the advantage of growing them in pots, boxes, or narrow troughs, surrounded with fermenting material, and from which superfluous moisture can be quickly withdrawn.

Cucumbers.

Unless pits and frames are extra good, well situated, and the fermenting material is assisted by hot-water pipes, the fruit which they will produce will now be of little value; therefore, if the plants can be dispensed with, these structures may be turned to better account for stores of winter Lettuce, Violets, and a host of things which revel in a little latent heat. If, on the other hand, they cannot be cleared of their summer occupants, and fire-heat is not available, old linings must be pulled down and replaced with fresh fermenting stable manure, care being taken that all crevices are well stopped to keep out noxious steam, and good covering with thick dry mats, or, better still, waterproof canvas, must be employed during the hours of darkness. Meantime the first batch of early plants in span-roofed houses must be pushed forward, as their work will be over when the main crop comes in, say in January. The weather so far has been highly favourable, and plants from seeds and cuttings with us would produce any quantity of fruit, but the latter being of little value, they are only allowed to carry sufficient for daily use. Grossness at the outset being objectionable, plants in this stage should not be overdone with liquid; better water freely when they require it with warm, soft water, and top-dress lightly with fresh maiden turf and lumps of old lime rubble; also crop lightly, and keep them free from all male and superfluous female blossoms. As growth becomes weaker and more fruit is wanted, the pots or hills being full of healthy roots, diluted liquid, guano, and clarified soot water may be given with advantage, as there will be thousands of mouths ready to consume, and the plants will be in a fit state to assimilate mild stimulants. The first and last may also be used for damping the surface of the beds, but unless spider is present, direct syringing must be discontinued.

The main crop.—As dark, dull November steals upon us, plants in various stages of growth will be found occupying the positions in which they will remain throughout the season, that is, provided they escape the many accidents winter Cucumbers are always liable to. A good start in bright, clean, efficiently heated pits is a very important matter, but something more is needed; daily and nightly attention to the simplest rules and smallest details must not be neglected, otherwise checks to foliage or roots will speedily close the most promising plant's existence. With fresh fermenting material, new maiden soil, and wholesome, well-ventilated structures to grow in, plants put out in October make satisfactory progress so long as they have plenty of room for extension; the proper degrees of heat and moisture are maintained, and premature fruiting is not indulged in. The first thing to be guarded against is a sudden check, no matter whether it is brought about by too much or too little heat; the second to be decided upon is the range of temperature, and this the cultivator must fix for himself. Some can afford to start at a night heat of 70° and a bottom-heat of 80°. Others are obliged to be content with a lower minimum, and although their progress may not be so rapid, it may be equally sure and perhaps most satisfactory in the long run. The first can dispense with night covering; the second must run down waterproof blinds, not only to economise fire-heat, but also to keep their lower temperature steady, and husband moisture by checking radiation. To lay down hard and fast lines for either of these cultivators would be simply impossible, but, speaking in general terms, they will not go far wrong if, from fermenting material or hot-air chambers, they secure a bottom-heat of 75° to 80°, and, aided by hot-water pipes and covering, the pits range from 65° to 70° through the night. The maximum, it is hardly necessary to say, should run 10° above the lowest point, and as much higher as gleams of sunshine on bright afternoons will carry it. When the young plants have nearly reached the top of the trellis, the points should be pinched out of the leaders; all side shoots should be trained horizontally and in order to increase their strength, all female and male blossoms should be removed as they appear. Plants in pots or on hills will grow quite strong enough in good compost without the assistance of animal manure, provided they are regularly top-dressed with rough pieces of light turf, charcoal, or lime rubble, and warm soft water in sufficient quantity to reach the lowest roots is given with a liberal hand. Direct syringing should not be necessary during November and December, as ventilation will be reduced to a mere chink at the apex for a short time on the brightest days, but atmospheric moisture must be regularly supplied by damping the paths, walls, and other surfaces several times during the hours of daylight. I have often pointed out the importance of keeping the atmosphere sweet and healthy by the removal of all decaying vegetable matter, by a frequent dash of whitewash round the walls; and last, but not least, by light dressings of fresh loam to which burnt earth or charcoal may be added. When the plants begin to bear fruit, a few only of the most promising must be allowed to swell, and these should be cut when 12 inches to 14 inches in length, as nothing so severely saps the constitution as allowing winter fruit to form seeds whilst hanging upon the plants.

Figs.

The trees in early houses may now be pruned, cleansed, and tied in ready for starting in November. Being subject to insect pests, this work cannot be too carefully performed; therefore, if the roof has not been stripped and the lights painted, the latter should now be well scrubbed with strong soap water, when the walls may be washed with a solution of quicklime and sulphur. If bug has gained a footing, a small quantity of turpentine may be added, not only to this wash, but also to the water with which the trees are cleansed. Many people paint their trees with favourite mixtures of soap, sulphur, tobacco water, and clay, but, judging from the perplexing way in which a few finely developed representatives of the family sally forth when they are least wanted, it is evident that a thick coating of paint is not quite so efficacious as one could wish. At least, this is my experience in the cleansing of old trees full of knots and gnarls, and from which large branches have been removed in years gone by. Better wash them twice over and stop every hole with pure Gishurst, and then it will be necessary to keep a sharp watch for the parents of a fresh race should they emerge from their impenetrable hiding-places in the spring. If pot trees are standing or lying on their sides out of doors, no time must be lost in getting them washed and housed. A little frost does them no harm, neither does it do them any good; therefore, if thoroughly rested, their arrangement on the pedestals in a dry, airy house will be found the best place, especially if the mild autumn has forced the embryo fruits into prominence.

Succession houses in which the trees occupy internal borders may now be kept dry and cool, as they have a good two months' rest before them. With us the trees are barely clear of their foliage, and until this has fallen naturally and the buds are well hardened, washing and training will be deferred. When root-pruning is put off until the wood is ripe, the leaves fall quickly, but I prefer giving them the annual check as soon as the last ripe Fig is gathered, and whilst the foliage is sufficiently fresh to favour the formation of new rootlets. The leaves then fall gradually, and the few roots which they have assisted in forming are ready for their work when the stored-up sap is exhausted in the dark, dull months of January and February. Root-pruning is a very important operation, as Figs in permanent borders soon become gross and unfruitful where it is neglected; therefore, it is better to prune late than not at all. Start the trees gradually, or a little later, and make up for lost time under solar influence in the spring.

Branch-pruning.—The pruning of Vines, Peach, and other fruit trees upon the extension or spur systems is generally understood and carried out in a satisfactory way, but the Fig in many gardens, both under glass and on open walls, is still an enigma to a great number of cultivators, and simply refuses to be reduced to fertility by the unmerciful use of the knife. When planted in dry, sunny corners and space is unlimited, it grows itself into a fruitful condition, and not unfrequently produces immense crops for a great number of years. In course of time it forms a complete bower of tangled branches and pushes forth thousands of Figs, nine-tenths of which, owing to obstructed sun and light, never reach maturity. In cold, wet seasons, large, but crowded, trees on south walls, even in Sussex, never ripen a fruit, and I have been told a good aspect within two miles of the sea does not suit them. My reply has been, the leave-alone system, which has been allowed to obtain in houses as well as on walls, is the prime cause of failure. With spades and forks strike a blow at the roots—the larder, a well-known writer might say—cut off the supplies, limit the root space, and relay the roots in light, rich soil resting on good drainage. Let this work be performed before the leaves fall, but do not rush in with the knife immediately; give the superfluous shoots time to assist in the formation of new rootlets, and when this stage is reached thin out the branches. If the trees are on open walls or in cold, unheated houses, defer pruning until all danger of severe frost has passed away; then thin out all gross, unwieldy branches and lay in the best short-jointed, spur-like pieces of wood with good points sufficiently wide apart to admit a relay of summer growths. If any part of the tree is destitute of fruit-bearing wood, cut back shoots that have reached the extremity of the wall or trellis, and latent buds in plenty will break and finish during the summer. Keep these—indeed, all growths—closely nailed or tied in, pinch before July any that are growing too strong, and thin out all weak spray when and wherever there is danger of sun-heat being shut out from the brickwork.

Where, under the impression that Figs in hot houses do not require pruning, and a dense labyrinth has been formed, the knife may follow root-pruning in November or December. The fan training of old negected trees being the only practicable system, branch-pruning, or cutting out shoots that have reached the extreme limits of the trellis, answers better than continuous pinching and shortening back to make room for summer growths, which in their turn must be pinched when the trellis, before the first crop is ripe, becomes crowded to confusion. To avoid this, a goodly number of the most promising branches should be retained to form the framework of the tree, and all that are bare of spurs or superfluous should be pruned back to a good break or cut out altogether. Wisdom will dictate the retention of as many spur-like pieces of wood as can be laid in, but these should be evenly placed, with plenty of room for extension, as the finest Figs are obtained from shoots which can be trained forward without becoming crowded or requiring pinching. In course of time, perhaps not in one year, the most abandoned trees can be brought into fair shape, when the annual removal of a few of the least promising shoots will induce back breaks, from which the second crop of fruit will be gathered; and although the Figs will be as fine and good, the trees will not be so handsome as young ones which the modern grower manipulates with the finger and thumb and trains upon an improved principle.

Eastnor Castle, Ledbury.

Trees and Shrubs.

The Redwood Tree.

(Taxodium sempervirens.)

"G." (p. 370) anticipates a fair future for the timber of this fast-growing tree, but I am doubtful if owners of land in this country will ever plant it in sufficient quantity to make it pay. They need not, however, wait for English-grown trees to set the matter at rest, as I believe balks from its native habitat are already in commerce. In course of conversation with two friends—the one a timber merchant, the other a large builder—a year ago, I learned that a quantity of a new timber called the redwood had been imported from California, but whether or not this handsome Conifer produced it I am not prepared to say. After trying all his persuasive powers, the man of balks left without a line for redwood, and I learned from my friend that it might prove as useful as Memel Pine for inside work, but he was not particularly in favour of it. Of its durability he knew nothing; consequently his refusal to buy cannot be set down as an argument against it. It is just possible it does not suit his trade, also that the redwood of commerce may not be the redwood of our pinetums at all. One thing is certain: the Taxodium with us is a faster grower than the Wellingtonia, and, judging from the way in which it holds its girth, a circumstance which may be due to the frequent loss of its leader, it is probable that it will make more cubic feet of timber in a given time. Some forty years ago the late Lord Somers planted this tree rather extensively, both on the limestone marl and on light, rich soil resting on broken igneous rock. The trees on the limestone have made the largest specimens, but then they are well sheltered from west winds, and the soil being deep and moist, they do not suffer in dry seasons. Here even the leaders suffer, and sometimes the flat-spreading branches get broken by heavy falls of snow. I have just measured a very fine lawn tree which was planted forty years ago, and although it has lost three leaders within the last quarter of a century, its height is exactly 70 feet, and it girths 10 feet 6 inches 3 feet from the ground. The fine branches sweep the turf, and its lovely red-barked trunk, as straight as an arrow, is a marvel of beauty. Several trees on the red soil have, I have no doubt, equally fine trunks, and the branches, equally healthy, take a greater sweep, but being fully exposed to western gales the leaders are frequently carried away. Although leaders are constantly snapping, the trees keep laying on wood and soon send up fresh ones, which require reducing to the strongest and best, but, quickly as they recuperate, each decapitation must represent a loss of at least 10 feet. This calculation may be wrong, and I stand open to correction; but, assuming that I am within or near the mark, our limestone tree, had it escaped the gales, would now have measured 100 feet in height. One quality in Taxodium "G." has overlooked, or perhaps not noticed, and that is, its adaptability for game covert. Many I know have planted Scotch Spruce and other fast-growing Conifers, and cut out the leaders at a given height, but they soon become bare and hollow near the ground. Not so the Taxodium, as vigorous young trees can be cut over with knife or billhook a foot or more from the ground line, and the more they are cut the more they stool, throwing up numerous shoots or leaders thickly clothed with their lovely grass-green foliage. The tree is cheap, tolerably, if not quite, hardy when planted in game coverts throughout Britain, and, being a rapid grower on almost all soils, this quality cannot be too widely known. Cupressus Lawsoniana and Thuja Lobbi, now called gigantea—two fast-growing trees from California, and hardy as English Oaks—are equally accommodating, and quite as well suited to ornamental covert planting. Some twenty years ago I purchased 500 of each, and used them for nursing purposes, but, finding they overtopped the trees they were intended to shelter, some, not all of them, were sawn off 2 feet or 3 feet from the ground. The side shoots soon became strong leaders, when they also were headed back, and these broad-spreading stools not only keep down weeds, but form very handsome under-covert for game.

W. Coleman.

Eastnor Castle, Ledbury.

Sea Buckthorn.—I saw this the other day growing in great luxuriance on the sandy seashore of Courtown demesne, Co. Wexford, covering vast tracts of sand, and at first sight forcibly recalling the Olive woods of the Mediterranean coast. Lord Courtown informed me that it had been introduced by the late earl, his father, from the east of Scotland, and that it made an excellent hedge where the "Quickset" (Hawthorn) refused to grow. "J. T. P." may be interested in learning that it bears its pretty orange berries freely, often so much as to produce orange patches against the grey foliage when seen a little way off. This year I learned it was not fruiting as well as usual.—Greenwood Pim.

Retinospora filifera.—This Japanese Conifer is distinct from any of the others; indeed, with the exception of Biota pendula and a thread-branched form of Cupressus Lawsoniana, there is nothing among Conifers at all approaching it. When allowed sufficient space in which to develop itself, R. filifera forms a rounded bush, broad at the base in proportion to its height, and narrowing upwards but slightly. At times the regularity of this arrangement is broken up by some of the branches being more vigorous than others, and when such is the case the long thread-like character of the spray is even more noticeable than in a compact specimen, though at all times a healthy plant of this is a beautiful object. The colour of the foliage is a sort of ashen

green. This Retinospora is well suited as an isolated specimen on small lawns, and also for planting in cemeteries, as it will not soon outgrow its bounds, and the long pendulous shoots suggest themselves emblematical of grief in the same way as the Weeping Willow. Another point worth consideration is that it may be easily kept within bounds by pruning, as it can be readily pruned without detracting from its beauty if the operation is carefully performed. Cuttings of Retinospora can be struck without difficulty if put in during the autumn and kept in a close frame till rooted. True, they will not strike as easily as some of the Retinosporas, ericoides and squarrosa, for instance (which are about the least difficult of all Conifers to increase in this way), but filifera is, in this respect, about on a par with R. plumosa, R. pisifera, and the varieties thereof. T.

MAGNOLIAS AT HOME AND ABROAD.

Few hardy trees have more claims upon the planter than Magnolias. Michaux, who in his "Sylva" has described and figured all the fine species indigenous to America, is unbounded in his praise of them. M. macrophylla he carried home with him to the Empress Josephine, in whose garden at Malmaison it bloomed for the first time in 1811. "The Magnolias are all natives of North America and Asia, none yet having been found in Europe or Australia. They also occupy nearly the same parallels of latitude, from the 28th to the 42nd. Michaux states, that of the thirteen species known to exist when he published his work (1814), eight were from America and five from Asia; but Loudon, in his 'Arboretum' (1842), only enumerates twelve species, and one of them a doubtful one, viz, M. pyramidata. Adopting his classification, seven are natives of America, viz., M. grandiflora, glauca, tripetala, macrophylla, acuminata, cordata, and auriculata, and four of Asia, viz., M. conspicua, purpurea, gracilis, and fuscata. But there are many varieties and hybrids of the above, numbering in all about twenty." M. A. Mongredien, in his "Trees and Shrubs for English Plantations," describes eight species only.

One circumstance appears to have militated against planting Magnolias, and that is, an impression that most, if not all, of them are partially tender and difficult to manage. Unfortunately, the most majestic of all the species, M. grandiflora, is the tenderest, requiring some slight protection, such as that of a south wall. The Asiatic species appear to be quite hardy. They are, however, of low growth compared with the others, but, nevertheless, very beautiful, particularly M. conspicua, which, in a favourable position, grows into a large tree, fine specimens of which may be seen in some parts of this country. The American species which attracted the attention of the first botanists who went over to examine the riches of the transatlantic flora were transplanted to the gardens of England and France a century and a half or so ago. M. acuminata, known as the Cucumber Magnolia, is one of the hardiest of the species, as well as one of the most beautiful, equalling in altitude and dimensions M. grandiflora. It indeed often exceeds 80 feet in height in its native forests; the northern limit of its growth is Lake Erie, and it abounds along the whole range of the Alleghanies to the southward, where it is found in rich mountain acclivities and moist sheltered valleys. The leaves, which are large, are 6 inches or 7 inches long and 3 inches or 4 inches broad, even on old trees and on young and vigorous ones nearly twice that size. They are oval, entire, and very acuminate. The flowers are from 5 inches to 6 inches in diameter, of various tints, from bluish green to white, with a tint of yellow and have a slight odour. In its native state the cones or fruits are about 3 inches long, nearly cylindrical in shape, and when green resemble a Cucumber, and hence the American name, Cucumber Magnolia. This species Michaux characterises "as one of the finest trees of the American forests." Its large flowers, abundantly displayed amid its superb foliage, have a fine effect, and render it one of the most desirable of the larger growing kinds. In its native habitat it grows most abundantly on the declivities of mountains, where the soil is deep and fertile and the air moist. It is not found within 100 miles of the Atlantic coast, which Michaux attributes to the nature of the soil and the extreme heat, and we have it on his authority that most of the inhabitants bordering on the Alleghanies gather the Cucumber-shaped cones about midsummer when they are half ripe, and steep them in whisky; the liquor produced they take as an antidote against the fevers prevalent in those districts. The wood of the tree is of a fine grain and of an orange colour. M. auriculata is regarded next in size and grandeur to M. acuminata, attaining, according to Michaux, a height of from 40 to 50 feet. It is quite as remarkable for the beauty of its foliage and the size of its flowers as the preceding, with this addition, that they possess an agreeable odour; they are of white or yellowish white colour. The leaves are narrow, 8 inches or 9 inches long, and from 4 inches to 6 inches broad, and in young trees one-third longer; the base of the leaf is divided into rounded lobes, and hence its specific name. The cones are 3 inches to 4 inches long and of a beautiful rose colour at maturity. M. auriculata is found growing only in a small tract of country, in the Alleghanies which traverse the Southern States, 300 miles from the sea, and on the banks of the rivers which flow into the Ohio, from Kentucky and Tennessee. Bartram discovered it in 1786. It is most abundant in the lofty mountains of North Carolina. It is said to be hardier than M. acuminata, and in the most northerly parts of our island only requires the precaution of training it to a wall.

M. tripetala, the Umbrella Magnolia, is found in the northern part of New York State, but more abundantly further south; it is also plentiful in the Western States. It is a smaller tree than either of the two already described, rarely growing more than from 30 feet to 40 feet high. Its leaves are, however, larger, being 18 inches to 20 inches long, and 7 inches or 8 inches broad, and often displayed in rays at the ends of the vigorous shoots, like an umbrella, and hence its American name. The flowers are also large, 7 inches to 8 inches in diameter, white, produced at the ends of the shoots, and scarcely so fragrant as those of the others. The fruit is conical, 4 inches to 5 inches long, and they assume a fine rose colour in autumn. It makes a superb tree; its long smooth shoots, its huge foliage, its elegant flowers and showy fruit formed successively through the year are objects of the most attractive interest. Its growth is rapid and it flowers when comparatively young; it is very hardy, but rather short-lived. It is found to thrive tolerably well in the northern parts of this island.

M. cordata, the Heart-leaved Magnolia, has been confounded with M. acuminata. Loudon states that it is only a variety of that species, but Mr. A. J. Downing considers it to be a distinct species. It attains about the same altitude as M. tripetala, and only differs in its broader leaves, which are 4 inches to 6 inches in length and 3 inches to 5 inches in breadth, and its flowers, which are lemon-yellow, marked inside with a few reddish lines. The cones are 3 inches long, green, and the seeds deep red. M. cordata was discovered by the elder Michaux, who found it on the banks of the river Savannah, in Upper Georgia, and on those of the streams which traverse the back part of South Carolina. It never makes its appearance in forests, but only in isolated situations along the banks of rivers. This species is rarely met with in cultivation, and is less known than either of the foregoing, though Michaux speaks of it as "resisting an intense degree of cold," and, therefore, an interesting and suitable one for amateurs. It flowers abundantly, will sometimes produce two crops in one season, and it will flourish in any good locality throughout England, and probably further north.

M. macrophylla is a remarkable species, generally considered rather tender, though by some thought to be quite hardy. It is rather tender north of New York. It loves a good, generous soil, and a dry substratum, but soon perishes if the roots penetrate a wet subsoil. It is the most rare of all the American Magnolias, being only found on the mountains of North Carolina and in Tennessee, always sparingly dispersed, only a few trees being found together. In its general appearance it is like M. tripetala, and is always accompanied in its native forests by that species. The leaves are very large, often measuring 35 inches long and 9 inches or 10 inches broad; they are oblong-oval, and heart-shaped at the base. The flowers are the largest of all the Magnolias, being frequently 8 inches or 9 inches in diameter and of a fine white, with a small deep purple spot on the interior base of the petals, which are six in number; they also diffuse a fragrant odour. Nothing can excel the magnificence of its numerous blossoms, set off by the rich and luxuriant foliage which surrounds them. This species, remarkable for its gigantic foliage and flowers, is of slow growth and delicate constitution when young, but once well started and in a congenial situation, it puts forth its magnificent foliage with great luxuriance, as well as its noble blossoms, both which unfortunately, however, expose so large a surface to the wind as rarely to remain long unscathed. In the more northerly latitudes of this country its growth becomes slow and stunted. The tree attains only a secondary size, and is distinguished in winter by the whiteness of its bark compared with that of the others.

M. grandiflora, the large evergreen Magnolia or the Big Laurel of America, is the one perhaps best known in this country, and it is peculiarly indigenous to that portion of the United States south of North Carolina, where its stately trunk—often 70 feet in height—and superb pyramid of deep green foliage render it one of the most majestic of trees. Certainly, as regards majesty of form, magnificence of foliage, and elegance of flowers, it may be regarded as one of the finest trees in the world. Bartram says that its trunk represents a "beautiful column," and its dark green foliage is silvered over with "milk-white flowers." The leaves, which are evergreen and somewhat resemble those of the Laurel in form, are generally 8 inches or so in length, thick in texture, and brilliantly polished on the upper surface. The highly fragrant flowers are composed of about six petals, opening in a wide cup like form, of the most snowy whiteness of colour. Scattered among the rich foliage their effect is remarkably fine. There are several varieties of this which have been raised from seeds of the species; the most beautiful is the Exmouth Magnolia, or M. exoniensis, with fine foliage, rusty beneath; it produces flowers much earlier and more abundantly than the original form. It is often met with in this country mantling the walls of ancient mansions with its noble Laurel-like leaves and gigantic white flowers. It is the only species of Magnolia which is evergreen. It perhaps grows best in cool, shady places where the soil is loose and fertile. The growth is slower in the north than in the south and more southerly midland districts. The specimens found in Scotland are generally small and stunted. M. grandiflora is one of those shrubs which have a bad name because of the baneful emanations proceeding from them. As we have stated, its large white flowers emit a powerful fragrance. When wafted to a distance upon the air the scent is delicious, but when inhaled in the immediate neighbourhood of a group of Magnolias in flower it becomes overpowering. The Indians carefully avoid sleeping under a Magnolia in blossom, and it is stated that so powerful is the perfume of the flowers, that a single blossom placed in a bedroom is very injurious.

M. glauca (the Beaverwood of North America, the Magnolia of the swamps of New Jersey and the South) grows rather in the form of a large bush than a tree, with shining green leaves, 4 inches or 5 inches long, somewhat mealy or glaucous beneath. The blossoms, about 3 inches broad, are snowy white, and so fragrant that it is

said, where they abound in the swamps, the perfume is often perceptible for the distance of a quarter of a mile.

Of the Asiatic Magnolias, M. conspicua (the Yulan or Chinese white Magnolia) heads the list. This species is said to have been first cultivated in China as remote as the year 627, and has ever since that time held the first rank as an ornamental tree in Chinese gardens. In its native country, when fully grown, it attains the height of 30 feet and 40 feet; it also attains a good size in this country. The largest plant in Great Britain, fifty years ago, when it was measured by the late Mr. Loudon, was 27 feet high, and had at that time open 5000 blossoms. It would probably not be very difficult to match this tree in the present day. M. conspicua assumes a somewhat conical shape, with numerous branches and twigs, and the flowers, which are milk-white, expand before the leaves in April and May. It blossoms when only 2 feet or 3 feet high, and grows so well as to reach the height of 10 feet in six or eight years. Unfortunately, M. conspicua is liable to have its vernal beauty impaired by the late spring frosts that are so common to this country. It is a perfectly hardy species, standing a temperature of 25° below zero without the least injury. It grows readily, preferring a deep, rich, mellow soil, in a rather dry locality, and while quite small, if in a bleak place, may be protected, but as soon as well established it needs no more care than the hardiest shrub. It should find a place in every garden commensurate with its requirements.

M. purpurea, the Chinese purple Magnolia, a smaller growing species than M. conspicua, is found in China and Japan, and was introduced to England about 1790. When full grown it reaches a height of about 10 feet; the stems are numerous, not much branched; leaves large deep green; flowers large, purple on the outside of the petals, and nearly white within, the contrast of the two colours rendering them peculiarly beautiful; it flowers early. It should have a light, rich earth to grow in, and a dry subsoil, in which it proves quite hardy and a highly ornamental plant.

M. Soulangeana (Soulange's Magnolia) is said to be a hybrid between the two foregoing, and was raised at Froment, near Paris, by the late Chevalier Soulange Bodin. It so closely resembles M. conspicua when not in flower, that it is difficult to distinguish it; its flowers differ in being slightly tinged with purple. It is a fine shrub, and well deserving attention. M. Lenné is regarded as a fine, large, dark-flowered variety of M. conspicua by some, by others as a variety of M. purpurea, with larger blossoms; by others again it is believed to be a hybrid between M. conspicua and M. purpurea.

M. Campbelli is an arborescent species from the Himalayan Mountains, with magnificent foliage and flowers, with red petals, and larger than those of M. grandiflora. It was introduced in 1870, but is yet somewhat rare in gardens, and in all probability its hardiness has not been thoroughly tested.

Generally, it may be stated, that in order to thrive well, Magnolias require a deep, rich soil, which, in nearly all cases to secure their luxuriance, should be improved by adding thereto some leaf-mould or decayed vegetable matter from the woods. When transplanted from the nursery, they should be preferred of small, or only moderate size, as their succulent roots are easily injured, and they recover slowly when large. As lawn trees, their large and striking flowers and rich summer garniture of luxuriant foliage make them superb objects. If possible, situations somewhat sheltered either by buildings or other trees should be chosen for all the species, though acuminata will thrive in almost any aspect not directly open to violent gales of wind. W.

Conifers at Berkhampstead.—Among other Conifers to be seen in Lane's nursery are some Araucarias from seed produced in the nursery. They appear equally as vigorous as plants obtained from seeds imported from their native country; indeed, they may in all probability be found to withstand the variations in our climate even better than plants from foreign seeds. Thujopsis dolabrata, its variegated form, and the variety lætevirens are somewhat slow in growth everywhere; but if, as here, the situation is slightly sheltered and the soil good retentive loam, they soon become mature ornamental specimens. Cryptomeria elegans, another handsome Conifer, is now assuming its beautiful autumn tint. The Parasol Pine (Sciadopitys verticillata), although ultimately attaining a height of 100 feet, is perhaps the most distinct member of the Japanese Conifers; it is extremely handsome in a young state, and does not rapidly become too large for gardens of small dimensions. The larger growing members of this Order are represented by many handsome specimens, the soil and situation apparently suiting them admirably. —W. H. G.

Kitchen Garden.

GARDEN BEETS.

I was surprised to find the other day our old acquaintance, Dell's Crimson, brought out again as a new variety. How many diverse appellations this excellent sort has had given to it during the last twenty years it would be hard to say. That selection of any kind can do much to keep a stock pure and good is well known, and such stock is entitled to due honour if it be kept carefully selected; but its purity does not justify the appellation of Exhibition, Perfection, Superb, or some other exceedingly laudatory term, which may be just enough, but is still wrong, because it is not a new variety. My attention was first drawn to Dell's Crimson Beet in a garden in Hampshire full twenty years since. The stock was a remarkably good one, and its true or original name was not known, but it was being sent out by a local seedsman under some other designation. The stock then being well cared for was as good as the best of to-day, and I do not think that, whilst selection has kept it true, it has done anything more. That the kind owes very much to the beauty and rich dark metallic hue of its foliage there can be no doubt. It was this feature which years back gave it such prominence as a ribbon-border plant, and, without doubt, those partial to that style of decorative gardening find it hard to beat its outdoor foliage effects. The leafage is on strong roots, from 12 inches to 14 inches in height, and the leaf-surface is about 6 inches or a little more in length, and very elegantly reflexed or drooping. In small plants the rich dark hue is not found so readily as in larger ones, but those who wish to find this Beet true and deep coloured should raise some plants under glass, and when strong enough dibble them out where they are needed to grow. Not only is a perfectly even line of plants thus secured, but the coloration is even throughout the season. The comparatively hardy nature of Beet is one recommendation for its use in the flower garden, because it will remain effective a long time after Coleus plants have disappeared. Very pleasing effects are often obtained in kitchen gardens by sowing Crimson Beet and Carrots in alternate lines, as the Carrot foliage, if but green, is still very light and graceful. Whilst the colour of the flesh of Dell's Crimson is of a deep violet-purple, that of the old Pine-apple—the most widely grown kind for the London market—is of a rich blood-red, or really crimson, and the roots, as a rule, are rather larger than those of the preceding kind. The tops, however, lack that effective habit which the other possesses, as in the Pine-apple they are almost flat and spreading. The foliage is pointed and of a reddish hue, though usually green early in the season. For market purposes colour goes for so much, that the handsomest Beet in the world would not be acceptable unless the roots gave the desired deep crimson colour. It does not at all follow that crimson-hued roots are softer or better flavoured than purple ones, but the colour is that which gives the most general satisfaction. A very distinct and handsome kind is the Covent Garden. A well-selected stock shows good-sized, handsome tapering roots of a very rich crimson hue, tender, and good flavoured. The foliage is comparatively dwarf, the leaves evenly placed, and of a very pleasing reddish maroon colour. The leaf surfaces are shortish, almost rounded, and somewhat abruptly fashioned. The stock of this kind does not appear to be largely known, but it seems to be first rate, and if it can escape the general tendency on the part of seedsmen to re-christen Beets, it will probably have a long life as the Selected Covent Garden. Very good reputations have been enjoyed by Beets under the various designations Dewar's Dark Red, Cattell's Dwarf, Nutting's Dwarf Red, &c., but it is doubtful whether we have more than half a dozen really distinct good garden sorts with tapering roots, and if they are good, that number is ample. The Turnip-rooted kind is too distinct to be otherwise named, and it is useful enough for very early use, but otherwise it will not be widely grown. Form or beauty in Beet very materially depends upon soil, but something is due also to time of sowing, because to produce clean tapering roots quick growth is essential. If the seed be sown too early, the plants often become set or stagnant in their youthful stage, and then fork or produce side or lateral roots when renewed growth ensues. As a rule, the last week in April or early in May is quite early enough for Beet sowing, as from that time onward growth is more even and rapid. It will, however, be noticed that very often more growth is made by the roots in the cool autumn than during the hot summer. It is an undoubted advantage that with this root-growth continuing so late in good soil even very late sowings often produce fine handsome roots. Seed should be selected before sowing, the smallest being thrown away. Thin sowing in drills 15 inches apart is better than thick sowing with much smaller seed; and should there be vacancies, plants will transplant admirably if ordinary care be taken. A. D.

Mushrooms have been unusually scarce with us in this neighbourhood during the present autumn. What we have had, however, were of exceptionally large size; one was brought in to me last evening, from a field close at hand, which measured 10 inches in diameter, 2 feet 5 inches in circumference and weighed 1 lb. 1 oz.; it was a true Agaricus campestris in perfect condition. I may remark that in the first week of this month Mushrooms were profusely abundant in the fields around Spa, in Belgium, but were uniformly of extremely small size.—R. Milne-Redhead, *Holden Clough, Bolton-by-Bowland, Clitheroe.*

Lettuces in frames.—The time when good Lettuces are usually scarce is in February and March, and the Brown Cos, though hardy and excellent, is notoriously slow in turning in in spring, unless artificial heat can be employed to induce it to do so. And even then if warmth can be supplied, other kinds, such as the Paris Market and Tom Thumb, will turn into use much quicker. Considering the requirements of even moderate establishments, but few gardens are so well supplied with movable glass frames as they should be to make the most of things. Tom Thumb Lettuces set out now in glazed frames become very useful in February, and the Brown Cos might be planted for succession. If planted in the warm soil from which Melons and Cucumbers have just been removed, an impetus will be given them that will be useful, as there is no time now to be lost in the matter. The Tom Thumb should be planted 6 inches apart and Brown Cos 10 inches. The soil must be moistened when necessary, and frequently stirred between the plants during winter.—E.

Field market crops.—The very delightful weather experienced during the past few weeks has proved somewhat detrimental to green crops and Turnips, the latter in many places suffering greatly from the attacks of aphis; indeed, I have seen one big patch of some two acres literally cleared of every plant, the foliage being entirely eaten up by this pest. The Turnip beetle has not been troublesome appreciably, but, in addition to the attacks of aphis, drought is again telling upon the plants. We have had either hot days, or, if cold, attended with dry, cold winds, and almost always with clear, cold nights. These have not been at all favourable to growth, and Turnips are not good if not quickly grown. With respect to Broccoli, and especially Autumn Giant

Cauliflowers, aphis is unusually abundant, and heavy rains are sadly needed to wash the plants. Caterpillars have also arisen in great abundance; they suddenly spring up as it were in a day, the first evidence of their presence perhaps being a patch of plants almost denuded of leaves. In large breadths of several acres it is evident much harm may be done before such insects' ravages are discovered or checked. Their presence, too, in ever so slight a degree in any of the Cabbage tribe is not only very objectionable but detrimental to sale; as it is, no doubt all kinds of field greens will be very cheap, and in spite of the dry weather such seems to be the fate of Runner Beans, for I have recently heard of growers bringing back many bushels from market and throwing them upon the manure heap, simply because no offer was made for them. It is not merely in fruit that the market is glutted; the same thing exists with regard to common vegetables, and growers are being driven to their wits' ends to know what to do under such adverse circumstances.—A. D.

NEW KINDS OF POTATOES.

Judging by the number of new or seedling kinds of Potatoes grown at Chiswick this year, and also by the fact that several certificates of merit have already been awarded to selected kinds, it is evident that raisers are not checked in their interesting work by any coldness with which new kinds are sometimes regarded. Very probably one-half the gardeners in the kingdom know little about the numerous kinds which the enterprise of raisers has put into commerce. We have finer and more prolific Potatoes now than were dreamed of twenty years ago, and these fine kinds may be materially excelled twenty years hence. None are perfect, though all are good, and in all there is room for some improvement or other. What is almost an evil in one sense has grown out of this wealth of fine and prolific kinds. Potatoes are a great crop and wondrously cheap; indeed, it would seem, judging by the past few years' experience, that we shall never know what a Potato famine is again. The sudden appearance of the disease-spots in the tops, and which spread with such rapidity in many places as to literally sweep off entire breadths of haulm in a short time, seems now to have been checked, and where growths have been only partially hit or escaped, there is still luxuriance and comparative health. Tubers have not been materially injured, the worst evidence of disease, as usual, being found in strong-manured soils; but on the whole so far, disease in the tuber is but partial and trifling. Thus we have a great prospect again this year of a heavy crop, considerable size in the tubers, and, having regard to the comparative dryness of the soil, quality should be excellent. Under the circumstances it does seem as if Potato raising was hardly a promising occupation, but past successes rather more than present prospects seem to stimulate efforts in the development of new kinds. Certainly raisers who produce their score or even hundred seedlings every year can and do say that even if all turn out indifferent, none are wasted, as they can be eaten, and that fact encourages many to continue. Again, any new kind—and to be worth preserving it must be very prolific—is rapidly increased. The seed of the spring will perhaps give two pounds of tubers the same year, thirty pounds perhaps the second season, and the next year perhaps three or four bushels, or more, so that in a very short period a big stock is obtained. If any kind does not increase rapidly it is of doubtful value, except in the case of very early ones. The raising of what may be termed natural seedlings is sheer waste of time, and those who purpose producing seedlings should effect their own crosses if they are to aim at some special result, and also find special pleasure in their labours.

It will be remarked that all the kinds certificated the other day at Chiswick were white ones. No doubt, for general purposes, white kinds are the most popular, but we should be sorry to see colour totally eliminated from Potatoes, for many, in addition to capital quality, have great beauty, not only in form, but in colour also. A couple of handsome flattish oval rounds, white of skin, and having in the one case carmine, and in the other purple blotches or markings, give not only distinctness but beauty, great crops, and fine quality. These certainly are worthy of praise. A well selected collection of twenty-four dishes of tubers is quite a picture, and unquestionably beautiful. Because beautiful, certain people decry table quality, but that is absurd. The very same kinds under widely different circumstances and in some other soils might be rough-skinned enough, and not be a whit superior in quality. In spite of criticisms, enthusiastic Potato raisers will still go on producing new kinds in plenty. A. D.

Ceropegia elegans. Flowers white, blotched with brown.

SHORT NOTE.—KITCHEN.

Peas in America.—An American paper states that of all the sorts of Peas of recent introduction, Carter's Stratagem, Sharp's Early Paragon, and Invincible are the best. Stratagem is described as a new green wrinkled Pea of great merit, and probably the handsomest and most productive of its class. It grows about 2 feet in height, and bears immense pods, filled with Peas of the largest size, of the finest quality for the table. This variety has invariably taken the first prize during the season whenever it has been put in competition.

INDOOR GARDEN.

CEROPEGIAS AND THEIR CULTURE.

The plants belonging to this genus are for the most part small-growing, slender climbers, with tuberous roots. They have a beauty peculiarly their own, but are not frequently found in cultivation, except in gardens where large collections of plants are maintained; this is much to be regretted, as they form charming ornaments, and are excellent companions for the smaller kinds of Aristolochia, such as A. ridicula and A. elegans, recently noticed in The Garden.

These curious and remarkable plants usually inhabit rough, stony ground, and scramble amongst the low bushes which are to be found near them. We have found them to be very effective when allowed to grow amongst sprays of Birch or other twigs; these their branches overgrow and festoon in a very pleasing manner, and the flowers show themselves to the best advantage when thus allowed freedom of growth. For soil we have found a mixture of about two parts loam to one of peat, with the addition of some sharp sand and broken brick rubbish, to suit them admirably. The temperature of an intermediate house is sufficient for their development, but they enjoy full exposure to sun and light.

The genus contains a great number of species, some of which do not recommend themselves to the horiculturist; the kinds which we enumerate, however, are all distinct and well deserving attention; we have grown handsome specimens of them under the conditions here given. C. Gardneri, from Ceylon, is an elegant twining plant, with stems slightly stouter than a wheat straw; the opposite leaves are borne upon short footstalks, and are between 3 inches and 4 inches long, sharply lanceolate in shape, deep green on the upper side, tinged with slaty purple beneath. The flowers grow in small clusters upon short footstalks, which spring from the base of the leaves, and are about 2 inches long; they are tubular, slightly swollen at the base, with a narrow neck, and a large spreading five-lobed limb; these, just before opening, bear a strong resemblance to an open flower of a Stapelia, but when open these lobes remain joined at their points. A good idea of their appearance may be gleaned from the accompanying figure. The flowers are creamy-white, spotted all over with brownish purple like a cheetah; the edges of the lobes are fringed with numerous small hairs which turn inwards. It blooms during the greater part of the summer. C. vincæfolia, from Western India, is a more robust plant than the preceding; otherwise it resembles it in general appearance. The tube of the corolla is narrow in the middle, creamy white freckled and dotted with crimson, base of the lobes green; the limb is reflexed, not jointed in the edges, and dull purple in colour. It blooms during late summer and through the autumn months. C. Bowkeri, from Caffraria, can scarcely be called a climber, although it delights to grow through and about twiggy brushwood. The stems are very slender, furnished with narrowly-linear, opposite leaves some 3 inches in length, and pale green in colour. Flowers mostly solitary, borne upon short foot-stalks; tube of corolla narrow in the middle, brownish purple within; the lobes of the corolla are free, longer than the tube, and reflexed; ground colour yellowish green, over which are numerous blisters of emerald green, the edges being ornamented with short hairs. It is a summer bloomer. C. elegans is a plant which much resembles Gardneri in size and habit. The flowers, although similar in shape, are somewhat smaller; they are also more in-

flated at the base. The neck, which is very narrow, is blackish purple; the limb is united at the edges of the lobes, where they are fringed with long black erect hairs. Corolla blackish purple, blotched and spotted with creamy yellow; inside it is sparingly dotted with purple. It comes from the Madras hills, and flowers during summer. C. sororia is a South African species from Caffraria. It has a slender twining stem bearing very narrow leaves, which are some 5 inches or 6 inches long, deep green on the upper side, paler and slightly glaucous beneath. Flowers solitary, on long foot-stalks; tube tapering upwards from the base, pale green, dotted with red towards the upper part; lobes of the corolla reflexed and free, about an inch long above, deep green transversely barred with purplish black, the under side of a uniform soft rosy mauve. It blooms during summer and early autumn. C. Cumingiana is a robust plant for a member of this family, with dark green egg-shaped leaves, which taper to a long point. The flowers are borne five or ten together and are funnel-shaped, the lobes not puffed out as in Gardneri, tube creamy white, the corolla dull brown tinged with red, the lobes joined at the edges, but destitute of hairs. It comes from Java and Luzon, and blooms during the autumn months. C. Sandersoni is also a robust plant, with a similar habit to the preceding, but is a native of Natal. The flowers are some 2 inches long, and are produced throughout the summer months; tube swollen at the base, with a contracted neck and spreading corolla; the lobes are joined at the edges and puffed outwards, forming a parasol-like covering to the mouth of the tube; ground colour yellowish green spotted with bright green, fringed at the edges with short erect hairs. W. H. G.

WINTER-FLOWERING PLANTS.

Eucharis amazonica.—This may be said to flower at no particular season; well-established plants of it will flower freely once during winter and again in spring, and where many are cultivated a few blooms are usually available at almost any time of the year. About four years ago we had a wretched stock of this lovely bulbous plant, and were thankful to obtain from them a few odd flower-spikes at rather wide intervals. At present we have an house full of healthy plants, some in large and some in small pots, and from these we obtain three good crops of strong blooms without any extra efforts on our part. The bulk of the plants are now pushing up more bloom than they ever have done before, though unfortunately this is a month earlier than they are required, but it is almost needless to add Eucharises are welcome whenever they are forthcoming. What we have achieved anyone else similarly situated may easily do. According to my experience, Eucharises when in bad health are not quickly recovered, and, on the other hand, healthy, well-rooted plants will stand a large amount of rough treatment before they eventually give signs of being injured. Half the instances cited of failures owing to the attacks of the Eucharis mite are really the result of bad treatment, arising from being left too long in a cool house for the purpose of resting them, and following it up by a sudden change to strong heat. Thus treated they will perhaps bloom strongly, but the roots may have perished, and a plentiful supply of water, as well as strong liquid manure, usually given during the flowering time effectually completes the work of destruction. Hotbeds have also much to answer for in the case of this plant; these, if excessively hot, cook the roots, and render them unfit to withstand rough treatment of any kind. The stock of plants found here were plunged in a hotbed, or what had been one, for the heating material was quite rotten, and so also were the roots of the Eucharis. My first thought on seeing these sickly-looking plants was that they were suffering from Eucharis mite. There were insects on the roots, as there usually are on almost any decaying matter, and had I been so disposed we might easily have credited ourselves with effecting a cure. There is, however, no cure for Eucharis mite. Our plants were sickly, owing to their having lost their roots, and a mass of sour soil surrounding the bulbs was not likely to induce the formation of fresh ones.

The best remedy in our case, and in any similar case, is to at once shake the bulbs clear of the soil. This may be done now, or any other time of the year; then repot in good fresh compost. If it is desirable to largely increase the stock then one strong bulb is sufficient for a 4½-inch pot, and three smaller bulbs should go in the same sized pot, but if bulbs be plentiful about six should go to a 9-inch pot. Some place a great number of bulbs in much larger pots, but, according to my experience, they become established more readily in smaller sizes, and can then be shifted gradually into larger pots. The pots in every case should be quite clean and well drained; we have had Eucharises do well in small pots without any drainage at all, but it was only for a time, as an overdose of water afterwards destroyed many of their roots. They require, when in good health, plenty of water, but it should pass away freely. If good fibrous loam is available, this should be broken up roughly, and be used at the rate of two parts to one of good leaf soil and decayed manure, with plenty of sharp sand and a sprinkling of charcoal. Our loam being of a heavy character and comparatively fibreless, we employ less of it, that is to say, at the rate of one half of the heap, and substitute one part good fibrous peat. A little bone meal, or even half-inch bones may be added to the compost with advantage, and a surface-sprinkling or top-dressing of bone-meal produced a marked improvement in the appearance of some of the weakest pots which we have. Washing the half-dead roots is of little use; we are content to pot them without that attention, the bulbs being imbedded in sand, and about three-parts buried in the well-firmed soil. Bulbs thus treated, whether for increasing the stock, or for rendering healthier, should be returned to an ordinary stove temperature. They should be very carefully watered till such times as they are well rooted, and should be carefully shaded from bright sunshine. The check sustained not unfrequently causes the stronger bulbs to throw up a flower-stem, but if the bulbs are not in good health, they ought not to be allowed to expend their remaining vigour on perfecting flowers; their removal would certainly expedite recovery. Single bulbs soon form suckers, and if when the pots are well filled with roots, and before they are root-bound, they are shifted into 8-inch pots, a strong clump of bulbs will be quickly obtained. We quite recently shifted a number into 8 inch pots, and already the fresh soil is occupied with roots. This fact further tends to confirm me in the idea that autumn is the best time in which to repot Eucharises. At one time we exposed our plants to too much sunshine, and the leaves were thin and flabby in consequence, but now we shade rather heavily in hot, clear weather with the best of results. Although Eucharises cannot stand sunshine, they delight in plenty of heat and a moist atmosphere during summer. For two seasons no air has been admitted through the ventilators, and with shade and frequent overhead syringings, the walls, staging, and floors being well damped at the same time, their progress is far more satisfactory than when treated in more orthodox fashion. It is the usual practice with many cultivators to either transfer the plants to a cool house or pit, giving much less water at the same time, or else to keep them where they always are, but giving them very little water, this being done for about six weeks. A sudden transition to heat and moisture, or a change to moisture at the roots only, has the effect, as I have just stated, of causing many of the bulbs to flower, and in this manner they can be timed to bloom at a time when their blossoms are most wanted. This system may be advisable, and doubtless answers well in the case of bulbs grown principally on hotbeds or even standing on a moist bottom, especially if at all crowded, but ours flower periodically and without any peculiar treatment in the way of resting. Nor are we at all singular in this respect, and it is my firm belief that it is not those experimental cultivators that secure the most bloom in a year. Let the plants never suffer from want of water, and if they are not often repotted they ought to receive frequent supplies of moderately strong liquid manure at blooming and at all other times. Without this aid they cannot reasonably be expected to flower strongly so many times in a year. Of the various uses to which Eucharis blooms are put but little need be said, as nearly everyone knows that they are invaluable for bouquets, wreaths, crosses, for dinner-table decoration, and for ladies to wear. For a button-hole the smaller flowers of Eucharis candida are preferable to those of amazonica.

Dipladenia boliviensis.—Although not so showy as the rest of the Dipladenias, this may be said to be the most generally useful, as it can be successfully cultivated in positions unsuited to the choicer varieties, and by those who cannot succeed with them. It is also the most continuous flowering; in fact, in well-heated stoves there is no reason why a few or many blooms cannot be had at any time of the year. It is strictly evergreen, and anything in the shape of drying off ought not to be attempted, though it should be understood that much less water is required during the winter months; nor do they require much pot room, a 10-inch pot being capable of holding sufficient soil to support quite a large plant. Ours receive a shift each spring, and good fibrous peat, with sand, crocks, and charcoal added, suits them. If extra good fibrous loam is available, equal parts of this and peat answer well, but, unless the loam is really good—that is to say, full of fibre and not clayey—it is advisable to dispense with it entirely. What is wanted is a pot full of roots and plenty of water, and frequent supplies of liquid manure can then be given with safety. In the autumn a top-dressing of rough peat and a sprinkling of bone-meal prove beneficial, keeping the roots active in a position where the genial atmosphere of the house is bound to reach and assist them. Unlike the other Dipladenias, this variety will bloom freely at a considerable distance from the glass. We have plants rooting in 9 inch pots that are trained up the iron supports of the roof of a plant stove, and here they bloom well during the summer, in spite of the shade afforded by a Stephanotis overhead. In the autumn, when the latter ceases to bloom, the Dipladenias are encouraged to ramble among it, and here they seem particularly happy. If a single plant is trained to one wire across the house, it soon becomes remarkably showy, as the main growth or growths push out lateral flowering shoots throughout the whole length of the plant. This will be found a better plan than training the growths in a random fashion over the roof trellis. It also succeeds admirably when planted out in a well-prepared, narrow border and trained up the back wall, and I have seen a whole thicket of lovely wreaths hanging from the back portion of a three-quarter span-roofed plant stove. Mealy bug is its greatest enemy, and if this is attacked with any insecticide strong enough to kill it, much harm will also be done to the Dipladenia. A pointed stick, a sponge, and soapy water are the best remedy, but this must be persevered with or the plants will never be clean. I have frequently used the blooms in bouquets and wreaths, and they can also be mounted and several blooms be formed into a spray for a lady, and on the whole they are more durable than their appearance would suggest.

Allamandas.—These are not usually classed as winter-flowering plants, but in many places they are kept in bloom till mid-winter and sometimes later. It is not the half-starved pot plants that are so continuous flowering, but the much more vigorous examples rooted in small borders. The leading branches of these if kept thinly trained, all superfluous growth being removed as fast as it is formed, produce strong flowering spikes, and

these continue to lengthen till some of them are 2 feet long and upwards, and it is the final flowers that we get during the early part of the winter. For some time much less water is given at the roots, the plants in reality being gradually ripened, though this does not interfere with the blooming, and by the time the last flowers are gathered there is no reason why pruning should not be completed. A. Hendersoni is our favourite variety. W. I. M.

PLANTS FOR COOL HOUSES.

Owners of gardens in which heated structures are plentiful find little difficulty in getting abundance of flowers at mid-winter; but those who have only cool houses have to be more careful in their selection of flowers to grow in quantity. It is useless, under such circumstances, trying to get plants to bloom during the darkest period of the year that require artificial heat to enable them to do so. There are, however, some striking exceptions to the list of heat-loving plants. First on the list may be named the Chrysanthemums, a host in themselves. Coming as they do into bloom at the very time when outdoor gardens are looking most dreary, they only need the protection of a glass roof to flower them in the greatest perfection, and by growing the latest blooming section, of which Meg Merrilies and Ethel are types, to succeed the ordinary show kinds, a succession may be kept up till Christmas, and even later. Schizostylis coccinea is also a real gem for cool house decoration; its value, indeed, has not yet been fully realised. It begins to send up its brilliant spikes of scarlet flowers in October, and continues to produce them for months together. Last season we lifted a quantity of this plant from the open ground in October, and planted them in an inside Vine border, where they continued to flower the whole winter through. They were planted out again in March under the partial shade of fruit trees, and they are now producing spikes of bloom that promise to be exceptionally fine and plentiful; they also make excellent pot plants. Iris reticulata, which is one of the winter-flowering bulbs that has of late deservedly attracted attention, has a great future in store for it, its blooms being of the most lovely purple imaginable, prettily streaked with orange, a fitting companion for the most costly Orchid. If potted in August or September, it will be in full bloom in January. We put three bulbs in 4-inch pots, and five bulbs in 6-inch pots, and very pretty plants they make. Veronica Andersoni only needs the protection of glass to insure its flowering freely throughout the winter months; plants of it are now covered with flower-spikes in various stages of growth. If fully exposed, they soon present a weather-beaten appearance; but under glass they continue to produce their purple blossoms for months in succession. The common Christmas Rose and its varieties, although often in bloom in the open air during the most inclement seasons, are nevertheless vastly improved by being under glass, as alternate frosts and thaws spoil the purity of their flowers, for which they are justly prized. The Laurustinus flowers profusely enough in the open air on the south coast during winter, but it is at the same time a really good cold-house plant, its blooms being much whiter and expanding much more fully under glass than out of doors. Dwarf standards, with heads covered with snowy clusters of bloom, are by no means unattractive plants in cool houses. Cape Heaths, too, in great variety are specially suited for cold-house decoration. Erica hyemalis and others of that type dislike fire-heat in any shape, and are much more lasting in cold than in hot houses. Many other equally useful plants might be mentioned, but the above cannot fail to give satisfaction. J. G.

Tuberoses.—I have grown these for several years without heat, as follows: In March I get some boxes about 1 foot wide, and 2 feet long, and 5 inches deep. I bore some holes in the bottom, which I cover with turfy soil broken into pieces about the size of an Apple; I then fill up the boxes with soil, and into this I put the bulbs about 3 inches apart, covering them over with soil. They are then placed in a cold frame and given no water until they have shown signs of growth, when they get some, and their supply is increased according to the amount of growth which they make. Thus treated they always flower well. This year I have had some of the boxes outside in a north aspect, and the Tuberoses are now flowering as finely as those which I get in May in heat. I have one box planted in July just starting; this I shall put in a warm house in November, in order to get a few flowers at Christmas. The compost which I use is two parts turfy loam, one of leaf-soil, one of road grit. The little attention which Tuberoses require and the reasonable price at which dry bulbs of them may be bought place them within the reach of all who love sweet-scented flowers. I might add that I bring the boxes into a cold house when the buds appear on the spikes, to open the flowers and protect them from rain. Treated in this way anyone may grow Tuberoses.—B. Phillips, *Ludgrove, Barnet.*

JAPAN LILIES IN POTS.

The different varieties of Lilium speciosum are among the best of Lilies for pot culture; they retain their foliage well under this mode of treatment, which is not the case with all Lilies, and, besides, they flower at a time when the choice of plants for greenhouse or conservatory decoration is but limited. These Lilies may be cultivated in pots with very little trouble. When growth commences, they may be plunged in the open ground and allowed to remain there till the blooms are on the point of expanding, when they must be taken under cover. Where large specimens are grown (that is to say, a number of bulbs in one pot), they must not be exposed to heavy rains in the early part of the season before the pots get filled with roots, as the soil will become saturated, and the plants suffer in consequence. For general purposes a good way is to pot the bulbs singly in 6-inch pots, as when in bloom they can be readily shifted about when required, and the flowers under this treatment are equally fine as those whose rooting space is not so restricted. We grow a considerable quantity for decorative purposes in this way. When the bulbs are received they are laid on an outside border and just covered with some sandy soil; then as the roots at the base commence to push freely they are potted, using for the purpose a soil composed of loam, well decayed manure, and sand. The bulbs must be kept well down, so as to leave a space at the top for some additional soil later in the season, when the stem-roots develop themselves. After potting, they should be placed on a bed of ashes and covered to a depth of 3 inches or 4 inches with the same material; then, just as the tops are about to start through the soil, the covering should be removed, and the pots plunged in a bed in the open ground, where they will remain till the flowers are on the point of expanding. A little care will be needed in removing the covering, as, if allowed to remain till the shoots make their appearance above ground, they will be blanched, and consequently must be protected, or are liable to fall a prey to frost; while, if exposed before the tops are above ground, they then push away sturdily from the first, and resist the cold better.

By growing them in this manner, not only is the glass at liberty for other things in spring, but the Lilies are rather later in flowering, and are consequently more useful, unless required earlier for some particular purpose. During summer all the attention needed will be to water when necessary, and as the pots get full of roots a top-dressing will be of advantage. As the buds make their appearance, a little manure water about once a week will increase the size of the blooms. In a general way they are not attacked by insect pests, but occasionally a few aphides make their appearance. These can, however, be easily got rid of by syringing with Tobacco water. As the stems increase in height, a few may need some support; and if such is the case, the stick must not be put in too close to the stem, as, if that is done, the probability is that the bulb will be injured. The varieties of Lilium speciosum announced in various catalogues are very numerous; but in reality the difference between some of them is so slight, that they are to all intents and purposes one and the same thing. For instance, the varieties roseum and rubrum, as imported from Holland, are usually both alike, and in some of the others it is impossible to tell where one begins and the other ends. Of white flowers we have album, album corymbiflorum, and Krætzeri, the latter being a Lily that has had a good deal of attention directed to it of late years. The flower-stems of this variety are green, and the outside of the bloom before expansion suffused with the same colour. The blossoms are elegantly reflexed, and a distinct greenish stripe down the centre of each petal is characteristic of this variety. In album the flower-stems are of a brownish hue, and the buds slightly tinged with the same colour. The flower has not the pleasing reflex of that of Krætzeri, while the whole contour of the plant is stiffer and less graceful. In album corymbiflorum the blooms are collected into a clustered head, but it is only worth growing as a curiosity. A distinct variety is punctatum, the blooms of which are white, or faintly suffused with blush, and studded with pink dots. Of deeper coloured flowers there is a long array of names, including roseum, rubrum, purpureum, cruentum, Schrymakersi, superbum, and rubrum corymbiflorum; while Melpomene, the supposed American hybrid between L. speciosum and auratum, is at all events, as generally met with in this country, only a good dark form of L. speciosum, for neither in foliage, flower, nor bulb does it suggest any relationship to L. auratum. Apart from the supplies of this Lily that are obtained from Holland, considerable importations reach this country from Japan, and occasionally amongst them are to be found some of the finest forms of L. speciosum that it has been my good fortune to see. The deepest coloured, as far as my experience goes, are characterised by good stout foliage, rather rounder than that of any of the other kinds, and very dark stems—indeed, a sort of reddish mahogany hue—and fine bold blooms. The distinguishing characters of the varieties roseum and rubrum are, that in roseum the stems and flower-stalks are green, while in rubrum they are of a reddish brown tint; but as above noticed, the two names are, generally speaking, used indiscriminately. Schrymakersi is a very good form of roseum, while purpureum, cruentum, and superbum all bear a near resemblance to rubrum. To rubrum corymbiflorum the same remarks apply as to the clustered form of album.

It will thus be seen that a selection of a few varieties will give greater satisfaction than if a long list of so-called kinds is grown. For myself, I am quite content with Krætzeri as a white, Schrymakersi as representing the best type of roseum, a good dark kind the same as that usually grown as Melpomene, and a few of punctatum, it being a distinct, but not very showy variety. I cannot help thinking (and that opinion is shared my many to whom I have spoken on the subject) that of late years a very inferior form of L. speciosum is imported into this country much more frequently than was the case some years ago. T.

Lifting and potting Chrysanthemums.—Many are of opinion that autumn and winter flowering Chrysanthemums succeed best when planted out-of-doors in summer, besides saving labour in watering in hot weather, which is certainly an advantage in the case of planted-out specimens. Where they have been planted out in this way, the time has now come when they should be lifted and potted. If this operation is delayed too long, or until the flower buds have almost opened, the blossoms are sure to be checked, and will not be first-rate. It is the danger of experiencing this check that causes us to retain our best kinds in pots, but if carefully lifted they will not suffer much. The ball of soil moved with the roots should be as large as can be got, and the roots should not be cut or beaten about in any way. At the same time superfluous soil should not be lifted with them, as a compact ball of roots only is wanted. The pots should always be sufficiently large to hold the roots easily, and some good rich sandy

soil should be rammed round them when put into the pots. They should also be staked and tied up firmly, and watered thoroughly immediately after potting. They must also be shaded for a week or ten days, and kept rather close until they have caught hold of the new soil. If they droop much they should be syringed daily; but care must be taken that this is not overdone, or the bloom buds may damp off in consequence. In cases where the balls of roots are very large, it may be most convenient to place them in boxes of various sizes, which answer the purpose just as well as pots.—CAMBRIAN.

Camellias as stove plants.—I see that "Hortus" takes exception to my note upon Camellias grown as stove plants at Beddington House, Surrey. I have watched these plants for several years, fully expecting that their end would speedily come, but, to my astonishment, they still continue not only to live, but to flourish and bloom annually in the most profuse manner. This, as far as my memory serves me, is the only time I have seen Camellias thrive under such conditions. The wall against which they are trained is 30 feet long and 10 feet high, and is quite covered with Camellias. The plants were put into the border about twelve years ago, and it is about seven years since the house was converted from a greenhouse to a stove. Flowers of all sorts are largely in request at this establishment for church decoration at Christmas, and the Camellias under stove treatment can always be depended upon for a supply at that season.—W. H. G.

Bouvardias in autumn and winter.—What Ixoras are in summer, Bouvardias are in autumn and winter, and the form of their flowers is not unlike that of an Ixora, while their blooms are equally attractive. Bouvardias make most effective pot plants, and as subjects for supplying cut flowers they are almost unique. Their blossoms are admirably adapted for button-hole bouquets, and also for all kinds of vase decoration of the choicest kind. In short, it is impossible to over-estimate their value, and, as they are produced freely in autumn and winter, this is another point greatly in their favour. We have grown quantities of Bouvardias for many years, and nothing could surpass them in usefulness. Some growers plant them out in summer and lift and pot them in the autumn, but I never found this plan to possess any advantage over that of constantly growing them in pots, which is what we practise. They will, however, succeed very well indeed in a cool frame in summer, and when grown in this and well exposed to the sun, they invariably bloom well in autumn and winter. They are not quite greenhouse plants in winter, nor yet are they wholly stove subjects; an intermediate temperature suits them nicely. The whole of them should now be moved into an intermediate house—*i.e.*, if still in frames or in any other cool place. The backward buds, in a temperature of from 60° to 65°, will soon open, and, as these fall off or wither, fresh shoots will be produced, and these will bring forth a new crop of flowers. They require to be freely watered at the root, and a damp atmosphere does not disagree with them, but a close atmosphere does not suit them at all, and must be avoided. Flowers which open in a close place fall off almost as soon as formed, and we have generally seen those which adhere until put in glasses fall immediately afterwards. This is not, however, the case with flowers opened in a bracing atmosphere; these remain fresh and beautiful for a week or more after being cut.—J. M.

SHORT NOTES.—VARIOUS.

Ipomæa Bona-nox.—Among some seeds which we got from South America was this Ipomæa, a flower of which we send you. We have grown it all along in a stove temperature. It only opens its flowers after sunset, and some of them have a sweet Jasmine-like perfume.—J. NICHOLSON, *Sewardstone Lodge, Chingford.*

*** A grand specimen of this too rarely seen species of Ipomæa, and most agreeably scented.—ED.

The Suwanee Lily (Zephyranthes Atamasco).—When I travelled in Florida last April, I learned that the people of the Suwanee region call this fine Amaryllid the "Suwanee Lily." It grows most luxuriantly on the banks of that far-famed river, and tourists are usually delighted to hear the pretty flowers called by that name. I am inclined to believe that many northern people only know this Zephyranthes by the name of Suwanee Lily. I have seen two forms on the Suwanee—a white one and a rose-coloured one.—H. NEHRLING, in *Gardeners' Monthly.*

FRUIT GARDEN.

PLANTING APRICOTS.

MOOR PARK still heads the list of good Apricots. It is more largely planted than all other varieties put together. The present is the best season for planting fruit trees, Apricots included. There is still a large proportion of summer warmth in the soil, and the roots start into action and the plants become established in it at once. It is not necessary to wait for the last leaf to fall, as, after such an autumn as that which we have had, no doubt need be entertained that the wood will be unripe. We are not likely to have a better autumn for fruit-tree planting in any future year than this is, for the soil is in excellent condition, and the wood also in good order to withstand removal. I should, therefore, recommend all who intend to plant to set about it at once. Apricots must have a good aspect, which need not, however, necessarily be full south. A south-east or south-west is quite as suitable—perhaps better in the southern counties. An idea seems to prevail that Apricots succeed best in the maritime counties, but where soil and climate are suitable I do not think it matters much where the situation is. Usually, within the influence of the sea, the climate is milder than inland, and that, perhaps, may have given rise to the idea that in maritime districts only will Apricot culture meet with full success.

Apricot trees like a dry wall. Garden walls are often damp through neglect; the coping perhaps gets out of order, the damp penetrates, the temperature of the wall is lowered, and becomes less desirable for fruit with tender blossoms. Apricots are often seen in better condition against a farm-house or other building than against a garden wall.

FRESH HEALTHY LOAM not too light nor yet too near the clay is the best staple for Apricots, and indeed for all stone fruits. No manure should be given to young trees. Rampant growth in youth has often to be paid for later on in the loss of branches when the tree ought to be settling down to steady work. The worst cases of branch-dying I have known occurred in trees planted in soil rich in turf-fibre, whose early progress had been rapid. The top spit, 4 inches deep, from an arable field that will grow good wheat will grow good Apricots for the first eight or ten years. Then when the trees have had their youthful vigour taken out of them, lift the extremities of the roots and apply turfy loam from a Grass field. If a tree is to have a long, healthy life, steady progress from the first is the best preparation for it. The border should be firm, and at least 5 feet or 6 feet next the wall ought to be given up to the trees. In planting young trees the trunk or stem should not touch the wall. It is better to set the crown or collar 3 inches or 4 inches away from it, to give room for growth in after years. Young trees planted now should receive what little pruning is required to lay a proper foundation just as the sap is on the move in spring. Apricots dislike the knife, and in purchasing trees I should not select those which have been at any time severely cut back. I should prefer either maidens or one-year-trained trees. Permitting young trees to run wild the first year from the bud and then cutting nearly all the growth away is bad practice; if the trees had been rightly managed from the first, such cutting back would be unnecessary.

WATERING APRICOTS.—In many instances this is necessary in dry weather, but a good deal depends upon the conditions to which the trees are exposed. I should never think of watering trees when the fruit was ripening, but I have seen much advantage follow the thorough moistening of the soil when the fruits were swelling. If the trees really need moisture, both the present and future crops suffer, but by the time the fruits are ripening the buds for the next crop will have taken the turn which leads either to fertility or barrenness, though it needs an average amount of autumn sunshine to complete the maturing process. Young trees the first year will, of course, need water if the weather is dry. And, speaking generally, I am convinced that in very many gardens wall trees, especially stone fruit, on the south wall do not get enough water.

PROTECTING WALL TREES.—I have tried a good many ways of sheltering the blossoms of wall trees, but I have found nothing better than small feathery sprays of Yew tucked in behind the branches, with a covering, in addition, of fishing net, one or two thicknesses according to situation and climate. A good many failures arise from immature wood. When the blossoms are weak no protection will induce them to set or the fruit to swell. Immature wood may arise from a lack of moisture in the soil in the month of July and the first half of August, or from a deficiency of solar warmth in the last half of August and the first half of September. This year the conditions have been suitable for the most part, and next year, if the blossoms receive the requisite protection, there ought to be full crops of Apricots.

E. HOBDAY.

The Morello Cherry as a standard.—Those who grow the Morello satisfactorily on walls are doubtless satisfied with that mode of treatment, and naturally conclude that no other method of cultivating this fruit is needed; in fact, the idea is general that, in order to grow the Morello properly, you must have a wall. When grown on a wall it requires training and pruning at least twice every year. In winter it needs re-nailing, and a good-sized tree of it will take a man a day to do that properly. Morellos on walls are troubled with aphides. When grown as standards they need no pruning, training, or nailing. Aphides rarely attack them. When planted they form themselves into umbrella-shaped trees, and seldom fail to produce abundant crops, and, being open on all sides to air and sun, one standard will yield a weight of Cherries equal to that of two trees on walls. The Morello, too, makes a capital lawn tree, which, when in blossom, is handsome, and when laden with fruit, equally so. Its graceful appearance, too, makes it at all times a favourite.—W. WHAIT, *Wyndham Lodge, Melton Mowbray.*

Select Apples and Pears.—Will you kindly give me the names of half-a-dozen of the best Apples and a like number of Pears for present planting; also the age at which, consistently with safety in transplanting, they may be expected to bear fruit?—SUBSCRIBER, *Woodlands, Bandon, Co. Cork.*

*** Assuming that the trees are required for garden culture, Apples on the English Paradise and Pears on Quince stock will best answer your purpose. Well formed pyramids or bushes from three to four years old, which have been regularly lifted and root-pruned, can be obtained from any good nursery. Older and larger trees may be recommended, but you will succeed best with fresh, healthy stock nicely set with flower-buds. If carefully and properly planted before the middle of November, they will most likely produce a little fruit next year and a good crop the season following. As you do not say whether the Apples are for culinary or dessert purposes, the names of six of each in their order of ripening are herewith appended. Dessert—Irish Peach, Worcester Pearmain, Cox's Orange Pippin, Claygate Pearmain, Scarlet Nonpareil, and Sturmer Pippin. Kitchen—Lord Suffield, Echlinville, Warner's King, Annie Elizabeth, Calville Malingre, and Dutch Mignonne. Pears may consist of Williams' Bon Chrétien, Marie Louise, Pitmaston Duchess, Doyenné du Comice, Winter Nelis, and Josephine de Malines. If very late Pears are wanted and the climate is good, add Easter Beurré and Bergamot d'Esperen.—W. COLEMAN, *Eastnor Castle, Ledbury.*

Variation in the flavour of Pears.—Can any of your skilled contributors inform me why Pears vary so much in different years? I have a fine tree, supposed to be Gansel's Bergamot, trained against an east wall, the fruit of which is generally delicious. This year the crop is lighter than usual and the Pears larger, but the flavour is poor and the flesh mealy, instead of being juicy and rich. I have also a Beurré Diel bearing a small crop of fine fruits, but all are going off prematurely. On the other hand, I have a

tree, somewhat like that of a Duchesse d'Angoulême, trained to a south wall, the fruit of which is generally cold and tasteless, almost like melting snow, and this year, for the first time in fifteen years, it is excellent, hardly recognisable as the same Pear. What can account for these variations? The trees are all healthy and all in the same soil.—G. J. B.

Colour and flavour.—As a rule colour is the outcome of ripeness, and as it is also essentially the product of warmth and light, it is evident that true fruity flavour can only be found where these conditions exist. Flavour is in too many cases not regarded from a pure sense of its merits. Sharpness, which really means acidity, is liked by some and not by others. Real flavour seems to be a judicious compound of acidity and sweetness, neither predominating; the assumption that flavour in Apples and Pears is always associated with colour is true only in a restricted sense. No doubt the best coloured Ribston, Cox's Orange and Cockle Pippins, or Margil are the best flavoured, because the ripest, and having experienced the greatest amount of sunshine, but relatively they do not show nearly so much colour as Cellini Pippin, Worcester Pearmain, Duchess's Favourite, or Fearn's Pippin, and yet these latter are not so good in flavour. The same will be found in Pears; indeed, russetty skinned kinds in both Apples and Pears are, as a rule, the best flavoured, although fruits of these kinds having colour according to their kinds are, without doubt, better than are others of the same kinds that are deficient in that respect.—A. D.

—— In answer to "Hortus" (p. 372) I have to say that I am not involved in a discussion with "T. B." on the subject of colour *v.* quality. Indeed, I agree with "T. B." that eating Gros Colmars and other big fruits in preference to kinds of much better quality is about as bad as eating green Muscats or red Hamburghs, which I feel sure even "T. B." will not do unless compelled, nor will any good Grape grower. What, however, concerns "Hortus" is his admission that himself and some others, whom he does not name, had, through the force of circumstances, grown so familiar with the green and sour Muscats and red Hamburghs, that they had actually come to prefer them to those that were golden, like the Berkhampstead Muscats, for example, or black, like the prize examples seen at exhibitions, and "Hortus" was asked to produce examples of such produce and its consumers just to allay people's curiosity. There should be no difficulty in this, but there are one or two of your correspondents whose vertebræ always give way when the burden of proof is laid upon their backs, and "Hortus" appears to be one of that class. A couple of berries of each sort in a pill-box sent to the office or to some expert, one would think, would not be a hard thing to do, but it is an ordeal "Hortus's" green Muscats and red Hamburghs do not appear capable of enduring.—Chief.

Canadian Apples.—The members of the fruit committee were called together on Wednesday, at South Kensington, for the purpose of examining a very fine and special exhibition of Canadian fruit displayed in the conservatory. In addition to a large and very varied collection of farm and garden roots, Tomatoes, Capsicums, &c, there were placed on two broad tables some 2000 or more dishes of Apples, Pears, Grapes, and other fruits from various districts in the Dominion. For colour in Apples, nothing has previously been seen like this show, very many of the samples being not only very fine and wondrously handsome, but also superbly coloured. Pears were also good and varied, though pale as compared with the Apples, and they had travelled less safely. Some 200 or more dishes of out door Grapes were shown, some very black, many quite red, and others greenish white, but generally somewhat acid, even where apparently quite ripe. Of course, the long journey had materially detracted from their ordinary appearance. In addition to passing a special resolution thanking the Canadian commissioners and the exhibitors for their fine display, and fully recognising the excellent size and beautiful colour found in the fruits, the committee tasted several seedlings, giving three marks of approval to Trenton Seedling, from Mr. Dempsey, of Ontario, a very handsome rich-coloured fruit, and to Mr. Fitzgerald, London, Ontario, for a handsome seedling, rich in colour, and having soft, good flavoured flesh. Mr. Dempsey also received the same award for a capital seedling Pear, Dempsey's Seedling, from Williams' Bon Chrétien and Duchesse d'Angoulême, a rich melting fruit of fine form. Several others were tasted, also a couple of seedling white Grapes, one named Emerald being esteemed the best flavoured. Several well-known Apples—Ribston Pippin, King of the Pippins, and Gravenstein—were also tasted and found to be excellent.

Nouveau Poiteau Pear.—I have a free-growing pyramid tree of this capital Pear some 16 feet in height, and carrying a grand crop of fine, clean fruits. I say clean, because they are free from spot or crack as seen in so many kinds on free stocks. This variety does not seem to be either well known or widely grown, and yet we have few Pear trees which naturally grow into handsomer pyramids on free stocks, or crop more regularly. The fruits, which are large, are obtuse, obovate, or semi-pyramidal in form. They have a greenish skin, somewhat russetty in places, and they are fairly handsome. Their quality is excellent; indeed, the flesh is fine grained, soft, melting, and juicy, and excellently well flavoured. They are ripe in November, the chief Pear-ripening season. I am obliged to tie up some of the side branches to keep them intact.—A. D.

Peaches at Ditton Park.—Two thousand Peaches from open walls! That is the number "A. D." reports to have been gathered this year from the Peach wall at Ditton Park. Who shall say that Peaches cannot be grown out of doors after that? One of our best gardeners of the old school once told me that cheap glass would do away with Peach growing outside, "and," said he, "the seasons will be blamed; but that will only be a lame excuse in order to get out of the difficulty. In a few years young gardeners will not know how to grow a Peach outside." This was said some twenty years ago—not a very long way back—and yet his prophecy is beginning to be realised. If one requires a young man to work chiefly outside, you may advertise for one, but there will be but few applicants. Peach failures are generally put down to the seasons having changed, but twenty-nine years ago I cannot say the seasons were more favourable than now, yet there were Peaches, and plenty of them, on open walls. Last year was not too favourable as regards the ripening of Peach wood and buds, and the late spring was not one of the best, yet for all that Peaches, not only at Ditton Park, but also in many parts of the country, were really good crops; and if properly grown, as at Ditton and Burghley, I maintain that this fruit can be still well grown outside without the aid of glass, or even tiffany, in spring. Peaches succeed well in France, and yet the climate there is not in some parts so good as it is in the south of England, or even in the midlands. Good Peach growers, like Mr. Lindsay, will tell you that in order to have good crops you must have good trees, for even good seasons will not make unhealthy trees produce fruit. Good trees will withstand much bad weather, and produce a crop of fruit in the majority of seasons.—W. C. L.

SHORT NOTES.—FRUIT.

Dried Apricots.—These are becoming very popular in California, and drying Apricots is becoming a profitable branch of industry.

Apple culture in Nova Scotia.—Apple culture is progressing in this province to such an extent, that 100,000 barrels were received in England last year. The red Canada seems the variety chiefly depended on.

The American Apple crop.—Mr. P. Barry, of Mount Hope Nurseries, Rochester, N.Y., informs us that with him the Apple crop is a total failure. "Our Pears," he adds, "are superb; we are shipping Angoulêmes to New York daily in bushel kegs, which fetch 12s. to 14s. per keg. Anjous by-and-by will fetch double that amount."

Marie Louise Pear.—About three years ago a short note about a Marie Louise Pear tree growing here, appeared in The Garden; since then it has done remarkably well. Last year we gathered four bushels of good fruit from it, and this season, although not so favourable generally, this Louise Pear tree is remarkably fine, bearing some sixty dozens of good fruits.—J. H. Goodacre, *Elvaston Castle, Derby.*

Damsons.—I do not know whether or not Mr. Muir includes amongst his flavourless Damsons found in shops the popular market kind called Farleigh Prolific or Crittenden, but if he does, he makes a mistake. I have had an opportunity recently of tasting fruits of both this and the old oval sort picked up ripe from the Grass on which it had fallen, and I have been unable to discover that these latter were in any way superior to the former, although the crop in the former case was about six times as heavy as that in the latter. The Farleigh Prolific when employed in tarts or stewed, or made into preserves, is a very richly flavoured fruit; indeed, to my mind, almost too much so, and in tarts especially it is best, I think, mixed with Apple. Very likely the round kinds referred to by Mr. Muir are seedling forms never grafted. Damsons have a special merit. In good holding soils, and where not exposed to fierce winds, they will hang on the trees for a long time, and are thus better adapted for profitable utilisation than other Plums.—A. D.

The Catawissa Raspberry.—When we read here and there that this or that variety of fruit is "no good," we must remember that this is usually from the market-grower's standpoint. The Catawissa Raspberry would not earn its salt from anyone who should plant it for market. But what a glorious delicacy it is for the amateur! Plants should be cut to the ground in the spring, and very rich food given them. Through August and September they will yield large quantities of Raspberries of the most delicious flavour. We know of no variety that can compete with it in toothsomeness.—*Gardeners' Monthly.*

ORCHIDS.

COOL HOUSE LADY'S SLIPPERS.

Cypripedium insigne.—This, though old, is undoubtedly one of the most useful of Orchids, and one which may be used either for dinner-table decoration or room furnishing. It may be successfully grown in an ordinary greenhouse, but in order to induce it to throw its blooms well up it requires a little more than ordinary care. For dinner-table decoration we grow it in pots 5½ inches in diameter and 4 inches deep, inside measure. Plants in such pots are well adapted for the dinner table, as the foliage being low and the blooms thrown well up, they offer no obstruction to the eyes of the guests. From this time on towards Christmas, I question if there is another Orchid that will stand such hard wear and tear as this will. It keeps in bloom several weeks if free from damp. We grow some dozens of it in the pots just alluded to for indoor decoration. Each plant bears from 8 to 12 blooms, on stalks from 1 foot to 18 inches high, the individual blooms being from 5 in. to 6 in. across. Plants of this description are much more serviceable than very large plants, which as a rule can only be seen in the houses in which they are grown. When our plants have done flowering in January, they are thoroughly overhauled, cleaned, and any dead and decayed material is cleared from the surface of the pots. Top-dressing they cannot get, as the pots are full of hard closely-packed roots. They were potted two years ago in fibry peat, but now there is little else but roots. These Lady's Slippers, which are put at the cool end of a stove, stand upon 3-inch pots to allow the syringe free play among them when the weather is favourable. Twice a week all through the season they are lifted down and examined, and if at all dry they are thoroughly soaked in very weak, perfectly clear sewage water. They remain placed as just described until the first week in August, when they commence to throw up their flowers; after that they are not syringed overhead, an operation which might cause the young flower-stems to damp off. They are then removed to a vinery in which Grapes are ripening, away from draught and where there is a night temperature of about 60°, a position in which they receive more air than hitherto, but no syringing overhead. The foliage of the Vines affords good shade for them; here they continue to throw up their flowers in a most satisfactory way. When

the flowers begin to open the plants are removed to a cool airy pit (from which Melons have been cut); there they are subjected to a night temperature of about 55° and kept free from damp. Plants thus treated keep in good condition till after Christmas, when they are again consigned to the cool end of a stove to make another season's growth. This plant flowers beautifully at the cool end of a stove, but the blooms are much clearer and finer under the treatment just described.

C. VENUSTUM is another good old cool house Lady's Slipper, and when in flower in pots similar to those just named its dark coloured marbled foliage looks well, and as it flowers in the depth of winter it is valuable for room decoration. Under such circumstances I have had it in good condition for over a fortnight in January, and again it comes into flower on the heels of C. insigne and lasts in flower well into February. Though the individual blooms are not showy, they last in good condition for several weeks, and compact plants in small pots will carry a dozen blooms or more.

Fox Warren, Cobham. J. R. HALL.

Anguloas.—The Anguloas are bold-growing plants, with large dark green pseudo-bulbs and massive plaited leaves. They succeed in the same temperature as that previously given for cool-house Oncidiums, but the various species belonging to this genus are great lovers of shade. They enjoy an abundant supply of water during the growing season, after which a season of rest is necessary. This is brought about by withholding water, which should not, however, be carried to extremes, for should the pseudo-bulbs be starved they will show signs of shrivelling, and the next season's growth will be weak in consequence. The flowers of Anguloas are produced along with the young growths, and expand when the young leaves are about three parts developed. They are large, Tulip-like, and borne singly (and upon rare occasions in pairs) upon stout erect scapes, about 9 inches high. They last a long time in full beauty if not sprinkled with the syringe. Should they, however, be syringed, the flowers soon become spotted and unsightly. The soil for Anguloas should consist of large nodules of fibrous peat and some Sphagnum Moss, and the pots should be thoroughly drained. All of them are natives of Columbia. The best kinds are A. Clowesi, a species which produces large, rich, deep yellow flowers about midsummer; A. Ruckeri, similar in general outline, and producing flowers at the same season, but the colour externally is a uniform brownish orange, the inner surface being profusely spotted and dotted with reddish crimson. A variety of this, called sanguinea, produces flowers of a deep sanguineous red, the outside being yellowish green. A. uniflora, the smallest of the family, produces flowers correspondingly small compared with those of the others. It is a variable plant; in some of its varieties the flowers are of a uniform creamy white, while in others the interior surface is more or less spotted with pink, and sometimes the scapes bear a pair of flowers.—W. H. G.

Cypripediums in flower.—These Orchids are great favourites with Mr. Williams, in whose nursery the following kinds are in bloom: C. euryandrum, a beautiful hybrid, the parents being C. Stonei and barbatum. Of the latter species, it retains the peculiar leaf-markings and the habit of the former in bearing two or three flowers on a stem; the individual flowers are large and bold; the upper sepal is broad and convex, white, more or less stained and striped with crimson and claret in colour; the petals are long and strap-shaped, white, suffused with purplish crimson and ornamented with bands of blackish purple spots; lip, pouch-like, large, rich brownish crimson in colour. C. selligerum, somewhat resembling the last-named plant in the marking of its petals, yet quite distinct; the dorsal sepal is larger, and the pouch is different in shape and of a vinous red; it is the result of a cross between C. lævigatum and C. barbatum. C. Harrisianum, the oldest of hybrid Lady's Slipper Orchids, still retains the reputation of being a free-grower and an abundant bloomer, whilst the variety in flower with Mr. Williams is very highly coloured. C. Sallieri is a cross between C. villosum and C. insigne, both of which produce solitary flowers, but the offspring bears from two to five flowers upon a stem, and whilst the sepals are as in insigne, the petals and lip are as in C. villosum, and retain the peculiar varnished appearance of that species. C. Haynaldianum, a species from Luzon, somewhat resembles C. Lowei, but is lighter in colour. The lovely C. Spicerianum has many varieties, all good. C. insigne punctatum violaceum, with its large white dorsal sepal ornamented with purple spots, is a most desirable kind. Other kinds of Lady's Slippers of less beauty now in bloom are C. javanicum, C. Crossianum, and the little-known C. purpuratum.

Trichocentrum albo purpureum.—This is a delightful small-growing plant admirably adapted for growing upon a block or in a small basket in the cool Orchid house. It is an abundant bloomer, and the flowers are large for the size of the plant. The outer part of the flower is tawny yellowish brown; the lip is large, white, bearing two large rosy purple blotches near the base; there are also a few lines of the same colour on the crest of the lip.

Orchids at Holloway.—It affords one pleasure to find Orchids obtaining as much attention as they do at Mr. Williams' nursery. Such old species as Lælia Perrini, Miltonia Clowesi, Sophronitis grandiflora, Odontoglossum grande, Vanda tricolor, and Dendrobium formosum giganteum are now making a fine display of bloom. Phalænopsis amabilis and grandiflora are just coming in, and, together with such kinds as Vanda cærulea, Dendrobium Dearei, Cattleya Eldorado, Dendrobium bigibbum, Lælia Dayana, Oncidium tigrinum, O. Forbesi, O. prætextum, and O. Jonesianum produce a really brilliant and charming effect during the dull season now fast approaching.

Masdevallias.—These are grown well in the Pine-apple Nursery, Maida Vale, under very cool treatment. It is found, however, that although these plants enjoy a low temperature, they do not like the atmosphere to fall to the freezing point. It is also found that M. tovarensis enjoys a greater amount of heat than any of the other kinds; quantities of this species are now in bloom, the spikes in nearly all cases producing two and three of its pure white, sweet-scented flowers at the same time. Formerly we rarely had more than one flower open at a time on a spike. Is the greater development which we now enjoy due to cultivation, or is the form we now have distinct from the earlier introduced one? M. amabilis and its variety lineata, with their bright rosy carmine flowers of various shades, are also gay. M. ignea, bearing bright cinnabar coloured flowers streaked and flushed with reddish crimson, is one of the brightest in bloom.

Lælia Dayana.—This beautiful Lælia is well worth attention. Being compact in growth, it takes up but little room, and, producing as it does fine large blooms when Orchid bloom is scarce, it is very valuable. It lasts, too, in bloom several weeks if not kept too damp. At The Firs, Lawrie Park, Sydenham, there is just now in bloom a fine form of Cattleya marginata, the flowers of which are fully 4½ inches across, deep rose in colour, and the lip rich port-wine colour margined with rose. The culture of this and the Lælia is very simple; place them in a cool house in baskets or on blocks, and put some fresh Sphagnum round their roots. Suspend them near the roof. They should be moved in the first week in October to the Cattleya house, as the flowers develop best in a little more warmth. They should remain in the Cattleya house until March, when they may be placed again in a cool house. Water may be freely used, erring, however, on the dry side, through the months of December and January.—R. R.

Lælia præstans var.—By far the largest-flowered, richest-tinted form of this superb Orchid we have seen is that possessed by Mr. R. J. Measures, of Cambridge Lodge, Camberwell, who sends us a specimen. The flower measures fully 5 inches across; the sepals and petals are of a deep rosy lilac, flushed with crimson. The lip is 1½ inches across, of an intensely deep maroon-crimson, and has a prominent crest on the inner surface. Mr. Simpkins, the gardener, says that, though a large number of plants of this Lælia has flowered with them this season, this one stands out conspicuous from all the rest. There is not a more beautiful dwarf Orchid than this for flowering in autumn, and it is altogether superior to its relatives, L. Dayana and L. pumila. Accompanying this specimen there are other flowers of choice Orchids from the same garden. These include the true Cypripedium purpuratum (Lady's Slipper Orchid), a variety seldom seen; Cattleya Eldorado splendens, a grand variety highly coloured; Miltonia candida; Odontoglossum Insleayi splendens, cut from a spike bearing five flowers, a very fine form; Lælia Perrini major, much larger than usual; and Cattleya Schilleriana, a fine variety, more highly coloured than is generally seen.

OBITUARY.

MR. Z. STEVENS.

WE regret to have to announce the death of Mr. Stevens, who for many years has been gardener to the Duke of Sutherland at Trentham. He had been long a sufferer from, we believe, some bronchial affection, to remedy which he made protracted stays recently in various places where the climate was milder than that of the midlands. He lately spent some months at Cairo, and returned apparently improved in health. He, however, died on the 20th inst., at the early age of 52. Mr. Stevens was an excellent gardener, as the noble gardens under his charge abundantly testified. Of late years his success in cool Orchid culture astonished even Orchid growers of long experience. He was known by a wide circle of friends, who will regret his death, which is, indeed, a sad loss to horticulture.

MRS. STENGER, wife of Mr. Hermann Stenger, well known to many of our readers as the representative of Messrs. Vilmorin in this country, died somewhat suddenly on the 14th inst. For some months she had been unwell, but, although she was known to be suffering from some internal complaint, her death was quite unexpected.

Cupressus macrocarpa.—What is the best time of year to thin out the branches of Cupressus macrocarpa; they seem to be growing very fast now?—J. A. C., *Waterford.*

*** We should prune this Conifer any time between the end of March and the end of May.—ED.

Names of plants.—*J. R. (Preston).*—Your leaves are indeterminable in present form; send specimen when in flower.——*Hibley.*—A form of Clematis lanuginosa.——*M. S. (Tenby).*—1, Polystichum, too young to identify; 2, Scolopendrium vulgare; 3, Pteris aquilina; 4, Lonicera reticulata aurea ——*Mrs. R.*—Chrysanthemum (Pyrethrum) uliginosum, Helianthus giganteus var.——*R. Lloyd*—Hieracium aurantiaeum.——*G. W. L. S.*—Pleione Wallichiana.——*C. C Chapman.*—Scarlet Thorn (Cratægus coccinea).——*W. H. M*—Acer colchicum rubrum; leaf is from A. pseudo-Platanus fol. purpureis.——*A. K.*—Not an unusual occurrence in the Osmanthus; O. myrtifolius is probably only the sport from the Holly-leaved form.——*A. Chapman.*—Dianella cærulea, New South Wales.——*G. F. G.*—1 and 2, varieties of Aster Novi-Belgii; 3, Aster longifolius; 4, Solidago angustifolia; all very inferior kinds, not worth growing in comparison with others in cultivation.——*W. E.*—Aster lævis.——*J. R. Droop.*—Evidently some species of Willow (Salix), but we cannot name from specimen sent.

Naming fruit.—*Readers who desire our help in naming fruit will kindly bear in mind that several specimens of different stages of colour and size of the same kind greatly assist in its determination. Local varieties should be named by local growers, and are often only known to them. We can only undertake to name four varieties at a time, and these only when the above condition is observed. Unpaid parcels not received.*

Names of fruits.—*S. C. Cay.*—Your Pear is named King Edward, an old English dessert Pear; ripens in October and November. It is one of the largest melting Pears, but very poor in quality.——*Loughborough.*—1, next week; 2, Souvenir du Congrès.——*B. N. Foster.*—Blenheim Orange Pippin.——*H. B.*—1, Black Hamburgh; 2, Black Alicante; 3, Madresfield Court.——*H. G.*—Red Costard.——*B. L.*—Pears: 1, Beurre Bosc; 2, Beurre Clairgeau; Apples: 2, Cox's Orange Pippin; 3, Blenheim Orange.——*Pears.*—Your Pear is named Knight's Monarch, and is a first-class variety; but, strangely, in some places, it will not succeed at all.——*R. Howard.*—Beurre de Capiaumont.——*C. Dawson.*—1, Flemish Beauty; 2, Bishop's Thumb; 3, Swan's Egg; 4, Louise Bonne of Jersey.——*J. B. Sutton.*—2, Court of Wick; 3, 4, too small to determine; Plum, Ickworth Imperatrice.——*E. S.*—Pears: *a*, Louise Bonne of Jersey; *b*, Beurre d'Aremberg; *c*, Thompson's; Apple, Mother.——*Four Apples in cigar-box—no letter.*—1, Cellini; 2, Lane's Prince Albert; 3, Margil; 4, King of the Pippins.——*E. J. Kigwell.*—Louise Bonne of Jersey. Others will be named next week.

WOODS & FORESTS.

MEASURING STANDING TIMBER.

As the season is now approaching for the selection of timber for the winter sales, a few observations on the measuring of standing trees may be of some benefit to the young forester in this branch of his work. A beginner in tree-measuring should not trust to his eye alone in estimating the dimensions of either the height or girth of the trunk of trees, and must consequently have recourse to some mechanical aids to assist him, though often at much sacrifice of time, which is not always compensated for by greater accuracy of results. By much careful practice the eye can be trained to estimate distance and size with considerable precision, and likewise the dimensions of standing trees with facility and correctness, but it is different with beginners. The height of a tree may be measured in several ways, but simplicity in any instruments used for that purpose, lightness, and ease in handling are the considerations. Several ingenious instruments have been made and used for this purpose, such as Kay and Mackenzie's dendrometers, the apomecometer, hypsometer, and the pocket sextant. The two first occupy some little time in setting and adjusting. The three latter are light instruments, easily carried, and used from the hand without the aid of a tripod or staff. In using the apomecometer or hypsometer the operator must place himself on a level with the base of the object to be measured, and at a distance from the object almost equal to its height; but with the sextant the case is different, and the attainment of a proper position less difficult. If the index of the sextant is set at 45°, then it is used in the same way as the apomecometer and hypsometer, at a distance from the object equal to its height, but with the index set at 63° 30', he distance of the operator from the base would be just half the height of the object, and a position on a level with the base of the object more easily attained. In practising with the sextant in measuring standing timber, a mark should be put on the tree to be measured at a height equal to the height of the eye above ground; a knife, nail, or bradawl stuck through a piece of white paper into the bark is a good mark; then, if the ground is fairly level, set the index of the sextant to 45°, and walk backwards in the plane of the tree until that part of the tree, the height of which you wish to ascertain, is shown in the glasses of the instrument as level with the mark made on the tree; then measure the distance from the tree, add to that the height of the mark upon the tree, and the product is the height required. Should the surface of the ground be very irregular, or brushwood or other obstacles obstruct the sight at 45°, set the index to 63° 30', perform the operation as already described, but multiply your distance from the tree by 2, and add the height of the eye or mark as before for the required height of the object. To use the sextant for this purpose, set the index to the necessary angle, take the bottom of the instrument in the right hand, hold it in a vertical position, with the index facing to the left, look through the eye-hole and unsilvered part of the object-glass at the mark on the tree, and move backward or forward until the point, the height of which you wish to ascertain, is reflected from the index-glass to the silvered part of the object-glass, and appears exactly on a level with the mark on the tree; then, according to the angle at which the instrument has been set, calculate the height of the tree, as already explained. After a good deal of practice the eye can be trained to estimate both height and girth with considerable accuracy. A very good method of practise is, when timber is being cut, to estimate by the eye the dimensions of the trees while standing, and measure for proof when the tree is on the ground, comparing actual dimensions with those of the previous estimates, and as experience extends, the estimates will approach nearer the truth. But anything like facility in estimating accurately in this way is only acquired by extensive and careful practice, and that practice must not be allowed to lapse for any length of time, or the eye forgets its previous lessons, and has to undergo another course of training. When estimating the contents of standing trees, the quantity of measurable timber in the tops should always be taken into account and entered in a column of the book separate from the contents of the trunks. Oak tops are sometimes of considerable size, and when the calculation includes their measurable contents, the probable yield of bark can be pretty accurately predicted. A. P.

FORESTRY NOTES.

Corsican and Austrian Firs.—I find there is some confusion as to "which is which" of these two Firs. It is surprising it should be so, for they are, when true, quite distinct in a young and old state. Still I find the Austrian Fir is sold for the Corsican, and cultivated as such in some places, and that it has been for years. This is a pity, because, although the Austrian Fir may produce as good timber as the Corsican, it cannot match it for shape and habit of growth, and the Corsican is the best tree of the two to grow for poles. The Corsican is not pyramidal in shape, but, as more truly described in Veitch's "Manual of the Coniferæ," it has a very elongated pyramidal outline. This shape is due to its paucity of lower branches, which do not extend to limbs, as in the case of the Austrian, but are few and small, the most luxuriant growth being always nearest the top, even when the tree has room; hence the wonderfully even thickness and straightness of the trunk, which makes it such a valuable timber tree. The Austrian Fir is conical in shape, but varies much, while the true Corsican does not. Some Austrians are nearly as broad as long, owing to their wide-spreading branches. Some trees, about fifty years of age, which I saw the other day were shaped more like Cedars than anything else, their lower branches having grown into horizontal limbs, and the trunk being comparatively small in consequence.

It is time to utter a warning on this subject because the Corsican is scarce in our nurseries, and the trade are propagating it as fast as ever they can, their losses being greater in transplanting it than in any other Fir. There are, however, several varieties of the Corsican as it exists in different European countries or islands. For instance, there is Pinus taurica, which authorities, including Veitch, give as synonymous with Pinus Laricio (Corsican), but which, in my opinion, is different, though the difference is not great. We have one solitary tree of P. taurica here growing well on an exposed spot where such as Nordmann's Spruce will not live, and about 50 feet high. I long regarded it as a Corsican, although its general appearance and bark did not quite resemble the common type of the latter as I know it, and to be sure I sent branches of both to an expert, and had them returned—the Corsican named right and the other named taurica. This is significant. I have also shown the tree to foresters familiar with Corsican Pine, but they did not recognise it as belonging to that species. All I can say of P. taurica is that it appears to have all the good qualities of the Corsican. In our tree the leaves have no twist whatever, and it is probably this which deprives it of the general appearance of the Corsican Fir.

Planting Corsican Firs.—We shall soon have completed the planting of nearly 25,000 of these in the nurseries and woods, and it is only October t yet. I find our earliest planted Corsicans have everywhere done best, and we now begin first with them as soon as their terminal buds are formed and the leaves are moderately stiff. But a friend of mine, a nurseryman, tells me the best time to lift any of the Pine tribe is between spring and summer. He has lately planted all the summer, and declares Corsicans, Austrians, and Scotch do better than when planted at any other season. I have a strong impression myself that many of the losses in young plantations are due to too late planting, and careless planting in the case of Firs, at least.

Home nursery plants best.—There can be no doubt about the fact that young trees out of the home nursery always thrive better than those just bought in. The reason of this is obvious. When in the home nursery they can be lifted as required, need not be long out of the soil, and are generally got up with better roots. I must say that in some nurseries young trees are lifted in a careless manner, and, what with the counting and bundling of them, the roots get dry and shrivelled, and when planted out in the woods direct, where watering is out of the question, they die. I never enter the gate of a certain nursery during the planting season but I see large quantities of Larch and other trees lying about by the thousand in bundles, waiting to be sent off, and simply perishing in the interval. No kind of tree can stand such treatment long, and least of all bad transplanters like the Corsican Fir. Therefore, I advise all doubtful subjects to be first started in the home nursery, and only such things as Sycamores, Poplars, Scotch Fir, and others of the hardiest species bought in.

Thinning woods.—General advice of the best kind on this subject should be "thin not at all," unless you can spare the time from felling and planting. In managing woods to pay you can do without thinning, but you must fell and plant, and in the culture of woods for profit these, together with draining where required, constitute the chief objects to be kept in view. There are plenty of woods in England at the present time that should be cut down, or have the timber taken out of them that is going the wrong way and being lost, and if this was done, and mature crops of timber reaped when ready funds could be found for planting, on a far more extensive scale than is the case now on many estates, and a fair margin of profit realised besides. It should be borne in mind that those who fell much timber for the market can well afford to plant far more than an equivalent, as far as quantity goes, in the shape of young trees, and in that way maintain the valuation while earning an income from the woods at the same time. From fifty to one hundred thousand young trees annually is not an extravagant estimate on any good estate where, perhaps, three or four thousands of pounds worth of timber is disposed of in the same time, and the price and planting of the hundred thousand should not cost more than as many hundreds, or not as much. Where woods are properly managed at both ends, and the planting is in proportion to the reaping, there should always be a crop ready for the axe.

Valuing timber.—"W. B. H." and others simply make a bogey of this subject. There is neither difficulty nor mystery about valuing and selling timber. There are two ways of setting to work. On some estates the timber is all felled by the forester's own men, measured after it is down, dragged to some accessible spot near at hand, lotted, and then sold by auction to the highest bidder who can furnish security for payment in a stipulated time. He must be a dull-minded individual indeed who cannot superintend such simple duties as these. There is no uncertainty about the plan, and any schoolboy can measure fallen timber. We have many men who do little else than fell timber all the year round, more or less, and although some of them can hardly sign their own name they can all measure correctly, and mark the number of feet on the butt of each tree as they go on. We call this "feller's measure," the men felling at so much per ton, and it is rarely disputed by purchasers or anyone else. It is not

even questioned by the railway people in loading. The other plan is to value the timber standing and sell it in that way, and it has struck me often as a rather significant thing that purchasers who have bought much standing timber at forester's valuation prefer to buy it that way whenever they can. I can only attribute this to the fact that foresters are no greater adepts at valuing timber than they are at growing it. What I state is a fact at all events, and will not be disputed. Yet valuing standing timber is an easy enough matter, and if the plan was more generally adopted of paying the forester or valuer by commission on his valuation or sale, he would generally find it all there. Where trees are large and sound, and perhaps amount to a hundred or two, their contents may be very closely reckoned by anyone who chooses to take the trouble, and large quantities of small stuff may soon be averaged. The only advantage an experienced forester has over the novice in valuing standing timber is, that he can guess the contents of a tree more readily by sight, but he does not trust to this faculty when much money is involved, and should not do so at any time. I am speaking from a knowledge of facts, and I know gardeners both in England and Scotland who set out annually some of the largest timber sales in the country, and who, in some cases, have done so for nearly thirty years, with great credit to themselves and advantage to their employers. As to the "many details that go to make up the work of the forester," according to "W. B. H," would he specify a few that a gardener could not do or superintend? We have to do with thousands of acres of woods on more than one estate; our sales amount to some thousands of pounds yearly, and we have planters, fellers, hedgers, fencers, drainers, timber leaders, and rabbiters, not a few, under us, and yet we confess to being ignorant of the "many details" of management any intelligent gardener may not understand or very soon learn.

YORKSHIREMAN.

NOTES FOR THE SEASON.

THE time is just upon us when the bulk of the year's transactions in timber felling and selling will have to be carried out. I think, therefore, that a little consideration as to the course the business is likely to take, and a little mutual information as to how matters stand in various districts, would be very helpful. So far, general appearances do not seem unfavourable, but there is little tangible enough to lay hold of in respect to an upward movement of prices. There is one factor which has an important bearing upon the whole thing, and that is, the gales we are now experiencing. In some respects the conditions are very similar to those which existed when the first of the series of gales of late years took place, viz., the trees still carry the greater portion of their foliage, and the soil is becoming soddened with the rains. If another week or two passes without any similar catastrophe to those which have played such an important part in bringing down figures during the last five years, there will be reason to reckon on comparative safety for the present season. Another thing which should somewhat strengthen the position of sellers is the fact that, irrespective of what has been rooted up by gales, the cuttings of home-grown timber of late years have been above the average, and this is a practice which cannot continue for any length of time. As soon as any light breaks on the agricultural outlook the fellings are pretty certain to be curtailed, but, apart from disposition on the part of landowners, their resources for the time being in respect to timber large enough for the market will be run through. If, in connection with these two points, any expansion of trade in general takes place, there would seem to be good ground for the hope that many kinds of wood will see an increase in price this season, if only small. To judge from reports, which cannot be especially emphasised in this district, the Oak seems to be going worse than ever, but, be this as it may, it will not greatly affect what is being done, or will be done, during the next three or four months, as very little bargaining in this wood takes place until the barking season is within a measurable distance. Foresters complain that stripping leaves barely any margin, but still there seems to be little or no inclination to abandon it and cut in the winter season with the other woods. So far as this district is concerned (Wilts and adjoining counties), I look upon it that the price of Elm will be maintained, and this more especially for the better qualities. For middling and low-class qualities and sizes there seems little likelihood of any advance being seen, unless a decided change takes place in the industries for which it is most used. For good Ash there is pretty sure to be a market, as, although we have no large implement works near at hand, there is always a considerable local demand and one or two special outlets. Inferior wood will be sure, as usual, to be at a considerable discount, as bad Ash is one of the most difficult of woods to clear. Beech, where good and sound, almost always holds its own, and it is a wood which maintained the higher level at which timber stood a few years ago longer than many others. With respect to underwood, there is not much to be said, as the trade seems to be more irregular and of smaller extent than in many districts, such, for instance, as Sussex. In the neighbourhood of bobbin mills and the like it meets a fairly steady sale, but there is none of the Hop-pole trade which seems to be such a feature in the Hop-growing districts. A great deal of the underwood hereabouts goes for the fire, the best, such as Hazel, being reserved for staking and hurdle-wood. The effect of it in any case upon the market is but small. It would be interesting to hear from any districts where this journal circulates whether any noticeable movement has made itself apparent. There are, no doubt, some districts which would feel it quicker than others, and the intimation of a better state of things having set in would be welcomed as a harbinger of what is in store for those more remote.

Wilts.

SCARCITY OF ASH TIMBER.

THE remarks I made upon this subject have elicited the information from "Yorkshireman" that both the Ash and Sycamore are now raised and sold in nurseries to an enormous extent, and in our woods of the future they are likely to be rather too abundant, if anything. This leads one to ask, Where? With reference to the length of time taken by Ash timber in growing, if "Yorkshireman" will refer to what I said, he will see that I did not state that half a century must elapse before a crop of Ash becomes useful, but that it would require this time before it would be large enough for many purposes for which it is used. The rate of growth will certainly vary according to soil and situation, but I do not think I am very wide of the mark in speaking, as I was, of timber trees. An important point certainly is the way in which it can be best grown, and I see "Yorkshireman" quotes a writer who held the view as to plantation propagation. I fail to see any practical objection to the plan, and if the fact of rabbits being one of the greatest enemies of young trees is borne in mind, it seems another reason why it should be planted in compact masses where these animals may be kept at bay as much as possible. I suppose one of the objections to planting with Ash alone is the belief that its superficial roots when the trees are in such close proximity to each other, as is necessary when a plantation is composed of a single species, would too much impoverish the soil for the trees to thrive properly, and thus the system of alternating with more deeply rooting kinds is favoured. I do not say that growing the Ash with Oak, for instance, which answers this end, is at all a bad arrangement, but experience tends to prove that there is more thought of the drawbacks of raising surface-rooting trees together than need be. The Beech, which very frequently grows in woods by itself, is a very good example of this, as the best wood generally grows where there is so little space between the trees that they have been unable to put forth branches, except at the extreme top, and the trees often grow to a very great height. This is precisely the way in which trees should be grown to have the highest value in the market, and there seems every reason why such a plan should be adopted in growing Ash. In many ways there is an analogy between the Beech and the Ash, and the Beech more often than not grows on soil which is of small agricultural value, on account of its shallowness. Indeed, I have often seen the cleanest and best Ash growing side by side with the best Beech. It would be very interesting to hear what is being done in the direction of this system of planting entire plantations of Ash. If, as "Yorkshireman" says, enormous quantities of the tree are being raised and sold, the information as to the method adopted in planting should be forthcoming. If, on the other hand, the impetus in raising is the outcome of what has been said and felt lately about the scarcity, and the young trees have not yet left the nursery, it is all the more essential that the most desirable plan of planting should be decided upon without delay. With respect to producing good timber, there can be no two opinions that trees grown closely in enclosures are, foot for foot, of much greater value than those which are isolated. What really requires to be satisfactorily established is the knowledge whether there is any practical difficulty in so raising trees. From what I have seen of the habits and growth of the Ash itself, and of trees to a great extent analagous to it, I am inclined to believe that plantation propagation of Ash, pure and simple, or with Sycamore, if this is wanted, has very much to recommend it.

J.

THE MANAGEMENT OF WOODS.

THE extent to which a gardener may be qualified to undertake the duties of a forester depends obviously upon the individual himself. I do not see that his occupation when confined to the garden pure and simple can give him much insight into the art of wood management. Whatever experience he may gain will be more from accidental association than from anything he learns whilst in discharge of his ordinary business. It is the fact of men being upon the place and the incidental knowledge as to management they thus gain that gives them the opportunity of occasionally obtaining a forester's position, rather than from gardening and wood management being anything like interchangeable professions. At any rate, such is my view of the case, for there is no reason why any intelligent man who happens to be upon a place and has an inclination to direct his attention to the woods should not be as suitable as a gardener. Take an estate carpenter, for instance. As with every other trade, the majority may be content to remain in the place where they first find themselves when launched upon the world; but if an estate carpenter has an inclination to become a wood manager and backs his inclination by acquiring the ins and outs of the business with which he from his occupation is accidentally associated in the same way as the gardener is, there is no reason why he may not as readily and successfully undertake the management of woods as the other. This I look upon as being the key to the whole question, and however self trained foresters may be disparaged by those who believe nothing can be done in wood management without school-trained men, those men who have gained their knowledge by using their own powers of observation in contradistinction to what classes and schools may impart are the backbone of what wood management now exists in this country. I do not despise scholarly attainments, as I believe they may be very useful, but I do believe that improved management will be brought about more by the necessity of such attracting the attention of intelligent young men scattered here and there in places where they can see what is being done, and "when found, to make a note of," than by turning them out at so much a dozen from any systematised institution. In this way anyone who has mental adaptability may by mere accidental association become a more qualified man than another who runs the whole gamut of the sciences without it. If posts with salaries worth from £100 to £500 a year were within reach, then there may be some encouragement to enter upon such preparatory study, but, looking upon the pay which ordinarily falls to the lot of a wood manager, the whole idea wants inverting, and the intensely interesting, but relatively valueless, scientific knowledge be gained as opportunities offer whilst the actual business is being carried on.

"This is an Art
Which does mend Natnre: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

OVER-TIDINESS IN GARDENS.

IN most gardens now-a-days the labour is not provided to maintain that degree of tidiness that used to be considered essential—nay, imperative—in all well-kept gardens. I say nothing against tidiness and neatness in a garden whenever these can be maintained without working mischief in the way denoted by "Veronica," or otherwise, and I would be the last to inculcate the notion that trimness and order are not two of the first points of good gardening and garden management. The very word "garden" itself conveys the idea of a place that is "dressed and kept," and the common saying, "kept like a garden," expresses one's conception of such a place correctly; but, granting all this, there can be no doubt that some gardeners and owners of gardens hold extravagant notions on the subject, as, for example, when at this season the abundant foliage of the trees is falling like rain they insist upon a gang of draggled boys, or men or women, being daily employed—may be in front of the windows of the mansion—collecting the fallen leaves into barrows and baskets, the obstruction of so much labour and bustle always giving one a far more vivid impression of disorder and untidiness than the fallen leaves that strew the lawn here and there would do if left undisturbed. Far better is it to let the leaves alone till they have all fallen and then clean them up where necessary. To people who have not over-strained notions of tidiness, falling leaves suggest nothing offensive. They can exclaim, with the poet, rather—

Come autumn, sae pensive in yellow and grey,
And soothe me with tidings of Nature's decay,

and enjoy the placid beauties of autumn in the same spirit in which they rejoice in the freshness of spring or the glories of summer. If gardeners would only think so, there is nothing objectionable in the wreaths of dead leaves that accumulate among shrubberies and on the lawn at this season, provided the walks are kept passable and dry. Another point in the keeping of a garden is to make no pretence of much trimness where it cannot be kept up. For example, a footpath looks much better and is better than a neglected gravel walk in which the edges are ragged and uneven and the surface covered with weeds. Nothing looks more really untidy than a dirty walk, because its untidiness is borne on the face of it and obtrudes itself on the eye. So, too, a hayfield is better and looks better than an ill-kept lawn—at one time rough, with perhaps a crop of Dandelions and other weeds in it, and at another shorn by the scythe in the hands of a bad workman down to the soil or the yellow bottom of the Grass when it ought to be green. As regards borders and beds of hardy plants, I confess that allowing the bleached and dead bundles of stalks standing all the winter is, however, going rather farther than I would go. A bed in that condition does not appear to be natural, nor does it look clean. In the wild garden where there is Grass among the plants and less pretence of tending and keeping it does not matter so much, but in beds containing select collections of plants of different kinds, it is, I think, preferable to remove the dead stalks and blown leaves and mulch the surface instead. Accumulations of leaves or litter allowed to remain on mixed herbaceous beds encourage a too early growth in many things, the tops of which perish or get injured when the protection is removed. Tender subjects that are apt to rot by the water trickling down from the crowns must be cared for, but as a rule a moderate mulching is a sufficient protection for the most delicate subjects worthy of being called hardy, and it looks clean and comfortable. Beds full of dead and blackened tops of herbaceous plants in front of a house and on a well-kept lawn, and associated with clean walks and other signs of good order, look out of place to most people, and are a blemish on an otherwise fair picture discernible by the most casual observer. For that reason we prefer to clear all such eyesores away as soon after this season as possible. One ought to be logical even in such matters as these, and avoid the mistake of allowing what we aim at making ornamental and orderly in summer to become an unsightly object at any other season of the year.

I now come to the kitchen garden, where in times past so much useless labour has been spent and over-tidiness been most conspicuous, not in one thing, but in almost everything—in the planning of the ground, in the planting and arrangement of the fruit trees, and in the keeping of walks and borders. I never could see the common sense or utility of having extensive flower-beds and pleasure grounds in their proper place, and encumbering the kitchen garden with an almost endless extent of flower borders as well, and with useless walks and edgings, unless it happened to be a place where the kitchen garden was near the mansion and had a thoroughfare through it to the house or pleasure grounds, and that is not often the case. The present condition of many kitchen gardens where the labour has been reduced shows all this plainly. The ground not being laid out for economical management, the walks and borders present nothing but signs of neglect, and would be far better dug up and cropped, with narrow alleys substituted for the walks, and with one good cart road through the centre of the garden to facilitate the removal of crops and transport of manure. Fastidious trimness in vegetable beds and quarters is purely nonsensical, and it is a pity that there has been so much waste of labour in that respect in times past. In growing vegetable crops in a private garden there is no more occasion for doing work not essential to the production of good crops than there is in a good market garden, where the quality of the produce is generally all that could be desired. The best sign of good culture is the excellence of the crops and their abundance, and not over-trimmed walks, edgings, and useless borders on which too much attention bestowed must represent a loss to the cropping department, or, at any rate, to the owner of the garden, like all other useless work. S. W.

SINGLE V. DOUBLE DAHLIAS.

THE discussion on this subject seems to turn on the question of the quality of single Dahlias as cut flowers for decorative purposes. They are said to be not so good as double Dahlias for this purpose. Granted, but I should like to ask gardeners who have many vases to fill if they ever used the big lumpy double Dahlias for such purposes at all, or at least to any extent; or if it is not the case that they have taken to Dahlias as cut flowers only since the single varieties came in. It seems rather beside the mark discussing the qualities of single *v.* double Dahlias as cut flowers when it is well known that the latter have never had a place either in the drawing-room or boudoir or anywhere else except on the trays of exhibitors at flower shows. I admit that the Pompon doubles are useful, but commend me to the singles for the border, the bed, or the bouquet. The single Dahlia is one of the best things we have ever had given us, and I hope familiarity with it and easy culture will not render it unpopular, as has been the case with not a few other things. What if single Dahlias do not last so long as some flowers in a cut state; are they not produced in the greatest abundance wherever a few plants are put out right away from June to November? and if they are wanted for vases, cannot fresh flowers be got to replace the faded ones? No; Dahlias were hardly of any use as cut flowers before the single sorts were introduced, and it seems rather unfair to institute comparisons between them and doubles that never did and never will take their place.—J. S.

—— It is good news to learn that "T. W. G. has in prospect a really dwarf strain of single Dahlias. During the recent hurricane the plants of the present tall strain terribly came to grief, being swept and twisted about in the most rude fashion, leaving some complete wrecks. It was difficult to avoid this result, as it is not possible to have the plants tied up so firmly or tightly as to secure them against all injury from wind. Had the plants been but some 2 feet in height, they would have suffered but slightly. The day after the storm, having bandaged the wounds as well as I could, I was pleased to note after all they had gone through how fresh and beautiful the flowers looked, even though then raining. Without doubt these Dahlias are both more beautiful and more serviceable in the autumn than in the summer, when great heat causes them soon to collapse. Now that the weather is cool, not only do the colours seem brighter, but the flowers endure much longer. I have, indeed, found cut blooms to last for a week in a cool room. A good handful of some half-dozen colours dropped half-negligently into a vase is quite a thing of beauty. We may be enchanted for the moment by the more massive and enduring properties of the bouquet or bedding kinds, but it must after all be conceded that single Dahlias are exceedingly beautiful. I have from seed this year found several plants giving us many diverse hues and with heights not exceeding 30 inches, and some not more than 20 inches. I trust they will adhere to this habit, as if so, it is certain that in a year or two we may dispense with all the present leggy race, and enjoy to the full a really dwarf free-blooming strain.—A. D.

—— "T. W. G." is obviously on the right track in regard to these. Single Dahlias from 9 inches to a foot high, bushy and floriferous throughout the season, carrying their tiny 2-inch-across flowers well up above their leaves on stiff stalks, are types wonderfully in advance of all that have yet appeared. On these lines, too, we may find a class of Aster Dahlias that will indeed be invaluable. That reminds me that very little has been said of the white Aster Pompon Dahlia, undoubtedly one of the finest of its class, not even excepting Lady Blanche, and also of quite a new decorative character that may be developed through a peculiar mode of treating these small doubles, Cactus and also single Dahlias, though with the advent of real dwarfs it may not be needful to adopt it with the latter class. Insert cuttings of lateral or even terminal shoots, say six in a 4 inch or 6-inch pot, early in August. Place them in a cold, close frame near to the glass; nearly every cutting will root and immediately show bloom. Grow them on slowly, either in the frame with abundance of air or in the open air, and towards the middle or end of October the potfuls of cuttings will be masses of bloom within from 4 inches to 6 inches of the surface of the soil. These have a pretty and even unique effect either on a window-sill, greenhouse shelf, or a dinner table. The double Pompons are perhaps the most effective, resembling at a distance a new and enlarged sort of Daisy. The Cactus Dahlia does well treated in the same manner, but three cuttings in a 4-inch pot are sufficient for this stronger growing variety. This reminds me that my chief object in writing was to urge upon "T. W. G." and others the bringing of the Pompon Dahlias nearer to earth. Their chief fault at present is that most of them are still too tall. The earwig objection—a very real and tan-

gible one—against the larger double Dahlias hardly applies to the Pompons, in which the petals are so closely compacted together, that these most disagreeable lady-frighteners can neither get in nor hide up if they do.—Hortus.

NOTES OF THE WEEK.

Tecoma capensis.—This, grown as a pot plant in Mr. Low's nursery, is very showy, its large trusses of bright scarlet flowers being very effective. The plants of it now flowering would appear to be terminal shoots struck in the way of cuttings, and when they have attained a height of some 2 feet or 3 feet they commence to flower freely.

Erica hyemalis, E. gracilis, and **E. colorans** are now charmingly in flower in Mr. Low's nursery. These sorts are valuable at this time of year and on through the winter, and therefore the demand for them is great. Here they are grown by tens of thousands, all furnished with long flowering shoots and feathered with foliage to the base.

Nerines.—I send you blooms of two more Nerines, namely, N. coruscans major and N. amabilis. These are quite distinct from those sent previously.—E. Peters, *Somerset Terrace, Guernsey.*

*** Nothing in its way could be finer than the variety herewith sent called coruscans major. Its flower-heads are unusually large and brilliant in colour.—Ed.

Pernettyas.—I send you herewith seven varieties of Pernettyas, known as Davis's varieties. They have been planted three years, and have been fairly successful.—F. Bedford, *Straffan, County Kildare.*

*** The specimens sent are densely furnished with large berries, varying in colour from deep crimson to pure white. These Pernettyas should be largely planted for autumn and winter decoration.—Ed.

Tropæolum tuberosum.—I have sent you a few flowers of this Tropæolum which is now grandly in bloom here, and, indeed, has been all summer. It is now beginning to ripen seeds—a rather unusual occurrence. I have heard that bulbs of it left in the ground flower equally well as those planted in spring.—John Barnes, *Monkstown, Dublin.*

*** Beautiful orange-red flowers, bright and cheerful-looking at this dull time of year.—Ed.

Fuchsia General Roberts.—Amongst Fuchsias brought before the public during the past few years this is probably one of the most distinct and handsome. Grown as a specimen plant in a pot, or used as a basket plant, it is equally effective. The flowers are large, the sepals bright rosy carmine, well reflexed, and the corolla very long and regular, and rich purple in colour shaded with violet. It is especially valuable as a late-flowering variety. We recently saw it finely in flower at Swanley.

Habenaria militaris.—This new species from the Philippine Islands is a valuable addition to autumn-flowering Orchids. Some good examples of it were offered for sale by auction the other day. In habit it resembles our native kinds, but the leaves are tinged with purplish grey; the stems are about 18 inches high, and bear a spike consisting of some two or three dozen brilliant scarlet flowers, with a very long green spur. The blossoms are somewhat larger than those of Impatiens Sultani, which in other respects they somewhat resemble.

White Daffodils.—The suggestion of Miss Wemyss is a good one, and as many by this time have planted their bulbs, it will, I think, be best to postpone sending bulbs to Chiswick till next August. I have adopted the suggestion, and I hope all our friends—Irish friends especially—will join in this work, seeing they claim to be the "stock"-holders of white Daffodils. If, as Mr. Hartland states, Narcissus tortuosus tenuifolius is Leda, then Leda is simply N. tortuosus of Haworth. I procured N. tortuosus tenuifolius to see what the new name represented, and found it to be simply N. tortuosus in shape, size, smell, and colour. I hold that the committee erred in giving the name Leda, but that there may be no mistake of judgment on my part, bulbs have been purchased under the name Leda and planted side by side with N. tortuosus. There appears to be considerable confusion in the varieties of N. spurius; I am of opinion that there is only one in Ireland, and would suggest that those who have forms of this type should next August send bulbs of these also to Chiswick. One member of the Daffodil committee states he has at least a dozen forms of spurius; I have not seen so many, and I doubt the assertion, even after adding the most recent additions. I am also of opinion that the N. spurius forms may be distinguished by the bulb. At page 8 of Haworth's "Monograph of Narcissus" there is enumerated but one Narcissus nanus; therefore, will Mr. Hartland tell us the chapter and page where Haworth says there are seven or eight varieties? I have for the last year or two been trying to make out a second form of nanus, as I have a suspicion such a thing exists, but so far have not been successful.—P. Barr.

Exhibition vegetables.—Canadian growers, present at South Kensington on Tuesday, referred to the show of vegetables as very remarkable to them, and showing taste, cleanliness, and quality, not at all prevalent in their young community. Those who saw the garden vegetables staged by the Canadians last week in the same place must admit that our products were literally miles ahead of those from the Dominion. It is to be hoped that some of the higher taste shown at home will be manifested in connection with colonial vegetables in time to come.

Abutilons.—In Messrs. Low's Bush Hill Park Nursery are some very handsome varieties of Abutilons—small plants in 6-inch pots, but finely in bloom. Most conspicuous amongst them are Illustris, a kind with large salmon-crimson flowers; Violet Queen, with deep rosy violet flowers; Lemonei, canary yellow; Pacotti, rich orange-yellow; King of Roses, large and deep rose; and Emperor, a sort with very large reddish crimson flowers. The old and well-known white-flowered Boule de Neige seemed to be equally free-flowering, even in a very small state. These plants deserve to be far more extensively grown than they are for winter blooming.

Double white Begonia.—One of the most attractive exhibits at South Kensington on Tuesday last was this new Begonia, which came from Swanley. The plants were remarkable for their erectness and compactness of growth and extreme floriferousness, all being masses of white bloom. The flowers are medium-sized, perfectly double, pure white, and hold themselves out firmly on the shoots. They do not indeed show the least tendency to droop, which is a common defect in double Begonias. We have rarely seen such well grown Begonias, or a sort that pleased us so much, and a cultural commendation was deservedly voted to the exhibitors.

Aralia Sieboldi.—This flowers freely in some places about this season, but too late to ripen seeds out of doors. Under cover, the flowers, although not conspicuous, are, nevertheless, not without interest, and seeds are produced in abundance. These, if sown directly they turn black, germinate quickly, and even small seedlings, if planted out in good soil in May, make capital plants for room decoration by the autumn. We have just lifted and potted seedlings treated in this way, and they are certainly far better than plants kept in pots all summer. When lifted and potted, if care is taken not to break the roots much, they quickly become established, and when well rooted hardly any plant will endure so much rough treatment as this Aralia will do.

A new Primrose (Primula Reidi).—This was one of the few really interesting plants shown at South Kensington on Tuesday last, and it certainly is one of the most remarkable that have been placed before the committee this year. It is a Himalayan species, and its fortunate possessor is Mr. G. F. Wilson, Heatherbank, Weybridge, who had seeds sent to him. The specimen he showed was but a tiny plant, but still it was in bloom and quite sufficient to show that it will in future be a most beautiful Primrose. It is, we imagine, a very near relative of P. sikkimensis, for its flowers are of the same drooping bell-like shape and of the same size, or larger and snow-white. The flowers are borne in a crowded cluster on the top of the stems. These may rise quite as high as those of sikkimensis, and then what a lovely plant it will be. The leaves are inclined to be hairy, not glabrous, and wrinkled like sikkimensis and others. We hope to see this Primrose again next year grown to a large size and bearing tall flower-spikes, which we certainly think it will develop.

THE VICARAGE PORCH AT ODIHAM.

Next to a tastefully planted garden there is nothing that adds to the charms of a country house so much as creeper-clad walls. Few things are more incongruous to landscape scenery than the garish glare of new or bare walls. Pretty gardens and climber-covered houses generally go hand in hand. You rarely see one without the other; old houses are generally the most densely clothed with climbers, and old gardens are, as a rule, the most delightful. The gabled porch of the old vicarage at Odiham, one of those quiet antiquated towns, or large villages, one often sees in Hampshire, is so beautiful that we have been tempted to illustrate it. This old house is said to be 400 years old, and is no doubt contemporary with the royal palace, of which there still exist here the remains. The garden about the vicarage is as unconventional as the house itself; the flowers in the borders mingle with the creepers, so that the whole place is bright and fragrant in summer, and even in winter it always has a cosy look. It cannot be said of hardy climbers that they are not "half enough planted," to use a common phrase, for everybody is delighted to see a house smothered in greenery; the fault rather lies in ill-chosen selections, but now that we have climbers suited for every soil and aspect, there is no reason why any wall in or near a garden should be bare. One often sees a beautiful old house or cottage covered with a dense lugubrious growth of Ivy, which, though better than nothing, is monotonous, and quite devoid of that gracefulness which makes most other climbers so charming. The walls of a house, a verandah, or pergola may now be clothed so as to be bright and interesting throughout the year. Even in the dead of winter the golden glitter of Jasminum nudiflorum is most beautiful, especially if intermixed with Ivy. Then come the fragrant white Honeysuckle (Lonicera fragrantissima), the Chimonanthus, and others in succession, and carry on the interest till summer when there is a profusion of bud and blossom.

As the present is the planting season for climbers, a list of the best may be useful to those who want to plant a selection. For winter effect plant Jasminum nudiflorum, Pyracantha, Lonicera fragrantissima and Standishi, Cydonia japonica, and Chimonanthus fragrans and Garrya elliptica, Cotoneaster microphylla and C. Simonsi. Some of these are not actually climbers, but they are suitable for training against walls, which they soon cover. For spring and summer bloom some of the best are Clematis montana, Lonicera sempervirens, Magnolia conspicua, Wistaria, Jasminum officinale, common white; Lonicera brachypoda, flexuosa, and the commoner kinds of Honeysuckle; Berberis Darwini, Forsythia suspensa, Prunus triloba. In late summer and autumn the most prominent climbers and wall shrubs are the various kinds of Ceanothus, Hibiscus syriacus, the noble-leaved Magnolia grandiflora, Solanum jasminoides, Clematis Jackmanni, Bignonia radicans and grandiflora, Passiflora cærulea in sheltered spots, and Escallonia macrantha. These are a few of the flowering plants, and then there is a host of climbers with handsome foliage, such as the Virginian Creepers (Ampelopsis), Aristolochia Sipho, Ampelopsis Veitchi, Menispermum canadense, Ivies (particularly Hedera dentata, maderiensis, and the new amurensis), Stauntonia latifolia, Smilax mauritanica, and Muhlenbeckia complexa. In the mild districts of the southern coast and all round the seacoast one might add largely to this list. Among these are Physianthus albens, like a Stephanotis, Boussingaultia baselloides, Berberidopsis corallina, Cobæa scandens, and others. W. G.

Indoor Garden.

FUCHSIAS TREATED AS ANNUALS.

It may be stated with reference to my knowledge of Fuchsias that when I commenced gardening there were only fourteen distinct kinds in cultivation. They consisted of thirteen species introduced from Chili, Mexico, New Zealand, and Port Famine; the other was F. globosa, an English hybrid, which for many years was a great favourite. An Irish hybrid named F. recurvata made its appearance in 1835. In 1837 that grand old species fulgens was introduced, and when well grown, as I have had it upwards of forty years ago, it has a noble and imposing appearance. About this time came F. cylindracea, which was followed by F. corymbiflora and serratifolia, and from that period was commenced the raising of really distinct varieties and subvarieties. When we take a retrospective look at what has occurred in the way of Fuchsia raising during these last fifty years, we cannot be unmindful of the good work which our predecessors performed. Raisers of seedlings fifty years ago had to contend with many disadvantages unknown to modern practitioners. It was at that time almost an impossibility to raise even the Fuchsia and flower it in the same season; whereas now we can sow its seed and by careful attention have young plants in bloom in a few months. One of my earliest seedlings, raised in 1863, was named Lord of the Manor. It had flowers of large size and was a free bloomer, but as the flowers aged they became somewhat coarse. Since then I have made it a practice to raise seedlings annually, the seed being saved from plants carefully hybridised, so as to obtain, if possible, distinct kinds, both in habit and flower. Proper attention paid in the way of crossing will sometimes bring about results of the most interesting description. The hybridist has certain points in view which he wishes to secure, and uses his skill accordingly; for instance, I obtained a double mauve Fuchsia seven years ago which has not yet been surpassed if, indeed, equalled. It was got by crossing a white variety with a purple-coloured sort.

In saving Fuchsia seed care must be taken to have it fully matured. Some dry the pulp of the berry and keep the seed in that way until it is required for sowing, but my practice has been to smash the berry on the palm of the hand and extricate the seeds by means of the point of my knife. I then placed them upon white blotting-paper, and when dry they were put into small packets, labelled, and placed in a box or seed-drawer until the time for sowing arrived. Some recommend sowing in autumn or as soon as the seed is gathered, but I see no advantage whatever in thus prolonging, as it were, the season of growth; my practice, therefore, is to sow about the middle of February in pots, pans, or sometimes well drained shallow boxes. These are divided into little beds by means of slips of thin wood, and each bed is numbered, the numbers corresponding with those of notes relating to pedigree, &c., as it is most interesting to know the source from which each sowing has been obtained. In this way one gets at the results in a definite form as to the various crossings or hybridisings that have been made. The seed is covered slightly with fine mould, and the pots, pans, or boxes, as the case may be, are plunged in gentle warmth, derived from a hot-water tank.

The Vicarage porch, Odiham, Hants.

A piece of glass is laid on the pot or box to prevent the soil from being in any way disturbed or becoming too moist. This covering also assists in securing greater uniformity as regards the germination of the seeds. The young seedlings will make their appearance in about three weeks from the time of sowing; when the seed-leaf has become fully developed the young plants are carefully pricked off, placing them round the sides of new pots, in each of which a small pot is inverted in order to secure efficient drainage and also to form, as it were, a warm-air chamber. Nicely adjusted, too, it prevents the ingress of worms, should there be any in the plunging material in which the pots are again placed. In the course of a few weeks the plants will be sufficiently grown to enable them to be potted singly in the smallest-sized pots. We use plenty of drainage and give a slight watering with tepid water, and return them to their original quarters. As the young plants begin to make growth they must have a corresponding amount of ventilation in order to ensure sturdy and robust growth. Shading must also be carefully attended to. As soon as the young roots reach the sides of the pots a shift should be given into 4-inch pots, and they should be set in some warm corner of the greenhouse. Unremitting attention must be paid to shading and ventilation when the external atmosphere is genial. Give just water sufficient to moisten the ball of earth, and no more, repeating the same when required, but not before it is needed, as, should the young succulent plants become waterlogged, it would at once arrest the healthy root action. In short, no checks of any description should be permitted to occur. Successive shiftings as the pots fill with roots must be made, but generally my plants show their bloom-buds when in 5-inch pots, *i.e.*, about the middle or towards the end of June. As growth progresses the interest in the plants increases, and should anything very promising show itself, it is at once encouraged and given a shift into a larger pot. I rarely stop the growth of any of my seedlings; such as are not deemed worthy of greenhouse culture are planted out in some partially shaded bed or border, where they continue to bloom until autumnal frosts set in. Should, however, any of them prove to be distinct, they are secured before they sustain any damage, otherwise they undergo the same ordeal as plants properly designated annuals. When the plants in pots have exhausted the soil in which they are grown, top dressings or liquid manure must be given them. When some of the artificial manures, now in use, are given, however beneficial they may be, they leave a crust-like deposit on the soil which in time becomes unsightly, and, moreover, impedes root aëration; hence it is a good practice to frequently stir and remove this crusted surface and replace it with fresh soil.

Fuchsias will grow in most ordinary soils, especially when turned out in the open ground, but for pot cultivation they flourish best in the decomposed top spit from a sheep pasture or good meadow, good clean leaf mould, a small portion of cow manure, thoroughly decomposed and used in a dry condition, a small portion of upland peat, and a liberal portion of silver sand. I prefer to mix my compost at the time when it is required for use, and I never sift it. It is simply broken up into proper condition with a spade, using the finer portion for plants in a young state, and somewhat rougher as they increase in size. As the

plants grow they require support; many of my plants, however, need but one central stake, to which the main stem is fastened, and thus treated they assume a pleasing and graceful form.

As I may say all our Fuchsias, with the exception of one variety, viz., globosa, have been raised during my time, it may interest some to know the names of a few of the more prominent men who have thus enriched our gardens. Knight, of Battle, Sussex, in the autumn of 1839, raised and distributed four varieties: one named elegans superb took a first seedling prize at the Hastings Horticultural Show of that year. Mr. Morris Todd, of Rolvenden, Kent, raised several seedling Fuchsias. Some old growers, who survive, may remember his Moneypenii, which I used to grow. To these must be added the names of Youell, Standish, Fowle, Cripps, of Venus Victrix fame; the indefatigable Mr. Banks, of Deal, who contributed numbers of good varieties; but to Mr. Story, of Newton Abbot, I must give the highest praise for his beautiful white double and single corolla'd sorts. GEORGE FRY.

Further Green, Lewisham.

VIOLETS WITH TOO MUCH LEAF.

"ENQUIRER," who complains of the above (p. 380), probably grew his Violets in too rich a soil, and possibly in a shady place. The best antidote to an excess of leafage is to grow the Violets on an open piece of ground in the garden far from the shade of bush or tree, and of rather a hard than a loose texture. A piece of ground in good heart without the addition of manure is also the most favourable for the production of floriferous Violet plants. The plants should also have plenty of room, from 9 inches to 1 foot being the best distances apart. Any stimulating manure or leaf-mould should be avoided. The latter especially forces Violets into leafage rather than bloom, as if in haste to get back to its original source. Shady places are also most favourable to leaf-growing rather than bloom. It is quite a popular error to imagine that shade is needed for the successful culture of the Violet. Those grown on shady borders and those cultured in the full eye of day are so different, as often to be mistaken for totally distinct varieties, and the difference merely consists in the percentage of leafage and flowers. Fully exposed, the leaves are so much smaller and shorter as to give the crowns—the seat of bloom—the full benefit of the sun's light and heat, and these crowd them with bloom as pins in a pincushion. The Violet also likes maiden soil, and if it has to be grown on the same spot for the sake of convenience, the soil should be wholly or partially renewed every year if possible. Some rather singular rotations also seem to suit the Violet exceptionally well. One of our cleverest cultivators in the eastern counties (I may, I think, name him—Mr. Allan, of Gunton) obtains some of his most brilliant victories in Strawberry culture by running Strawberries and Onions abreast and also in succession on the same ground. He also does Violets remarkably well, but not, so far as I am aware, abreast with or in succession to Onions, though some of the most floriferous Violets ever grown were so produced. The Onion soil, being in good heart after the crop was harvested, was merely dug up and left to mellow and consolidate throughout the winter. Part of the ground was planted with Violets in April, the soil being tolerably firm and the plants well compressed in the act of insertion.

A few surface scarifyings and the vigorous suppression of all runners were all the Violets needed until potting or framing time in October, when the plants seemed all bloom, as practical men express it. Many fine plants have been seen and handled since then; but perhaps, on the whole, none to equal those that succeeded the Onions. Could the antipodic unlikeness of the two crops have had anything to do with the exceptional success? More likely the exceptional consolidation of the root-run, the absence of all rank, or, indeed, of any manure, the heavy Onion crop having appropriated and exhausted the heavy dressing given the previous winter, were the chief causes of the exceptional floriferousness of the Violets. If "Enquirer" can, he perhaps could hardly do better than go and do likewise. Neither must he be too much disappointed with his present plants. Probably they are only late, as not a few Violets are this year, and beneath the excessive canopy of foliage he may yet find advancing to the front a fair crop of Violets. Most of the single varieties seem over-leaved this season; the Neapolitan, blue and white, are in a similar plight in some places, whereas the Marie Louise has about its usual average of leaves.

But the percentage of leafage to bloom is largely a matter of culture, and is also much influenced by soil and climate. It is even possible to grow Violets almost all bloom, so that leaves of other varieties must be used to fringe with verdure the larger handfuls of blossom they yield. A week or two since someone complained of some of their white Neapolitan showing a peculiar affection on its leaves. This was said to be red spider. I have, however, seen a few cases of this where no red spider was present. Plants were attacked here and there in a healthy border, as if frost-bitten or smitten with the Potato disease. Fortunately, I have not heard of its spreading much or far. But this Violet seems considerably more tender than Marie Louise, or even the coloured Neapolitan, from which possibly it may be a sport, or is it a seedling? Certain it is it promises to be a magnificent companion either to Marie Louise or the Neapolitan in bouquet, wreath or vase work, or in miniature decorations. D. T. F.

WINTER-FLOWERING PLANTS.

ZONAL PELARGONIUMS are most appreciated during the dull winter months. No other flower equals them as regards brilliancy of colour, and their blooms, moreover, are specially serviceable in a cut state. They are generally considered to be strictly greenhouse plants, and very few attempt to force them. In reality, an unheated greenhouse, or one warmed only when frosts are imminent, is altogether unsuited for a continuous production of bloom during winter. In order to have them in perfection at that season, resort must be had to fire-heat. Single flowering sorts are certainly the prettiest, but, nevertheless, much less serviceable than a good selection of semi-double varieties, nor will they stand so much heat, as that induces rank flowerless growth. What they require is plenty of room on either light staging or shelving near the glass in a house maintained at a temperature ranging from 45° to 50° by night, and from 5° to 10° higher in the daytime, with plenty of air whenever that can be safely admitted; then, if they are kept rather on the side of dryness at the roots, and the floor of the house is also kept as dry as circumstances will permit, there will be but little damping off, and a fair amount of bloom will be constantly produced. I ought perhaps to add that plants allowed to bloom all the summer are too much exhausted to be serviceable in winter. Those, therefore, who require a good late autumn and winter display ought always to prepare a number of strong sturdy plants especially for that purpose. Some of the best sorts for winter flowering are Lord Chesterfield, magenta; Crimson Gem, one of the best; Metis, crimson, very bright and free; Mrs. Gordon, crimson, with a white eye, trusses large; Ferdinand Kauffer, magenta-purple, upper petals orange-scarlet, a beautiful variety; Mrs. George Gordon, pearly white, with a pink centre; Lady Chesterfield, deep salmon; Sophie Birkin, mottled salmon; Mrs. Strutt, pink-shaded purple; Mrs. Robertson, rose-pink, very free; Olive Carr, pink; Queen of the Belgians, white, and very perfect; Bianca, white, very free and good; and Niphetos White Nosegay, very free, trusses large, forces well. Semi-doubles are most valued, and every winter one forcing house and the shelves of another are, in our case, devoted to their culture. Few appear to realise how serviceable Pelargoniums of this class are. They are not adapted for mixing with the ordinary occupants of a plant stove, as they require more light and room than most plants and a good circulation of air. A high temperature, *i.e.*, anything above 60°, and much moisture induce rank growth, and less bloom is the result, though the ever-flowering Guillion Mangilli will bloom under almost any conditions, if we except a low temperature. Ours are forced in a Melon house, but prior to their introduction to that structure all the soil is cleared out, and the house is regularly cleaned from top to bottom. There is, then, nothing but a dry temporary staging not far from the bottom-heat pipes for the plants to stand on, and to this dry heat, coupled with the admission of plenty of air when the weather permits, we attribute much of our success. Small plants in 5-inch pots or less are flowered on the back shelves near the glass, and larger plants in various sized pots occupy the remainder of the house. If we purchased, at the present time, a number of sturdy, strongly rooted plants, we would unhesitatingly give them a shift into pots two sizes larger than those they are in, using fairly good loamy soil with plenty of grit in it, and potting firmly. This would encourage them to grow strongly, and yet not prevent them from flowering freely. Well-established plants under the treatment just described may also be safely given liquid manure occasionally, in order to increase the size of the trusses. Every season we try several new semi-double kinds, and only the best for winter blooming are kept, but none surpass the old Guillion Mangilli; in fact, there are none that equal it for forcing. The colour is a rich crimson, and what we are both trying to raise and to procure are good scarlet and white companions for it. Ludwig Ferchl, bright scarlet, is useful, but we prefer F. V. Raspail, deep scarlet, and a fairly good forcing variety. Lord Mayor, pink, suffused with purple, fails sometimes, but where variety is liked it is worthy of a trial. Madame Thibaut, of nearly the same shade of pink, is particularly serviceable, quite the smallest plants producing fine globular trusses. Mrs. A. Lattey, pale pink, is one of the best for winter flowering, the trusses being large and plentiful. Grand Chan Faidherbe, deep crimson, is very handsome, and we are increasing our stock of it. James Vick, deep salmon, and very distinct in every way, produces very large trusses, the pips of which are also large; in mid-winter it fails, but is nevertheless worthy of a place in every collection. Louis Buchiner, salmon, has rather small trusses, but these are plentifully produced, and the colour is indispensable. Le Cygne is the best white, both truss and individual pips being of good form and pure white. Candidissimum plenum is also very serviceable, and is less liable to be tinged with pink than Madame Amelie Baltet. Heroine, white, produces extra large flowers, and Madame Leon Dalloy, blush white, is a very fine variety.

ABUTILONS.—These are by no means so popular as they should be. A few plants of them may be seen in every collection, but, as a rule, they present a half starved appearance and are certainly not attractive. For pot culture young plants are the best. Cuttings strike readily in a brisk bottom heat, spring being the best time in which to pot them. They should be potted off singly in 4-inch pots, and from these shifted into 6-inch pots before they have become root-bound. A compost consisting of two parts fibrous loam to one each of peat and leaf-soil with a sprinkling of sand suits them well. No stopping should be resorted to, a single branching stem being preferable to several weakly, branchless shoots. During summer they may be grown in cold pits or frames provided plenty of air is given them, or they may be set in the open air. If large pot plants are required, old cut-backs may be planted out on a sunny border, where they will, with but little attention, develop into strong, bushy plants, which may be potted up without much injury accruing to them. They do not continue to flower throughout the winter in a cold greenhouse, but will do so if the house is warmed night and day by means of a little fire-heat. It is when planted out in roomy conservatories that they prove most serviceable,

though if given too rich a border or unlimited root run they are apt to grow much too strongly. If the roots cannot be confined to a limited area, it is advisable to keep them in pots, plunging these deeply in the soil, into which roots will quickly find their way. Under this treatment they form sturdy, branching growth, and flower most abundantly. They are well adapted for clothing pillars and archways, as well as high back walls. They are also suitable for planting in the centre or at the back of large beds of mixed conservatory plants. Boule de Neige, white, is the most serviceable variety with which I am acquainted, especially when allowed to grow unrestrained. It is particularly suitable for those who require an abundance of white flowers at all seasons. The yellow stamens should be removed and the petals reflexed, in which state they are suitable for either wreaths or crosses. Fire King, rich red, is a handsome free-flowering sort, and the same may be said of Golden Gem. Canary Bird is the best yellow; in habit it much resembles Boule de Neige. King of the Roses is also free and good.

Cinerarias.—Everybody who has a greenhouse cultivates a few of these showy plants, but it is not often one sees them particularly well cultivated. Too much sunshine in summer and too much fire-heat in winter are to blame for many failures, the former being the sole cause of a mysterious so-called disease that has proved destructive to innumerable plants; while the fire-heat weakens the plants, and appears to render them liable to be infested with greenfly. During summer Cinerarias are best grown in frames at the back of a north wall, where, if not allowed to become badly root-bound before they are repotted and are not unduly crowded, strong and clean plants will be the result. When we grew them in a sunny position, no amount of shading prevented the loss of numerous plants; this usually happened soon after they received their final shift, but since we have given them a cooler site not a plant has been lost. During winter they ought to be kept clear of other greenhouse plants, otherwise they soon become drawn and somewhat disfigured. If, owing to necessity, they are placed on a latticed staging over hot-water pipes, the boards should be well mossed over, a dry heat being thus prevented. They grow most sturdily on the front staging of a lean-to house, and when well in bloom they may be taken anywhere. The best and most enduring lot of plants that I ever saw were in a conservatory where sunshine seldom reached them. A very moist bottom does not suit them during winter; it encourages damping off. If they must be kept in cold pits or frames, they should be placed on inverted small pots. A very little frost proves fatal to them, and in anticipation of this the frames ought to be banked up with dry litter or leaves, and the glass well covered over every night and during very frosty days with mats and litter, if need be. Plenty of weak liquid manure ought to be given to all well-established plants. Unless, too, greenfly is kept down, the blooming period will be unsatisfactory and of short duration. Occasional weak fumigations with tobacco paper before the plants are badly infested are much the best remedy, and should be persevered in by all who wish to succeed with Cinerarias. The single varieties are the most generally grown, but we find double sorts to be very useful in spring, and they are certainly the best for cutting and packing. Seed of the former, sown in April, furnishes flowering plants at the present time and onwards, and to succeed these more seed should be sown in June and July. It is only by sowing early that an early display can be secured, as Cinerarias will not force. A good percentage of double-flowering varieties may now be obtained from a packet of seed, and seedlings are more easily grown to a good size than plants obtained by division. We favour the latter plan, as we do not want large plants, only 5-inch and sometimes smaller pots being employed in their culture. Single blooms of Mr. Thomas Lloyd, wired and dotted among other flowers in vases, are very effective, and this fine double, deep purple-coloured variety is still second to none as regards utility.

W. I. M.

Camellias as stove plants.—Permit me to thank "W. H. G." for his note giving further information concerning this interesting case, which is so unique that perhaps "W. H. G." may take the further trouble to give us the average winter temperature of the stove. It would not seem that there is any unusual percentage of bud-dropping at the critical swelling season, as otherwise the supply of flowers would not be so ample. Possibly, as not seldom happens in old-fashioned houses, the back wall and portions of the stove against it—that is, the Camellia side of the stove—may be cooler than the other portions. The facts of the case rather favour this supposition, as it is no uncommon thing for Camellias to be in full flower at Christmas in cool, and in fact almost unheated, houses. These sentences are not penned to throw any doubt on "W. H. G.'s" statements, but to clear up a most interesting question, viz., whether Camellias will really expand their blooms in a temperature of, say, 60° or 65° without the loss of an enormous percentage from bud-dropping. That Camellias will bear a stove temperature when making their growth, and not seldom are the better for it, is well known. But if they will open their flowers in it without undue loss, hundreds of us will gladly thank "W. H. G." for calling attention to such facts, and giving us some further hints, if possible, as to the most likely way by which we may go and do likewise. Under stress of urgent need of Camellias at early seasons, such as October and November, I have frequently attempted to force the well-formed buds to expand before time, and the results, broadly stated, have been failures. A few buds at times have held on and opened, but the bulk invariably have been found scattered over the stove floor or surface of the pots. Hortus.

Flower Garden.

THE PRIMULA FAMILY.

The culture of this interesting class of plants doubtless received a considerable impetus from the Primula conference held at South Kensington last May, but if that interest is to be maintained it will be necessary to hold an annual conference. Perhaps it would not be necessary to make such an extensive display as was made on the occasion just alluded to, but groups of plants ought to be invited, and owners of new, distinct, or doubtful forms would have an opportunity to exhibit them. By that means many disputed points might be cleared up and much useful information obtained. I was interested in reading the note on Primula purpurea in The Garden (p. 357). It may be a fair question to ask, What is the true Primula purpurea of Royle? Is it a species, or merely a variety of P. Stuarti? Next season several new Himalayan Primulas will most likely be flowered in this country. The European species are but little known beyond the limits of botanical gardens, except those in the hands of a few specialists, like Mr. Llewellyn and the Rev. Wolley Dod, or such trade growers as Messrs. Backhouse, of York. What an interesting study is the whole group of alpine Primulas. Most of them are easily grown, too, if they receive the attention which they require, and when they succeed well either in pots or planted out, there are few indeed who would not be delighted with them. First in importance in this group is the well-known P. Auricula; it is rather sportive in its native mountain home, but that is nothing compared with the surprising results which have been obtained by the patient labours of the florist. The usual form with its leaves rather thickly dusted with farina is a pretty border plant, producing golden flowers freely. A more delicate and prettier plant is the variety called marginata; we have in a frame protected from wet a few plants of the true variety, which are beautiful in leaf. The variety Balbisi is also an excellent green-foliaged pot plant. Other varieties are in cultivation, but I have no knowledge of how they grow either as border or pot plants. A group of any of the kinds named would be charming in the rock garden. Indeed, that is the place for them, as when in pots they require considerable attention all the year round. They like deep sandy loam, and a position where the sun does not shine upon them during the hottest part of the day.

Primula villosa var. nivea.—The Snowy Primrose, usually grown under the name of P. nivalis, is one of the most beautiful of spring flowers. It is easily grown, and can be very rapidly propagated by division. I have saved seeds of it and raised plants from them, but they cannot be depended upon to come true to name. A few have white flowers, but more are pale purple and lilac-coloured; they are, however, all pretty and interesting. The true P. nivalis of Pallas and Willdenow is a different plant, and is identical with P. longifolia, published in the *Botanical Magazine* in 1797. This, again, has been decided to be a synonym of P. auriculata, and is a Siberian species.

P. villosa (the Mountain Primula of Curtis) was figured in the first volume of the *Botanical Magazine*, t. 14. It is there stated "that a variety of this plant with white flowers, brought originally from the Alps of Switzerland, has for many years been cultivated in a garden in Yorkshire." I have no doubt, therefore, that this white variety has been propagated upwards of a hundred years in English gardens by division of the plants. The ordinary form has sported very much from seeds. We have a dozen distinct varieties raised from the original species, besides many more from the white form, and it is also rather curious that the seedlings from the variety nivea are much smaller growing plants than the parent. When planted out or grown in pots I know of no Primula superior to P. villosa as a decorative plant for the spring garden. Varieties of P. villosa are grown under the name of intermedia, but any hybrid may have this name given to it. The original P. intermedia is a form of P. farinosa, and is figured in the *Botanical Magazine* (t. 1219). It varies but little from our own Bird's-eye Primrose (P. farinosa). By the way, this interesting little plant does not take so kindly to cultivation as one would like it to do. It is somewhat of a bog plant, and neither takes kindly to the ordinary open air garden nor to pot culture. I had fifty plants of it brought to me from a native bog some five or six years ago, but they are now reduced to four or five. I find many delicate-growing Primulas with slender root-stocks and hair-like roots when attacked (as they often are) with the Auricula aphis to be most difficult to clean, and the aphides certainly injure, and sometimes destroy, the plants. These pests are very partial to P. minima, and quite overpower the plant. They swarm above ground over the roots, and prevent the healthy development of fibres near the surface. P. spectabilis is not only one of the prettiest of the alpine species, but one of the easiest grown. I grow several varieties of it, but none succeed so well as the typical form. It is as easily managed as a pot plant. As an alpine Auricula in the York Nurseries it grows most luxuriantly near the margin of water at the base of some artificial rocks. What masses of P. marginata are also to be seen in these nurseries! This is one of the best for pot culture, but P. marginata grandiflora and P. m. cærulea only ought to be grown in that way. All the varieties of marginata are readily propagated by division, and they grow freely in a compost consisting of a third part of turfy peat mixed with loam. The pretty little P. mistassinica ought not to be omitted from the Bird's-eye group. The mite of a plant of it exhibited by Messrs. Veitch this year attracted much notice on account of its diminutive size. The judges gave it a first-class certificate, which some thought was too high an award for such a small Primrose. It is figured in the *Botanical Magazine* for the year 1830, from specimens or seeds gathered by Richardson and Drummond in the Arctic Circle. It is a pretty little plant, and should not be despised because it is small. It is

found in Canada distributed over a wide area. The whole of the alpine species should be grown in the rock garden, and one at least of each should be kept in pots. Our insular climate does not suit all Primulas out of doors. They do not mind melting snow if the snow could be depended upon to remain over them for any length of time. It is our changeable climate that is so injurious to many choice alpine plants. The snow melts and soaks the plants; a spell of fine weather sets in and starts them into growth; anon the biting east winds blow over them, freezing and nipping the incipient growths; and so on until April or later alternate thaws and frosts, rain, snow, and hail make sad havoc with plants that might stand bravely through a Siberian winter if under a thick covering of snow.

Our own common Primrose is the most esteemed of all in gardens, and for wild places the yellow variety is most appropriate. Many fail to grow this native English plant in their gardens, simply because they are not aware of the natural conditions under which it succeeds. It will not grow well on dry, sunny banks. Its natural position would be the north side of a bank, and one that did not become quite dry in summer. In light, dry soils the Primrose does not grow naturally, nor will it succeed if planted there. The natural home of this species is on good deep yellow loam, constantly moist, and all its allied forms will succeed under similar circumstances. In fact it is marvellous to see the clean, strong, rapid growth which some Primulas make when their roots are below the level of water and the leaves overhanging its banks. Those who have had any difficulty with the Himalayan species should try them close to the margin of artificial ponds. Dig a hole for the roots within 3 inches or 4 inches of the margin. It should be made 3 inches or 4 inches deeper than the water surface; fill the hole up with good loam, and in it plant your Primulas and await the result. How they would succeed entirely covered by water, if the banks should overflow, I cannot say. I write of artificial ponds that never rise above one uniform level. Sufficient water to keep the roots constantly wet suits them admirably. We have many new Himalayan Primulas raised from seeds, but until one sees whether they intend to flower or not it is useless directing further attention to them.

J. D. E.

MICHAELMAS DAISIES.

Several correspondents have written in high praise of these Asters, but none of them have given the names of the varieties which they consider best. Numbers of amateurs would not only willingly, but gladly purchase selections of them if some of the readers of The Garden would name a few, say a dozen each of the best dwarf, the best medium, and the best tall growers. In large gardens where space is abundant, and stout stakes or miniature Hop poles plentiful, tall varieties, like lævigatus, Archer-Hind, Robert Parker, and others, tell well against green hedges or thrown well back in the shrubbery borders, but owners of many small gardens would most likely give preference to the medium and dwarf growers, especially as some of them are equally beautiful and suffer less from wind and rain in stormy weather. My own collection being very small, including possibly a score of varieties, I am quite incapable of undertaking the task, but others, possibly "Veronica," will, I have no doubt, confer a favour upon readers of The Garden by giving us their experience with regard to them. One of the qualities in a really desirable Aster, independently of its moderate height, should be its staying powers under stress of weather such as we have lately passed through. Beauty, "Hortus" assures us, is only skin-deep, and this reminds me that I ought to take off my hat, although my office is cold, while I acknowledge the compliment which he has paid me in regard to Peaches. But I digress. On looking over our own Asters, which were very beautiful before the recent storm of wind and rain came on, I find that all but one have more or less suffered, and that one is A. Amellus bessarabicus. This variety attracts attention as soon as it starts from the ground; it grows nearly to the height of 2 feet, when the large bluish purple stars, even on weak plants, expand and form beautiful panicles a foot or more across. To this, previous to the downpour of rain, I had affixed the usual cross, as I intended to increase it, but having passed through the rainfall apparently without injury, I have this day honoured it with a second mark of approval. Another pleasing variety, also a front-row plant, is longifolius formosus, a kind with rosy pink flowers. This and also three or four more have been marked for propagation, but being myself only a very small grower of Asters, I will withhold their names for the present, as my best stars may be eclipsed by lists from more experienced cultivators.

W. Coleman.

Eastnor Castle, Ledbury.

SEA HOLLY.

(ERYNGIUM MARITIMUM.)

This native of our sandy coasts and seaside sandhills well deserves a place in the garden. Though lower in stature than the large Eryngiums of our flower borders, it is a plant scarcely less important in interest and picturesque beauty. Its pale glaucous colour and rigid structure give the impression of its being fashioned in some living metal. In its seaside home the roots run far and deep into the loose sand; in gardens it will thrive in any light soil. Sea Holly makes a useful winter bouquet; whole branches cut now and arranged in some suitable jar without water will retain their form and nearly their living colour throughout the winter.

Flower-spray of Sea Holly (Eryngium maritimum).

The Cactus Dahlia (D. Juarezi).—The "one fault" which "Hortus" so fully describes (p. 335) as being the only drawback belonging to this brilliant and decorative Dahlia has been so thoroughly and satisfactorily overcome by a simple mode of treatment which I have practised on my plants this year, that I would wish it to be more known than it is. The plants which I grew last year were divided in spring at planting-time, and at once placed where they were required to bloom between large clumps of the white Anemone japonica, with which they contrast so well. When the liberal growth of young shoots was forward enough to thin out, they were reduced to three, and later on the greater part of the side shoots, which so rapidly smother the terminal blooms, was nipped out, leaving only the stronger ones required to produce a succession of bloom, and these again had their side shoots removed, with the result that there was an almost unthought-of supply of really first-class blooms as to size and quality so fine, that when I exhibited a stand of blooms last August it was said they must have been grown under protection. The plants continued to produce abundance of bloom until cut down by early frosts. It merely requires a little thought and some practice as to which are the best shoots to leave, remembering always to keep the centre of the plant from being overcrowded.—J. T. Poë, *Riverston.*

WALL GARDENING.

Wherever there is a wall with crevices on the top or sides there plants will grow—not every species, I grant, but still quite enough to make the wall ornamental. Everybody has seen the Wallflower quite at home on old ruins. In the spring of last year I saw a great golden cluster of it growing out of Peterborough Cathedral 40 or more feet from the ground, and the walls of the cloisters, too, were charmingly furnished with Wallflowers and other plants. Antirrhinum rupestre and other sorts will grow on walls; also all the Aubrietias and many of the dwarf Campanulas, especially C. garganica. Erinus alpinus in such a situation is a little gem. Erodium romanum succeeds well on a sheltered wall. Linaria Cymbalaria is a well-known wall plant. Not far from where I am writing Linum alpinum and many Saxifrages, Sedums, and Sempervivums thrive well; as do also Silene alpestris, Thymus citriodorus, Veronica fruticulosa, and others. The number of Ferns which may be planted on old walls is much larger than many would suppose. Near here is a good-sized specimen of the Shield Fern growing out of the side of a brick wall. It is in a north aspect, and in such a situation seems to be quite at home. In many parts of the south of Ireland Fern-covered walls are quite common, and very beautiful they are. Amongst the Ferns found growing in this way may be mentioned Ceterach officinarum, Asplenium Trichomanes, A. Ruta-muraria, Scolopendrium vulgare, and various others. In Yorkshire, too, we have seen Phegopteris Dryopteris, various forms of Lastrea Filix-mas and Athyrium Filix-fœmina, Polypodium vulgare, &c., occupying similar situations; whilst in Scotland, Asplenium septentrionale and Allosorus crispus in some of the old quarries drape the face of the rocks in a most charming manner. I have a friend living in a neighbouring town who is exceedingly proud of a young Sycamore that is growing out of a crevice at the top of a wall at the rear of his house. There is a mystery as to how it came there; but about a dozen years ago a little green leaf sprouted out, and was succeeded by another and another, and year after year its leafing was watched for, and still it grew and flourished, and has ultimately developed into a low-spreading bush. I mention this to show that Nature has a way of her own in adapting such things to surrounding circumstances. As regards the best way of locating plants on walls, in some cases seeds may be scattered in the crevices, and the holes afterwards filled up with fine soil. This is the natural way, but a more certain method is to raise the young plants elsewhere, and when well rooted lift them with little balls of earth attached to them and press them firmly into the holes and crevices, making all firm and secure. In this way a wall may soon be furnished. Those plants should have the largest openings which require the greatest amount of sustenance.

E. H.

Different sorts of Pampas Grass (p. 365).—Pampas Grasses vary wonderfully in form, colour, and height, the strains most valued being the whitest. They also seem to vary considerably in hardiness, as well as season of growth. These two are also very much linked together, the earlier varieties being, as a rule, the hardiest, and for this simple reason that, as no Pampas Grass grows in our climate too early to be caught by the late spring frosts, the earlier it can finish in the autumn the hardier it will

be. A prompt remedy for somewhat hastening the progress of these plants in the spring is to set fire to them. This does double duty—clears off the dead, unsightly refuse, and wakes up the plants very promptly indeed from their winter's sleep. Neither do they suffer injury from this rude awakening. One great difficulty in improving Pampas Grass is the difficulty of seed-saving in most places. The plumes are so late, that the seeds do not ripen; neither do the varieties come true to type when saved. The process of improvement of strains through root-division is somewhat slow and tedious, as those who have tried have found. Latterly, I have seen a good many types varying so much, that the worst were hardly worth growing contrasted with the best, and some of the pure silvery forms were simply magnificent. Could hardier, earlier, and finer varieties be selected for culture in their native climate, and reliable seeds thus be provided, this magnificent plant ought to be more widely cultivated than it is, not only for ornamental effect, but as game covert in woods. The severe frosts that come every now and again play sad havoc with the Pampas, even when protected by its own *debris* and partially sheltered by trees. Hardier and earlier strains would doubtless pull through. Where they do so, as in the milder counties, the Pampas Grass adds a unique mixture of grandeur and grace to many a pleasure ground and woodland landscape.—Hortus.

NOTES ON POPULAR PLANTS.

Pansies cannot be grown so well in the south during summer and autumn as in the moister and cooler atmosphere of the north of England and in Scotland, but southerners have the advantage in early spring. In order to have a fine display of bloom, seeds should be sown about the middle of August. The young plants when up should be pricked out in the first place about 2 inches or 3 inches apart, and when they have grown into thrifty, dwarf little plants, prepare for them a piece of rich, deep soil in October, and set them a foot apart. A few years ago I had a bed 60 feet long and 6 feet wide treated in this way. They began to flower in March, and as we supplied them freely with water in hot, dry weather, they were a blaze of colour all through the summer and autumn months. Named varieties debilitated by repeated renewals from cuttings do not produce such a wealth of bloom in the first place as do seedlings, nor do they continue so long in flower; many of them, too, die off in summer, but seedlings do not fail in that way. Pansies during spring when grown in pots with merely the shelter of a cold frame are lovely. What we do now is to pot up one or two plants of each variety, and plant the others out in beds or borders. It is not safe to trust entirely to out-of-door plants as part of the stock may be lost by alternate frosts and thaws.

Hollyhocks.—If it is desirable to raise Pansies from seeds in order to obtain vigorous plants, it is equally so in the case of the Hollyhock. Seedling Hollyhocks are not so variable as those of Pansies; they may, therefore, be expected to produce flowers as good as those of their parents, *i.e.*, fifty out of every hundred of them. Seeds saved now if sown next May will produce strong-flowering plants in the following autumn. We have left plants out in the open garden for two winters without interfering with them, and disease has not shown itself at all this year. Plants thus treated did not produce such handsome spikes as young plants, but they succeeded fairly well. We ought this year to lift the stools and either pot or plant them out in a cold frame, in order that we may be enabled to get cuttings from them in spring. Plants raised from eyes or cuttings during the summer and autumn should now be repotted, so that they pass through the winter without becoming pot-bound. When they get into that state they become stunted in growth, and start prematurely into bloom. In order to get cuttings early in spring, the plants should be potted and placed in a greenhouse during the winter months.

Ranunculuses are being more grown during the few years than hitherto, but not yet so much as they ought to be. I took seventy-two blooms of the best double Ranunculuses to a flower show, and I did not meet with anyone who knew what they were. There are different times and seasons at which to plant them. Where the soil is dry and the situation otherwise favourable, some of the tubers may be planted out now, but it is better to reserve the main collection until February. We plant some hundreds of tubers as late as the first week in April. This year they flowered late, but better than they did from February-planted tubers the previous year. Plant the little shrunken tubers in rows 5 inches apart and 3 inches or 4 inches asunder. Draw drills for them about 2 inches deep.

Seeds of Ranunculuses may be sown in January in shallow boxes filled with light compost. Miller, in his "Gardener's Dictionary," says, "sow about

The Cretan Mullein (Celsia cretica) in flower in Surrey. Engraved for The Garden.

a quarter of an inch deep," but the best growers of the olden time merely covered the seeds with fine soil, which is the right way. It does not take long to produce flowering roots of the Ranunculus from seeds. J. Douglas.

Transplanting Christmas Roses.—"Hortus" in his remarks (p. 362) on the planting of Christmas Roses says that it is best to split them up into one, two, or, at the most, three eyes. "Hortus," I expect, grows his Christmas Roses in some light black soil. In my heavy, strong soil it would be almost fatal to do as he recommends. I have heard of instances in which hundreds of plants have been sacrificed by such treatment, all having died the first year after planting. I have never planted them outside in autumn, but I can believe it would be a very bad plan to do so, as they could not have time to make fresh fibres before winter set in, and consequently they would be unable to stand the effects of frost and wet. I always plant my Christmas Roses in February after forcing them. I then split them up into pieces of about half-a-dozen eyes. As the weather after February generally improves, they are able to take a firm hold of the ground before the drought of summer sets in; while in autumn it gets worse every day after planting, and the result is that the plants lie dormant all winter, and when a plant is in that state, slugs and vermin of all descriptions flock to it. The crowns are then eaten away, and the plant does not appear in spring. Another important point about the planting of Christmas Roses is the depth at which they should be put. Some plant them with the crowns above ground, while others put them down a few inches. I prefer to plant them with about an inch of soil on the crowns. I find that after they stand two or three years the crowns work upwards. I have often seen plants which had been planted with their crowns 2 inches in the ground after two years have them quite exposed, and thus circumstanced they are apt to be eaten with slugs, or to get trodden on, and the flowers which they produce are always unshapely and discoloured.—D. W.

CELSIA CRETICA.

This stately plant, nearly related to the Mulleins, though a native of the Southern Mediterranean coasts and the island of Crete, is hardy in the south of England. The individual flowers are larger than those of any of our Mulleins, and deeper in colour; in the centre is an Orchid-like appendage of a sumptuous brown colour, which adds much to the richness of the individual flower. The buds have a curiously square and flat look. The plant is of rapid growth, flowering the same year if sown early, or if sown in May, making good plants to put out in autumn for flowering early the next summer. The centre spike is succeeded by a number of flowering laterals. The flowers have a sweet smell, like honey or Agrimony. Well grown, it is a handsome plant of fine habit and form, and rich and good in colour.

RENOVATING WALL CREEPERS.

There are many kinds of wall creepers which, owing to the luxuriant growth they make, quickly exhaust the soil in which they are growing, and then, if flowering subjects, the blossoms become small and few in number, and in the case of non-flowering plants, such as Ivy and Virginian Creeper, the growth is weak and the foliage bad in colour; not unfrequently, too, large plants are destroyed under the impression that they are dying or cannot be made to be of any further service. All this may be obviated by renewing the soil. In order to do this no serious disturbance of the roots is necessary, and in two years many a sickly-looking plant, however large, may be restored to a healthy and vigorous condition. When practicable, 6 inches or 8 inches of the surface soil should be removed; this need not interfere to any great extent with the roots, *i.e.*, if the work is carefully done, and it will pay for being done well. If a few roots can be laid bare, it will be all the better, as they will the sooner feel the effects of the new material. Substitute for the old soil taken away some good rich and holding compost. For the majority of plants a mixture of half turfy loam and half rotten manure is the most suitable, but good kitchen garden soil that has been annually manured will be better than nothing. In not very bad cases a good dressing of rotten farmyard manure will restore an unhealthy plant to vigorous condition. I have known a good thickness of old hotbed manure laid on the surface to do a good deal of good, but

for climbing Roses there is no better plan than removing the surface soil and substituting manure and loam. Within the past two years we have converted some very old creepers that had become weak through poverty of the soil into luxuriant health by forking in about their roots a couple of cartloads of vegetable mould, the result of rotting down the refuse of the garden. Ivy on walls is, in bad cases of soil-exhaustion, often more yellow than green; all this may be changed by either laying on the surface a thick layer of rotten manure, or by taking away a good portion of the old soil and putting fresh material in its place. The last plan is much the best, as its effects last the longest. J. C. C.

EARLY AND LATE CLEMATISES.

Lovers of Clematises must often, I feel sure, find it difficult to know what to purchase. I have known an order sent to a nursery for half a dozen good varieties; they have been sent, but without any information as to the treatment they needed. Spring and summer-flowering varieties are occasionally both included in the selection, the result being that if the spring-flowering types are pruned in the same way as the later summer-flowering kinds, there is no head of bloom to greet the cultivator when he looks for it. Not long since I was called in to see a Clematis that did not bloom, and to give a reason for its not doing so. A lady had ordered a blue and white Clematis at a nursery, and Jackmanni and Miss Bateman had been sent her. She was advised to prune back Jackmanni rather hard in the winter, and, thinking this treatment applied to both, she did the same with Miss Bateman, with the result that it never flowered. I advised her last autumn not to touch the white form with the pruning knife, but leave the vigorous shoots intact. She did so, and in June she was rewarded with a grand display of white flowers. I mention this case because it seems to illustrate the marked difference that exists between the patens or spring-flowering, and the Jackmanni or summer-flowering sections. As there are some charming varieties among the patens section, some of these should be grown; they do well on warm walls, or on pillars, or on wire trellises; but owing to their early flowering character the blossoms are in danger from late frosts; therefore it is of advantage to have some shelter. The varieties included in this section bloom from the old wood of the previous year, and not from the new wood of the current year, as do the varieties of the Jackmanni type. Now, this is a distinction of the greatest importance; because one may cut down a plant of C. Jackmanni almost to the point where it was grafted, and still it will put forth vigorous shoots that will bear flowers; but if a patens variety be cut away in the same manner, no hope of flowers the following year need be entertained. All that is required is to thin out any decaying wood, but to leave the rest—by decaying wood I mean that which has borne flowers. A few of the best of the spring-flowering, or patens section of Clematises are the following, viz., Edouard Desfosse, flowers large and abundant, having from six to eight petals, which are well imbricated, colour deeply shaded mauve, with darker centre and red anthers; Lady Londesborough, silver-grey with pale bars; Lord Londesborough, deep mauve, flowers large and attractive; Miss Bateman, white with chocolate anthers, flowers of fine form, and petals of great substance, one of the best white Clematises grown; Mrs. George Jackman, satiny white, with a creamy bar—this variety will often flower on the young wood; Mrs. Quilter, pure white, fine in form and substance; Mrs. S. C. Baker, delicate pink, changing to French white, and furnished with claret bars; and Sir Garnet Wolseley, pale blue, with a bar of plum-red on each petal, a very distinct kind.

I would strongly recommend amateurs who have a greenhouse to grow some of these spring-flowering Clematises in pots. They are easily managed and very effective. They can be grown in almost any sized pots, not below 7 inches or 8 inches in diameter, and a rich loamy compost suits them perfectly. In pots of this size the plants could be trained over cylindrical trellises of about 2 feet high and 1½ feet across, or some stakes 2 feet in height could be placed round the pots and the shoots trained to them, tying them first to the base of the stakes and gradually carrying them upwards. Let it not be forgotten that they flower on wood of the previous year's formation, and hence a supply of this wood must be kept up annually by encouraging free growth after the flowering season is over. During the summer months, when free growth is desired, it is advantageous to plunge the pots in some porous medium, as old tan ashes or Cocoa-nut refuse, and also to mulch the surface-soil in the pots with half-rotten manure. In this way admirable specimens can be grown that will make the conservatory gay for a considerable time.

When planted out of doors, either against walls or as pillar plants, the ground intended to receive them should be deeply dug or trenched; a dressing of good manure should be well mixed with it, and, if possible, a portion of chalky soil should be added. Two essentials to their success are deep soil and thorough drainage. The shoots from which flowers are expected should be carefully nailed to the wall or tied to pillars, care being taken, if the buds are formed, not to rub them off. During spring and summer a good mulching with manure will be found to be advantageous. The shoots made after the plants have done flowering should be carefully nailed or tied in, so that they may extend and strengthen themselves without injury.

Let us now advert to the varieties of the Jackmanni section, which bloom from July until October. I have already mentioned that the sorts included under this heading flower on the young growth of the current year. If the growth is too thick and some thinning is required, then the weak shoots should be thinned out and the strong ones retained, because it is these that give the finest and most numerous flowers. The following is a choice selection of these autumn-blooming kinds, viz., Alexandra, pale reddish violet, free blooming; Gipsy Queen, rich, bright, dark velvety purple, a very attractive variety; Guiding Star, a fine variety of a purplish hue shaded with crimson, and with a band of maroon down the centre of each petal; Jackmanni, deep violet-purple, flowers produced in masses, one of the best for decorative purposes; Lilacina floribunda, pale greyish lilac, deeply veined, flowers large having six petals, and perfect in shape, the lightest variety in this section; Magnifica, reddish purple with red bars, flowers very large, stout, and well formed; Prince of Wales, deep pucy purple; Rubella, velvety claret-purple, distinct, and very free; Star of India, reddish violet-purple, with red bars, distinct and effective; Tunbridgensis, deep bluish purple, free blooming; Velutina purpurea, blackish mulberry, distinct; and Victoria, a handsome free-blooming variety, flowers large, composed of five or six petals, well formed, and in colour deep reddish mauve.

There yet remains the lanuginosa section, a useful one, in which there are some very fine varieties. They are hardy in constitution, tolerably vigorous in growth, and they produce blossoms of very large size; so that liberal cultivation is for them a matter of absolute necessity. They will, indeed, succeed in any good, sound, well-drained garden soil which is freely and annually manured, but they would, no doubt, prefer a light, mellow loam to any other, and therefore, in the case of very light soils, it would be best in trenching it to mix with it some good loam. As a matter of course, the more fertile the soil the less manuring will be necessary, but all Clematises are gross feeders. The varieties of C. lanuginosa are well adapted for conservatory decoration, for planting against walls and pillars of verandahs and trellises, and they also make very fine pyramids. When so employed they should be tied to stout stakes, and they should be annually pruned down to about 3 feet from the ground, to prevent them from becoming lanky and bare, the tendency of the new growth being to develop itself with excessive vigour at the extremities. When thus cut rather low, so as to secure a supply of foliage at or near the base, the beauty of the plants is much enhanced. A few of the best varieties of the lanuginosa section are as follows, viz.: Blue Gem, pale cærulean blue, very free flowering; Excelsior, colour rich deep mauve, large, finely shaped, and occasionally double; Grand Duchess, white slightly flushed with rose, a strong-growing, large-flowered, and very effective variety; Lawsoniana, rosy purple, with darker veins, distinct and very showy; Lord Nevill, rich dark plum, large and well formed, stamens light with dark anthers, edges of the sepals finely crimped; Louis Van Houtte, deep violet-purple with darker veins, very free; Madame Van Houtte, white, extra fine; Princess of Wales, deep bluish mauve with a satiny surface, a very fine Clematis; Sensation, rich satiny mauve, flowers large and showy; and William Bennett, dark blue changing to lavender. It will thus be seen that this section of Clematises includes some very fine showy varieties.

Brief reference may be made to the small C. Viticella section. Varieties belonging to this class attract rather by the profusion of their flowers than by their individual size. These plants, while it is requisite they should be fed to the very utmost in order to meet the excessive demand upon their powers, should be pruned hard back every autumn, unless a considerable space is intended to be covered, and the young shoots should be trained up to their full extent in the early part of the summer until flowers begin to appear, when, as all the lateral growths develop flowers, it may be better to let them fall in graceful wreaths of pendent spray. It is, therefore necessary that the plants should have a rich soil and be highly manured.

The following varieties are well worth cultivation, viz.: Lady Bovill, greyish blue, flowers a little cupped, very free; Madame Grange, crimson-violet tinted with red in the centre, distinct and beautiful; Madame Thibaut, lilac with a distinct bar of rose on each petal; Mrs. James Bateman, pale lavender; Othello, dark velvety purple, medium-sized flowers, fine shape; and Thomas Moore, rich pucy violet with white stamens. R. D.

Tropæolum tuberosum. — "J. W." says (p. 361) that this is a sparse bloomer, except when planted in poor, dry soil and in a sunny situation. That is not my experience with it. I have it planted almost everywhere, and the piece which has bloomed best is in heavy clay soil; it climbs round the stem of an Apple tree, and gets but little sun, as it has trees nearly all round it; hence it is evident that sunshine is not essential. However, where some tubers were planted in rich soil and somewhat shaded, they have bloomed badly; but I think it seems to like heavy clay, though, of course, it would be a risk to leave it there in a hard winter.—Greenwood.

Iceland Poppies (Papaver nudicaule).—I have now before me a fine bunch of these beautiful Poppies, which, notwithstanding the fact that the flower season is nearly over, are still making a grand show, and, judging from the number of buds which I see upon my plants in all stages of development, they bid fair to defy the onslaughts of frost for weeks to come. These Poppies range in colour from the purest satiny white and yellow to the deepest glowing orange-scarlet, and have a delicious lilac-like fragrance. Plants of them form very ornamental tufts of Fern-like foliage, from amongst which the slender flower-stalks rise to about a foot in height and bear elegant cup-shaped flowers, the petals of which glisten like crushed satin. The profusion of blooms which they produce is really astonishing. I have frequently counted a hundred flower-stems upon a single plant, and they are produced in never ceasing succession from the beginning of June to October, especially if the old flower-stems are regularly cut off, one or two seed-pods left upon each

plant being more than ample. Not only are these Poppies attractive in the garden, but for elegance in a cut state they are simply unsurpassed, and they last quite a week if cut directly after they open. What can be more beautiful than an arrangement of these Poppies in various shades with some of the ornamental Grasses (either wild or garden-grown) in slender glass ornaments? I have had them thus associated all summer, and very attractive they have been. I may add that they produce abundance of seed, which germinates readily, and seedlings flower well the first year.—C. G. Morris.

EARLY-FLOWERING CHRYSANTHEMUMS.

I confess to having had a prejudice against these. Chrysanthemums in summer or early autumn seemed as incongruous as Camellias in June or Hyacinths in July. But after all there is perhaps more of sentiment than of sense in such feelings, and assuredly early Chrysanthemums have made their way. Every year one meets with more and better varieties of these in house and garden, and it seems probable that, what with the later and earlier classes, the season may be garlanded round with Chrysanthemums almost as brilliantly, though not so fragrantly, as with Roses. They are becoming great favourites for cutting where cut flowers are in large demand; as, indeed, where are they not now-a-days, as hardly any flowers can match them in staying properties. I saw in places recently visited large masses of Madame Desgrange and the golden Madame Domage grown in borders specially for cutting. Hitherto there has been a considerable dearth of colour among the early Chrysanthemums in general cultivation; but the florists now grow three or more dozens of varieties of almost every conceivable degree of size and colour. Among others who have made a specialty of these plants, Mr. Ware, of the Tottenham Nurseries, has taken a leading place. Early in October the following were noted as specially distinct and beautiful:—

Anastasio, dark purple
Comarie, bright, and very dwarf
C. Wermig
Golden Madame Desgrange, the counterpart of the white variety, light primrose-yellow. The white and this are two of the most useful
Early Blush
Fred Marronet, yellow-carmine
Flocon de Neige, very dwarf pompon
Flora, small yellow pompon
Frederick Pele, rich crimson, tipped with gold
Fiberta, rich soft yellow
La Luxembourg, bronzy yellow
Mignon, small yellow pompon
Madlle. Leoni Lassali, pure white
Madlle. Jolivart, pure white, fine
Mrs. Cullingford, fine white
Nanum, soft blush
Precocite, very bright yellow, extra fine
Roi des Precoces, brilliant Japanese
Surprise, rosy lilac, beautifully quilled
St. Croutts, white, tipped with pink, pure white fully expanded
Souvenir d'un Ami, one of the finest whites
Scarlet Gem, very small and brilliant
Tresorier Lacoste, light purple
Virginia, white pompon

D. T. F.

A charming combination.—A plant of Trepæolum Lobbianum had been planted at the foot of an Araucaria imbricata, and having got on to the lower branches, it had pushed forth several growths, which gradually spread themselves over the whole of the branches of the Araucaria, which was 6 feet or so in height, in the most negligent and yet most elegant manner. It was an admirable illustration of Nature's method of managing such matters. A common Trepæolum which, had it been growing upon the ground, would not have arrested attention, is here set off to so much advantage without material aid, as to command admiration; indeed, it is doubtful if human agency could have assisted to produce anything so full of natural beauty.—R. D.

Fixing botanical specimens.—Would you kindly inform me what gum or adhesive substance is best for fixing pressed flowers to paper or cardboard, and of the latter, which is the better?—J. G.

* The side to be fixed to the paper should be wetted with warm thin glue, and when the specimen is placed upon the paper it should be pressed down with a sponge first and the surplus glue removed, finishing off with a dry soft cloth. White cartridge paper is best.—Ed.

NOTES.

Tamarisk tree.—Now and then we meet with this feathery tree in Southern England near the sea, but it is not planted to the extent it deserves, for of all our half-hardy small trees we have nothing possessing the exquisite grace of the Tamarisk. It roots freely from cuttings planted now. In warmer countries than ours it is one of the easiest things to grow. It is one of the plants used along the sandy margins of the Suez Canal to bind the ever-shifting sand. The various species of Tamarix are mostly focussed naturally in the basin of the Mediterranean, where they attain a considerable size, and become beautiful objects when their salmon-pink plumes of flowers at the tips of the branches stand out in feathery masses against a deep and clear blue sky. In Southern and Western Europe these Tamarisk trees resemble, and seemingly represent, the Beefwoods, or Casuarinas of the East and Australasia, just as the humming-birds of South America are represented by quite a distinct race of sun-birds, which in habits of life, in size, and in plumage closely resemble them in the Eastern Tropics. At Bournemouth and other sea-side resorts we see Tamarisks used effectively in planting near the shore, and in Devon and Cornwall, and I believe in Scilly, it also forms a low tree of considerable beauty. One way of establishing this tree is to cut stakes, or truncheons now and drive them firmly into the soil, as is done with Poplars, Willows, and Mulberries.

The flowers of Shakespeare.—We know all, or nearly all, the flowers of our great playwright fairly well, because in a work all lovers of gardens and of old-fashioned flowers should read called "The Plant-lore and Garden Craft of Shakespeare," the Rev. Canon Ellacombe, of Bitton, has collected and arranged all the great poet's allusions to the plants and flowers of, or before, his day. Shakespeare died in 1616, and was born about the time Plantin set up his celebrated printing press at Antwerp, from which were issued the earliest European works on botany by Dodœns, Lobel (L'Obel), and L'Ecluse, or Clusius, as he was more generally named. This Clusius was one of the earliest botanical collectors, he having made several itinerant excursions after plants into Spain and Austria before his folio work appeared in 1601. Gerard compiled his once famous "Herbal" during Shakespeare's lifetime, it having been printed in 1597, and Parkinson's "Paradisus" was first published thirteen years after Shakespeare's death, viz., in 1629. In France (Du Bry's "Florilegium," 1614), Holland ("Hortus Floridus," 1612), and in Bavaria ("Hortus Eystettensis," 1612) illustrated works on garden flowers had been published during Shakespeare's era, so that we know with considerable exactness the flowers grown and valued during Elizabethan times. But who can tell us of the flowers of Chaucer? Of course, we know his love for the Daisy, and one of his characters is described as a "primerole" or Primrose, just as in Yorkshire to-day a girl of more than ordinary vivacity is called a Daisy-lass, but I should be glad to hear of some other source of information as to the flowers grown about the years A.D. 1340—1400 other than that afforded by Chaucer's own works.

Helianthus multiflorus major.—I originally obtained this noble plant from Mr. Robert Parker, of Tooting, who, I remember, was quite proud to show it to the "Ruskin of Hardy Flowers" and myself when we called upon him some six or seven years ago. The original reference, with a woodcut figure, appears in Vol. XX. of The Garden, p. 481 (not p. 48, as in the General Index). Then on p. 500, same volume, is a note by "F. W. B.," who seems to have thought very highly of it at the time. This note brought corroborative testimony from "S. D.," on p. 520; and it may interest Mr. Dod to know that the last correspondent incidentally mentions in his note that it "seeds freely." But I am especially interested to hear what Mr. Dod himself has said of it, and on p. 66 (Jan. 24, 1885) he supplies a description which accompanies a coloured figure there given of this noble plant. I, of course, agree with Mr. Dod that the shorter and more explicit Latin names are the better; but I received the plant as H. multiflorus simplex maximus from Tooting, and I have since used it almost unconsciously, although I knew quite well that H. multiflorus major is the more correct and authorised name. But Mr. Dod knows perfectly well that if we go to Asa Gray as an authority—and I believe he is one of the highest on this group of Sunflowers—then we must call our plant "Helianthus decapetalus hort. var. multiflorus major." In The Garden (Vol. XXVII., p. 66) we have Mr. Dod's own testimony that this is the case; and while he protests now (Vol. XXX., p. 382) against the very necessary word "simplex" as used by me, he neither protested against nor adopted Gray's name as above, although he confesses, "botanically speaking," that it is the correct one! I am afraid Mr. Dod is afflicted, like myself, with a short memory, nor does he make good use of the file of The Garden, or he would doubtless have credited Mr. Parker with being the first, or at least one of the first, in the trade to introduce this noble plant into gardens. I never trouble my head about "science;" all I am anxious about is truth.

Late flowers.—The latest and best of flowers which, notwithstanding that we had 8° of frost on the 17th inst., are Gladioli of various kinds, the freshest being G. Ville de Versailles, a white variety with bright rosy crimson markings. It is always the last kind to open its flowers, and is well worth pot culture at this season, when, if we except Chrysanthemums, flowers generally are rather scarce. Seedling forms of the G. Lemoinei hybrids are also now fresh and beautiful, and come in very acceptably for cut flowers. Mignonette is sweeter now than ever, and there are white Chrysanthemums in bloom by the walls, and these outdoor flowers endure fresh and fair after being cut far better than do those from pot plants indoors. This is a point in favour of open-air culture which I have not seen alluded to before. The best of Roses are all over, but the old Souvenir de la Malmaison continues to yield us a few of its lovely flesh-coloured buds and blossoms. It is one of the very best, perhaps the best of late kinds. Erigeron speciosus is yet flowering freely, as it has done all the summer; indeed, the more the flowers are cut from this plant the more profusely it blooms, and the same is true of Harpur Crewe's Doronicum. Of all the Michaelmas Daisies the very best and freshest now in flower are Aster diffusus, and, better still, the white feathery A. ericoides, than which nothing is more elegant for large vases indoors. It has feathery Asparagus-like growths covered with greenish buds and small silvery white Daisies, and a few of its sprays add lightness and grace to any other flowers. Belladonna Lilies cut just before their flowers expand open out fresh and perfect in water indoors, just as do the Gladiolus and scarlet Schizostylis. Saxifraga Fortunei is just now at its best, its dark glossy leafage being surmounted by feathery white plumes of flowers. Viola Countess of Hopetoun is yet in flower, and with a few sprays of Mignonette makes nice sweet-smelling posies. While there are big bushes of Arbutus and Veronica Andersoni flowering freely, and just now at their freshest and best.

The Elk's-horn Ferns.—The Platyceriums are so distinct and noble in habit when well grown, that the wonder is they are so rarely seen in luxuriant condition in our glass-house gardens. Naturally, they are true epiphytes, a fact which is probably overlooked by the average cultivator. The first time I saw them growing wild was in Johore on the high trees near the saw-mills, but I afterwards saw fine cultivated plants in the collars of Orange trees both in Johore, Singapore, and in other islands of the Malayan Archipelago. In going up the rivers inland in Borneo amongst the first things the traveller notices are great Mistletoe-looking masses of growth on the out-hanging branches of the highest trees near the streams. At closer quarters these reveal themselves to be masses of the Elk's-horn Fern, and very beautiful they appear as seen through a good field-glass or binocular. Some of the plants are big enough to fill a cart, and look odd, as perched up bird's-nest-like in the air and sunshine. Now and then, after heavy rain, these great masses become too heavy for the comparatively slender, horizontal boughs on which, as seedlings, they first had life, and then the crashing sound they make in falling is only surpassed by the occasional fall of the large forest trees themselves. Seeing that they exist as epiphytes naturally, when grown in pots it is as well to plant them in charcoal, peat, and Moss, much as one would Orchids or Bromeliads. An even better way with small specimens is to fasten them firmly to a piece of board, or on teak wood rafts with a little peat and Sphagnum. So treated, they grow quickly and are admirably adapted for covering bare back walls or gables in warm plant stoves, or Fern houses. One of the finest species is P. grande, and P. biforme is another noble species, but even the common P. alcicorne soon makes a fine specimen as grown in a hanging basket or on a raft.

Sweet-smelling leaves.—The late Miss Frances J. Hope in her "Gardens and Woodlands," a work filled with shrewd and genial observations on gardening and garden flowers, is one of the very few horticultural writers who have thought it worth their while to allude to beautiful or fragrant leafage. Being a highly sensitive lady, she felt the full value of the naturally sweet odours of the garden as opposed to those of the shops. I am quite as fond of rich colour as anyone; even a glasshouse full of zonal Pelargoniums at this season of the year is a positive delight to me; but, much as I value colour, I like it even better when augmented by the graceful leafage of Palm and Fern, and, most of all, when colour, form, and subtle fragrance appeal alike to eyes and to memory at the same time. Colour is subtle enough, as everyone knows, but the fragrance of leaves is even more deliciously so, whether it be the refreshing briskness of a Lemon leaf when crushed, the piquant odour of the sweet Verbena (Aloysia), the soft and voluptuous fulness of Patchouli or Cherry Pie (Heliotrope), the spiciness of Cinnamon, Cardamom leaves, the tonic bitterness of Diosma, or the healthy resinous odour of Pine needles, Camphor, or of Blue Gum leaves. A garden or a greenhouse even without its quota of sweet-smelling leaves lacks something immeasurable, but most desirable withal. The most untangible of garden delights are, after all, the most precious ones. The best of all things in art are the morsels of truth which remain untold, the trifles light as air which, fairy-like, elude chisel, or the brush, or the pen. Of course, such things as Cinnamon and Allspice require a hothouse in which they may thrive, but the cottager or artisan even may grow sweet Verbena and the best of a dozen or more sweet-scented Pelargoniums of the Stag's-horn or Lemon-scented types, while in the very tiniest of out-of-door gardens, in a window box even, one may grow silver or golden Thyme, or a rooted spray of Rosemary for remembrance. In every garden worthy of the name there should be a corner or two sacred to fragrant leaves.

Autumnal Croci.—Despite the swirling winds and pelting rains, these fresh and shapely little flowers are very beautiful. I saw a good clump of the little Crocus Clusii the other day that actually seemed to give one a foretaste of spring. It was flowering dwarf and vigorous in the sun, and formed quite a dainty little picture as it nestled on its gritty bed in amongst the rockery stones. C. longiflorus and its variety pulchellus have both been very floriferous and showy, but two of the most distinct of all the species now in flower are the purple C. iridiflorus (byzantinus) and the pale flowered C. cancellatus. This last is a very variable plant, differing in colour from nearly white through all shades of lilac to a distinct blnish purple. Mr. Maw in his "Monograph of the Genus Crocus," p. 185, tells us that "C. cancellatus has a great range of altitude; on the flanks of Phanoromani, in Santa Maura, it is abundant within 600 feet of the sea level, and in the Taurus it occurs up to a height of 8000 feet. Its flowering season extends from the beginning of September to December. It is a robust species, easy of cultivation." The Iris-flowered Crocus (C. byzantinus) is, as I think, very distinct and beautiful; its three inner perianth segments are much smaller than the outer ones, and this gives quite an Iris-like contour to the deep purple flower. C. pulchellus is another free-growing species of a deep blue colour with a fiery orange stigma, and as it is now more plentiful than many others, it is cheaper also; but, in addition to this advantage, it also happens to be one of the most beautiful kinds we grow. It has been flowering for nearly six weeks, but is now nearly over. These autumnal-blooming species are lovely as grown in pots, and as so seen near the eye, and sheltered from wind and rain, they are very beautiful.

Plant names.—Whatever Mr. Wolley Dod writes anent garden plants is, as a rule, well worth our reading, but there are at least two sides to the protest he utters on p. 382 as to the correct name of the greater perennial Sunflower (Helianthus multiflorus major). For example, such names as Sunflower Dorothy or Sunflower Mikado would prove most misleading if adopted for varieties of Helianthus multiflorus unless with the addition of the prefix perennial, since were they adopted, as he suggests, there would be no distinguishing these from the now numerous forms of the Sunflower (Helianthus annuus) or the varieties of any other species equally different. Among the names especially offensive to men of common sense as well as of science come a whole group of bastard names, of which Helianthus multiflorus is itself a patent example. Helianthus is a compound name from the Greek, while multiflorus is from the Latin. This is as correct as it would be for me to call my friend Monsieur Boulanger Master Boulanger, or Monsieur Baker! Fancy the raking up of the roots of two dead languages to get a bad scientific name for a perennial Sunflower! I am quite in favour of good English names for all garden varieties, but they should be definite and correct, and not of the slip-shod kind such as Mr. W. Dod suggests (p. 382). I fully and freely acknowledge that the name Helianthus multiflorus simplex maximus, as used in The Garden by me, is not the right name, but at the same time the fact remains that it is more correct and expressive than is the generally accepted one of H. multiflorus major, just as the English name of greater perennial Sunflower is infinitely preferable, because more definite than either of the popular names Mr. Dod himself proposes. At one of the meetings of the Daffodil committee, Mr. Dod suggested Leda as a better name for a white Daffodil than White Swan, the name proposed by its exhibitor, and I argue that the latter is infinitely preferable in every way. In a word, it is far easier to coin misleading Latin names, or scientific ones that are ridiculous or useless, than it is to apply correct English ones. Veronica.

Garden Flora

PLATE 568.

NEW DOUBLE CHINESE PRIMROSES.*

The double white and rose-coloured forms of Primula sinensis fimbriata were in cultivation for some years before additions were made to them. The first step in advance was a new double form named atro-rosea-plena, first exhibited in 1860. It possessed a robust and vigorous constitution, and produced large, double handsomely fringed purple flowers; the origin of this variety is uncertain. Then came two semi-double varieties, viz., nivea plena and rubella plena; these were found to possess the property of reproducing themselves from seeds. They appeared in 1861, and seedlings from them were also semi-double and varied in colour. Then followed in 1862 delicata, The Fairy, and rubra grandiflora, all raised from seed. They bore very fine and fully double flowers, and yet were capable of reproducing themselves from seed, for in 1863 seedlings from them, in which the colours were exactly reproduced, were exhibited, but other seedlings from them developed some distinctness of character; one named purpurea erecta had finely fringed flowers of a purplish rose colour; another named Queen of England was of a pretty bluish tint and very fine as regards flowers. In 1865 and 1866 were exhibited several new double forms, such as Glen Eyre, kermesina splendens plena, maguifica, alba gigantea, &c. These were raised at Glen Eyre, Bassett, Southampton, by Mr. Thomas Stewart who, observing that some of his single varieties came with a twisted petal or two in the centre, carefully fertilised these with pollen taken from others of a like character, with the result that the foregoing varieties were obtained from such crosses. Since that time Mr. Gilbert's fine varieties, chiefly light-coloured kinds, made their appearance and speedily became favourites. During the past six months Messrs. Sutton, of Reading, have flowered a number of semi-double seedlings so varied in character and so pleasing, that there is reason to think they will eventually take the place of the single forms as decorative plants. Their history may be told in a few words. They are the result of taking advantage of the smallest abortions in the form of duplicate petals thrown up from the centre or eye of the single sorts. For years past a double carmine form named Prince Arthur has been well known to Primula raisers, and though occasionally a new semi-double form put in an appearance, the multiplication of these has not been systematically followed up until Messrs. Sutton took the matter in hand and obtained a break remarkable alike for variety and high class quality. Some of these have been selected for the accompanying illustration.

Most of the fine double varieties of which mention has been made do not produce seeds, and, therefore, have to be increased by means of cuttings. The more double the flowers are the

* Drawn in Messrs. Sutton & Sons' Nursery, Reading, March 31, 1886.

less likely are they to produce seed; but the Reading-raised varieties, while producing perfect semi-double flowers, are all fertile, and can be reproduced from seed. The flowers show the usual flat pip, with its symmetrical and stout florets. From the centre, but round the circumference of the eye, rises an upright circle of florets, like a collar, but with the colour outside, not inside, and thus exposed to view. As the flowers age the centre appears to fill up more and more, thus making the flower appear to a larger degree of a double character, but without destroying the capacity to produce seed. Now, many of the blossoms of the single forms of the Chinese Primrose are short-lived; the flowers fall almost as soon as they become fully developed. Not so the semi-double varieties, the flowers of which are quite persistent, even in a cut state, and, therefore, much more lasting than those of single sorts, while the colour is bright and effective. It is this characteristic that leads us to think they may in time, if well followed up, displace as decorative plants in a large measure the single forms.

The following varieties may be found in the Reading collection, viz: Scarlet, very fine and bright; Carmine, a decided improvement upon the old Prince Arthur; Lilac, pale lilac, with a distinct white margin to the petals; Red, dark reddish lilac; Carnation Flaked, a charming variety, pure white, with purple stripes, extra fine; Crimson, very fine in colour, a seedling from the Giant Single White, and most effective; Shaded Carmine, a very pleasing shade of clear pinkish carmine; and Rose, a kind which opens delicate pink and changes to rose with age. With the exception of the Rose and Lilac, all these have dark leaves and leaf-stalks; the rose and lilac have pale leaves and leaf-stalks. But, singular to state, there are among them this season two double blue forms that have appeared for the first time; one having dark palmate; the other, dark Fern foliage. It is the shade of colour of the single blue, but semi-double, and therefore a novelty.

That the new strain of double Primulas raised at Reading can be reproduced from seed is a great advantage, inasmuch as it obviates the necessity for propagating by means of cuttings. One of the most successful growers of double Primulas propagates his plants as follows: late in spring when the plants go out of flower, a layer of fine charcoal is laid upon the surface of the soil in the pots; then the operator takes a sharp knife and cuts half-way through the stems of the lower-most branches, nearly close to the plants, but not severing them entirely. In a short time the wound made by the knife calluses over, and roots are pushed into the soil beneath; then the shoots are entirely severed from the plants and potted, and in six months or so they make fine specimens, being at their best in November and December. It is to be regretted that these fine double forms of the Chinese Primrose are not more grown than they are. They are not only valuable decorative plants in winter, but their flowers when taken singly and wired can be employed in many ways for indoor floral decorations. R. D.

Double Chinese Primula.

WORK DONE IN WEEK ENDING OCT. 26.

October 20 to 26.

The 22nd was the only really fine day of the week. Gales and rain-storms of greater or lesser severity on every other day have sadly hindered our open-air work; at least, that description of work, such as fruit-tree and shrub-planting, that we like to get done in early autumn, but our soil being light and workable in all weathers except when frost-bound, we have managed to make good progress with trenching in the kitchen garden, also in digging and preparing soil for fruit-tree planting and potting purposes. On Wednesday morning, the 20th, the heaviest storm that has occurred for many years in these parts—nearly 1¼ inches of rain in two hours—has caused us a lot of extra work in the way of repairing roads and walks, some parts of which were completely ploughed up, and this work, however fine the weather may be, will for some time to come make us behindhand with garden work proper. We have, however, managed to get up all tender plants from the flower garden, and have partly replanted the beds for the winter, mostly shrubs, though Hyacinths, Tulips, and spring flowers form a part of the arrangements. Besides doing such cleaning up of walks and the most frequented parts of grounds as must of necessity be kept in something like neat order, there has been no time to do any other outside work. Indoors our energies are taxed to the uttermost to find sufficient space for all plants that must be housed. Late Grapes are not yet ready for housing, even though we had Grape room space for them—which we have not—and, therefore, no plants can be put in these vineries; the consequence is that other houses are getting overcrowded, but there being no help for it we work accordingly, by watering sparingly, picking over the plants often to remove decayed leaves, and turning the heat on in the daytime when fine, the ventilators being wide open the while so as to expel damp. Chrysanthemum flowers have damped off badly, but this, I think, has been partly caused by the buds getting saturated with water prior to housing. I am confirmed in this opinion because the latest flowers are not damping, though it is well to be on the alert by taking preventive measures against damping by the means just mentioned. Our Strawberry house is now very gay with Bouvardias, Cyclamens, Carnations, and double-flowered Pelargoniums. We keep the temperature about 60° by night and about 5° higher by day; the artificial warmth that we constantly keep on enables us to give abundant ventilation, and this keeps the plants in a sturdy condition, which vigour is the best antidote against attacks of mildew. Primulas and Cinerarias in heated pits we treat the same, *i.e.*, using heat combined with free ventilation and damp rarely troubles us. Potting and boxing up such old plants from the flower garden as are likely to be of service, owing to the young stock being short. As a rule, we throw the bulk of the old plants away; there are exceptions, however, as, for instance, old plants of Fuchsias are much to be preferred to young ones, because they furnish the beds quicker and flower more profusely; the same is true of large plants of Heliotropes, which we use as central plants for large vases and beds; old plants of Grevilleas and Abutilons are also most useful in the same way, and if space can anyway be afforded, a quantity of these we always save. Notwithstanding the recent heavy rains, Grapes still hanging on the Vines give us very little trouble, but we look them over frequently to cut out all decayed berries. Thorough ripeness is the best preserver or preventer of decay, of course, when coupled with a fair amount of attention in respect of timely removal of any berries that are decayed. A number of Smooth Cayenne Pines that have about completed their final swelling before colouring has been given a thorough soaking of warm liquid manure, which watering—at this season of the year—will probably be all that they will require, though if they should get dry we shall not scruple to water them, but it will need to be done with judgment, as too much would make the flesh black at the core. A comparatively dry atmosphere and a mean temperature of 70° will now be maintained. Succession plants that have completed their growth, and are expected to show fruit from Christmas onwards, are now having the moisture both at root and atmosphere gradually reduced, to give a short rest, but on no account do we ever allow them to get dust-dry. The younger succession stock will be kept growing on for a month or so yet. All our Pines are grown in pots—a plan that, besides other advantages, enables us to retard ripe fruit by shifting the pots into cool vineries or fruit rooms, according as may be deemed desirable at the time. Hants.

FRUITS UNDER GLASS.

Pines.

With the exception of winter fruiters, which must be kept at 70° by night and as much higher as moderate fire heat and gleams of sunshine will carry the temperature through the day, all the plants in every compartment will now be comparatively quiet. The swelling of the best winter varieties through the dead months in the mildest weather is uphill work, the progress slow, and unless the structure is light, well equipped with hot-water pipes and the bottom-heat sharp and steady, proper development ceases and the fruits ripen prematurely. Owners of these unsatisfactory houses, of which there are not a few, even in these days, should either put them in proper order or give up the attempt to ripen fruit in winter, and confine themselves to the more profitable growth of summer Queens. Of these every Pine-grower cultivates a few, and as the most forward plants will still be resting, care must be taken that the bottom-heat does not sink lower than will be good for the tender roots now coiling round the insides of the pots and through the drainage. Should this condition show signs of creeping on as the weather becomes colder, prevention being better than cure, now is the time to counteract it,

not by renovating with fresh material, as that would most likely produce a contrary effect, but by moistening the old tan or leaves with warm water and the addition of a layer of half-spent material over the surface of the bed. If the bottom-heat ranges from 70° to 75°, it will be wise to leave well alone, but should extra firing raise it above those figures, the lower valves may be closed until it subsides. Although it is not a good plan to move large plants more than one can possibly help, it sometimes happens that the best of managers are obliged to transfer their most promising starters to another section to throw up and swell the fruit. If under one and the same roof, this can be carried out in defiance of the elements, but then even timely preparation is an important factor, especially where fermenting material is the principal agent employed for giving bottom-heat. Cleanliness being imperative, the pit, which is about to do nine months' service, should be cleaned to the bottom, well scalded to destroy cockroaches and crickets, two troublesome marauders, and the walls washed with quicklime. The glass, woodwork, and other parts of the structure will, of course, receive proper attention, but all these matters are mechanical and can be carried out by willing hands; not so the plunging material —the hinge on which success or failure may be said to hang. To this, then, the greatest care and judgment must be devoted, as too much or too little heat may ruin the most promising prospects at the outset. If tan fresh from the pits or tree-leaves are used, the first should be secured and placed where it can drain and ferment, and be frequently turned to prevent it from burning, a considerable time before it is placed in the pit. The second, if well harvested last season and kept in a dry shed, must be carefully selected, the flakes thoroughly shaken to pieces and slightly moistened if too dry to revive fermentation. In either case the materials should be kept under cover and properly sweetened by fermentation and frequent turning to favour the escape of injurious gases. When fit for use, removal to a warm house will revive fermentation, but this in a great measure may be prevented by firm treading and closing the bottom-heat valves. A bottom-heat thermometer and patience will settle the rest, and when the mercury registers 85°, the plants may be lightly plunged in shallow basins scooped out without disturbing the bed.

Successions in various stages and sizes must now be let down to their proper winter temperatures, which may range from 60° to 65° by night and 70° to 75° by day, more or less, according to the state of the weather. The larger and stronger will, of course, be kept at the maximum figures, whilst the smallest, including autumn-potted suckers, will take no harm if the minimum is touched, especially in dark, dull, or severe weather. The plants—indeed, all the stock—should be kept as near the glass as possible, and much fuel and anxiety will be saved by covering the pits through the night.

Vines.

Early and second early Vines, it is well understood, must be pruned and got ready for next year's forcing as the leaves fall, and, if practicable, some weeks before they are again excited into growth. Many gardeners are obliged to turn their early houses into plant stoves throughout the autumn and early winter, and not unfrequently make a compromise by no means beneficial to the Vines, which cannot be kept too cool during the season of rest. If houses can be kept dry and open to a continuous circulation of air until the time arrives for starting, the severest weather only will necessitate firing, and then the object will be the preservation of the pipes from freezing, as a few degrees of frost will do the Vines no harm. If, on the other hand, they must be occupied, then the plants should be capable of accommodating themselves to cool greenhouse treatment, and subjects that will not require frequent supplies of water. If eyes for propagation are wanted, a few of the firmest pieces of wood should be selected and laid in for future use, as thorough maturity is one of the great secrets of success in pot Vine culture.

Ripe Grapes, particularly thin-skinned varieties, will now require continuous attention, as too much fire heat will cause them to shrivel and too little will let in damp, which will speedily destroy them. Of the two, a moist, stagnant atmosphere is the most fatal, no matter how often the bunches are looked over for decaying or mouldy berries. But why allow them to hang when bottling before the stalks become black or mould has set its seal upon the berries answers so much better? Hamburghs, for instance, now quite ripe and as well fit for bottling as Lady Downes are at Christmas, may be cut and placed in the late or Muscat house, where they will keep for several weeks in the best possible condition. The bottles, I may observe, should be filled and made dry externally before they are taken into the house, and all the leaves, but none of the laterals, must be removed as the Grapes are cut from the Vines. Lacking a late vinery, a dry store or Grape room will answer equally well, but I give preference to the former, especially at this season, as Grape rooms are not yet in working order.

Late Grapes.—If Lady Downes and other late keepers are not by this time quite ripe and properly finished, fire-heat with diminished ventilation will not produce the desired effect. Fire-heat to a certain extent will, of course, be necessary, as the leaves now falling produce and hold moisture, which must be dispelled, otherwise the berries will soon perish. Although I do not approve of the detachment of leaves with the hand, I am always very glad to see the last of them when they begin to fall; hence the importance of cutting out all growing laterals which retard the process by keeping the sap in motion, also the maintenance of a dry, buoyant atmosphere that will prevent condensation of moisture on the berries. Houses in which the foliage is still fresh and green do not come under this mode of treatment, as the Vines have not nearly finished their work, and will most likely remain active until frost throws back the sap. But this is not ripening; it is a rude shock, which will speedily clear the Vines of their leaves, when the berries, be they black or red at the footstalks, will almost immediately show signs of shrinking. Growers who begrudged fire-heat in the spring and now find themselves in this plight will do well to choose the least of two evils, and that is, I need not say, a continuation of fire-heat with as much air as conditions will admit, and just sufficient warm water to keep the surface-roots in action. Another step they may take, and that is an examination of the external border, as Vines that make roots late in the season not unfrequently lose them during the winter, and have to undergo the exhausting strain of making new ones late in the following spring. In this way many late Vines lose the vernal force, rest when they ought to be growing, and persist in growing when they should be ripe and resting. If an examination reveals the fact that the roots have got into the drainage, or perhaps out of the border altogether, and this is the cause of late growth, the remedy lies in lifting, in cutting off unwholesome food, and in relaying in fresh porous compost. Many are afraid of interfering with the roots before the Grapes are cut, but, provided the internal borders are satisfactory, there is not the slightest cause for alarm; indeed, I have known bad cases of spotting and rotting completely stopped by lifting and relaying the external roots of late Vines in October. Another advantage gained by the replacement of large masses of inert soil with a smaller quantity of new compost is the perfect colour and finish of the berries the following year, the early maturation of moderately strong wood, and, although the bunches may be smaller, they will be compact and in the best possible condition for keeping both on the Vines and after they are cut for bottling. At the present time I know a Muscat border which has been reduced in width, all the inert soil has been removed from the surface and replaced with a thin layer of new compost, and the result is highly satisfactory. The berries in September did not seem inclined to put on their rich golden colour, but persisted in damping at the footstalks or near the points, and the laterals kept growing. A few, only a few, roots had passed through the retaining wall of turf into some decaying manure lying at its foot, but they were the aggressors, and their removal has not only put a stop to damping, but the berries, not less plump, are now the colour of virgin gold.

The Orchard House.

Fruit trees in pots are going to rest under unusually promising conditions, and, provided they are properly wintered, will no doubt produce good crops next season. The amateur for whose benefit these lines are written may wish to have a practical interpretation of the word "properly," as he must by this time have learned that casting the trees aside as soon as the leaves are off and allowing them to stand high and dry is not the best method. And yet some early treatises on pot culture, still in circulation, and by which so many amateur fruit growers are guided, lead to the conclusion that soil as dry as a mud wall and a sharp, whistling wind are beneficial rather than otherwise during the winter—fatal rock on which many a promising set of trees has been wrecked and ruined, and from which many an enthusiast has turned in disgust, as no tree so quickly resents dryness at any time as the Peach. But why winter well ripened trees in houses at all, when the latter may be turned to profitable account in other ways, and the owner may steer clear of rocks and breakers by placing them out of doors? If any there be who have not yet departed from the high and dry path, let me advise them to do so without delay, for now is the time to make a beginning. Let them select a clear open spot well sheltered from the north and east, but fully exposed to a free circulation of fresh air. Upon a good bed of lime rubble, coal ashes, or concrete impervious to worms, the trees may be arranged in the order in which they will be required for taking in again. If by chance or intention any of the balls have become dry, they must be watered until the soil is properly moistened, as the roots of stone fruit trees keep working and feeding the buds all through the winter; whilst anything approaching a check causes the most prominent to drop, perhaps not at once, but when they ought to be expanding into perfect blossoms. When placed, all spaces between the pots must be closely packed with Fern, litter, or other material that will keep out frost and prevent the escape of moisture, and a few strong fronds of Pteris aquilina drawn amongst the shoots will protect the blossom-buds during the most inclement weather. These, it must be observed, should only be introduced during the continuance of severe frost and taken out as soon as it is over. Once plunged and well covered up a few inches above the rims of the pots, winter rains and snow will keep the roots safe from drought and the buds will begin to swell gradually towards February. When this stage is reached, trees for forcing having been taken in before, the latest must be housed and kept as cool as possible, but on no account must they feel the want of water. The greatest, perhaps the only, enemies to trees during the time they are exposed are bullfinches and sparrows. These sometimes attack the buds of Peaches and Pears, but more frequently those of Plums and Cherries. They do not, however, like the looks of herring-nets, and prevention being better than cure, these should be cast lightly over them at the commencement of the winter.

W. Coleman.

Eastnor Castle, Ledbury.

Gold and Silver Ferns.—I have derived some useful practical hints from the remarks on Gold and Silver Ferns, published in The Garden the other day (p. 373). I quite agree with the writer's views respecting the two kinds of Maidenhairs; I find them to grow well in a cool, even a very cool, temperature. The names given in the article in question include the majority of powdered Ferns, but one to which I should like to direct attention, viz., Cincinalis

Hookeri, an elegant kind, is omitted. It is figured in Lowe's "Ferns," and is often confounded with Cincinalis nivea, from which, however, it is abundantly distinct both in shape and density of fronds; and besides the white powder of the under surface, the upper sides are frequently as white as if dusted with a miller's bag. I find the different kinds of Cincinalis rather tender subjects to carry through the winter; indeed, this one in particular with me seems to be more like an annual than a perennial, but I consider its loveliness amply repays for any care or trouble bestowed upon its cultivation.—Thomas Fowler, *Halifax.*

Fruit Garden.

APPLES FOR THE FUTURE.

In the fruit reports given in The Garden some time ago, a correspondent remarks with regard to Apples, "bush and pyramid trees are bearing well." No one apparently refers to a good crop of Apples on standard or orchard trees, and I believe that standard trees are for the most part barren this year in all parts of the country. What, then, is the best form of tree to grow for the future? If we are to be guided by the experience of a single season, of course the question admits of but one answer, but that would be taking an extreme view of the case. No one can ignore the fact that standard trees have done occasionally good service, and we may reasonably hope that they will do so again. Still, we cannot afford to overlook the good services that dwarf forms of trees have rendered us when others have been conspicuous failures. It appears to me that the past season's experience should be turned to profitable account, for although I have not a word to say against standards in their proper place, I am quite satisfied that they may be dispensed with without any risk of diminishing the quantity of fruit if proper means are taken to supply their place with dwarf trees. There are thousands of standard trees in the country that only bear a crop once in two years, and they cover as much ground as half a dozen pyramids or bushes would do. According to my experience, too, the dwarf forms of trees bear every year more or less fruit and a judicious selection of sorts that submit to being restricted both as regards roots and branches will invariably bear good crops; in this opinion I know I shall be supported by large numbers of cultivators. The reason why this form of tree bears more regularly than standards is not far to seek. In the first place, being chiefly grown in gardens surrounded by high walls or otherwise well sheltered, they are are not so much exposed to the influence of the weather as orchard trees; therefore they are under much more favourable conditions. But the chief point in reference to their constant fruitfulness is the fact that being in the garden they are better cultivated than orchard trees. They get more regular attention in regard to pruning at the proper time, and for the most part they grow in a better description of soil; occasionally, too, they get a little manure, which is given the land for the use of vegetable crops growing near them. In short, they get more shelter and a better soil than standards do—important factors in the production of a crop. Admitting, then, that bush and pyramid trees are more regular bearers than standards, it becomes a serious question as to which form we are to adopt for the future. My own conviction is that it must be some form of dwarf tree. It does not matter much whether it be a pyramid, bush or cordon, or even the old-fashioned espalier. It is a significant fact that for the past ten years all the most practical writers on fruit culture have gradually come to recognise the value of pyramid and bush trees as regular fruit-producers, and it is equally significant that so many fruit growers should in one season corroborate each other as to the value of these forms in such a direct manner, and that, too, from widely different parts of the country. I must not, however, be understood to be advocating the use of trees that have only bearing surface sufficient to fill a dessert basket. The tree I have in view is capable of bearing from one to two bushels of fruit; therefore, with the same space devoted to them as is now devoted to standards, the supply of fruit would be more regular, and, taking an average of seasons into account, equal to that from standards. With regard to cultural details, the more simple the lines on which the dwarf forms of trees are conducted, the more satisfactory will be the results. The man who is a stickler for perfect symmetry in his trees must be prepared to sacrifice a portion of his crop. Many trees that will bear our best and handsomest Apples do not take kindly to severe pruning. Amongst these I may mention Peasgood's Nonsuch, Emperor Alexander, Blenheim Orange, Gloria Mundi, and Tower of Glamis. These and several others that make strong growth are better grown as bushes than as pyramids.

Future success will depend a good deal upon the treatment which the trees receive during the first five years of their existence, as during that time the branches require more attention than the roots. The future form of the tree will in a great measure have to be provided for in the early stages of its growth. Pyramids will require to be formed as growth progresses, and bushes (if such as I have in view can be called bushes, for they must be at least 10 feet high) must have their branches directed into form for the first few years of their existence, so as to secure a good spread of the leading branches, and also to have the centre of the tree open so that light and air can circulate amongst them. With regard to the roots, the character of the soil will have a good deal to do with the time at which they will require attention. In a strong, rich medium they will make much more vigorous growth than in a poor one, and as the condition of growth in the branches must decide when to operate on the roots, it will be necessary to attend to them earlier when the branch growth is forced by a rich soil than under other conditions. But it is important to bear in mind that the trees should be allowed to form a fair amount of bearing surface before the roots are interfered with. Generally speaking, it is not desirable to check the roots in any way until the end of the fourth or fifth year, and then the trees should be lifted bodily and replanted, an operation which will effectually check any undue luxuriance for several years to come. In fact, it is a great chance if the same operation will require to be repeated for many years. Judicious root-pruning of such as are making too much wood is all that they will require to keep them in a fruitful condition. J. C. C.

Two good late Apples.—Two of the very best late-keeping Apples for orchard planting are the Alfriston and Norfolk Beaufin. The former is a large green fruit tinged with red on the side next the sun, excellent for cooking, and in April and May, when it has parted with some of its acidity, it is not bad eating. The tree is a good grower, and worked on the Crab makes an excellent orchard tree and bears freely. The Norfolk Beaufin is a well-known kind, which seldom fails to bear well. We have a large old tree of it standing out in the grounds sheltered by some old Elms, growing near it, and for the last twenty years and probably much longer it has never failed to produce annually good crops of handsome highly coloured fruit. This Apple improves by keeping till after Christmas. We had it fresh and firm last June.—E.

Apple trees from cuttings.—The sooner cuttings are now taken from the trees and planted firmly in a shady border the more time there will be for root-formation before March winds set in. The cuttings should be taken from healthy, fertile trees, and should be as large as can be spared. I have sawn branches off from 1 inch to 2 inches in diameter and 3 feet to 4 feet long. And if there is a knot, a cluster of spurs or an excrescence on the lower end of the branch, roots will generally form more readily there than where the bark is bare and smooth. Branches from 1 inch to 2 inches in diameter make bearing trees at once. I do not suppose that Apple trees from cuttings will ever take the place of trees grafted on a stock possessing more vigour than the scion possesses, but many may like to have dwarf Apples on their own roots, and if so, the sooner the cuttings are planted now the better. Such trees are well adapted for small gardens, as they occupy but little room and begin bearing directly. Kinds with Codlin blood in them seem to root the quickest, but other kinds will root readily if taken from healthy trees, and planted rather deeply in a cool border under a north wall, and mulched with manure. I have tried cuttings from young wood, but they are too uncertain and take too long to grow into fruiting plants to make it worth while to follow such work up. It is very important that the cuttings be planted firmly in the ground, and at least 8 inches of the stem should be buried.—E. H.

PEARS VARYING IN FLAVOUR.

I can confirm "G. J. B.'s" experience in this matter (p. 396), though I cannot unravel the causes of it. Some sorts, however, are much more variable than others, and your correspondent has selected three, perhaps, of the most variable in cultivation. Gansel's Bergamot I have met with in almost every conceivable degree of worthlessness and excellency, and it is pronounced by many so inconstant as to be but little grown, but when really perfect I quite agree with your correspondent that it is quite delicious. On the Quince, however, and as a pyramid it is mostly hard and gritty, and seldom or never attains to full size. This Pear also wants to be eaten at the right moment, else it becomes mealy, which is the precursor of its rotting. This fine Pear, whatever its origin, and it is probably a seedling from the Autumn Bergamot, is far more tender than that useful variety which resembles it, excepting in being much smaller; it needs a west, south, or south-east wall to do it justice. It is also, like the smaller Begamot, naturally more or less gritty; hence your correspondent's east wall is probably too cold for this variety. But this by no means solves the difficulty why it should generally be delicious and this year so inferior. The difficulty is increased, and becomes more insoluble as we read exactly *vice versâ* of the Duchesse d'Angoulême, cold and tasteless for fifteen years, and this year, under the same conditions, so excellent as hardly to be recognisable as the same Pear. Most Pear growers and eaters will agree that the general character of this Pear is inferior, the flesh sweet, but coarse grained, cold, and gritty.

No doubt most Pear growers of as long standing as your correspondent have had this Pear at times so well ripened and high flavoured, as hardly to be recognisable when placed side by side with fruit of average quality. The Beurré Diel, again, is a Pear that has been vastly overrated by the authorities. Most of these describe it as large, rich, sugary, buttery, delicious, melting, tender, and so on; and so it is at times; but it is also not seldom coarse, cold, and little better than a Turnip, and hardly any Pear is more subject to going off prematurely, as described by your correspondent, than the Beurré Diel. Its large leaves are also often attacked by black fungus that overruns the fruits or speckles them all over, and the whole of these fruits rot before they are quite fit for use. This pest is more prevalent than usual. The crop, which was a fair one, is also smaller and more irregular than usual, and the spotted ones are going fast. And yet now and then Beurré Diel justifies the high praises of the authorities. Another Pear which seldom does its best out of Jersey occasionally surprises us with a crop of exceptionally fine fruit. This is the well known, but little grown in England, Chaumontel. We have had a few trees of this as a pyramid on the Quince for a dozen years, and never had a satisfactory crop till last year; there was a full crop which ripened of fair size, and the quality was

quite equal to that of any Channel Islands or French Pears of this when perfect.

Other sorts in plenty might be named that have their seasons and caprices, a word used here to define their incomprehensible variations. But, as if to increase the mystery of such matters, we have other Pears almost constant in their qualities, provided they are grown under the same conditions and such as are favourable to the hardiness or tenderness of their constitutions. Among such may be enumerated such well-known varieties as the Jargonelle, the Autumn Bergamot, Winter Nelis, Marie Louise, Williams' Bon Chrétien, Glou Morceau, Passe Colmar, Golden Beurré, Beurré de Capiaumont, Louise Bonne of Jersey, &c. —Hortus.

—— There is nothing unusual in the behaviour of "G. J. B.'s" Pears (p. 396), with the exception of Gansel's Bergamot. This is generally first-rate in flavour, and it ripens, as a rule, every year about the same time. Beurré Diel I always consider to be unreliable in flavour. With us, grown on a south wall, it is always gritty, and only fit for culinary purposes; but in Devonshire I have tasted it from pyramid trees of the best texture and flavour. Where Pears are grown on walls I am satisfied that aspect has a good deal to do with their flavour. Here Louise Bonne of Jersey is not eatable when grown on a west wall, but on a east wall or on pyramids its flavour is excellent. The Chaumontel, which I have known to produce fruit of excellent flavour on standards in Surrey, I cannot grow here in Somerset, except on a south wall. As pyramids, the trees fruit abundantly, but the flavour is very indifferent. For the first time in my experience Comte de Paris is this year gritty and indifferent in flavour; one, therefore, gets perplexed as regards the strange vagaries played by Pears.—J. C. C.

Pears for market.—At a meeting of the New Jersey Horticultural Society, Mr. Quinn, according to the *Country Gentleman*, said that for successful Pear culture the land should be rich enough to produce 150 bushels of potatoes an acre. On his soil, he would prefer to pay the price of young standard trees to getting dwarfs for nothing. He would select for market Bartlett, Clairgeau, and Anjou. Mr. Moon said one of the most profitable Pears was the Rutter. Mr. Ward named for profit Giffard, Clapp, Bartlett, Williams' Bon Chrétien, Boussoch, Seckel, Sheldon, Clairgeau, Anjou, and Dana's Hovey. Mr. Repp found Duchesse d'Angoulême quite profitable. He had specimens large enough for twenty to fill a basket. Out of seven or eight hundred bearing trees only one has blighted. To this statement we may add that after seeing many thousand trees of different sizes of Angoulême, we never saw more than three that had died of blight, and it is certainly one of the hardiest of all Pears.

Russian Apples.—I have fully 100 varieties of Russian Apples growing in my grounds, many of the trees being 16 and 18 years planted. One thing is fully demonstrated, viz., that these Apples are, as a class, very much hardier against adverse climatic influences, and especially against winter's cold, than those previously grown here. This alone gives them enormous value for the "cold north," where, without them, tree fruit culture would be impossible. In productiveness, and size and beauty of fruit, the Russian Apples are, on the average, more than a match for those of Western Europe, and for our native seedlings thence derived. The disputed question in regard to them is as to their quality as dessert fruit. I say disputed, but it is now disputed only by those who have only a very limited acquaintance with this class of fruit. People who judge them in this respect by the Duchess of Oldenburg, Alexander and Red Astrachan, while admitting their beauty and prolificacy, undertake to denounce the whole race of Russian Apples as "useful only for cooking." So earnest and continuous has been this outcry, on such manifestly insufficient grounds, that it would seem as if something more than a general interest in fruit culture were behind it. However that may be, those who have an extensive acquaintance with Russian Apples know that there is among them quite as large a proportion which deserve to rank as of dessert quality as there is among the common sorts. True it is that but few of these finer sorts have yet been much distributed, but they are known, and as soon as the public becomes acquainted with them this unjust stigma attached to Russian Apples will be effaced. Among these fine dessert Apples the Yellow Transparent, Grand Sultan, Switzer, Charlottenthaler, Berkoff, St. Peter, Longfield, Golden White, Streaked Red, Summer Calville, Noble Redstreak, Russian Gravenstein, Red Anis, Titovka, White Russet, and several others have now been sufficiently tested to establish the fact of their excellent eating quality, joined, in most of them, with great beauty of form and colour.—T. H. Hoskins, M.D., in *Rural New Yorker*.

OLD FRUIT TREES.

All old trees when they cease to bear good fruit, and a fair crop of it, should be grubbed up and converted into firewood. There are far too many old useless trees in orchards. The feeling which prompts people to cling to old trees is an ancient one, but it cannot be defended on sound commercial principles. In order to keep up the stock of fruit trees in a garden or orchard in the most fertile condition there should always be young trees coming on to take the place of those that are getting too old; then when a tree on the wall, an espalier in the fruit border, or an orchard tree became old and decrepid it could be removed and a young bearing tree put in its place. It is sound policy to have a few trees in training, and those who like to do grafting and stock-raising at home may keep up their orchards and fruit gardens without cost. Though all old worn-out trees should be cleared away, before condemning them we should make sure that they really are worn out past resuscitation, because many trees are decrepit through neglect. Orchards on Grass fed off by sheep are perhaps not badly off, but where the Grass is mown and converted into hay, and in any case where the produce of the land is carried off and nothing brought back, the trees must suffer and become prematurely barren. Orchard or other trees that are not past recovery should be seen to at once, and rich top-dressings applied. I have seen great good to result from the application of liquid manure to old exhausted trees in winter, when it could not be so profitably used for other crops. Sewage from the house and drainings from stables and other farm buildings may be profitably utilised now, as the hungry soil will become enriched by the water filtering through it. In substituting young trees for old ones, the young trees should not occupy exactly the same position without, at least, a partial renewal of the soil. In the case of wall trees, if maiden loam cannot be had, the old soil should be removed, and fresh soil not exhausted by fruit trees of the same kind brought in from some other part of the garden. There should be no difficulty in this, as the labour would be but trifling in comparison with the good likely to result from it.

E. Hobday.

Sedums and bees.—In answer to several enquiries, I may state that I believe the Sedum which seems to stupify bees is the Sedum spectabile, but I have so long known it as the rosy Sedum, that I would rather not be too positive. It is so beautiful and full of bloom, that it well deserves the specific name. It is the only one that I have observed to have any stupifying effect on bees. They seem wild with a sort of delirious joy when they first alight, then become quieter and yet quieter, finally sluggish, stupid, a sort of paralysis in which they remain for days, then topple or are washed off and perish. They have now disappeared, or I should have sent you some in the different stages. I find, too, that mice or some vermin have made short work of their carcases, as there is little but wings now left under the flower branches.—D. T. F.

Rose Garden.

WILD ROSES.

Little is known of the origin of our garden Roses by those who cultivate or those who plant them. And yet the wild Roses which bloom all over the northern hemisphere are all beautiful, most of them are exquisitely fragrant, and many of them have a simple grace of form that none of the garden hybrids can equal. The garden Rose as a shrub is too often stiff and ungraceful, while the foliage and habit of some of the untamed species are sufficiently attractive to make them worth growing if they never showed a flower. The wild Rose is usually found on dry soils, though a few species inhabit swamps, and the climbing varieties are usually among bushes or hedgerows. In the warmer latitudes they are always white and generally single, although in Italy, Greece and Spain double varieties are found now and then, it is said, in the woods and fields. The genus, botanically, is in great confusion, and it is almost impossible to say where a variety ends or a species begins. The species I shall name are the most promising for cultivation, and, although no one expects or hopes that they will supersede the improved hybrids, still there is room for both. One charm of the natural species is that many of them are bright with fruit in autumn and all through the winter.

Rosa kamtschatica is a strong grower from the cold region which gives it its specific name. It has bold foliage and a coarse stem, wearing a strong armour of defensive prickles. The flowers, which appear in July, are larger than those of R. rugosa, but of a paler pink. Its brilliant scarlet fruits make it a desirable ornament in large shrubberies.

Rosa spinosissima is the old Scotch Rose, a dwarf grower, with neat foliage and delicate flowers, varying from white and pink to yellow, which are succeeded by dark purple fruit. It comes from the north of Great Britain, and the Scotch gardeners have raised many interesting varieties, double, semi-double, and of almost every shade. It is one of the earliest to flower, coming hard after the alpine Rose.

Rosa lutea, the Austrian Brier, is a native of the East, and is known through its offspring, the Austrian Yellow and Harrison's Yellow, a seedling said to have originated in America. We rarely see these early semi-double yellow Roses, once so common in old gardens, and yet we rarely see anything more beautiful. The leaves of the species have a faint Sweet Brier odour.

Rosa sulphurea, another yellow species, comes from the Himalayas, but is hard to grow. In a greenhouse its flowers open well, but out of doors there does not seem to be heat enough at its time of bloom, although that is late in June. I think it might do well farther south, in a warm, rich soil and an open, sunny situation.

Rosa rubiginosa is the Sweet Brier of poetry, a native of Europe, but now often found wild in this country, where it has escaped from cultivation. Its neat pink flowers and red fruit are well known, as is the delightful fragrance of its leaves, especially when set with dew. It attains a large size—will clamber to the top of a support 30 feet high and then flow downward in a cataract of long, streaming branches. There are several well marked varieties, such as major, a semi-double kind, the clustered Brier and others.

Rosa alpina opens its light flowers in the latter part of May, and these give place to Pear-shaped fruit, orange and red. Its branches are thornless. It is the parent of the old-fashioned Boursault Rose, now rarely seen, and of other varieties well worth growing, especially as pillar Roses.

Rosa arvensis, the field Rose of Europe, makes a rampant growth among the bushes. In England it runs 20 feet in a season. The flowers are of a pale rose colour, and keep opening from May until August. The Ayrshire Rose is a variety of this species, with pale pink double flowers. It grows rapidly, but is somewhat tender here. There are other varieties which I have not tried, but which are commended highly.

Rosa multiflora.—The plant received from Japan under this name is a beautiful shrub, flowering in clusters of pure white, which resemble Strawberry blossoms very closely. As many as a hundred flowers appear in one cluster. One plant kept last winter in an 8 inch pot had 3000 flowers. To my thinking it is one of the finest additions to our gardens in the way of a single Rose. If worked up it might become the parent of a new section of half-climbing hardy Roses. It is also an admirable stock on which to work hybrids for forcing, as the plants on exhibition at the Massachusetts horticultural shows have proved. This species (or variety) differs widely from the so-called multiflora which we grew some years since, and from which Seven Sisters sprang. It differs widely, too, from the so-called multiflora received from the Himalayas. I am half-inclined to consider it the species described by De Candolle as R. fragariæflora. The fruit is a small, reddish berry, but it comes in great clusters which remain all winter on their stems. It is one of the few species whose seed germinates the first season after sowing.

Rosa setigera, the Michigan or Prairie Rose, is certainly a more attractive plant than many of the hybrids derived from it. Its vigorous growth and abundant bloom after the garden Roses have faded make it most effective in a shrubbery. The deep rose colour of its bloom slowly fades to a pale pink, so that the plant appears to bear flower-clusters of several distinct varieties at once. Baltimore Belle, Mrs. Hovey, Queen of Prairies, and other pillar Roses have been derived from this.

Rosa lucida, our dwarf wild Rose, takes its name from the shining upper surface of its leaflets, and is very variable in flower and foliage. The colour of the bloom may be nearly white, and it ranges from this to a deep rose colour. From Massachusetts to Florida it flourishes on every kind of soil, from the dryest to the edges of swamps. The flowers keep opening from May till July, while the showy fruit hangs on till well into winter, and the autumn colour of its foliage in large masses is striking. Its low, half-trailing habit makes it an admirable shrub for covering unsightly banks, and its method of spreading by underground shoots or stolons adds to its value for this purpose. It is easily renewed by cutting over once in three years.

Rosa nitida, the narrow-leaved, shining Rose, is not so common as the former one, and is usually found in damper soil. Its flowers and fruit are both more showy. It is sometimes found in gardens near Boston under the name of the Jackson Rose, and few single Roses give more satisfaction when cultivated.

Rosa foliolosa comes from Texas, and is among the latest species to bloom. Its pale lemon-coloured flowers begin to open in July and continue until September. It is seldom seen in cultivation, but its fine, distinct foliage and apparent hardiness commend it. Its features are all so marked that the hybridisers ought to experiment with it. Its blood, mingled with that of other types, might produce a new and worthy race.

Rosa blanda, the early wild Rose, is not common here in Massachusetts, but is more abundant to the northward. It is a modest plant, the least striking of our native species, but yet well worth a place in shrubberies. Its variety, scopularis, from the Rocky Mountains, is most interesting. The flowers are pale and are followed by large Pear-shaped hips, which ripen in September and are more beautiful than the fruit of any other American Rose. Our plants are from seed sent by the late Dr. Engelmann, and I do not know that this Rose is in cultivation outside of the arboretum.

Rosa carolina, the Swamp Rose, is one of the strongest growers among our native species, often reaching a height of 7 feet or 8 feet, with stems 1 inch or 2 inches and even more in diameter. It flowers from June till September, and the globular hip is brightly coloured. Although a native of wet places, it does well in ordinary garden soil, although to do its best it needs much moisture. This is the stock upon which we graft many of the hybrids that come from Germany. One reason why these Roses do not flourish like those on the Manetti stock is that this swamp Rose needs to be brought on slowly, and its roots need abundant water while growing.

Rosa arkansana is very desirable for the brilliant scarlet of its fruit. It is a neat shrub, 2 feet or 3 feet high, flowering well in clusters during June.

Rosa Fendleri comes from the Pacific region and is conspicuous for its early bloom, the flowers opening in the middle of May. This habit, with its bright red and abundant fruit, will make it a general favourite in cultivation when once introduced.—*Arnold Arboretum.*

MR. G. W. HOYLE.

Like the late Mr. Edward Beck, the late Mr. G. W. Hoyle, of Reading, was one of the foremost Pelargonium raisers of his day. That he did excellent work in improving the large-flowered or show Pelargonium there can be no doubt, but the details of his work are somewhat scanty. One thing is certain: he laboured very assiduously to obtain and improve the high-coloured show Pelargoniums approaching to scarlet—a section of Pelargoniums for which we are mainly indebted to the persistence of the Royal Botanic Society in offering awards for improved flowers of this class at their exhibitions. There is reason to believe that Mr. Hoyle never trusted any of his seedlings to chance fertilisation, but selected parents of which he approved. In the January number of vol. i. of the *Florist*, published in 1848, Mr. Hoyle has a paper on seedling Pelargoniums, in which he laid down the principles which should guide raisers in the production of new varieties, form and colour being his two cardinal points. The following are varieties of Mr. Hoyle's raising, viz., Belle of the Village, Crusader, Flamingo, Prometheus, Sparkler, Superlative, Sarah Jane, Terpsichore, and Titus. Up to this time (1849) the principal raisers of Pelargoniums had been Catleugh, Gaines, Nairn, and a few others, but Mr. Foster was undoubtedly at work before Mr. Hoyle. The first of Mr. Hoyle's Pelargoniums figured was Crusader, which appeared in the *Florist* for December, 1849, and subsequent volumes of that work gave further coloured illustrations of his seedlings. The last of Mr. Hoyle's seedlings were put into commerce in 1871; they consisted of Asteroid, Cardinal, Duke of Edinburgh, Eldorado, Exemplar, Holkar, Magnificent, M. de Lesseps, Pasha, and Sunshine. Imperator and Zephyr, by the same raiser, were exhibited in 1871, and distributed in 1872. Mr. Hoyle was for a few years secretary of the Reading Horticultural Society. He died on May 26, 1872.

G. W. HOYLE.

ORCHIDS.

CANADIAN ORCHIDS.

Deep hidden in the damp recesses of the leafy woods many a rare and precious flower of the Orchis family blooms, flourishes, and decays, unseen by human eye, unsought by human hand, until some curious, flower-loving botanist plunges amid the rank, tangled vegetation and brings its beauties to the light. One of these lovely natives of our Canadian forests is known as Orchis spectabilis—Beautiful Orchis, or Showy Orchis. This pretty plant is not, indeed, of very rare occurrence; its locality is rich Maple and Beech woods all through Canada. The colour of the flower is white, shaded, and spotted with pink or purplish lilac; the corolla is what is termed ringent or gaping, the upper petals and sepals arching over the waved lower-lipped petal. The scape is smooth and fleshy, terminating in a loosely-flowered and many-bracted spike; the bracts are dark green, sharp pointed, and leafy; the root a bundle of round white fibres; the leaves, two in number, are large, blunt, oblong, shining, smooth, and oily, from 3 inches to 5 inches long, one larger and more pointed than the other. The flowering time of the species is May and June. The exquisite cellular tissues of many of our flowers of this Order delight the eye, and give an appearance of great delicacy and grace to the blossoms. In this charming species the contrast between the lilac-purple colour of the arching petals and sepals and the almost pellucid lower lip, or somewhat broadly lobed under petal, is very charming. The large shining leaves lie close to the ground when the plant is in flower. Transplanted to gardens, the Showy Orchis rarely survives the second season of removal from the forest shade. It will not grow freely exposed to cold wind or glaring sunlight. It loves moist heat; the conservatory would probably suit it, and it would be worth a trial there.

Lady's Slippers or Moccasin Flowers.

Whether we regard these charming flowers for the singularity of their form, the exquisite texture of their tissues, or the delicate blending of their colours, we must acknowledge them to be altogether lovely and worthy of our admiration. One of the rarest, and at the same time most beautiful and curious, is the

Ram's-head Orchis (Cypripedium arietinum), which has smooth glaucous green leaves, and small purplish flowers bearing a close resemblance to a ram's head with the horns and ears and a tuft of wool on the top of the head. It is seldom over 6 inches in height, and grows in cold peat bogs, and flowers in July. Associated with it we find our most gorgeous representative of the family, the

Showy Lady's Slipper or pink flowered Moccasin plant (C. spectabile).—This grows chiefly in Tamarack swamps and near forest creeks, where, in groups of several stems, it appears, showing its pure blossoms among the rank and coarser herbage. The stem rises to the height of from 18 inches to 2 feet. The leaves, which are large, ovate, many-nerved, and plaited, sheathing

at the base, clothe the fleshy stem, which terminates in a single sharp-pointed bract above the flower. The flowers are terminal and generally solitary, although old and strong plants will occasionally bear two, or even three, blossoms on one stem. The unfolded buds of this species are most beautiful, having the appearance of slightly flattened globes of delicately-tinted rice paper. The large pouch-like inflated lip is slightly depressed in front, tinged with rosy pink, and striped. The pale thin petals and sepals, two of each, are whitish at first, but turn brown when the flower is more advanced towards maturity. The sepals may be distinguished from the petals, the former being longer than the latter, and by being united at the back of the flower. The column on which the stamens are placed is three-lobed; the two anthers are placed one on either side under the two lobes; the central lobe is sterile, thick, fleshy, and bent down, somewhat blunt and heart-shaped. The root of the Lady's Slipper is a bundle of white fleshy fibres.

Stemless Lady's Slipper (C. acaule).—This differs from the former species by the pouch, which is large and of a beautiful rose tint exquisitely veined with deeper red zigzag lines, not being closed, but merely folded over in front; this is not observable until you examine it closely. The scape rises from between the two large oval leaves, which lie horizontally on the Mosses amidst which the plant grows. A time will come when these rare productions of our soil will disappear from among us, and will be found only in those waste and desolate places where the foot of civilised man can hardly penetrate, where the flowers of the wilderness flourish, bloom, and decay unseen.

Yellow Lady's Slippers.—Of the golden Moccasin flowers we boast of two very beautiful species, C. pubescens (Hairy Moccasin flower) and C. parviflorum (Lesser-flowered Moccasin flower). The larger plant is the more showy; the smaller the more graceful, and has a delicate fragrance which is not so strong in the larger flower. The long spirally twisted petals and sepals, of a purplish brown colour sometimes tinted and veined with red, give the smaller flower a very elegant appearance, though the rich golden hue of the larger is more striking to the eye. C. parviflorum affects the moist soil of wet grassy meadows and swamps, whilst the larger plant loves the open lands among shrubs and tall Grasses. In the month of June, when it may be seen beside the gay Painted Cup (Castilleja coccinea), the blue Lupine (L. perennis), the larger white Trillium, and other lovely wild flowers, it forms a charming contrast to their various colours and no less varied forms. The stem of the larger Moccasin flower is thick and leafy, each many-nerved leaf sheathing the flowers before they open. The flowers are from one to three in number, bent forward, drooping gracefully downwards. The golden pouch-like lip is elegantly striped and spotted with ruby red; the twisted narrow petals and sepals, two in number of each kind, are of a pale fawn colour, sometimes veined and lined with a deeper shade.

Rattlesnake Plantain (Goodyera pubescens).—This is a formidable name for a lovely little plant, the leaves of which are prettily netted over the dark green surface with milky-white veinings. The ovate, pointed leaves are set close to the ground; from the centre of the leaves rises a naked stalk of pearly white flowers in a slender spike; corolla ringent with inflated lip; root-stock somewhat creeping, soft and fibrous; the flowers are slightly fragrant. This pretty little plant is found in the forest, often on fallen decayed trunks of trees, or in light fibrous mould. It is very nearly allied to the

Slender Ladies' Tresses (Spiranthes gracilis).—The flower-stem of this singular plant is twisted, so that the blossoms are turned to one side, forming a spiral of great beauty. The flowers are larger than those of the Rattlesnake Plantain and sweeter; greenish white, lipped and fringed. The two leaves are closely pressed to the ground, and are little seen after the plant is in bloom. There are several species of these graceful Orchids. The spiral arrangement of the flowers probably suggested the ringlets on some fair lady's head. The old florists and herbalists of former times were more gallant than our modern botanists, for they gave many pretty names to the flowers instead of the harsh sounding, unmeaning ones that we find in our scientific manuals of botany. So we have among our local and familiar names such prettily-sounding ones as Ladies' Tresses, Sweet Cicely, Sweet Marjoram or Marjory, Marigold, Ladies' Slipper, with a number of others that I could name—besides descriptive names, which form a sort of biography of the plant, giving us a correct idea of their characteristics and peculiar uses or habits.

Small round-leaved Orchis (Platanthera rotundifolia).—This is one of the lovely native plants of the Orchis family, of which we boast many remarkable for beauty as well as for the eccentric forms which arise from the peculiar arrangement of their floral organs. The one here named is worthy of attention. Our quaint old herbalists would have called it the Holy Dove, or some such name, from the curious resemblance that the petals and sepals take to the body and extended white wings of a hovering dove, the lower lobed petal taking the semblance of the tail and wings, the upper ones meeting over the anther cells, which might be likened to the two eyes of the bird, and the arched hooded appendage above to the head. The scape of this pretty Orchis is furnished with one handsome round or shield-shaped leaf of shining bright green, and a bracted spike of white flowers, spotted with delicate pink, as also is the throat of the arched petal that partly covers the anthers and stigmatic disc. Our beautiful Orchids, with many other rare bog plants, repay the difficulties of obtaining them in their native haunts, such as Cedar swamps, Cranberry marshes, Poplar swales, and peat bogs; where, however zealous, our lady botanists may not venture without risk. These rare plants, growing in lonely isolated places, are little known and but seldom met with, unless, as I have said, by the enthusiastic botanist who is not afraid to seek for such floral treasures, however difficult they may be to obtain. A curious and handsome species is the

Striped Orchis or Coral-root (Corallorhiza multiflora).—This plant is leafless, silvery-sheathing scales taking the place of leaves; the roots are branched and knobby, like some kinds of coral; the scapes, many-flowered, growing up in clusters from 12 inches to 18 inches high; the flowers are pale fawn, striped and dotted with crimson or purple. Such was a plant that I found at the root of a big Hemlock tree, near the forest road where I often walked many years ago. There are several different species of this curious Order, varying in size and the colour of their blossoms.

Of fringed and tufted fragrant kinds, we have the Pearly White and the Fringed Pink Orchids. These are very pretty and not uncommon flowers. I first saw them on my voyage up the St. Lawrence, when the ship was anchored off Bic Island, and the captain brought me a noble posy of sweet flowers, the first Canadian flowers I ever saw. Among wild Roses and elegant blue Lungwort (Mertensia maritima), which I had also seen and gathered near Kirkwall, in Orkney, there were yellow Loosestrife, Harebells, and the sweet-scented White Fringed Orchis, the Pink Fringed Orchis and some elegant cream-coloured Vetches, and several other flowers then unknown to me.

There are many other plants of the Orchis family scattered through our woods and swamps and on the rocky or low islands of our northern lakes. Among those not already mentioned, the Larger Fringed Orchis (Habenaria fimbriata) may be named. This is a tall handsome bog plant, flowering in the beginning of July, with large rose-purple, deeply-cut petals. Another less conspicuous species, found in dry woods, is the Northern Green-man Orchis (Habenaria viridis var. bracteata). The scape of this species is furnished with long narrow sharply-pointed bracts and greenish flowers. In some of our Orchidaceous plants, when examined, there will be seen at the base of the fleshy scape two roundish bulbs or tubers—farinaceous masses, whence the bundle of white fibres, the roots and rootlets proper, proceed, and which contain the prepared food to support the growth of the year. From one of these tubers, the scape, bearing the scaly or leafy bracts, root-leaves, and flowers, springs, and at the flowering season is much larger than the other. The flower-bearing bulb decreases from exhaustion of its substance, shrivels, turns brown, and begins to decay; while the other continues slowly but steadily to go on increasing, bearing in its bosom the embryo flower-stem and foliage which are to appear the following year. Another tiny bulb is also preparing in like manner, attached by a slender fleshy cord to its companion. Thus from year to year the process goes on, each one taking the place of its predecessor after its office has been fulfilled. This singular mode of reproduction seems to supersede the necessity for the development of seed, as in other flowering plants; nor is it so common to find seedlings of the Orchids springing up round the parent plant as in the case of other flowers. The reason why so few amateur florists succeed in transplanting the native Orchids into their gardens arises from want of due care in taking them up. The life of the plant for the following season being contained in the new forming tuber, if this be in the least injured the chance of another flower in the future is at an end. The succulent tender roots are easily broken or wounded, and these strike rather deep down in the soil, and must be taken up uninjured, with a good portion of the mould, or there is small chance of life for the plant. Nor will the Orchis thrive in common earth; it requires fibrous, peaty soil, moisture, and some shade, with the warmth that arises from the moist soil and shelter of the surrounding herbage. They all thrive best in the conservatory or greenhouse. —*Plant Life in Canada.*

Drip in Orchid houses.—Like many other Orchid growers, my house possesses the unfortunate condition of a low-pitched roof, with the inevitable consequence of drip from condensed moisture. I have tried zinc channels under the rafters and other places without any success. The zinc in the course of a short time assumes every form of curve. Drip for Orchids and most other plants is utter ruin, more especially for Cattleyas. I have now adopted a plan which has proved a perfect success; it is that of suspending strips of grooved glass with copper wire under each rafter, and the channel or furrow in which forms a perfect conductor for every particle of moisture. This plan is so simple and cheap in its application, that I am sure if any of your readers saw it in my house they would at once adopt it. If the roof is very flat, it is advisable to let the glass touch the rafter at its upper end only, and this will give an increased fall of 2 inches.—W. Soper, 307, *Clapham Road, S.W.*

*** We have seen Mr. Soper's plan for remedying drip in a flat-pitched plant house, and think it both effectual and simple. The strips of glass possess the advantage of being nearly invisible, and the slight groove or depression upon their surface causes the water to run down rapidly. Moreover, glass is not affected by heat or moisture, whereas zinc, or even Bamboo rods, warp in an unsightly manner.—Ed.

Cypripedium Arthurianum.—Many orchidists consider this to be the finest of all the Lady's Slippers, but, be that as it may, it cannot be said to have many rivals; its quiet beauty and singular form are remarkable. It is a hybrid between the old C. insigne and that precious gem, C. Fairieanum. It combines the colour of the two parents admirably, and, what is more peculiar, the tendency of the side sepals, as in Fairieanum, to drop is transmitted to the progeny, and this affords always an unmistakable distinguishing feature in Arthurianum. It is one of Mr. Dominy's hybrids; he showed us a flower of it the other day by the side of C. vexillarium, also a hybrid between C. Fairieanum and C. barbatum. There is more colour in the flowers of vexillarium and the side sepals are depressed, but it lacks the subtle tinting of Arthurianum.

Kitchen Garden.

RIPE AND GREEN TOMATOES.

Never perhaps have Tomatoes been more abundant than this season, outdoor crops having up to the present time (Oct. 23) escaped both disease and frost. Many, therefore, would doubtless like to know how best to utilise their surplus ripe fruit, so as to have a supply in some form or other during the winter. Tomato sauce would appear to be the only resource known to the majority of housekeepers, and even this but few succeed in keeping long after it is made. I have in my possession a considerable number of recipes for making this sauce, and each season more are added to them, but none that I and others have tried make a sauce that will keep good for any length of time. Tomato ketchup, however, will keep, in some instances, for years if the bottles are properly sealed down, and all with whom I am acquainted are delighted with it. Fully ripe Tomatoes are required for the purpose, and these should be baked in a jar till quite tender; then they should be strained and rubbed through a sieve. To every pound of juice add a pint of chili vinegar, an ounce of shallots, half an ounce of garlic, sliced, a quarter of an ounce of salt, and a quarter of an ounce of white pepper finely powdered. Boil the whole till every ingredient is soft, and then rub the whole again through the sieve. To every pound add the juice of three Lemons, and boil again to the consistency of cream. When cold bottle it, and either tie bladders over the corks or seal them down. Store in a dry place till wanted for use. We are using some of this ketchup made this season, while a friend has some that was made last year, which seems to be improved by keeping.

Another method of making Tomato ketchup I can vouch for as being a good one. Select half a bushel of ripe fruits, wash them, cut them in pieces, cook until soft, and strain through a sieve, pressing them well to obtain the pulp. To this add half an ounce of cayenne pepper and a small teacupful of salt, stirring these into the ketchup. Bruise an ounce each of cinnamon, cloves, allspice, mace, Celery seed, and half an ounce of black peppercorns; then tie them up in a muslin bag, and when the strained Tomatoes have boiled an hour and a half put in the bag of spices and boil another hour and a half. Add a quart of good cider vinegar, boil for half an hour, and turn the whole into a stone jar to cool; after which mix a pint of brandy or pure spirits of some kind thoroughly with the ketchup and bottle it, putting a strip of Horse-radish root in each. The bottles should be very carefully corked up and sealed. Store in a cool, dark place.

Fully grown, yet green, Tomatoes cut before they are damaged by frost, and hung up in bunches or stored on dry shelves either in a warm plant house or in a kitchen, will ripen in the course of time, and if not fit to eat in a raw state are very good when cooked. It usually happens that there are considerable numbers of partially developed fruits, and these it is useless to attempt to ripen. Instead, however, of allowing them to spoil they should be utilised for pickle-making, and with a little trouble they can be made very palatable. Take 4 lbs. of green Tomatoes and break or pull them into pieces, take also four or five medium-sized Onions and slice them up moderately fine, add six chilies, and scatter salt freely over the whole. Let it stand for fifteen hours, then strain away the moisture, place the remainder in a jar, and cover it with good vinegar. Bake this in an oven for one hour, and then press it into jars. Next take two dessert-spoonfuls of a mixture of mustard, pepper, and spice, a teaspoonful of sugar, a few cloves, a little cinnamon, and four chilies, adding sufficient vinegar to make the whole quite thin; boil for a short time; while still boiling hot pour this mixture over the contents of the jars. Carefully cork the jars or wide-necked bottles, that answer equally well, and cover them in the usual way with bladder. Store them in a dry place. The following is also a good method of pickling green Tomatoes, and this will not be found so peppery as the preceding: Scald and peel the fruits; lay them on dishes and strew salt thickly over them Let them stand twenty-four hours, occasionally pouring off the liquor extracted by the salt. Drain them and gently squeeze them at the same time, as it is this juice that interferes with their keeping. Take a large jar, put in a layer of Tomatoes, then a layer of sliced Onions, mustard seed, cloves, and white pepper, or whole black pepper; or two pods of red pepper may be broken up and put into the jar. When the latter is full pour very strong vinegar over the whole, and in a few days they will be ready for use, or will keep if need be all the winter. Store in a cool, dry place. W. I.

COLEWORTS.

There are few members of the Brassica family which more quickly show any tendency to roguishness than do the Rosette Coleworts. In this neighbourhood, where they are largely grown, one may look over a piece several acres in extent and not find a single defective one. There is such remarkable evenness throughout, that any bad form may be detected easily if present. Of course, such good form is found only where the strain is a first-class one and sown with care. Some seedsmen have special reputations with the market growers for this Cabbage, and are trusted to the utmost. At this time of the year, early in the morning or in the evening when vapour has settled upon the plants in the form of heavy dew, the breadths of Coleworts resemble broad sheets of silver. The general tendency of the plants to turn in simultaneously is so far advantageous to the grower, that he can clear off breadths as he goes, although very much exception may well be taken to the method by which bunching and loading is done, as too often the Coleworts are pulled, flung into heaps, pitched into carts and taken to where the bunching is done, pitched down again, and finally loaded, to receive several more tossings and tumblings in the market. All this sort of usage materially depreciates the quality and value of the Coleworts, as it necessarily robs them also of their freshness and beauty—if such a term may be applied to these really pretty little Cabbages. Were it the rule to cut Coleworts and pass them direct into big lattice baskets ready for loading, how much of all this tumbling and rough usage might be saved. The stalks go to London or elsewhere, to be returned again as refuse, perhaps as manure; whereas they might just as well be left at home. No doubt these stalks comprise quite one-third of the load where the plan so common of pulling roots and all and bunching them is practised. Anyone who has seen the sort of handling recorded must admit that through it the market value of the heads is materially affected. Without doubt, one of the chief elements in the delicious tenderness of texture found in good fresh Coleworts is due to the rapidity of growth made by the plants. They are invariably put out to follow early Peas or Potatoes, and as the soil is just then well pulverised, root is soon made and the plants are quickly established. Autumn rains very soon promote growth, and in some six weeks quite a remarkable transformation has taken place. If the soil be deep-worked and well manured, so much the better, because growth is so much the quicker. Coleworts have found in Autumn Giant Cauliflowers formidable rivals, as, like the Cauliflower, their season is limited to the autumn months. If the winter remains open, breadths may be left till Christmas, but too often rains and frosts discolour or injure the heads, and when that is the case, not only is appearance marred, but the fresh mild flavour found in Coleworts in November is destroyed. The practice which lately has grown up of getting Brussels Sprouts out early, and thus obtaining sprouts to gather quite early in the winter, brings in yet another formidable rival to the Colewort. On the other hand, this latter vegetable is so short a time on the ground, that it gives little trouble and is not exhausting. Put out at about 12 inches apart each way, the soil is literally filled with plants, and no further trouble is given beyond perhaps one hoeing until pulled in the autumn. Another dressing of manure fits the soil again for Peas or Potatoes, and so the round of cropping goes on. Market gardening around London is rarely high-class, and falls far below what may be seen about Paris or in Belgium. Our system is really market farming, for the gardens are practically farms, and the gardening art finds no appreciable display in them. A. D.

Effects of deep tillage.—As an illustration of the beneficial effects of a thorough breaking up of moderately stiff soil on vegetable growth, we may quote an experiment conducted at Rothamsted many years ago with white Turnips on three plots of ground, each plot being manured in exactly the same way, namely, with 11 cwt. of superphosphate per acre.

No.	Treatment of Land.	Average Weight of Bulbs.	Produce of Bulbs per Acre.
		Lb.	Tons cwt. qr.
1	Dug 9 inches deep.. ..	1·20	13 8 2
2	Dug 18 inches deep.. ..	1·30	14 4 0
3	Ploughed 5 inches deep ..	1·17	12 13 3

These results, says the *Gardeners' Chronicle*, indicate the character of the soil-conditions required in root culture, and show a more rapid bulb formation, with a corresponding increase of crop in proportion as the land was broken up and pulverised.

Garden Destroyers.

GALL-LIKE SWELLINGS IN CONIFERS.

I send you a specimen of diseased twigs of Pinus nobilis from a tree 70 feet high, and a very beautifully grown one it is, but it is feared the disease in question will impair its health. At present the evil is confined to the lower limbs of the tree, which last year produced an abundance of splendid cones; this year they are much fewer. I shall, indeed, be obliged if you can suggest a remedy. —S.

*** The gall-like swellings on the shoots of your Pinus nobilis are curious. I have seen somewhat similar ones before, and then (as now) was unable to ascertain their origin with certainty; there are no insects feeding within the nodules, and yet one cannot but feel certain that they are of insect origin. I sent some to one of our most eminent entomologists, and he replies: "I have little doubt that these swellings are primarily due to the attacks of one of the Pine tortrices" (a family of moths, many of whose caterpillars are very injurious, some specially to the young shoots of Firs). If this be the case, and I have no reason to doubt its being so, I imagine the caterpillars must have attacked the terminal buds of the shoots, but did not entirely destroy them, and the vitality of the shoots enabled them to continue growing beyond the injured parts, which, being in an unhealthy condition, a morbid growth was set up, forming swellings. In course of time the terminal bud was again attacked, and another swelling formed. This is the only way I can account for these abnormal growths. Next spring, in April and May, I should examine the young shoots and try and find the offender. At that time it would be worth while to thoroughly wet the branches with one of the following mixtures, applied with a syringe or garden engine: 2 ozs. soft soap, 2 ozs. flowers of sulphur, boiled in 1 gallon of water; or 8 lbs. of quassia and 4 lbs. soft soap, boiled in 10 gallons of water and strained before using; or soft soap 8 ozs., 1 gallon of water made to boil, then add 2 gallons of kerosine and mix thoroughly with a syringe for 10 minutes; for use, mix 1 pint of this emulsion with 9 gallons of water. I do not think because your tree bears fewer cones this year than last that it is necessarily an unhealthy sign. Few trees bear an equal amount of fruit every year.—G. S. S.

The Larch aphis.—I can find no account or description of Larch diseases in Brown, Grigor, or other books on forestry. I should, therefore, be very grateful if you could name the disease with which the twigs herewith sent are affected. The

rees are sixteen years old, grown in double trenched, ight land. They have been thus affected this year only, but previously many had sores on the stems, and these were cut out. Is there any chance of their recovery next spring? or should all be cut down and the branches burnt? Many trees have lost all leaf. This has happened on the outside of the covert, and in the case of trees more recently attacked.—E. R. P.

*** Your Larches are infested by the Larch aphis (Chermes laricis), a very common pest on Larches. Some of the latest hatched aphides survive the winter and lay their eggs in the spring just as the young leaves are beginning to appear; these now hatch, and the young at once attack the leaves. These insects appear to thrive best on trees which are not in a perfectly healthy condition from a damp, stagnant atmosphere, or some other cause. As soon as the leaves are down in the autumn or early in the spring just before the buds burst, syringe the trees with one of the following mixtures: 1 cwt. of fresh lime in 80 gallons of water allowed to stand for a week; then drain off the clear fluid and use. To 6 gallons of water add 10 lbs. of soft soap, and either 2 lbs. of bitter aloes or 6 ozs. of tobacco, and boil together; having strained it, add 36 gallons of water to every gallon before using it. Or, 1 gallon of water and ½ lb. of soft soap; make boiling hot, and add 2 gallons of kerosine, and mix thoroughly with a syringe for ten minutes; for use add 9 gallons of water to each pint of this mixture. I cannot imagine that your trees are hopelessly injured, unless they have been very much weakened by the sores you mention.—G. S. S.

TREES AND SHRUBS.

TAPERING TREES.

Essential as are the trees that drop their shoots toward the earth to the planter who wishes to realise to the full the beauty of our cultivated tree flora, they are scarcely so much so as those of which every branchlet points skyward—those of the tapering tree, from the stately Lombardy Poplar to the slim Irish Juniper. We have round towers as well as fountains of verdant life; the leaf-builders raise spires as well as castles. There is no tree yet discovered more effective in the landscape than the Lombardy Poplar, towering above our numerous round-headed trees. This is what may be considered the king of our pointed trees; it is as familiar to all as any tree can be, and abundantly planted. But there are other tapering trees to which we wish now to advert.

Pyramidal Acacia.—One of the trees next in value to the Lombardy Poplar is the pyramidal Acacia. Everybody knows the common Robinia or Acacia—which, if it never answered the expectations which Mr. Cobbett placed in it, is, nevertheless, a welcome ornament in our pleasure grounds, and is one of the best of all trees for garden or street planting in cities, as it retains its verdure for months after the common Lime. Every form of this tree has, indeed, "the verdure of ten meadows in its gracefully cut leaves." The pointed form of such a tree must be valuable, and this is one that is easily procured, and should be planted everywhere. It grows as compactly and is as distinctly tapering as the Lombardy Poplar, and has all the charms of the species as regards verdure. It is almost useless to plant such trees, or any trees, where, from being crowded up with other subjects or badly placed, their peculiar character is half obscured. Not growing so tall as the Lombardy Poplar, or not so vigorously, this should be associated chiefly with medium-sized trees and vigorous shrubs. It is also a capital plan when dealing with a subject of any character like this, instead of putting it in the centre of a group of low trees or as the centre to a company of vigorous shrubs, to boldly place it on the very margin of the mass. For isolation such subjects are peculiarly suitable.

Evergreen Cypress.—A lovely tapering tree is the Cypress (Cupressus sempervirens), as all know who have observed it in mild districts where it is much planted. We have noticed it thrive most commonly in districts under the influence of the sea, but the best specimens we have ever seen are at White Knights, near Reading. A fine, old, healthy specimen of this upright Cypress is one of the most charming trees to be seen in the world. The fact that it grows with us into such specimens as those at Reading proves that it is not those only who live round the basin of the Mediterranean, or in sunny Italy, that may enjoy it in their gardens.

Lawson's erect Cypress (C. Lawsoniana erecta-viridis) is likely to form one of the most valuable of all tapering trees. The normal form of Lawson's Cypress, found wild in Northern California and Oregon, is naturally one of the most graceful of all trees, attaining a height of 100 feet in its native wilds, and quite hardy everywhere in these islands. The erect variety is to the normal form what the Florence Court Yew is to the common Yew. It is very erect and dense in habit, and of a light rich vivid green, not glaucous like the species. There are other erect forms of the same species, but none of them have the peculiar and very desirable green hue of this, although in other respects they are very desirable. From its thorough hardiness, this tree may be used in districts where the upright Cypress would perish from cold; in fact, it is likely to be everywhere useful. As the species to which it belongs naturally attains a great height, it may be expected to form a stately tree. This should be borne in mind in planting it, as it will doubtless prove effective in many positions in which the medium and smaller sized tapering tree would not be suitable.

The Red or Virginian Cedar (Juniperus virginiana)—Sometimes in our rich and well-sheltered pleasure grounds the Virginian Cedar resembles common spiral or Fir-headed trees; but almost everywhere one sees it in the Eastern States it is as decidedly tapering as the upright Cypress, as anyone may tell who has travelled by rail from New York to Philadelphia. Along many parts of the line the Red Cedar is common—a close, tapering, low green tree, with from 4 feet to 10 feet of the base of the stem quite bare and weather-beaten. On the mountains near Newburgh, on the Hudson River, the wild specimens and groups of this species seemed in the distance upright Cypresses planted by man, so effective did they appear in the landscape, and so diverse were they in aspect from any tree common in natural woods. The Red Cedar grows over a vast area, inhabiting some of the coldest as well as the warmest regions, and is quite hardy in this country. Considering this and its peculiar habit, the tree is a neglected one, and far more worthy of the attention of planters than many of the half-hardy kinds sold at high rates.

The Irish Yew (Taxus baccata fastigiata).—This beautiful variety of the common Yew is so well known and so frequently planted that it need only be mentioned here. It is very likely that we shall soon have a variety of variegated forms of the same type, as, apart from varieties already announced and sent out, others of a decidedly tapering form have sprung up in several different nurseries. The Irish Yew originated at Florence Court, in Ireland, about a century ago. It is also known under the names of columnaris, compressa, and intermedia.

The Pyramidal Plane should prove attractive to every planter, and particularly to every city planter, as where there would not be room for the great arms of the common Plane to spread forth, this might find a place. We have, however, not seen specimens of it sufficiently developed to say anything of its character as a tapering tree; but young specimens promise well. There can be no doubt, however, as to its deserving a place in the front rank of our noblest trees.

Tapering Oak.—There is a tapering form of the common Oak (Quercus pedunculata fastigiata) which deserves attention from the planter, not only from its interest as a very remarkable variety of the British Oak, but also from its distinct and picturesque port. The best specimens I have seen were in Central France; but doubtless there are many good ones in various parts of England. It is to be regretted, however, that trees of this character so rarely show themselves in our pleasure grounds, as this proves that they are either not planted at all, or so badly placed that they are either unnoticed or hidden. Q. fastigiata viridis is another variety of Oak with a tapering habit, also well worthy of a place in our collection.

The Erect Birch (Betula fastigiata) must be classed among the best tapering trees, as it is so very ornamental. Amongst the varieties of the common Hawthorn may be found a good type of a pyramidal tree in a form of Cratægus Oxyacantha called stricta. This differs but little from the common May in anything but habit, which is erect and tapering, its branches being almost perpendicular.

The Irish Juniper (Juniperus hibernica).—This very distinct variety of the common Juniper originated in Ireland, most probably from seed, and on account of its singular habit of growing in a slender, compact column it has proved to be a most useful Evergreen for utilising in Italian and other geometrical gardens, where stiff and formal-looking plants are needed to please the tastes of those who cultivate this style of gardening. This Juniper is not only strikingly distinct in form, but its foliage also affords a decided contrast in colour to that of most other Evergreens, being a mixture of light green and silvery glaucous hues. It is effective when planted alternately, or in conjunction with the Irish and Golden Yews and standard Portugal Laurels. As a dwarf tree for planting sparingly in a cemetery or churchyard it is peculiarly suitable on account of its comparatively slow growth, as well as its slender form occupying but little space; it is, moreover, perfectly hardy, and will grow in any common garden soil, but doubtless prefers a moist, rich, heavy soil to a dry, gravelly, poor one. J. hibernica compressa is similar to the above in habit and colour, but very much slower in growth, and smaller in all its parts. It forms a compact, slender pyramid. For parterre winter gardening on a small scale this little Juniper would be invaluable. It is not difficult to transplant; indeed, it is so dwarf a tree that it could be grown on for years in a moderate-sized flower-pot, thus insuring its safety when removed from its summer to its winter quarters, and *vice versâ*; the rate of its growth I do not believe exceeds an inch a year. G.

Noteworthy evergreen Oaks.—In the beautiful grounds surrounding Wilton House, Salisbury, are two notable evergreen Oaks. One of these may be termed a souvenir of the Czar Nicholas. Fifty years ago, when on a visit to Wilton, he planted this tree, and as it bids fair to develop into a fine specimen, it may probably outlive some of the interest now attached to it. Nearer the house there is a much older specimen, remarkable not for either its history or height, but on account of the great spread of its branches, many of which have now to be propped up in order to keep them from being broken. The area of ground covered by this tree is about 177 yards, in this respect probably surpassing any tree of its kind in the country.—W. I.

Hardy Heaths.—I have just noted the following as being in bloom here: Erica vagans, the Cornish moor Heath, a free, vigorous grower, forms a bush about a yard high, and each shoot is terminated by a cluster of purplish red blossoms. There is a variety (rubra) deeper coloured than the type, and another very pretty form in which the flowers are white. This Heath is also sometimes known as Gypsocallis vagans. St. Dabeoc's Heath (Dabœcia polifolia) has been in flower for months, and still continues in that condition. It is one of the very finest of all hardy Heaths, for not only does it bloom continuously, but the flowers are among the showiest of any. Besides the ordinary purple-flowered kind, there is one with white blossoms, and another with both white and purple flowers on the same plant. Many forms of

the Heather are still in bloom, though in most cases their freshness is over, a notable exception, however, being the variety called E. Searlei, which, given favourable weather, will yet bloom for some time. The blooms of this are pure white. E. ciliaris and its beautiful variety Maweana are still in flower, and if the old blooms are removed as soon as they wither, they keep long bright and fresh in appearance; and the same may be said of E. tetralix and Mackiana. E. multiflora, a free-growing kind with rosy red blossoms, is also valuable as a late flowerer.—West Surrey.

Societies and Exhibitions.

ROYAL HORTICULTURAL.

October 26 and 27.

A great show of vegetables was the chief feature of this meeting, nearly the whole of the building being occupied by them. A capital display of Chrysanthemums, pot plants and cut blooms, made the place attractive, and new plants and flowers were rather numerous. The following were awarded first-class certificates:—

Rhododendron jasminiflorum carminatum.—A variety of the well-known white greenhouse Rhododendron, having flowers of a beautiful rich carmine colour. It is a decided acquisition, as it flowers so freely, and the colour is quite distinct from that of all the hybrid sorts raised of late years. Shown by the raisers, Messrs. Veitch, Chelsea.

Cratægus tatarica.—A new and very handsome Thorn, remarkable for the large size and bright colour of its fruits and beautiful foliage, which is of a purplish hue. The fruits are the size of Cob-nuts and bright orange-red. We know nothing as to its habit of growth or hardiness. Shown by Messrs. Veitch.

Bignonia Chamberlaynii.—This old-fashioned greenhouse climber, known also as Anemopægma racemosum, was shown beautifully from Mr. Scrase-Dickins' garden at Coolhurst, Horsham, some long branches being quite wreathed with long, tubular, pale yellow flowers. It is one of the best greenhouse climbers we have for late autumn flowering.

Cattleya Eldorado virginalis.—A lovely variety having the flowers pure white, excepting a dash of yellow on the lip. In other respects it does not differ from the type. Shown by Mr. H. M. Pollett, Fernside, Bickley.

Odontoglossum blepharicanthum.—A pretty plant, much resembling O. crocidipterum. The flowers are of the size of those of O. odoratum, white, and copiously spotted with coffee-brown. Exhibited by Mr. Tautz, Studley House, Hammersmith.

Chrysanthemum Flambeau Toulousaine.—A Pompon variety with small compact, globular flowers, quilled petals of a deep rose edged with white. Shown by Messrs. Cannell, Swanley.

Chrysanthemum Wm. Stevens.—A beautiful Japanese variety, having large flowers, long narrow florets of a bright chestnut-brown. Shown by Mr. Stevens, Putney.

Chrysanthemum Buttercup.—A valuable addition to Japanese Chrysanthemums, as it is the brightest and finest yellow sort yet raised. The flowers are large, finely formed, and of a peculiarly rich yellow. It is one of Mr. Salter's new seedlings. Exhibited by Messrs. Veitch.

Chrysanthemum Mdlle. E. Dordan.—An exquisite little pompon variety, having medium sized flowers, perfectly globular. The colour is a deep lilac. It is one of the most pleasing Pompons we have seen. It was shown by no fewer than four exhibitors, viz., Messrs. Laing, Forest Hill; Messrs. Cannell; Mr. Davis, Camberwell; and Mr. Owen, Maidenhead.

Primula Reidi.—A botanical certificate was awarded to this plant, which is described in another column.

Among other interesting exhibits were the following: A remarkable specimen of Dendrobium superbiens came from Mr. Tautz's garden. It had a growth quite 2 feet high, bearing two fine flower-spikes. A cultural commendation was accorded to the gardener. Messrs. Low showed a very fine specimen of that rare Orchid, Warscewiczella cochleata. It has rather large flowers, ivory-white sepals, and a broad labellum of rich purple. Mr. R. J. Measures, Cambridge Lodge, Camberwell, sent spikes of Cattleya bicolor marginata, the flowers of which have the lips margined with white, as in the variety Measuresiana. Herr Max Kolt sent from the Botanic Garden at Munich a plant of Anthurium Martianum—rather a noble-leaved species, but not remarkable. Mr. H. B. May, Edmonton, sent plants of a new Fern named Pteris tremula grandiceps, but its resemblance to the typical P. tremula was not close. It is a graceful Fern, and may be a hybrid. Mr. Ware sent from Tottenham plants of the pretty Saxifraga Fortunei, the latest of all the genus in flowering, and a really beautiful plant, both for the open border and the greenhouse. It has large foliage and crowded spikes of white flowers. He also showed Colchicum speciosum, which is very fine just now. Mr. B. S. Williams exhibited a group of his autumn-flowering Amaryllises, which are hybrids from A. reticulata. There are now several varieties, all very lovely, the colours being so delicate and pleasing. Among the sorts shown were Mrs. Garfield (figured some time ago in The Garden) and Mrs. Lee, which is the darkest in colour. They are invaluable for the stove house just now. Messrs. Cutbush, Highgate, sent bushes of several sorts of Pernettya mucronata, with berries of various tints. They are very attractive at this season, and are really the prettiest shrubs one can have in the garden just now. Mr. R. Dean, Ealing, sent a gathering of Polyanthuses and Primroses—a remarkable exhibit at this season.

Among new Chrysanthemums shown the following were conspicuous: Among those from Messrs. Veitch were William Clarke and Alfred Chantrier, both Japanese sorts, the first a kind of pale nankeen yellow, the other buff-yellow. Mr. Molyneux, of Swanmore Park, sent flowers of a sport from Bouquet Fait, named Marie Louise. It is a fine flower, with white florets turning to deep lilac. Mr. E. Beckett, Elstree, sent a sport from Baronne de Prailly, named Carew Underwood. It is much lighter than the original. Among a large collection of cut blooms from Messrs. Cannell, of Swanley, were some uncommonly fine blooms of such beautiful sorts as Flambeau, Mad. Cossart, Mad. Jacotot, Mad. de Sevin, Margot, Gloire Rayonnaise, J. Laing, and the pretty single Mary Anderson. Mr. Owen also had some good new sorts, the best, we thought, being those named E. G. Henderson, W. E. Boyce, W. Bealby, and Villatte de Pragues. Mr. Owen also had some pretty varieties of Chrysanthemum carinatum and coronarium, both useful at this season for cutting from.

There was a competition for groups of Chrysanthemums in pots and for cut blooms. Four groups were shown, all excellent, the finest being that from Mr. Davis, of Camberwell, who had a compact and bright group, chiefly of Japanese sorts. Mr. Stevens' group was likewise bright and good; and that from Mr. Measures' garden, Camberwell, was distinct from all in being made up chiefly of white sorts, the new Lady Selborne being very prominent. The cut blooms were excellent, considering the early date. The best collection of twenty-four blooms came from Mr. Ridout, of Reigate, the sorts most prominent being Mad. Sevin, Dr. Macary, Lady Selborne, Mr. Laing, W. Robinson, Phœbus, Bouquet Fait, La Triomphante, Comte de Germiny, M. Délaux, Margot, Triomphe du Nord, Chang, and M. Rendatler. The other collections were all bright and composed of good selections of sorts, but it was evident that some of the exhibitors had a difficulty in making up a full collection of good blooms. Messrs. Paul, Cheshunt, showed a new pillar Rose, a single white, which seems to bloom freely in late autumn. It is pretty. They also sent plants of that handsome hardy Heath Erica Maweana, one of the best in every way. Messrs. Hooper sent a pretty new tree Carnation named Prince Alexander.

Fruit committee.—There were not many exhibits submitted to this committee, the most noteworthy being the following: A fine new kitchen Apple named Bismarck was shown by Messrs. Veitch. The fruit is very large, of even shape, and said to be of excellent quality. A pyramid bush was shown by Messrs. Veitch bearing several fine fruits. Some bush trees of the Melon Apple were shown by Mr. Roupell, of Streatham. These were on Paradise stocks, which evidently suits this variety. The fruits are large and handsome, and of delicious flavour. Mr. Scrase-Dickins sent from Coolhurst about a dozen fruits of the Hollandbury Pippin, as fine in size and colour as we have ever seen. Mr. Laxton showed fruits of his Pear Robert Thompson, and Mr. Divers, of Ketton Hall, Stamford, sent a dish of excellent Salwey Peaches from a cool house. Mr. R. Dean sent samples of Madresfield Court Grape grown out of doors. The berries were small, but of finer flavour than one would suppose.

Vegetables.

Turning now to the competitions and taking them in the schedule order, we find *Celery* in bundles of six heads first. Of these there were fourteen lots, mostly red, the judges showing a prejudice in favour of that colour by passing over a lot of Grove White, very clean and perfect, in favour of Clarke's Red, the best of this coming from Mr. Pope, of Highclere Castle, the second lot of the same from Amersham, and the the third best, Standard Bearer, from Somerley Park. Then of *Parsnips* there were seventeen half-dozens, mostly very large, almost too big in fact, yet full of flesh. Mr. Meads, of Shrivenham, had the best, viz., Student; Hollow-crowned Improved was second; and Maltese from Bletchley was third, and yet it would have puzzled anyone to tell why these Parsnips should have three diverse names. *Carrots* were represented by twenty-eight lots of six roots, nearly all New Intermediate or Matchless, and mostly very clean, tapering, and handsome. It is very evident that no other kind can stand on the exhibition table, or, indeed, anywhere against this recent introduction. Mr. Neighbour sent the best from Bickley Park; the second best came from Mr. Lee's garden at Aylesbury; and the third lot from Bampton, Oxon. A very beautiful lot from Wycombe, and a second and rather larger sample from Daventry seemed, in this case, to have been overlooked, so good were they. Then came twenty-four bunches of Turnips, nearly all of the Snowball and Six Weeks types, with just one yellow and one purple-topped lot. Snowball from Barnet, from Edgcote, Banbury, and from Bletchley had the prizes. Then followed twenty lots of *Onions* of various kinds and sizes. There the judges broke away somewhat from the usual course; passed over some huge flat samples in favour of a very fine rounded brown sample named Weldwich from Mr. Finlay, of Lee Court, Faversham; good Anglo-Spanish came second from Bampton; and very handsome, solid, good keeping Wroxton of the true oval or James' Keeping pattern from Coleshill was third. Brussels Sprouts were shown in dishes, but were hardly good, as it is yet a little early. The best, the Wroxton, came also from Mr. Finlay, neat, medium-sized, and firm; the Aigburth from Newbury came next, and Mr. Pope, of Highclere, was third with an unnamed kind. There were seventeen dishes of these, and twenty-five lots of *Beetroots*, generally rather large, the best good Dell's Crimson coming from Bickley Park, Mr. Waite, of Esher, having handsome Pragnell's Exhibition—a selection of Dell's—for second place, and the same kind was third. *Cauliflowers* came next, sixteen lots of three heads being shown—all capital samples, big ones being carefully avoided. All appeared to be Autumn Giant, the best coming from Mr. Miller, of Rood Ashton, clear white and solid, Mr. Miles having the next best; whilst Mr. Meads was third, our leading vegetable growers being thus well represented. Then came thirteen lots of *Leeks*, Mr. Miles having the finest in The Lyon; Mr. Ross was second with Ayton Castle; and Mr. Waite third with Prizetaker, all capitally blanched. Then of dishes of twelve *Tomatoes* there were thirteen, Mr. Farrance, Chadwell Heath, coming first with fine fruit of Trophy; Reading Perfection was second; and some smaller samples of the same kind third. Now came the great contest for the society's prizes, viz., the collection of eight kinds of vegetables, a grand competition of thirteen lots being shown and wonderfully even in quality. The collection from Wycombe Abbey was in Mr. Miles' best style, and literally perfect at all points. In it were Onions, Stamfordian Tomatoes, Imported Brussels Sprouts, Leicester Red Celery, Autumn Giant Cauliflowers, Chancellor Potatoes, Lyon Leeks, and Intermediate Carrots, all weighty

kinds; Mr. Neighbour came next with fine Mushrooms, Ne Plus Ultra Peas (really first-rate for the season), Vicar of Laleham Potatoes, Intermediate Carrots, Reading Perfection Tomatoes, White Globe Onions, &c.; Mr. Haines was third with a collection of the fine Coleshill form, including Student Parsnips, Rousham Park Onions, New Intermediate Carrots, &c. Collections were unfortunately unplaced that were highly meritorious.

Potatoes.—Two classes were set apart for these in the society's schedule, and there were no less than sixteen collections of twelve dishes, and twenty-one lots of six dishes. In the former class Mr. Hughes, the famous grower from Byfield, was first; Mr. Wills, of Edgecote, was second; and Messrs. Kerr, of Dumfries, and C. Clayton, of Mildenhall, Suffolk, were placed equal third. All the samples were beautiful, those from the two former exhibitors exceptionally so. The best included, of whites, Chancellor, Fidler's Prolific, London Hero, Harvester, Nelson's Seedling, Abundance, Favourite, Colonel, Reading Giant, Schoolmaster, Edgecote Seedling, First and Best, and Snowdrop. Coloured kinds good were Reading Russet, The Dean, Hughes' Purple Perfection, Adirondach, Vicar of Laleham, Rosebud, Rufus, Beauty of Hebron, and Edgecote Purple. The prizes for six dishes went to Messrs. Hughes and Wills; Mr. Howard, Canterbury, was third. Here, again, were singularly beautiful samples of Harvester, Blanchard, London Hero, Snowdrop, Chancellor, Sutton's Seedling, and Abundance; and of coloured ones, Purple Perfection, The Dean, Vicar of Laleham, Rosebud, Reading Russet, Edgecote Purple, Radstock Beauty, Rufus, and Mr. Bresee. It was distinctly noticeable that rounds greatly predominated in all the classes throughout the show. On the whole, the average, if hardly so good as that of last year, was almost as good as could have been anticipated.

Special Prizes.

Of these, and they were on this occasion numerous, the first on the list, given by Messrs. Carter, was for four kinds of specially named Potatoes, viz., Ashtop Fluke, a Lapstone form; Sukerete, rather large and coarse; Village Blacksmith, round, having a very rough tawny skin; and the purple Fir-apple kind, Cetewayo, which is ugly and utterly useless. Six collections were staged, making a very poor show indeed; the only good dish was one of Ashtop Fluke. It seems impossible to conceive what benefit can result from encouraging such kinds as the black Fir-apple forms.

Onions.—Mr. Deverill, Banbury, offered prizes for his fine Onions, Rousham Park, Anglo White Spanish, Main Crop, and Wroxton. The first three seem to be exceptionally fine white Spanish forms, and the latter, a capital, clean, oval-shaped Onion. The best collection of these four kinds, from Mr. Wingrove, Rousham Park, Oxon, were very fine clear samples; the second lot from Hassocks, Sussex, wanted finish; and the third lot, much cleaner, from Wroxton Abbey, were fine samples. Potatoes were again in strong force in the classes provided by Mr. C. Fidler, Reading. First, came nine dishes, distinct, including General Gordon, Reading Giant, and Snow Queen. Here Banbury, with Mr. Wills, was first, with a beautiful lot added to the above three kinds, being Abundance, London Hero, Chancellor, Edgecote Purple, Vicar of Laleham, and Queen of the Valley. Reading Russet, Mr. Bresee, &c., were also prominent in other collections. Mr. Hughes was a good second, Mr. Allen, Hungerford, third, and Mr. Kerr, fourth. A class for six dishes, including Fidler's Perfection, five lots being staged, placed Mr. Hughes first; he had Crimson Beauty, Reading Russet, Vicar of Laleham, Abundance, London Hero, Snowdrop, Reading Giant, &c., in prominence. In another class for three kinds of Mr. Fidler's Potatoes, the prizes went to Edgecote, Byfield, and Hungerford.

In the special prizes offered by Messrs. Sutton, Reading, the first class was for two of their kinds of Potatoes, Abundance and Seedling, both fine flattish, oval, white, round, and fine croppers. Superb samples of these came from Edgecote, Byfield, and Mr. Chopping, of Sittingbourne. There were nine lots in this class, and in the next one of nine dishes, open to any of the firm's sorts, there were eleven lots, and grand samples, too. The redoubtable Mr. Hughes was here again first, having Ruby, a beautiful red kidney, Prizetaker, Lady Truscott, Early Regent, Woodstock Kidney, Abundance, Seedling, Favourite and Reading Russet. The second best collection, from Edgecote, was a duplicate of the previous one. There were no less than seven prizes, comprising a total sum of nearly £13.

Celery of this firm's well-known White Gem, a dwarf, compact, and solid form, came next, three heads being shown. There were eleven lots, the best, though dubiously true because too tall, came from Somerley, the tops having been cut clean off. The next best came from Sutton District Schools, and the third from Esher, smaller, perhaps, but very clean and good. Then of Sutton's Dark Red Beet there were sixteen lots, Mr. Waite being a good first with very pretty and proper-sized roots, the second best coming from Byfield, and the third lot from Wycombe Abbey.

Carrots of the New Intermediate form were wonderful, exceeding in size and beauty all previous exhibits. There were no less than twenty-four lots of this fine sort, the best coming from Mr. Neighbour, though a little hard scrubbed. Mr. Robins, Aylesbury, came next with perfect samples in form and finish; the third lot, and very fine also, coming from Somerley. Then of

Prize-taker Leeks there were eight bundles, the best and the deepest blanched and very best in the show coming from Mr. Waite; the next best, also very fine white samples, coming from Wycombe and Brighton. Lastly, were thirteen lots of the *Student Parsnip*, wonderfully fleshy roots, the best coming from Mr. Lye, Newbury, Somerley, and Coleshill.

Collections of Potatoes from the trade growers were numerous and well displayed, Messrs. Sutton, Reading, showing an immense number of named sorts, with numerous seedlings not yet in commerce, showing that of new varieties there is a big reserve. As these are yet under number only, it is useless to particularise any of them, but of named forms very fine piles of Abundance and Seedling, very fine flattish round forms of the Reading Hero type were present, as also of Reading Russet, Reading Hero, Magoum Bonum, Ruby, First and Best, Early Regent, Ashleaf Kidney, The Dean, Vicar of Laleham, Miss Fowler, Chancellor, Prime Minister, Fidler's Prolific, and many other popular kinds. This fine display was quite in this celebrated firm's best style. Then from Mr. C. Fidler, of Reading, came a big lot, some of the prominent kinds, such as Reading Giant, White Elephant, Magnum Bonum, and Imperator being in great bulk; Snow Queen, Fidler's Perfection, Prolific, and Enterprise, Schoolmaster, Queen of the Valley, Vicar of Laleham, and others being in great form.

Messrs. Carter won a silver medal for their collection of dried Tobacco plants, which were effectively arranged on white card supports, the finest seeming to be Pennsylvania, Island Broadleaf, White Burley, and Glasner. They also had sixty dishes of Potatoes, including many popular kinds already often named, their rough-skinned Village Blacksmith and black Cetewayo being prominent. From the society's gardens came a collection of Potatoes, including several of the long French kinds. Mr. Deverill, of Banbury, had very fine samples of his large Rousham Park, Anglo Spanish, Wroxton, and Main Crop Onions; also Wroxton Brussels Sprouts, Ne Plus Ultra runner Beans, Leicester Red Celery, Crimson Beet, Intermediate Carrots, &c.

A selection of Canadian Apples, forming but a small part of the great display made of these fruits last week, was staged and received a silver Banksian medal, the rich colour found in most samples commanding warm admiration. A remarkable exhibit was a collection of wines of home production made from outdoor Grapes, Gooseberries, Rhubarb, and other fruit products, shown by Mr. Robert Fenn, Sulhampstead. Some of the samples had been in bottle since 1844, whilst others were of subsequent years' brewings, down to 1885. Many of these wines had been with the Royal Horticultural Society's shows at Birmingham and other provincial towns, and were also exhibited at South Kensington. Mr. Fenn complains naturally that people continue to use foreign wines, even though not good in quality, and utterly neglect the capacities of their own gardens to produce these drinks. Some of the wines were tasted by competent judges and pronounced exceedingly pleasant and refreshing. The chief difficulty in dealing with an exhibit of this sort seems to be in finding palates not previously vitiated by the partaking of French or Portuguese brandied wines, in which the alcoholic percentage is so much greater and the flavour so much more spirituous.

A full prize list is given in our advertising columns.

National Chrysanthemun Society.—At a meeting of this society, held at the Royal Aquarium, Westminster, on Wednesday last, Messrs. Cannell, Messrs. Veitch, Mr. Martin, Mr. Owen, and others exhibited Japanese and Pompon varieties of Chrysanthemums in great profusion, very few incurved kinds being presented. First-class certificates were awarded to Mr. Martin for Japanese Chrysanthemum Phœbus, a clear bright yellow flower with drooping petals, and La Triomphante, a large pink, flat-petalled bloom of good substance; to Mr. Shoesmith for La Triomphante; to Mr. Owen for Pompon Wm. Bealby, creamy mauve; to Messrs. Veitch for Japanese Chrysanthemum Phœbus and Buttercup, also a good yellow; to Mr. N. Davis for Pompon Wm. Bealby; to Mr. George Stevens for a new Japanese Chrysanthemum called Wm. Stevens, a dull crimson-orange; to Messrs. Cannell for Pompon Mdlle. Elise Dordan, an exquisite little flower, almost a perfect globe, and of a light mauve colour, and Pompon Toulousain, a good flower of a much deeper shade; for Japanese Chrysanthemum La Triomphante and large Anemone Cincinnati. There is every prospect that the show of this Society, to be held at the Royal Aquarium, will eclipse all others in extent, as it is yearly extending its influence over the country.

QUESTION.

5529.—**Cotoneaster Simonsi.**—Will anyone tell me how to prune this? It is growing up a wall, and for the last two years it has had single berries only when pruned, but when left alone it has bunches of scarlet berries. Unluckily, from its position it must be pruned.—G. C.

Celery (*W. W.*).—We do not find much the matter with your Celery. It has the appearance, however, of having been attacked by the Celery-leaf maggot; otherwise it is good.—R. C.

Names of plants.—*R. H., Didcot.*—Hieracium aurantiacum.——*A. Kingsmill.*—Calendula maritima.——*G. Close*, —1, Reidia glaucescens; 2, Adiantum Capillus-veneris; 3, Asplenium Fabianum; 4, Sclaginella uncinata; 5, Rhus Cotinus.——*W. E.*—Two Asters without numbers: small flower, A. dumosus; blue, A. Amellus.——*J. L. B.*—Salvia Pitcheri.——*James Graham.*—Orchid flowers correctly named.——*G. G.*—1, Spiræa callo a alba; 2, Pyrethrum Parthenium; 3, apparently Silphium laciniatum—cannot be certain without seeing bottom leaves; 4, Anthemis tinctoria; 5, Helianthus divaricatus; 6, Pyrethrum uliginosum.——*C. R. S.*—1, Cryptomeria elegans; 2, Taxodium sempervirens; 3, Juniperus—specimen insufficient; 4, Cupressus Lawsoniana.——*S. Knowles.*—Lælia Perrini.——*H. M. W., Rosrea.*—1, Phymatodes peltidea; 2, Adiantum affine; 3, Adiantum formosum; 4, Doodia caudata.——*L. H. L.*—Cyrtomium caryotidium.

Naming fruit.—*Readers who desire our help in naming fruit will kindly bear in mind that several specimens of different stages of colour and size of the same kind greatly assist in its determination. Local varieties should be named by local growers, and are often only known to them. We can only undertake to name four varieties at a time, and these only when the above condition is observed. Unpaid parcels not received.*

Names of fruits.—*R. T., Stroud.*—1, Duchesse d'Angouleme; 2, Beurre Bachelier; 3, Golden Noble; 4, Cellini.——*H. E.*—1, Dumelow's Seedling; 2, Pearson's Plate; 3, Constauzer.——*R. A.*—1, Hanwell Souring; 2, Dumelow's Seedling; 3, Marie Louise.——*S. D. K.*—Apple, Blenheim Orange; Pear, Alexandre Lambre.——*T. B. F.*—1, Marie Louise; 2, Broom Park; 3, Swan's Egg.——*C. H. S.*—13, Oslin; others not known.——*D. Bouse.*—1, Beurre Diel; 2, Vicar of Winkfield; 3, Fearn's Pippin.——*E. K. Bridge.*—1, Lane's Prince Albert; 2, not recognised.——*H. K. de W.*—1, Cox's Orange Pippin.——*R. W.*—1, Calebasse Bosc; 2, Brown Beurre; 3, Beurre Rance; 4, not known.——*W. Burn.*—1, Ribston Pippin; 2, 3, Blenheim Orange; 4, Lemon Pippin.——*Caboon.*—Scarlet Russet; now is the time to gather these.——*H. E. Jacobs.*—1, Beurre Clairgeau; 2, B. de Capiaumont; 3, B. Hardy.——*A. R. T.*—Cox's Orange Pippin.——*P. J. F.*—1, Beurre Clairgeau; 4, Bergamotte d'Esperen; 6, Pitmaston Duchess; 16, Fondante d'Automne; 19, Van Mons Leon Leclerc. Others next week.

WOODS & FORESTS.

THE REVIVAL OF FORESTRY.

I am strongly of opinion that the want of interest in forestry in this country in times past has been largely due to the lack of periodical literature on the subject. I think also that I am correct in my surmise, that since *Woods and Forests* became identified with The Garden, there has been a revival of interest in the subject among not a few proprietors of woods and their subordinates, and a looking-up generally in matters of management, disposal of timber, &c., where the woods were almost neglected before. I hear of instances in which a very active interest is being taken in the woods by those most concerned, and of enquiries on the subject of planting and the like that bodes well for future management. In some cases the result of investigation into the subject has led to the stopping of all work in the woods, except felling timber for sale and planting on a moderate scale—proprietors deciding that if they did not earn anything from their woods they would at least not lose by them till things mended, and no one can blame them for that decision. I have very good reason for saying, and I say it deliberately, that many woods, if not the majority, on large estates have for many years back been either a dead loss to the proprietor or have done little more than pay expenses. I could name some of the most extensive estates in England and Scotland of which this is said to be true; and it is a lamentable fact if it is so. The only woods that pay are small plantations belonging to small proprietors who have planted in times past waste spots and done nothing to the trees whatever till they were ready for felling. What a pity Sir John Lubbock's committee did not elicit information on this point; the revelation would have been startling. On one great estate in the north, at the death of the proprietor some time ago, when the legacy duty came to be paid, one of the first things done was to stop all work in the woods and plantations except such as was urgent, and for what reason does the reader think?—to save expense—the cost of the "able management," combined with the preservation of game, having resulted in times past in dead loss year after year. I doubt if you could find many examples of management that could bear being tested by a debtor and creditor's account. You may be told of instances of successful planting, &c., and that So-and-so has planted most extensively, and that his forester is an authority on everything connected with the subject, but you never by any chance hear how the ledger stands one year with another. In short, I doubt if many woods on gentlemen's estates do much more than pay expenses, except where left alone without any superintendence in the usual sense of the word. This is a strange thing on estates where the woods extend to thousands of acres perhaps, and where planting, &c., has been going on for generations, but I fear it is true.

If the subject of wood management, however, comes to be constantly and energetically discussed in periodicals like The Garden, an interest is sure to be created, sooner or later, in the subject among foresters and their employers, and the result, we may be sure, will be beneficial to all concerned. It is disappointing at present that there should be so few writers on forestry in those papers which are open to them, and that of those few some of the most pretentious have so little information to give us. In some quarters there appears to have been a rattling of dry bones in an attempt to keep abreast of current topics, but it seems clear we must look to other sources for inspiration than the present generation of woodmen, who, notwithstanding their number, appear neither to read nor write on anything connected with their business.

One sees so much work to be done in our woods wherever they go, and so much that represents real value and money's worth going to waste for want of judicious management and advice, and so much real loss generally, that such topics as the above force themselves upon the attention. One thing especially strikes all thoughtful persons, and that is the immense quantity of timber dying and going to waste on so many large estates through the inexcusable reluctance of the proprietor to have it cut down and sold to the advantage of himself and the public. No wonder we have discontented socialists, and the like, amongst us, when the sight of parks filled with thousands of dead or dying timber trees that should long ago have been disposed, like any other crop grown for use, meets them in so many places in the country—left to gratify a whim, probably, of some wealthy proprietor who could afford it. It is really amusing to read some of those exacting covenants drawn out for farm tenants, regulating the conditions of tenancy and the cropping of the land on estates, where by the far the worst offender is the landlord himself or his agent, whose mismanagement of the woods and the home farm is perhaps the worst in the whole district. Still I would exculpate proprietors in a larger degree than their agents and foresters, unless it be in the matter of game, and even in that matter they are becoming open to conviction. My experience is that proprietors are quite alive to their own interests in such matters when they are explained to them, and laid before them in a plain and intelligent manner, for they do not, as a rule, profess to be practically acquainted with the routine of estate work of any kind, hence the employment of agents on whom they rely, and who should be able to give them good counsel when required.

Y.

THE MANAGEMENT OF WOODS.

Mr. D. J. Yeo's letter on this subject last week is remarkable in its way. If he is a forester and really believes what he writes, viz., that an estate carpenter, because of his "accidental" association with the woods, may as readily become a forester as a gardener, then all I can say is that he must himself be ignorant of what a gardener's duties are, and must believe little or no education necessary for a forester, except it be to handle an axe and sell the timber. "There is no reason why a carpenter may not as readily and successfully undertake the management of woods as a gardener," says Mr. Yeo. What a confession to make from the forester's side. What insight it reveals of the duties of the gardener and woodman. I advocate the gardener's claim on the score that at the present time he is practically and theoretically acquainted with the forester's duties, and a great deal more that never comes within the ken of the forester. This knowledge of the gardener relates to botany, vegetable physiology, plant and tree culture, and everything bearing upon it connected with the soil, air, and moisture. These are the acquirements that fit him for the care of plantations, and, according to Mr. Yeo, such knowledge is synonymous with ability to use a hammer, a saw, a chisel, and a foot-rule—that is to say, the two sets of attainments are equivalent to each other for the same purpose. This is the inevitable conclusion to be drawn from Mr. Yeo's argument, that the carpenter is equally fitted with the gardener for the forester's duties. What a low estimate he must have of the latter. On the same line of argument a tailor or a shoemaker would be equally well qualified to fill the forester's place. But it is not so. With everything relating to propagation, planting, pruning, thinning, and the general culture of plants and trees the gardener is, or ought to be, familiar, and the periodicals and books practically created and written by him alone are a mine of wealth on almost everything relating to forestry and gardening, but in the pages of which the forester is conspicuous by his absence. When he does write he has to avail himself of the pages of a horticultural paper. Mr. Yeo is mistaken, too, in supposing that the positions of gardener and forester are "interchangeable." I never meant this. The forester cannot be a gardener, nor have I ever heard of his assuming the position. The average gardener differs from the woodman, inasmuch as he possesses a far more extensive experience of plants and trees and their culture than the forester does, whose duties are few and simple compared to the multitude that engage the gardener's attention. Some of the best and greatest authorities on forestry have been gardeners, like Loudon and Speechly, for example. Even Robert Brown, forester and author, admits in his book that a forester should have an education like a gardener to properly qualify him for his duties.—Yorkshireman.

—— "Y." fails to show in his writings why or on what grounds a gardener should supplant the forester, and he contents himself by denying that a forester needs any of the "ologies." I differ from his opinions, and I further say that a knowledge of all the "ologies" which I mentioned in my previous article are necessary to make a man a skilled forester. He endeavours to show that woodmen are ignorant persons, while gardeners are a cultivated race. It is true that now and then one may meet with an educated gardener. I know that the majority of gardeners about here possess but little of the scientific knowledge required by a forester. I am led to think that it would benefit a forester if he were to apply his study to land surveying, estate carpentering, selling, barking and timber conversion, than to Cucumber forcing, Potato or flower growing. "Y." admits that all woodmen are not experts in valuing timber; but of course a woodman is not a forester. But if such be the case, how are gardeners going to value and measure timber so easily as he would have us believe? Then, again, where are the handy labourers to manage the sawmill coming from? Many a handy labourer, and good labourers too, have I seen with ribs broken, arms, hands and thumbs and fingers off through attempting to work the circular saw. "Yorkshireman" had better visit the sawmills of his neighbourhood and inquire of the men their ideas of sawmill management before writing again. A forester is what I always put down to be a person to superintend general estate management—well, we may say an under or outdoor agent—men that can direct others rightly when they are doing a job wrongly. To get such foresters, we must have men that have passed through the plantation sawmills and estate offices. Until then our woods and timber will never be managed rightly.—Omega.

TREE GUARDS.

In forestry few things, it must be admitted, are so unsightly or have a more neglected appearance than trees and shrubs cut and barked by ground game and farm stock, and as various devices for preventing this evil have been suggested, I have thought that a line or two regarding our methods of procedure at Penrhyn may be useful and not at all ill-timed.

At the outset it is, however, well to bear in mind that fencing as a protection against ground game—hares and rabbits—is totally different to what is found necessary to prevent the incursions of farm stock generally—cattle, horses, and sheep; deer if you like—for what is found suitable in grazing ground is equally applicable, or at least with slight differences, for the deer park.

First, then, let us give an explanation of the various methods employed to counteract the mischievous and hurtful injuries caused by horses, cattle, and sheep—goats might likewise be added—to specimen trees and shrubs in the parks and grounds of an estate. As a neat and efficient tree-guard perhaps nothing equals the iron hurdles now made for the purpose; but as these are at first somewhat expensive and cannot, from a rustic point of view, compare with such as are neatly made from timber grown on the estate, we will confine our remarks wholly to the latter class. Another argument in favour of wooden erections might likewise be adduced, viz., that as timber of the class required for such work is at present almost unsaleable, what better purpose, might we ask, can it be put to than in the erection and repairs of its owner's fences instead of, as is unfortunately too often the case, allowing it to lie and rot on the ground while expensive iron and wire are substituted? As a guard for all large trees with unbranched boles we know nothing better and, when neatly put up, more ornamental than upright poles placed in a circle around the stem and joined near the top and bottom with hoops or wire.

Cut the poles—ordinary fencing poles, preferably Larch—about 9 feet or 10 feet in length, and not less than 2 inches diameter at the top end; lay them on the ground, butt ends equal and side by side, at 3 inches apart, until sufficient is arranged to equal the stem's girth. Next nail an iron or wooden hoop—extra strong wire we often use—to the poles, at about 2 feet from the top ends, and a similar one along within 1 foot of the lower or thick end. Now lift the whole guard intact, bend it around the tree's stem, fasten the ends of the hoops or wires, and the task is completed. It should be made to fit on easily, so as to give room for trunk expansion; but this, too, is immaterial, as the ends of the wires or hoops can be added to, and a pole inserted when the guard is getting too tight.

Another method of erecting the same protection is by having four of the poles made longer than the others, inserted 6 inches to 1 foot in the ground, and attached to the hoops. The remaining poles can easily be put in, and nailed one by one to the hoops until the whole is completed. I forgot to mention in the proper place that the top ends of the poles should be finely pointed, which not only prevents penetration of damp, but gives a more finished appearance to the guard, and likewise, to a great extent, keeps the horses from rubbing on and damaging the top portion of the erection. The guard should never be less than about 9 feet in height, as horses can easily reach to the trunk and injure the branches and bark if lower. This is a very effective and easily mended erection, and when tarred over is anything but unsightly, even in the more public portions of the grounds, and as neither horses, cattle, deer, sheep, nor goats can get near to injure the bark, it is well suited for use in the park, lawn, or on the farm. For single specimen trees that are branched to the ground, circular wooden fences, run just outside the spread of foliage, are best. These need not exceed 5 feet or 6 feet in height, and are constructed as follows: Dig pits 2 feet in depth and 6 feet apart in a circle around the widest spread of branches. Into these insert Larch posts 7 feet long and not less than 3 inches diameter at the small end; be sure they are put in perpendicular, and ram the soil previously taken out firmly around each. Paling rails 3 inches wide and 1 inch thick may then be nailed from post to post and at 15 inches apart, the intervening space between every pair of rails being taken up by a single wire placed exactly in the centre of the space and stapled firmly to the posts. This latter, which has a lighter appearance than if wood were altogether used, prevents the animals that may graze around the tree from inserting their heads between the rails and browsing on or injuring in any way the extending branches. The tops of the posts should next be rounded off, the whole fence tarred or painted over, and, should it be deemed advisable to protect the tree from ground game, a piece of 24-inch-high wire netting, rabbit-proof, nailed around the fence, 2 inches of it being inserted in the ground as a preventive against the burrowing of rabbits. A fence of this kind, if properly erected and made of well-matured, well-seasoned timber, will give no trouble for the first ten years, and even after that time, when repairs do become necessary, a post or rail is easily substituted for damaged ones at any time. A coat of tar given annually will considerably lengthen the lasting properties of the fence, as well as add to its appearance.

A much neater, but more expensive, fence than that just described is made as follows: Dig the pits and place the posts as directed for the last, nail two bars horizontally at 2 feet from top and 2 feet from bottom along from post to post. They should be morticed into the posts and the ends of every pair neatly joined for equality of surface in nailing on the uprights. These uprights are made of from 5 feet to 6 feet in length, 2½ inches or 3 inches wide, and 1 inch thick, and nailed at 2 inches apart on the horizontal bars, the top of each being neatly and sharply pointed. From the number of uprights required to erect a fence or guard of this kind, and as they must be run through the saw-mill to insure uniformity of size, it comes to be rather expensive, but this is to a great extent minimised by the stability and neatness which characterise such an erection. On an estate in Ireland I was much pleased with the guards of this kind that had been erected around the rarer Conifers in the park; and what I thought considerably heightened the effect and added much to the convenience of entering, as well as for cleaning, pruning, and repairs, was that a little gate of similar construction to the fence was added to each.

Where trees, hardwoods in particular, are simply to be protected from farm stock rubbing against their stems, the erection commonly in use is a single rail placed on and nailed securely to the posts that have been driven into the ground in a circle around the stem, but with the heads projecting outwards at an angle of, say 45° degrees. The posts should not be placed nearer the stem than 3 feet, and held in a slanting direction while being driven, a stout rail nailed from one to the other and on top of the posts completing the structure. We have found this method valuable, easily and cheaply erected, and not at all liable to get out of order. Of course, sheep will not be kept out from trees around which this is placed, but that is of little importance, for unless to young and tender-barked specimens their injuries are not of a deadly nature. A three-fold purpose is aimed at by such an erection—first, it withstands rubbing against better than posts that are driven in a perpendicular manner; second, less of the ground around the tree is taken up, although a like purpose is performed as regards keeping the stock at bay; and third, the expenses of wood and erecting are small indeed.

Wire netting placed around the stems of trees we have likewise found valuable for preventing horses barking and gnawing at them, but I am sorry to say that after a half-dozen years' trial we are not continuing the method, which of itself certainly speaks bad for the adoption of the practice generally, in this district at least. The second class of guards which are employed for protecting young trees principally from the attacks of ground game—hares and rabbits—we will now consider, but only such will be described as we have found really well suited for the end in view.

For small standard specimens having unbranched stems, nothing, in my opinion, equals, whether for appearance sake, efficacy, cheapness, or ease of application, guards made of bark. These we have used for a number of years, and, I may add, with the most satisfactory results, most of those made ten years ago being almost as good as when put up, and looking at present as if they would faithfully serve the intended purpose for years to come. The bark used is either Larch or Oak, but I have no doubt other kinds, such as that from the Spanish Chestnut or Elm, would do well; and I have also learnt on good authority that the bark usually sold for decorating ferneries, &c., is perhaps best of all. Cost will, no doubt, debar the latter from being used commonly, and rightly, too, for if that from home-grown trees, and which can be obtained for the stripping, lasts for half a score of years, it may be considered waste on the forester's part to cast this aside for the ready-made and costly foreign article. The bark should be put aside for the above purpose when Oak and Larch stripping is going on in the season, the straightest, cleanest, and that of medium thickness being preferred.

In applying the bark, simply bend it around the stem requiring protection, overlap the edges for half a foot or so, and fasten with wires at distances of 2 feet apart. Usually the bark laid aside for this purpose is taken off in 3-feet long strips, so that one length is perfectly sufficient for a single tree. The advantages of overlapping the edges are, that room is given for expansion of the stem, and additional bark will not need to be applied to make up this deficiency.

Ordinary galvanised tying wire we use for fastening on the bark, which is run right round the stem on the top of the bark and securely and tightly fastened wherever the ends meet.

For newly planted trees of small size, and such as are branched to or near the ground, either of the following guards will be found to answer well, and, being cheap and easily erected, should be largely employed on every estate where game abounds. Palings 3 feet long, 2 inches wide, and half an inch thick are cut at the sawmill—the remains of Spruce Fir or any other timber that has been converted for estate purposes will answer the purpose admirably—the ends pointed, and driven into the ground all around the young tree with the tops inclined outwards. Small-sized fencing wire is then interlaced between the palings at about 9 inches from top and bottom, this serving not only to strengthen the erection, but unite it together. A fence of this kind, including labour, costs but little over 6d, gives no trouble for many a day, and not only guards the young tree from the depredations of ground game, but in exposed situations is of immense value in the way of shelter. Frequently, when sawn wood runs short, we use small Larch poles of perhaps 2 inches or 3 inches diameter for the same purpose, and erect in a similar manner to that above described.

Another guard, cheaper than the latter, and of easy and almost similar construction, is made as follows: Drive 3-feet-long Larch posts of 3 inches diameter into the ground in a circle around the tree and just outside the range of branches. They need not be closer than 6 inches from one another, and inserted in an outward, slanting direction; warp Birch branches or Heather out and in between the posts from bottom to top, and an effective and durable fence, and one that costs but a trifle, is thus speedily erected. Numerous other guards made of rabbit-proof netting might also be described, and will, perhaps, be referred to in a future paper.

A. D. Webster.

Penrhyn Castle, North Wales.

TIMBER IN MONMOUTHSHIRE.

It may be interesting to some of the readers of *Woods and Forests* to know the present state of the timber trade with us here in Wales. The demand for Oak timber has fallen away considerably, chiefly owing to the railway wagon building being very slow just now, and, on the other hand, the Americans in many cases deliver Oak scantlings cheaper than we can.

I should advise landowners to be very careful in selecting their timber for felling, as there is little or no call at all for small Oak. Oak to sell now about here must be straight, clean, and of a girth of 12 inches and upwards. Even with Oak timber of large and clean dimensions prices have fallen very low. The Elm timber is at present about the same. Elm of good dimensions is in more favourable demand than for some time past. Poplar is somewhat the same as of late in price, but the demand for it seems to be increasing. Beech seems to be on the wane in price; we have bought and sold Beech much cheaper this year than last. The demand for it is lessening and prices lowering. Good Ash timber holds its position as well, and still continues to realise a good price per foot when of clean dimensions. For rough Ash, only fit for rough purposes, there is little or no price, as it is a difficult thing to dispose of. Ash at present must be clean and good; then it will fetch a very good price. Cherry, Alder, &c., stands with Beech. Pitwood and logs are very low here, and where a long carriage is on it, it is not worth cutting. French pitwood is filling our ports, and is bought up before our English pitwood. Coppice is not worth felling without it is of clean Ash, &c., fit for hurdle and fence making. I trust that our markets will again look up, so as to give landowners some encouragement to go on with planting and cultivating our woods in a proper manner. The timber sent into this country now by America is far ahead of home-grown timber for clean dimensions, and I consider it a question whether the merchants of this country will be able to compete with the Americans. If they are to do so, no time must be lost in planting, as there are very few lots of first-class hard-wood trees to be found in this country. The Oaks of 40 feet and 50 feet in height with proportionate girth which we once had in this country are seemingly all cut down, or, if not cut down, they are preserved for ornament. I measure daily large lots of Oak in Wales and the bordering counties, and I find but very few first-class trees, and the same will apply to Elm and Ash.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

BUSH FRUITS.

THE heavy demands made on all small fruits this scarce Apple season will doubtless have a tendency to direct increased attention to their culture. A dish of well-flavoured Gooseberries generally finds as many admirers as a dish of Grapes, or one of any other kind of fruit. Gooseberries should, therefore, be well treated. One thing is absolutely essential in light soils, and that is never to allow spade or fork to be worked amongst them after they are once planted; each quarter should receive instead a good heavy mulching of half-rotten manure as soon as fruiting is over, and this should remain until it is time to renew it another season. Our Gooseberry plantations are in three separate positions, viz., on wires in a warm sheltered spot, from which the bulk of our dessert fruit comes; Warringtons under a north wall for furnishing a late supply; and a main plantation of large bushes to produce fruit for picking green and for preserving. The trellis devoted to the dessert-fruiting series is some 4 feet 6 inches high, and consists of four stout galvanised wires, held firmly in their places by standards at either end, and running through (at intervals of 8 feet) uprights of flat thin iron. Each tree is furnished with about half-a-dozen branches, trained vertically, and these are invariably covered with fine fruits; indeed, as a rule, they literally hang like ropes of Onions. Some little discretion is required during the first year or two as regards the management of the different varieties, such as removing the fruit from the weaker growers in order that all may reach the top about the same time; but this end once attained, they give hardly any trouble except the removal of superfluous shoots in summer and an examination of the ties in spring. Where quantity from individual bushes is required, this mode of culture will not find favour, but where dessert Gooseberries in variety are needed it can be heartily recommended.

Late varieties (chiefly Warringtons) under a north wall furnish dishes after the greater part of the fruits on the trellis has been gathered, and thus prolongs its season. The main plantation for culinary purposes receives exactly the same attention in the way of planting, mulching, &c., as the quarters that furnish the dessert fruit, but the pruning is on quite a different scale; indeed, these last and the trellis bushes are examples of extremes in the way of extension training and restriction. We plant the bushes 6 feet apart each way, and allow 1 foot of room all round so that the heads are 5 feet through. We are not much troubled with bullfinches, which, I think, are kept in check by giving a good syringing with soapy water before lime is sprinkled on the bushes after pruning. The lime in this case adheres to the branches and buds until it is pushed off by spring growth.

With respect to varieties in Gooseberries, the following can be recommended for light soils, although, like all other fruits, they may doubtless vary considerably in different situations: For purely dessert purposes, irrespective of size, Green Walnut, Ironmonger, Keen's Seedling, Leader, Red Champagne, Rumbullion, Whitesmith, and Yellow Sulphur may be selected; for size, Freedom, Green London, Thumper, Leveller, Railway, Speedwell, and Dan's Mistake are good. These, however, are now comparatively old varieties, and may have been superseded. I may add, for the benefit of those who care to go in for trellis culture, that all varieties seem to answer well under this treatment. Weak growers, however, must not be cropped too heavily until they have become established.

As to Raspberries, where the soil is naturally light, it is as well to select the coolest part of the garden, and to substitute cow for stable manure at the first planting. If this is done, and attention given afterwards to annually mulching and keeping the surface firm, this delicious fruit gives very little trouble, except the yearly tying to stakes or trellises, as the case may be. I decidedly prefer the latter on the same scale as recommended for the Gooseberry. Old canes and all new wood not required for another season should be removed directly the fruit is gathered. Such treatment has the effect of ripening up the fruiting canes early, and is in every way better for the plantation. Carter's Prolific, Fastolf, and Fillbasket are the varieties which we grow.

Exactly the same system of culture as given for the Gooseberry is practised in the case of Red and White Currants, with the exception that in their case walls are utilised instead of trellises; and the Cherry Currant, Raby Castle and Warner's Grape are used respectively on south-east and north-west walls. To extend the season of fruits for tarts, the White and Red Dutch, together with Raby Castle, are grown as bushes. Black Currant culture may be briefly summed up in the advice to plant wide, *i.e.*, 6 feet or 7 feet apart each way. We thin fairly hard and early when the trees are established, and mulch at the fall of the leaf on a firm surface. It must be remembered that in the case of this fruit, as also in that of others, we are located on a very light soil. The planting in the first instance should always be thoroughly well done; a trench should be taken out the entire length of the row, and of sufficient width to give freedom to the roots without crowding; a layer of well-rotted manure should be placed in the bottom, and this should be lightly worked into the soil. A little of the same manure should be shaken over the roots before the soil is filled in, and the earth should be firmly settled and a mulching given. In the case of the Raspberry, and indeed, wherever the soil is naturally lighter than is thought to be conducive to the well-being of the fruits in question, cow-manure mixed with road-scrapings in the proportion of two to one, should be substituted for stable manure. In the event of very hot weather it is advisable, where the foliage is scant (as with trellis Gooseberries and Currants on south-east or south walls it generally is), to give a soaking of liquid manure and a little extra mulching just as the fruit is beginning to change colour. E. B.

Zonal Pelargoniums.—In the garden at Bridge House, Tooting, the residence of Mr. Bonner, it would appear to be a maxim that a few different kinds of plants should be cultivated, and that they should be grown as well as it is possible to grow them. One of the chief attractions here at present is the display of Pelargoniums, which give life and colour to the plant houses. The growth of the plants amply proves that the treatment to which they have been subjected has been congenial to them, and the selection indicates the advantage to be derived from not taking any kind for winter blooming that may happen to turn up. There are many varieties excellent as summer bloomers that cannot be induced to make themselves useful in winter. Amongst the sorts grown here we singled out the following as being the most showy and desirable, viz.: Queen Matilda—a charming variety of dwarf habit and a very free bloomer; trusses large; pips excellent in form, soft pink, the base of the upper petals being white; Queen of the Belgians—trusses and individual flowers large and pure white; a free bloomer, and excellent all the year round in any position; Lucretia—a profuse bloomer; pips medium sized, white, with just a faint tinge of rosy pink round the eye; John Gibbons—brilliant scarlet, and good all the year round; Surprise—a gem for winter blooming; flowers, although not large, numerous, and white mottled with salmon-pink, and very attractive; it is sometimes called Salmon Vesuvius; Queen Anne—another dwarf variety with very dark zone on the leaf; flowers large and rich salmon; Fanny Catlin—flowers mottled salmon, white eye; another salmon flower, but of a different shade and very handsome is Mrs. J. Gibson; Ferdinand de Lesseps is an old favourite; flowers large and brilliant scarlet with a distinct white eye; Henri Jacoby—one of the deepest crimsons in cultivation, useful also as a summer bedder; Mrs. Sturt—purplish pink; Sophie Birkin—mottled salmon; Queen Elizabeth—deep rose with a white eye; Circulator—cerise; Queen Adelaide, mottled salmon bordered with white.

NOTES OF THE WEEK.

Gladioli from Scotland.—On the 1st of November, Mr. Matthew Smith cut some spikes of Gladioli in his garden at Roselea, Prestwick, and sent them to us—magnificent spikes, quite as large as any exhibited in August, and equally brilliant in colour—a fact which shows that the Gladiolus can be grown to perfection in the north, and that its flowering season extends over a much longer period than in the south. Northern growers, however, are not able to get bloom so early in the season as we do in the south. The spikes from Mr. Smith arrived perfectly uninjured, even after such a long journey. They were ingeniously packed in specially made Gladiolus cases. These have a light wooden framework, the four sides of which consist of canvas, thus affording ample ventilation. The spikes thus enclosed are tied firmly to upright sticks, secured at the bottom of the case and also at the top. So treated they are immovable.

Clerodendron fœtidum.—For several weeks past this handsome shrub has been in flower against a wall in Kew Gardens, where it is seemingly quite hardy. It grows from 3 feet to 5 feet high, has broad noble-looking foliage of a peculiarly deep green, a colour which contrasts strikingly with the reddish brown shoots and deep rosy red blossoms. These are borne in dense clusters, terminating all the shoots, and often measure 6 inches across. In gardens along the south coast this plant is perfectly hardy, even if not planted against a wall. In Mr. Kennard's garden at Shopwyke, near Chichester, we lately saw a grand specimen of it carrying numerous heads of bloom.

November flowers.—From Mr. Loder's garden, at Floore, Weedon, I send you a few Dahlias, Tobacco, Heliotrope, Ageratum, &c.—a very unusual presentation at this season of the year. I also send you a bunch of Begonias, cut in the open, from plants raised from seeds sown in January. For the last month they have been as good as at any time during the season. Castor-oil plants are also as vigorous now as they were in August, and should the weather continue mild for a few days more, Cistuses will be in full bloom. We have now out of doors considerably over 200 varieties of plants in bloom.—GEORGE GOLDSMITH.

*** A beautiful and interesting collection of open-air flowers, all excellent for the season. The Begonias particularly fine.—ED.

Hybrid Nerines.—I send you three seedling Nerines, hybrids of 1885, viz., N. flexuosa × corusca major (Henderson), flexuosa × Fothergilli, and flexuosa × pulchella. They all throw up their foliage before they do their flower; that of flexuosa × corusca major is glaucous and 1½ inches broad; that of flexuosa × pulchella partakes more after that of flexuosa. The plant of flexuosa I possess I obtained from Henderson. I send you a blossom of it. My corusca major I also received from him. I observe in THE GARDEN of last week that you have received a flower of corusca major from Mr. Peters, of Guernsey, so that you will be able to judge the effects of

the application of pollen of it on flexuosa. I also send you flowers of two hybrids I sent you on a former occasion. They are hybrids of flexuosa × undulata and undulata × flexuosa. There is not much difference between them. I call one of them erubescens and the other roseo-crispa. One point I have aimed at in my hybridisation is to produce plants which are evergreen and which send up their leaves before their flowers.—THOMAS CAM.

*** An interesting and beautiful series of Nerines was sent with this note, some of which are very lovely, the best being those which have resulted from crossing the brilliantly-coloured N. cernsca major and Fothergilli with flexuosa and crispa. These have flowers almost as large as those of Fothergilli with the wavy-edged sepals of flexuosa and crispa, and of a bright carmine-cerise colour. That named erubescens has pale pink flowers with wavy sepals. These three new hybrids are decidedly worthy of distinctive names, though we think that, instead of Latin names, they should receive simple English names; otherwise confusion will arise, as in the case of Narcissi and other bulbs of which there are numerous hybrids.—ED.

Eucomis regia.—Accompanying the gathering of Gladioli from Mr. Smith came a very fine spike of this little-known Cape bulbous plant. It is not very showy, but interesting and attractive, owing to its being very unlike most other plants. The spike sent measured just upon 18 inches in length, and consisted of crowds of flowers, each about the size of a shilling, and greenish in colour with a purple centre. The leaves are a yard long, 3 inches or 4 inches broad, and wavy on the edge. Altogether, it is a noble plant, and one that many would like to grow were it more easily obtainable. There are a few other species grown in botanic gardens, among them being E. punctata, E. undulata, and E. nana, but E. regia is the finest of all.

Cestrum aurantiacum.—I have grown this beautiful Mexican shrub out of doors all this summer, and it is still beautifully in bloom, the brightness of its long spikes of orange-yellow flowers being most striking. I believe that this plant is as hardy as any of the kinds of Habrothamnus which thrive so well in the open air in summer in our climate. I presume it is a scarce plant, as I have not heard of it nor seen much of it.—W. E. R., *Paignton, Devon.*

*** It is by no means common. It used to grow and flower beautifully in the conservatory at Chiswick before it was converted into a vinery.—ED.

A November gathering.—This morning (November 1) I gathered from the open borders in my garden good flowers of the following plants, which is, I think, somewhat remarkable for a garden so near London. The plants now in flower are—

Abutilons, red and white	Mignonette
Ageratums	Pansies
Anemones	Petunias
Antirrhinums	Phloxes
Campanulas	Portulacas
Calceolarias	Pyrethrums
Chrysanthemums	Roses, Provence and Souvenir de la Malmaison
Dianthuses	Scabious
Dahlias, single and double	Stocks, single and double
Fuchsias	Salvia patens
Gazanias	Salpiglossis
Heliotropes	Sunflowers, two varieties
Helianthuses	Tropæolums
Helichrysums	Verbenas
Hollyhocks	Veronicas
Jasmines	Xeranthemums
Lilium auratum	Zinnias
Lobelias	Zonal Pelargoniums, twelve varieties
Marguerites, white and yellow	
Marigolds, African and French	

—J. DREDGE, *Clapham Lodge, S.W.*

Bouvardias.—I saw the other day in Messrs. Veitch's nurseries, at Chelsea, a new double Bouvardia, named Triomphe de Nancy, having pale bright red flowers of the colour of those of B. elegans and the foliage of B. Vreelandi. It is an excellent companion to President Garfield and Alfred Neuner. Elegans is a capital red variety—one of the best among the single forms; and Vreelandi is very free, and produces fine trusses. Maiden's Blush is very pretty indeed, and should find a place in every collection, and so should jasminiflora; one of the very best, and a gem in a collection is Priory Beauty, pale pink, very pretty indeed and exceedingly free; it beats longiflora flamnea. Hogarth is still very fine, and will hold its own for some time to come. There is just now a house of Bouvardias at Chelsea, and opportunity is afforded to anyone interested in these plants to form a collection. Those I have mentioned are well worthy of cultivation.—R. D.

Three good basket Ferns.—A beautiful trio of Adiantums for basket purposes are A. Edgeworthi, A. caudatum, and A. dolabriforme. The two first have simply pinnate fronds, the upper edges of the pinnæ being more or less deeply divided; the last named very much resembles A. lunulatum both in shape and habit; but A. lunulatum is a deciduous species, and always loses its fronds in winter, whilst the fronds of A. dolabriforme are persistent, and the semi-lunate pinnæ retain their vivid green throughout the year. These Ferns all produce young plants at the points of their fronds, a circumstance which gives them additional interest. We saw them all three in baskets, the other day, at Mr. Henderson's nursery, Maida Vale.

INDOOR GARDEN.

EUCHARIS AMAZONICA.

THE accompanying illustration of an exceptionally fine specimen of the well-known large white Eucharis (the correct name of which is E. grandiflora) is from a photograph, for which we are indebted to Mr. Boulton's gardener at Eastbourne. Mr. Jupp, who grew this specimen, informs us that it produced thirty-five spikes of bloom, each spike having from six to eight flowers, or buds, all at the same time. It was planted in a pot 20 inches in diameter, and has exactly doubled in size in five years. Mr. Jupp says he has never been troubled with the Eucharis mite, and we believe him, so far as this plant is concerned, for it is the largest and best flowered we ever heard of. Some correspondence took place in THE GARDEN a year or two ago relative to the number of times this Eucharis would flower in the same year; it is therefore interesting to hear that Mr. Jupp expects to have this same specimen in bloom again this Christmas, notwithstanding the heavy crop of flowers it bore in September last, when the photograph was taken. Many of our readers will say that there must be something else to relate in connection with this plant and its vigorous health, besides the negative information that it has not been troubled with the Eucharis mite. What soil, temperature, position, amount of water, rest, and light had this fine example of cultivation to bring it to such perfection, for it is to these points we must look for the real cause of Mr. Jupp's success. This Eucharis, and in fact all indoor bulbous plants, are easy enough to keep in health and in flower annually, if only they are in an atmosphere they like, and watered with the kind of water that suits them. We have seen gardens where the Eucharis has grown "like a weed without any trouble," and others where it has been the bugbear of the gardener's life; "it won't do here, no matter how I treat it." Of course, the latter's plants may have the Eucharis mite, and he not know it, in which case careful and rich cultivation aggravates rather than alleviates the disease. There can be no doubt now that the little mite which is found on the roots and between the scales of the Eucharis and other bulbous plants, and which is cousin to and not unlike the cheese-mite, is a most destructive enemy to the Eucharis plant. We have seen it increase at a rapid rate and literally destroy a healthy plant of E. grandiflora (amazonica) in one season. At the time when the controversy raged as to whether this mite was the cause of the disease, or whether it only played the part of scavenger, eating up those parts of the plants which had been disorganised in some other way, we saw an experiment conducted as above, and in one summer a few mites, which had been placed about the roots of a healthy Eucharis, took possession of all the space between the bulb scales, causing the roots to curl and look as if they had been poisoned with some corrosive substance, and after a time prevented the leaves from growing out of the bulbs by attacking them when inside. There are still cultivators who believe that the Eucharis disease is the result of bad treatment in some form or other, and of course these plants are subject to various other ills besides that of falling a prey to the mite; but the cause of the collapse of this plant in many gardens, as, for instance, in the gardens at Trentham, was the appearance of the tiny destroyer, known to entomologists as Rhizoglyphus Robini, among the bulbs. On plants infested with this disease the leaves, especially the younger ones, have patches of curled rusted tissue in more or less abundance, and on the roots the same reddish disfigured parts are also apparent. The best and only cure for this pest is the fire; at all events, we have never heard of any insecticide that will eradicate the disease without injury to the patient, or even destroying it. Sulphur, carbolic acid, paraffin, and lots of other specifics have been recommended, but they do no good, and after expending a great deal of time in applying them, one finishes by having to throw the plants away. We had this disease not only amongst the Eucharis, but on Pancratiums, Phædranassas, and Crinums, but directly it revealed itself we examined each plant carefully and burned all that we found infested with the mite.

The secret of growing this plant apparently rests on the depth the bulbs are planted and the kind of soil used, at least as much as on any other factor. Here is what we find answers for E. grandiflora, which grows well, has abundance of foliage, and flowers twice or thrice a year: Soil, a good fibrous loam with about one-sixth rotted cow manure; pots, roomy; depth bulbs are planted, their necks about half way down the pot; watering, copious all the year round, rather less before the flowering season; temperature, that of a stove all the year round; light, shaded in summer from bright sunshine. If Mr. Jupp would kindly say in what points his treatment differs from ours, we should all of us then know wherein our comparative failures with this plant laid. W.

Amasonia punicea.—This is undoubtedly a very valuable mid-winter flowering plant, and it may be said to have two successive periods of service; one when the pendulous tubular creamy white flowers, produced in twos and threes, are developed, the other when they have faded; and the vermillion-crimson Poinsettia-like spreading bracts, which are arranged in pairs along the entire length of the racemes, increase in size, become more brilliant in colour, and remain so for a space of two months. It is so free, that quite small plants obtained from cuttings were flowering in 2½-inch pots. It bids fair to rival the Poinsettia as a winter decorative plant, and it can be treated just as this well-known plant is. It is easily propagated by means of cuttings, and it does well in a mixture of peat and loam. It yet remains to be seen whether it will prove an exhibition plant in spring or summer; if it will also flower at these times, it is likely to prove of great value. As a winter-flowering plant it is undoubtedly in the front rank.—R. D.

Begonia John Heal.—This is a valuable winter-flowering hybrid Begonia—valuable not only because it is so free, but because its blossoms are so persistent. A few days ago I saw a plant in one of the houses at the Royal Exotic Nurseries at Chelsea, and I was informed that the flowers had been open for a space of fifteen days. This is such an unusual experience in the case of Begonias of this type, that it is worthy of notice. Some very interesting crosses have been made between the above and a fine form of the tuberous-rooted type, and I anticipate the result will be in the shape of some startling developments.—R. D.

BROMELIACEOUS PLANTS.

The Bromeliads, as the various genera which constitute this Order are called, consist of a large family of highly ornamental plants; some of the species have brilliantly coloured flowers and flower-leaves or bracts; others are remarkable for the extreme beauty of their foliage-markings, whilst not a few possess both handsome leaves and showy flowers. Notwithstanding these recommendations, they have never received that amount of recognition from English plant growers which they deserve, and which they certainly obtain on the Continent. This neglect is doubtless due to the fact that no English amateur has become a specialist as regards bromeliaceous plants, as has been done in the case of other Orders, of which Orchids, Ferns, and Palms are familiar examples; and thus, despite their great beauty, the majority of Bromeliads have remained comparatively unknown to most plant growers in this country. By the death of Prof. Morren, Belgium lost its great authority on Bromeliads. Under his fostering care the rich and rare collections of them to be found in that country acquired unprecedented dimensions; and if some one in this country would take this class of plants in hand with the same loving care, and make them popular, their cultivation would soon be taken up by others. Bromeliads are, without exception, natives of America or the American Islands, but many have been introduced to the western parts of Africa and various places in the East Indies. They are all capable of existing in a hot, dry atmosphere, without contact with the earth, on which account they are favourites in South American gardens, where they are suspended in buildings or hung to the balustrades of balconies, situations in which they flower abundantly, filling the air with fragrance. The cultivation of Bromeliads is extremely simple, growing, as most of them do, in a state of nature upon the branches of forest trees or upon high rocks; the whole of the smaller kinds take kindly to block culture, and when firmly fastened to a block of wood by copper wire, with some Sphagnum Moss, they give little more trouble beyond watering and syringing. The stronger-growing sorts thrive best as pot plants, many of them being massive and heavy; they are not easily accommodated in any other way; for these the drainage must be open and free and the soil should consist of two parts peat to one of loam and one part sand. The majority of these plants have a vase-like habit of growth, and the sheathing and overlapping bases of their leaves enable them to retain water in their crowns, which is highly beneficial to them, and when water is given these plants it should be given in that way. Any water which trickles down from the leaves will usually supply the roots with sufficient moisture. Bromeliads cannot be said to be cool-house plants, most of them enjoying strong heat and full exposure to sun-light, but with due ventilation any house in which they are grown need never be oppressive to visitors. The flowers and coloured bracts of Bromeliads are usually vivid and very persistent, often lasting months in perfection, and goodly numbers are produced during the dull months of winter. The kinds here noticed are all worthy of a place in the most select collections, and, moreover, are all distinct from each other.

Æchmea.—This genus contains many plants of great beauty. In habit they are more or less vasiform, which may be taken as the style of growth belonging to the whole family. Æ. Mariæ-Reginæ is one of the boldest, and also, when in flower, one of the handsomest. The leaves are deep green on both surfaces, spiny at the edges. The scape is clothed for about two-thirds of its length with large, oblong, boat-shaped bracts, which are vivid rosy magenta in colour; these last for several months in perfection; the flowers are not showy. Æ. cælestis has long strap-shaped leaves, which are spiny at the edges and deep green on the upper side, but pale beneath and transversely banded with deep green; the scape bears a dense panicle of flowers, which are pale blue, ornamented at their bases with small bracts of rosy red. Æ. glomerata is a bold plant, with recurved deep green leaves, armed at the edges with large black spines, scape erect, panicle dense, bracts numerous and blood-red, flowers small, deep violet. Æ. fulgens has bold, arching, deep green leaves, and an erect panicle of coral-red flowers, tipped with blue and black, but destitute of bracts. Æ. paniculigera, a strong-growing kind, produces a scape from 2 feet to 3 feet high, purplish red in colour and clothed with a scurfy-down; the bracts are rose-coloured, and the panicle very large; the lower part of the flowers is bright rose, petals purple. Æ. Veitchi (sometimes called Chevalliera Veitchi) has deeply channelled leaves, upwards of 1 foot long, toothed at the edges, pale green and sparingly spotted on the upper side with dark green; scape erect; flowers crowded into a dense cone-like head; these are red at the base of the cone, but paler towards the top, and the small-toothed or spiny bracts which spring from the base of each flower are bright scarlet. In Æ. disticantha the leaves are long and narrow, furnished sparingly with spines on the edges; the panicle is ornamented with somewhat small, closely-set, bright red bracts; the base of the flowers is rosy crimson and the petals bright bluish purple. Æ. Melinoni has large panicles of scarlet flowers, tipped with rosy pink. Æ. bracteata is a fine, bold-growing plant, bearing a large panicle of small yellow flowers; the latter are accompanied by large brilliant red bracts.

Eucharis amazonica. Grown at Torfield, Eastbourne. Engraved from a photograph for The Garden.

Billbergias are for the most part strong and robust in growth. B. macrocalyx has broad, furrowed, dark green leaves, which are sparingly spotted on the upper side with pale green, and faintly banded beneath, with mealy stripes; spike unbranched, erect, base of flowers mealy; flowers bluish purple in the bud, changing to greenish blue when expanded; bracts large, boat-shaped, and deep rosy red. B. Baraquiniana is an erect plant, the leaves of which are recurved at the ends and edged with numerous reddish spines; they are pale green and ornamented with numerous mealy bands; the flowers are densely powdered with a white scurf at the base, recurved, and green, with long, exserted stamens, which are also green; at the base of the flowers are several large, deep rose-coloured bracts, which constitute the beauty of this plant. B. pallescens has erect leaves, nearly 2 feet long, deep green above, and ornamented with distant white spots; under sides paler, faintly banded, and edged with a few distant, small spiny teeth; spike towards the top drooping; flowers greenish, tipped with violet; the bracts, which are all below the flowers, are somewhat narrow and bright red. B. Moreliana has broad deep green leaves, transversely banded beneath with a grey scurfy powder; flowers violet, bracts large and rosy red. B. thyrsoidea has plain, green, spiny-edged leaves, whilst both flowers and bracts are rich bright crimson. B. Libioniana is a

slender growing plant, with finely-toothed leaves, about 1 foot in length and plain green in colour; spike erect, bearing towards the top numerous large flowers, which are bright red and bluish purple. B. rhodocyanea, a bold-growing, erect plant, has leaves formidably armed with large black spines; their upper surface is deep green, the reverse paler and transversed with grey bands; the flowers, which are borne upon erect spikes that rise level with, or just above, the leaves, are blue and white, each being furnished with a large, pointed, and spiny-edged rose-coloured bract. B. miniata rosea is a small plant with recurved leaves, spiny-toothed at the edges, and pale green, dusted with a scurfy powder; flowers numerous and deep rosy red; bracts large, slightly mealy, red tipped with blue. In B. longifolia we have a handsome species bearing large crimson bracts and numerous long tubular flowers, which are yellowish green and blue. Other good species belonging to this genus are B. marmorata, melanocantha, nutans, sphacelata, Wetherelli, Reginæ Ameliæ, and Leopoldi, &c.

Tillandsia.—This genus contains some handsome species, the smaller-growing kinds of which succeed best when grown upon blocks suspended from the roof. The leaves of some are marked in a remarkable manner. In T. mosaica their ground colour is deep green, cross-banded on the upper side with creamy white or pale green, and on the under side they are reddish brown and crimson; the flower-spike, which is erect, bears rosy bracts and yellow blossoms. T. argentea possesses quite a different style of beauty, the whole plant being clothed with short, silvery white hairs, which give it the appearance of being covered with hear-frost. T. pulchella, which is similar in size and habit, has pale green scurfy leaves; the flower-spike, which is erect, is clothed with large bright red bracts, from which protrude white flowers. T. dianthoidea has short, closely-set, dark green, pointed leaves covered with a scurfy farina; the spike, which is erect, is furnished with (for the size of the plant) large rosy pink bracts and deep violet flowers. T. recurvifolia is similar to the two previously named kinds, but is scarcely so large, and the scurfy leaves are recurved; the flower-spike, which rises just above the foliage, is furnished with numerous broad, boat-shaped, rose-coloured bracts, whilst the flowers themselves are pure white. T. Lindeni has light green leaves streaked on the under sides with reddish brown; the scape, which is erect, bears an ovate, flattened spike furnished with rosy carmine bracts arranged in a two-ranked manner; the flowers, which are large and beautiful, are azure-blue, shading to violet, and the base of each petal is streaked with white, thus forming, as it were, a distinct white eye; there are several varieties of this plant, the most notable of which are Regeliana and Morreniana, which differ from the others principally in the size and colour of their distichous bracts and in the colour of their flowers. T. tessellata is large and vase-shaped, and its leaves are extremely ornamental; they are light glaucous green, mottled on the upper sides with transparent greenish yellow, and veined beneath with rosy purple. T. xiphioides has wholly grey leaves and flowers large, pure white, and very fragrant. Other good species of Tillandsia are splendens, ionantha, stricta, Rollissoni, Legrellei, Pastuchoffiana, &c.

Caraguata Zahni.—This plant resembles a Tillandsia in habit. It branches near the base, and ultimately forms a dense tuft. Its leaves, which are about a foot long and upwards of 1 inch wide, are broadly sheathing at the base, where the colour is yellowish amber, veined and lined with crimson; the upper part, as it ages, becomes suffused with reddish crimson, the tips only being green; the flowers, which are borne in dense panicles, are golden yellow, as are also the short intermediate bracts, those that are lower being larger, boat-shaped, and lengthened into long points, tipped with scarlet; below the flowers the stems bear a quantity of large, long, and narrow bracts of a brilliant scarlet hue. C. cardinalis has plain green leaves and erect spikes of scarlet flowers.

Pitcairnias.—These are mostly slender-growing plants with long narrow, spineless leaves and long spikes of handsome flowers. P. staminea bears large pendulous, tubular-shaped, brilliant red flowers, the stamens of which are very long and of the same colour. P. flavescens has long deep green leaves, clothed on the under sides with greyish scurf; the flowers, which are bright yellow towards the base, become greenish yellow at the tips. In P. Andreana they are erect and rosy red at the base, the upper half passing into canary yellow. P. undulatifolia has white flowers with brilliant scarlet bracts. P. tabulæformis is thoroughly distinct in habit from that of any other species; its leaves, which are broad and somewhat ovate, are closely imbricated and pale green, the whole plant being as flat as a table-top; the flowers, which are long, are dull red, and rise just above the leaves. Other good species are corallina, sulphurea, speciosissima, polyanthoides, &c.

Pepinia.—This genus consists of only a few species. P. aphelandræflora resembles more Dracæna congesta than a Bromeliad; it produces long spikes of brilliant scarlet flowers, with greatly exserted yellow stamens.

Guzmannias.—These are Tillandsia-like in habit, but nevertheless when in flower distinct and handsome. G. tricolor has smooth dark green leaves, and bears erect scapes, clothed with short ovate bracts; the lower ones are yellowish green, striped longitudinally with deep purplish black, the upper ones tipped with scarlet; the flowers are pure white. For a long time this was the only species of the genus in cultivation; now we have several others, the most noticeable of which are G. melinonis, grandis, Reginæ and grandis.

Nidularium.—In this genus the flowers are for the most part arranged in crowded terminal heads, which do not rise above the leaves, in which the chief beauty of the plants belonging to this genus resides. N. spectabile is a dwarf, vase-like plant, with leaves about a foot long and 2 inches broad; their upper sides are deep green, the ends blood-red, and they are sparingly edged with small teeth-like spines; on the under sides they are dull purplish and transversely banded with scurfy lines; their tips are blood-red, the calyx being large and of the same colour, and rising above the lavender-blue petals. In N. Innocenti the leaves are green above, claret-coloured beneath, and the flowers are orange-red. N. Laurenti has green outer leaves, and towards the base white inner ones shading off into pale green and spotted with brownish dots; the flowers are pale blue. Other good kinds are Morrenianum, amazonicum, Scheremetieffi, and princeps.

Encholirions.—These resemble Nidulariums in habit, but produce tall spikes of showy flowers. E. corallinum has sheathing, recurved, slightly glaucous leaves, dark green above and dull purple beneath; the flowers are yellow tinged with green, whilst the bracts are bright crimson. In E. Saundersi the leaves are glaucous green above, and mottled beneath with reddish purple; the spike, which is erect, bears flowers and bracts of a soft canary-yellow. Other notable kinds are Jonghi and sanguinolentum.

Vriesia.—This genus contains many showy plants, most of which bear erect scapes, furnished with flattened spikes bearing large bracts, arranged in a two-ranked fashion; some, too, are conspicuous on account of their curiously marked and beautiful foliage. Amongst the best known and most prized are V. speciosa, oftentimes called the Tiger plant from the markings of its leaves, which are bright green above, but on the under side barred broadly with transverse bands of black. The scape, which is tall, is somewhat sword-shaped, and the bracts are imbricated and bright scarlet; the flowers are white. V. brachystachys is very showy; the leaves are pale green; bracts crimson tipped with green; flowers crimson at the base, passing into rich yellow; tips of petals black. V. sanguinolenta has long, erect, spreading leaves of a glaucous hue, the undersides of which are profusely mottled and blotched with reddish crimson. V. guttata is a much shorter-leaved plant than the preceding, but equally handsome, the sheathing leaves being very broad at the base, glaucous green and distinctly marked with numerous, somewhat distant spots of purplish crimson. We have not seen either of these two plants in a flowering state. V. psittacina rubro-bracteata does not bear a flattened scape, and the leaves are dark green throughout; the flower-stem and bracts are brilliant scarlet, whilst the flowers are bright yellow with the faintest tinge of greenish blue at the tips.

V. hieroglyphica, a superbly handsome and robust plant, is vase-like in habit; the leaves are long and broad, with blunt ends; in a young state their ground colour is bright yellow, transversely banded with zig-zag lines of bright red; as they age they frequently exchange the yellow ground for bright light green, but in some instances the yellow only becomes deeper, whilst the zig-zag bands become very dark green on the upper side, those on the underside changing to purplish black.

V. heliconoides is a somewhat upright vase-like plant with recurved leaves of a metallic appearance. The scape, which is erect, bears very large Heliconia-like bracts arranged in a two-ranked manner, the lower half being rosy carmine, the upper part white; the flowers, which are white, do not rise above the bracts.

Puyas are large, bold-growing plants, requiring considerable space in which to develop their beauty. Being mostly natives of Chili, Peru, and Mexico, they thrive in a lower temperature than that needed for the majority of their kindred. P. grandiflora, gigantea, Whytei, and recurvata become grand ornaments for a large house.

Hechtias comprise a few handsome massive species, natives of Mexico. They produce long leaves, which are armed with rather formidable spines. Amongst the best kinds are Ghiesbreghti, glomerata, and argentea.

Ronnbergia Morreniana, a beautiful plant, bears leaves upwards of a foot long and nearly 4 inches broad, rounded at the base and tapering to a sharp point. The ground colour is light green, profusely streaked with irregular shaped lines and blotches of deep green, somewhat after the manner of Dracæna Goldieana. The scape, which is erect, is furnished with large sheathing, pointed green bracts. The flowers are white, and the petals are edged with blue.

Ananassa.—To this genus belongs the Pine-apple, and it also contains some few ornamental foliaged plants, of which the best is A. sativa variegata, the spiny leaves of which are green in the centre, broadly bordered with golden yellow; it also produces a small bright red fruit, which, although decidedly ornamental, is of little value for the dessert table, as the flesh is meagre and the flavour harsh and strong. A. Porteana is scarcely so showy as the last-named kind; although thoroughly distinct, it differs from it principally in having the centre of the leaf striped with white or yellowish white, and in the margins being of a deeper green. W. H. G.

Camellias as stove plants.—I do not see why any experienced plantsman should question the ability of the Camellia to endure a stove temperature, *i.e.*, if permanently treated as a stove plant. I can, however, speak from experience that Camellias will do so, as many years ago I had to manage a conservatory the temperature of which was never allowed to fall during winter below 60°. In this house, trained to pillars, and I think also on the roof, were such creepers as Stephanotis and Dipladenias and that heat-loving Passion-flower, Passiflora princeps; in this structure, too, were Camellias planted out in a border, and there they flowered freely every winter. It is sudden changes of temperature that Camellias dislike.—J. C. C.

*** We learn that the average temperature of the stove in which the Camellias are grown at Beddington, in Surrey, is during winter from 55° to 60° at

night and from 65° to 70° during the daytime. There are, we are informed, three Camellias in the house—one white, one red, and one pink.—Ed.

BOUVARDIAS PLANTED OUT IN PITS.

For producing flowers in abundance, choice in quality, and always highly appreciated during the months of August, September, and October, no plant excels the variety of Humboldt's Bouvardia called corymbiflora when grown under favourable conditions. It produces its blossoms so freely, that anyone having a pit or frame to spare cannot do better than devote it during the summer and autumn months to this Bouvardia. One-year-old plants, or even older ones, are preferable to plants grown from cuttings during the current year, as they are better furnished with shoots, and more bloom can be had from them; therefore anyone possessing a stock of plants which have bloomed the year previously in pots will do well to prepare them with a view to planting them out, and this can be done in the following manner any time during January; prune them down to within an eye or two of the old wood; then place them in a gentle heat. A vinery just started suits them well; syringe them freely, to induce new shoots to break from the old wood as well as from the new. This keeps the plants dwarf, and therefore they do not need much head room later on in the year. As soon as they show signs of breaking into growth, shake the roots out of the old soil, and replace them in pots as small as will hold them, simply allowing space enough for the roots. Use a light compost, consisting of equal parts of loam, peat, and leaf soil, with a free admixture of silver sand. Return them to the warm house, keeping them as near the glass as possible, to prevent them from becoming drawn. As soon as the shoots have grown about 2 inches, top them, and repeat this operation when 3 more inches of growth have been made. Keep them in a temperature of about 60°, gradually hardening them off until about the middle of May, when they can be placed in their blooming quarters. If old plants are not at hand, young ones can quickly and easily be had. Early in February procure some stout cuttings about 2 inches long, taken off with a heel; insert them singly in 3-inch pots, or several in a 5-inch pot in sandy peat and leaf-soil, and plunge the pots in a brisk bottom-heat. Keep them carefully shaded until rooted; then they should be potted off, but be careful not to use pots too large, as they do not make roots of large size, but simply a mass of fibres. Water carefully, and keep them near the glass in a temperature of 60°, and when about 4 inches high pinch out the point of each shoot, to induce the formation of side branches. When growing freely, gradually harden them off in the same manner as old plants, stop the shoots once more, after which no more pinching must be allowed, or the plants will not bloom so freely, nor will the flowers be so large as they should be. Then prepare the soil for planting, using the same proportion of ingredients as before; but it should be used in a much rougher state, and add to it a sprinkle of bone-dust. Choose for them a frame or pit in which the shoots can have about 2 feet of head room. The cuttings may be planted about a foot apart each way, the older ones 1 foot 6 inches or more, according to their size. Give a good watering, and keep them nearly close, syringing daily until they become established, when the supply of air should be increased until the lights can be left off altogether, except during long-continued rains; they will then need protection, in order to prevent them from being saturated. Well attend to them during the summer with water, both at the roots and over the foliage, and about the middle of August they will commence to bloom, when the lights should be placed over them, allowing, however, a free circulation of air. When the centre spike is cut from the stem, blossoms will start from the side branches, and will continue to do so until the end of October, *i.e.*, if protection is given to them on cold nights by covering the frame with mats. When they have finished blooming some of them can be taken up and saved for supplying cuttings for another season; but, if not required for that purpose, they can be thrown away. Other varieties of Bouvardia that are amenable to this method of cultivation are elegans and Vreelandi. Some of the later blooming kinds do not prosper so well, owing to their requiring more heat later in the autumn to induce them to expand their flowers.

Swanmore Park. E. Molyneux.

WINTER-FLOWERING PLANTS.

Cypripedium insigne.—There are a great many more attractive Orchids than this, but, as far as my experience goes, there are none more serviceable. We keep several dozen strong plants of it in pots ranging from 5 inches to 9 inches in size. These are now coming fast into bloom, and for many weeks they will be available for house and conservatory decoration. In a cut state, too, they are useful for filling vases and specimen glasses. For whatever purpose they are applied they will be found to be very durable, and a long stay in a house or cool conservatory does not injuriously affect them. For about four months in the year, viz., March to June inclusive, they are treated as stove plants, and during that time they form healthy fresh growth. When this is fully developed, *i.e.*, about the beginning of July, they are placed in sunny unheated pits, and there they remain till October, when they are transferred to a slightly-heated Rose house. They then speedily open their blooms, and a good succession is maintained till Christmas, and sometimes later. When treated as stove plants all the year round, they seldom do so well, as, instead of flowering, they are constantly forming fresh growths. A warm greenhouse suits them exactly, but, as a rule, they do not, under cool treatment, flower much before the spring. It is, however, during winter they are most prized, and it is then when all should strive to have them in bloom. At no time do we allow them to become dry at the roots, and when growing and rooting strongly they must have plenty of water, and occasional supplies of weak liquid manure. Four years ago last spring ours were all shaken clear of the sour soil and badly-drained pots in which they were trying to root, and were repotted. We used for them clean pots one-quarter filled with drainage, and a compost consisting of two parts of rough fibrous peat, one of fibrous loam, and a liberal addition of sand, charcoal and broken pots. The old plants, which were large, were pulled to pieces, and all had their dead roots cut away, and were then repotted, the divided portions being placed in pots just large enough to comfortably hold them, and the rough compost was firmly packed about the roots. This was done in the spring of 1882, and, with few exceptions, they have not been disturbed at the roots since. Constantly repotting them means constantly mutilating the roots; these cling tenaciously to the sides of the pots, and disturbing them does more harm than good. An annual top-dressing of turf is all that our plants get, and it is all that healthy, strongly-rooted Cypripediums require. When growing they will stand a moderate amount of shade, and an early vinery then suits them well, but they must be well exposed to full sunshine and light in order to mature their growth and ensure floriferousness. C. insigne Maulei, of which there are several forms of more or less value, is a decided improvement on the type, and quite as easily cultivated. According to my experience, there is little demand for this class of Lady's Slipper, but large quantities of cut blooms of it are now being sent to Paris from Belgium, and its blossoms may yet become fashionable on this side of the Channel. Quaint, but not pretty, is the verdict frequently passed upon them, but their very quaintness may give them a money value in the future; and therefore those who possess large stocks of this Cypripedium ought not to neglect them or be in a hurry to get rid of them.

Poinsettia pulcherrima.—During the latter part of November and December many stoves and plant houses are enlivened by the showy inflorescence of this plant, and it would be difficult to point out one more brilliant or useful. Nor is it at all difficult to cultivate. Cuttings made of the ripened growth, or young shoots taken off with a heel, may be struck in spring with the help of a good hot-bed or a close propagating frame; these may be gradually shifted into 6-inch pots, and transferred to a sunny pit or frame while yet dwarf and sturdy. Old plants that have been rested in a cool house will, if cut back in spring and started in gentle heat, break strongly; they may then be shaken out and repotted, using sizes a trifle larger than those from which they were taken. No particular compost is needed, though some growers consider peat indispensable. We find that a mixture of two parts fibrous loam to one of good leaf soil and plenty of sand suits them well. After the old plants have recovered from their rough usage they, too, will do best in sunny pits or frames, and all will require a little thin shading during the hottest part of bright sunny days. Then if given plenty of air all will be strong, though not lanky, by the middle of September, at which time they ought to be transferred to a sunny position not far from the glass in a warm stove or forcing house. They are certain to increase in height after this change, and no attempt that I have yet seen made to shorten them other than striking the tops can be said to have improved their appearance. The stems are somewhat flexible, and at the present time those of young plants may be safely coiled round the inside of the pots, the points being brought to the centre and staked upright. Last season we fairly doubled up some of the stems, thus reducing their height by about two-thirds, and, the work being done neatly, the stakes partly hid the bends. These sharp curves naturally had the effect of slightly reducing the size of the heads, while those coiled round the sides of the pots are much less checked; but they are not ornamental, and I should not think of placing them on a dining-table. Experts sometimes succeed in rooting strong tops of plants taken off with a few leaves as soon as the flower-heads show themselves, and I have seen very dwarf plants with fine whorls of floral leaves thus obtained. A brisk bottom-heat is required, but even with this more fail than succeed satisfactorily, and I should not advise anyone to attempt it unless they have abundance of tops to spare. All our plants, young and old alike, receive very liberal treatment. After the bloom-heads show themselves, abundance of liquid manure, either from the farmyard or made from sheep droppings and soot, is given, and also soot-water or sulphate of ammonia. These manures are applied frequently, and not too strong. Failing any of these, an occasional sprinkling of either Standen's, Beeson's, or Clay's fertiliser may be resorted to. Old plants are thus made to perfect three or four heads, and the young ones one head extra strong—*i.e.*, on an average about 12 inches across. Unless wanted for house or conservatory decoration, we prefer to keep our plants in heat, and if a rather drier atmosphere than usual is maintained, they will last much longer in good condition than they do in a cool house. The dry heat also hardens the stems, and a second lot of small heads is frequently pushed out lower down than the principal ones, and these prove serviceable for vases and table decoration long after the principal display is over. A dry heat also induces some of the flowers to set, and a few pods of seed are the result; the seeds germinate in heat as quickly as those of the Ricinus do. If the bulk of the plants must be employed in either the house or conservatory, they ought at least to be given the warmest positions possible, and in no case should they be set on a cold damp bottom. Water at all times should be given very sparingly. Unless these conditions are ensured them, both foliage and flower-heads soon damp or drop off. As a rule, Poinsettias are thinly intermixed with a variety of other plants, but small groups of them at intervals, or one large group in a favoured spot, will be sure to attract attention. We have two single varieties, equally valuable, one being a duller red than the other. It is also very distinct in habit, more short-jointed, much earlier, and of the two I consider it to be the more easily grown. The later variety develops the largest whorls and the colour is very brilliant.

Neither the double form nor the white variety is appreciated here.

Chinese Primulas.—These rank amongst the best of winter-flowering plants, and they well deserve all that is frequently stated in their favour. Not only has there been a marked advance of late years in these Primulas generally, but we have also improved in our methods of cultivating them. At one time it was the fashion to sow as early as March or April, the consequence of which was that either the seedlings were much neglected in their earlier stages, or the plants were grown to a great size long before they were wanted, several trusses of blooms perhaps having to be removed. The result of such treatment was shabby plants and shabby flowers. Now-a-days we sow quite two months later, *i.e.*, in May for the earliest, and in June or early in July for plants to form a succession. Then if grown steadily on in frames or pits, and finally shifted into 5 inch or 6-inch pots, they attain a good size by the present time or quite as soon as they are wanted. Moreover, when there is no need to remove the central truss, this and the surrounding later trusses gradually develop into a pyramid of bloom, which the fine healthy foliage shows off to advantage. Last season nearly the whole of our stock was raised early in July, and the bulk of the plants was flowered in 4½-inch pots. They received their final shift late in October, and no crocks were placed in the pots. During the early part of the winter they stood on the front bed of a house maintained at an intermediate temperature, and when transferred to a cooler house in February they were flowering grandly, surpassing any in the neighbourhood in much larger pots. Chinese Primulas must have a light position at all times, and warm greenhouse shelves suit them admirably. If mixed among a variety of other plants, they soon lose colour, and in cold positions damp off badly. Occasional supplies of liquid manure stimulate growth and improve the colour of the flowers. They are not much troubled by insect pests, but many plants are annually lost by disease in the form of canker attacking the stems. The old idea as regards prevention was to keep the collars of the plants clear of the soil, and I have, when a boy, spent hours splitting up sticks and propping up the long-legged youngsters, yet by this very plan of high potting we actually invited the disease. The seedlings should be sunk into the soil, so that the collar rests closely on the surface; the stems will then emit roots freely into the surrounding soil and become a source of strength instead of a sure source of disease. W. I M.

NOTES.

Nature's revenge.—We are beginning to patronise Nature a little by imitating her in the garden. It has simply come to this at last, after all our progress, viz., we are to-day planting our bulbs in the grassy lawn, while only yesterday we dug them from the grassy meadow, or hilly slope or mountain-side. Our ways are really very wonderful. For a long time we have tried to improve on Nature, or to "mend it rather," and although she has continually appealed to our eyes and hearts, yet it has only just dawned upon us that she knows more and can do more than is possible to us in the garden. I never met with evidence that Carl von Linné ever went into ecstasies over anything particularly rare or beautiful in the garden at Upsal, but history tells us that when he landed in England he reverenced the golden glory of our native Gorse and Broom-blossom by falling bare-headed on his knees. I was going down a valley in Sussex last April where the rocks cropped out naturally surrounded by great cloud-like patches of wild Primroses in the Grass. I was taken there by a friend who is responsible for the *renaissance* of hardy flower culture in England, and one remark made sank deep in my memory tablets just as the graver cuts into copper or steel. I was remarking the magic glow of even ing sunlight lingering on the budding trees, the bold grey rocks, and the flowers. "Ah! yes," was the reply; "the best of beauty is often outside the garden wall, if one only has the gift of seeing it." And so Nature takes a noble revenge; she is not flattered by our toy gardens or by our imitative moods; she is the great teacher ever luring us on to follow her, but how gently and how easily she surpasses us after all.

The best Ivies.—I wish some "wise man" would tell us of the best dozen kinds of Ivy, and more especially of the best of all the green-leaved kinds. Now that chill November has banished Clematis and Tea Rose, Ceanothus, and the great white Magnolia flowers, we shall every day value the deep green Ivy leafage more and more until such time as Daffodils and swallows return to us again. Veitch's Japan Creeper (Ampelopsis Veitchi) is fast losing its leaves of blood colour and bronze or gold, but the Ivies are now just attaining their freshest condition, and all the winter through will afford us pleasure. We have or may have varieties suitable for all purposes in the garden—some sorts which will not climb, but which creep and cling most beautifully to half-buried stones. Of tall or climbing Ivies there are many all perfectly hardy, long lived when once well planted, and most beautiful as seen on walls from 7 feet to 70 feet in height. There is a little dodge in connection with coaxing Ivy up a wall worth recording here, although as a matter of fact most people must have repeatedly observed the principle for themselves. If a broad expanse of bare wall has to be covered quickly, several years of waiting may be saved by fixing upright strips of timber or battens to the wall, near or up which the Ivy is not slow to make its way. You may often have observed that Ivy or Virginian Creeper makes most rapid ascent when it can creep upwards in the shelter of the down spouting from the ground to the eaves. The slightest protection or shelter of this kind makes a wonderful difference, and by fixing upright supports, which need not be in any way unsightly to the wall, Ivy may be induced to cover a wall in a third of the time generally necessary in exposed positions. I am very fond of Ivies, and never neglect procuring any good distinct kind. Of the best are the large-leaved or Irish, the large-leaved golden, the Algerian or dentata, Glynn's Ivy with a glossy leaf, the true Bird's-foot, the dark purple-leaved, the palmate, and the cordate or Hedera Rægneriana; but there may be others as good, or better, than these.

The winter Cherry.—Physalis Alkekengi is the name of a distinct plant of the Potato family, which is well worth growing in a sunny corner for the sake of its Cherry fruitage at this dull season of the year. Please note that that little word "dull" is added for the sake of euphony; it is a sort of poetic license; in a word, an untruth, for no true gardener can ever really believe that any season is dull or uninteresting in the garden. Flowerless it may be to a great extent, but dull, never, while there is life and hope of rootlet and bulb, and future beauty resting or working beneath the soil. Now this Physalis is, when growing all the summer time, a sombre, commonplace, or, as some say, a weedy sort of thing; but now that the yellow leaves have fallen, its fruits yield us precious glints of rich orange colouring, and light up warm and bright in the sun. Some people have called it Chinese Lantern, on account of its balloon-like shape and lamp-like brightness, as seen under the conditions above named. For indoor ornaments during winter its fruits are useful to those who have not yet learned to value fresh green leaves more highly, or they skeletonise most beautifully, if one has patience to dissolve away the cellular tissue from the fibro-vascular bundles, which last is the termed used by botanists when speaking of Nature's plant-warp or scaffolding. In some gardens whole beds of this plant are especially grown for the sake of its ornate fruitage, and the wonder to me is, that the market growers have not cultivated it by the thousand in pots for the flower markets of our large towns. Its thong-like white stolons or roots creep about in all directions, so that its increase is of the easiest possible kind. There is another sort commonly called the Cape Gooseberry (P. edulis), which is not hardy, but may be grown on the back wall of a warm greenhouse or vinery. Its fruits are not highly coloured, but they are edible, possessing an agreeably subacid flavour, something intermediate between a Gooseberry and a Tomato. It is easily reared from seed.

Wallflowers and Polyanthuses.—Again the rich crimson-brown and golden-yellow Wallflowers diffuse their rich odour, and the seedling Polyanthuses are also throwing up a profusion of flowers. The sunny weather and late drenching rains have been especially useful in adding freshness and vigour to these homely flowers. Both Wallflowers and Primroses, or Polyanthuses, are most vigorous and floriferous as raised from seed sown as soon as it ripens every summer. This is a point, for Primrose seeds sown as soon as ripe not only germinate quickly, but the plants are finer and more numerous than from an equal quantity of dried seeds. Another point is to give away your own seed in exchange for that of other growers, as in this way variety and luxuriance are both attained. Some of the finest Polyanthuses of the large yellow and white, or Oxlip, race I ever saw were grown in a Surrey garden in a deep sandy soil; but Ireland is, after all, the real home of the Primrose and Polyanthus, just as one must cross the Tweed to see the finest of velvet Pansies. I wish some one in Ireland would take up the race of coloured Primroses, pure and simple, as distinct from the Polyanthus. Home-saved seeds of these are useless if there is a Cowslip or a Polyanthus in the same garden, for the Primrose proper deteriorates in such company, as surely as do Melons or the best of Cauliflowers when rogues or bad varieties are allowed to flower near them. Of course, one can increase good forms by division, and with the double kinds this is the only plan. After all, in most gardens seedlings raised by the hundred give an abundance of flowers for cutting all through the early spring months, and in mild places all the winter also.

Muhlenbeckia complexa.—This is a New Zealand shrubby Polygonum not nearly so often seen as it deserves. It has been recommended as a plant for rockwork, but a more murderous Thug could scarcely be planted amongst delicate or dainty things. Planted along with any good Ivy at the foot of a tree, on the Grass, or near a wall, this complex puzzler, as it has been named, becomes a thing of grace and beauty, quite distinct in habit and elegance from any other climbing plant known to me. It was introduced about 1870, and is readily increased by layers or cuttings of the young shoots. I once saw a good mass of it on a lawn amongst outcropping rocks, its only companion being Cotoneaster microphylla, and the combination struck me as being a very happy and effective one. The foot of an Ivy-covered tree-trunk seems the most suitable place for this plant, or it may be planted with Cotoneasters, winter Jasmines, Honeysuckles, and Roses near a porch or doorway. It is a rapid grower, forming trailing shoots 10 feet or 12 feet long in a couple of years if near any suitable support, but n fully exposed and sunny places on the Grass

its growth is dense, and the mass roundish in outline. It is one of the plants worth a good and suitable place, and it then becomes one of the most distinct and interesting of all trailing or climbing shrubs.

PRIMULA FLORIBUNDA.—Of all the tender species of Primrose, this is, as I think, one of the most pleasing and distinct. It seeds freely, and seedling plants in small pots seem neater and more floriferous, to boot, than are those propagated by division. Its flowers are bright golden yellow, and at once suggestive of those of Jasminum nudiflorum, or Winter Jasmine of Japan, just now opening its earliest flowers on our old walls, its glittering stars set off to the best advantage by the wine-dark leafage of Hedera atropurpurea. As a plant for a sunny window outside in summer and in winter inside, I know of no Primrose quite so neat in its habit, so continually in blossom, and at the same time so bright and cheery, as is this with its golden clusters and fresh green foliage, always presentable all the year round. The pale lilac-blossomed P. obconica is another ever-bloomer, but it is coarse in habit and colourless when compared with this yellow-blossomed gem. It grows and blooms freely in small pots, and the best compost is sandy loam and leaf-mould, and just as the plants attain blooming size, which is when they are about six months old, then a little weak liquid manure helps them wonderfully, due care being taken not to pour it over their leaves. Both the species above mentioned are nearly hardy, but grow and flower all the winter in a sunny greenhouse, never below 45°.

ANEMONES AS ANNUALS.—The best plan of growing Anemone coronaria on rich, light soils is to rear it from seeds every year. In mild localities near the sea it may be had in bloom all the year round by a simple system of successional sowings or plantings of the roots, as the case may be. The best time to sow seeds for early autumn flowers is in February or March, and if the seed-bed is enriched well with cow-manure, the growth will be far more vigorous than in ordinary soil. The surplus seedlings transplant fairly well if the operation be performed during wet weather in properly prepared beds or borders. It is curious to observe that during very severe winters the transplanted seedlings seem hardier and flower more profusely than do those left undisturbed in thinning out the seed-beds, while during mild winters the reverse of this seems to be the rule. A good handful of crimson-red Windflowers, snow-white Christmas Roses, and sweet Violets is well worth any trouble to secure during December and January. It is now the fashion to import nearly all our bulbs and tubers from abroad, but Anemones and Ranunculuses have been as well grown in England in times past as anywhere, and the named double or semi-double Anemones are not better than those which may be raised from a packet of well-selected seed at home.

HANGING BASKETS.—Bare rafters are not the prettiest things to see, and yet in many plant houses they are most conspicuous, although easily draped with suitable creepers or climbers or, for the most part, hidden by hanging baskets. These last are easily made of stout galvanised wire. A ring 12 inches across is fixed to three upright pieces, twisted into a hook or loop at the top for suspension, then the lower part of the basket is formed of galvanised poultry netting, 1 inch mesh, which is firmly tied to the hoop or rim with galvanised wire. The bottom of the basket is covered with green Moss, and then soil and plants at discretion may be added. Ivy-leaved Pelargoniums, pendent Fuchsias, Harrison's Musk, Nierembergia frutescens, and such bulbs as Lachenalias form nice baskets for a cool greenhouse. In a warm conservatory or plant stove one may grow Maiden-hair Ferns, such as Adiantum amabile or A. farleyense, a lovely basket Fern, and Begonias, Fittonias and Panicum, or Selaginella may be used below pricked into the Moss. Begonia fuchsioides is a very pretty basket plant, so is the common Elk's-horn Fern (Platycerium alcicorne), and Davallia bullata also forms a lovely basket when well established. Very pretty baskets may be carpeted with green or golden Selaginella, and then planted with seedling Ferns, such as Pteris serrulata or Adiantums, or with the Begonias having coloured leaves. VERONICA.

FLOWER GARDEN.

LARGE WINTER-GREEN.

(PYROLA ROTUNDIFOLIA)

THERE is a charm about the modest beauty of some wood plants that cannot be equalled by the most brilliant of our border flowers, and their wonderful harmony with the sentiment of poetical mystery that reigns in woodlands cannot fail to impress every true lover of Nature. Such gems as the little Twinflower (Linnæa), Trientalis, and the Winter-green might escape notice in the full light of an open place, but in the half light of their shady world, set in Moss, and the rich quiet colourings of forest earth-clothing, their little bells and stars have the value of precious jewels.

The Winter-green (Pyrola rotundifolia) in a Surrey garden. Engraved from a photograph for THE GARDEN.

Christmas Rose failure.—Will some kind correspondent of THE GARDEN tell me the reason why my Christmas Roses are showing neither bloom nor leaf? In February—or rather nearly March—I bought a fine large stock of established plants, consisting of niger, maximus, altifolius, &c., from a garden which was being done away with. They apparently did well and the leaves grew, but early in the summer there was a great drought and the Hellebores were much scorched. However, the crowns still looked plump and well, and I was told not to mind, as in the winter time the flowers would all appear as usual. This, I am sorry to say, has not been the case, as, where the flowers are appearing on isolated crowns, they are stunted and unhealthy-looking, and in many cases I see as yet no appearance whatever of bloom. Are the plants likely to recover? Should they be shaded from April onwards? They are planted in a corner under an east and south wall in rows to admit of their being covered by frames in winter. The soil is rich and rather heavy loam mixed with a little clay.—D. E. W.

OCTOBER PRIMROSES.

THE note on Pansies in September reminds me that I have been gathering Primroses quite plentifully all through this month. It is by no means uncommon to see Primrose blooms in autumn, but these generally come sparsely and are seldom much as regards quality. In the present instance, however, the blooms are abundant enough to render the plants fairly effective, and they are almost, if not quite, as good in size, form, and colour as those produced at their usual blooming time. I used to think that I should not care to see Primroses in bloom out of their ordinary season, but when they flower as well as they have with me this autumn they are certainly welcome. My plants were raised last September twelvemonth; they remained in the seed pans, and were sheltered in a cold frame till the end of March. They were then planted out in good free soil in a north border, and were well watered and daily sprinkled in hot weather. Although we had red spider bad enough on many things the Primroses escaped entirely, and to this, the good food and attention in watering which caused an uninterrupted growth all through the hot months, I attribute their floriferousness. In August, when Primroses and Polyanthuses generally have lost their foliage, these were green as Leeks. I do not know if this autumnal bloom will prejudicially influence the spring display. I do not think it will much, for the plants are so strong that they ought to be able to throw up well again in spring. The quality of the bloom on young plants is so superior to that furnished by old specimens, that everyone should annually raise some seedlings. The annual raising of Primroses from seeds forms the keystone of success in the culture of these charming spring flowers, and on parching soils it is the only way of growing them successfully. J. C. B.

Anemone japonica.—At page 172 it is inferred by "D. K." that the type of Anemone japonica is the peach-coloured form in the accompanying plate (558). To most gardeners who have known these plants for many years, this statement will appear most novel. Is not the dark purple form with very irregular flowers the original type? This surely is what is figured in the *Botanical Magazine* or *Botanical Register* about 1840, then lately introduced by Fortune. I think he states that he found it on Chinese tombs. I do not remember that he says anything about Japan; nor have I ever seen it or its varieties in any Japanese paintings. Where does "D. K." find his reference for the *locale* of Anemone japonica? It has always seemed to me that there must be a truly single type, and perhaps a white variety, somewhere in China or Japan, of which Fortune's dark purple was only a garden variety. Granted that the dark variety of Fortune was the first variety introduced and named Anemone japonica; next, I believe, came Anemone japonica hybrida, the peach-coloured form. I have not the time to search the pages of THE GARDEN, but, I believe, some years back Mr. Niven, of Hull, explained that this was raised at Kew as a cross between Fortune's dark Japanese Anemone and Anemone vitifolia. That

accounts for the peach-coloured form; and is it not a likely origin, seeing that it has some of the irregularity of Fortune's flower and much of the extreme regularity of vitifolia? Next, for the glorious white kind. Was not this introduced by Lady Amherst from her garden in France—at Tours, I think? and somewhere in THE GARDEN will be found an account of the original plant sporting from a plant of the peach-coloured variety. And I well remember it was first called Anemone vitifolia var. Honorine Jobert. What does Max Leichtlin or Mr. George Nicholson say in reference to this matter?—FRANK MILES, *Sunnyhill, Shirehampton.*

THE PAMPAS AND OTHER GRASSES.

I HAVE occasionally heard it remarked that the Pampas Grass is a grand plant by the side of streams and brooks. So situated in some places it is, no doubt, quite at home. But the finest plumes are always on plants grown in good holding loam, well drained, and where the plants can be well fed with manure water during the summer months. We have several specimens in various parts of the grounds—some on a steep sloping bank facing the south; others in different positions. All grew and flowered satisfactorily, with the exception of two plants, which had a very stunted appearance compared with the others. This was observed for three seasons in succession. When we examined the roots we found them in a very wet and stagnant condition. We, therefore, ran an ordinary drain pipe nearly close to the bases of the plants, and since then they have greatly improved. This season they have each produced from 3 doz. to 4 doz. plumes. Another variety (G. pumilum) I saw a short time ago, which is much dwarfer and more compact than the ordinary Pampas. This seems but little known, but it would be valuable for planting in the foreground of shrubberies and similar places. Arundo conspicua is another valuable early flowering Grass, though its plumes are not so fine as those of the Pampas. They may, however, be improved by an occasional deluge with manure water. This Grass is useful in the flower garden, blossoming as it does when the flower-beds are at their best. The striped-leaved Eulalia japonica is another valuable plant in isolated positions. If planted in good soil and afterwards well fed with manure water, it assumes a very different appearance from what it does when left to take care of itself. The Eulalia japonica zebrina makes a grand companion to the last-named kind, *i.e.*, if treated in the same liberal manner. J. R. HALL.

Fox Warren.

HARVESTING GLADIOLUS BULBS.

As this important process must now be effected, it may not be out of season to consider how it may best be done, the time and mode of doing it, and, of course, there will be here, as in most other things, differences of opinion. The French growers say always in their catalogues that November is the season for the lifting of the bulbs, and yet in a letter I had about a fortnight ago from the celebrated Fontainebleau growers, Messrs. Souillard and Brunelet, they say, we have already commenced the lifting of our bulbs at Montereau (where, and not at Fontainebleau, is their principal culture); where acres of them are grown, there must of necessity be a forestalling of the time which to an amateur might seem the best, or the work would never be done. Mr. Burrell, of Cambridge, tells me that he likes to see the stem keep green as long as possible, and will even cover them over with litter when there is fear of frost. I think, perhaps this late lifting, running on into December, may be due in some measure to the character of his soil, which, being more retentive of moisture, would naturally keep the plants fresher than in a lighter soil; and, therefore, the end of October or beginning of November is about the best time. It must be remembered that there is also a difference in the time of flowering these bulbs, some varieties being much earlier than others, and, therefore, it will not do to go to a bed and at once lift all, no matter what their condition, but judiciously take up such as show signs of being fit for it, by yellowness of the foliage, &c. I have to-day (Oct. 25) cut a spike; now it would be absurd to lift that bulb at the same time as others which flowered a month or five weeks ago. We had a fine ripening time in September and the bulbs were evidently enjoying it, but during this month we have had nearly 4 inches of rain already, and this, especially where the ground is at all heavy, must retard the operation. I do not quite understand what "W. I. M." is aiming at when he finds fault with me in what I stated about Cambridge. I never said that the climate was the same as at Fontainebleau, but that it approximated towards it more than any other part of England that I knew. I know Fontainebleau well; I know sweet Clonmel too; and I had rather grow Gladioli in Cambridge than in Tipperary, or, indeed, notwithstanding so many things in its favour, than in Somersetshire.

How, then, are they to be harvested? Here, too, there is some difference of opinion. I think it was "W. I. M." who advocated lifting them up with the soil and storing them in that manner. All I can say is, that I have never anywhere seen it done. It is not so done either at Fontainebleau or Langport. The point to be arrived at is gradual drying off. I have tried various plans, but think that hanging them up with the stem cut to about 18 inches in a dry shed where they can have a good current of air is about the best plan. It will sometimes happen that the stem breaks off, so that there is nothing to hang them by. In that case I place the bulbs on a shelf. When all are well dried off I take them down, cut the stems close off to the bulbs, and place them in a frame specially made for them, through which the air can pass; I then write on each bulb its name, and then place them in a cellar out of the way of frost. There they will remain until planting time comes round again. I may say that, so far, the bulbs have lifted very well, but I found, as usual, many going off in the inexplicable way they do. It is utter nonsense to talk of degeneration being the cause. Let me give one instance that has just come before me. I received, amongst other bulbs from France this year, two of Mascarille, a new variety let out last autumn. They bloomed—did not seed; but after flowering there was a suspicious look of premature decay I did not like, and on taking them up I found them as black as coal; in fact, I never had any worse diseased. Independently of its being a French bulb, it being a new variety entirely put degeneration out of the question; in fact, whatever be the cause of the disease (for disease it is), it is one of those things of which we know as little, and against which we are as powerless, as the Potato disease.

In harvesting the bulbs care will be taken where the variety is at all scarce to save all the spawn or bulblets which cluster round the bulb in greater or smaller numbers, according to the habit of the individual variety. Some grow a large number, and some hardly any at all. I do not think that it is worth while to trouble oneself about the spawn in the case of the older varieties, as they are to be had so low priced now. When the spawn has been taken off it should be put into paper bags, with some quite dry sand.

I should like to put in a plea for Gladioli, as now is the time for purchasing bulbs. Many are deterred from growing them by, 1, their supposed dearness; and 2, by the fact that so many go off without any means of preventing it or curing the attack when it comes. With regard to the first, let me say that things are greatly altered within the last few years, and that, except in the case of novelties, they are to be had—really good exhibition varieties—for a few pence. I have now two lists before me, one of Messrs. Vilmorin, the other Mr. Burrell, of Cambridge (Mr. Kelway's I have not yet received), and I find that such kinds as Meyerbeer, Horace Vernet, Archduchesse Marie Christine, Benvenuto, Dumont d'Urville, Flamingo, Jupiter, Ondine, Le Vésuve, Adolphe Brongniart, Murillo, Dalila, Rossini, and others are to be had for under 1s.; while newer kinds are 1s. 3d. and 1s. 6d.; and then it must be recollected that every one of these bulbs, if judiciously examined before planting, may be cut into two, so that if a purchaser buys a dozen bulbs, he may make two dozen of them at planting time. The second objection, that one loses so many of them, is partly met by the above; it may be so, and sorrowfully I bear witness to the fact; but there is this consolation, that they are very cheaply replaced. If we take another very popular bulb, the Hyacinth, every year those who grow them order a certain number of bulbs with the positive certainty that they will be of no manner of use the following year, unless to put them out to take their chance, and no complaints are made; but in the case of the Gladiolus such a result need not be anticipated; some are sure to succeed and bloom a second year well, although others go off, and Mr. Burrell tells me that some of his exhibition spikes were from bulbs cultivated by him for three years. Of course, all growers will understand that it is not the same bulb, but that a fresh one is formed each year above the old one.

I now subjoin a list of what a beginner may safely grow as some of the very best exhibition kinds, and which in Messrs. Vilmorin and Mr. Burrell's list are all priced under 1s.:—

Addison,	Jupiter,
Africaine,	Lacepede,
Amalthee,	Leandre,
Anna,	Le Vesuve,
Benvenuto,	Matador,
Cameleon,	Meyerbeer,
Carnation,	Adolphe Brongn'art,
Cervantes,	Murillo,
Colbert,	Ondine,
Dalila,	Orphee,
Dauberton,	Ovide,
Dumont d'Urville,	Panorama,
Feu Follet,	Rayon d Or,
Flamboyant,	Rossini,
Flamingo,	Schiller,
Hesperide,	Shakespeare,
Horace Vernet,	Teresita.
Jeannette,	

All of these have appeared in winning stands this year. Another list of dearer varieties, varying from 1s. 3d. to 2s. 6d., is as follows:—

Abricote,	Gloire de Fontainebleau,
Atlas,	Grand Rouge,
Baroness Burdett Coutts,	Mabel,
Bicolor,	Mount Etna,
Camille,	Nereide,
Colorado,	Tamerlane,
Crepuscule,	Tour de Monde,
Demosthene,	Victor Jacqueminot.

There are, as in all flowers, newer and dearer varieties, but I very much question if there are better; at any rate, I should be perfectly satisfied to confine myself to these for exhibition, and should hope to be successful with them. Probably when people succeed with them they might be tempted into larger ventures; but, at any rate, I would advise plant-lovers to try these most charming and graceful of autumn flowers.

DELTA.

Schizostylis coccinea.—We have lately been cutting basketfuls of brilliant spikes of bloom from plants of this growing in the open ground, and they give just the colour that is required for mixing with Chrysanthemums, which still lack a real scarlet or crimson, although there are near approaches to the latter colour. Our plants of Schizostylis are grown between rows of bush Apple trees that afford a good deal of shelter and shade as long as the leaf holds on, but as soon as the leaves drop, if the weather turns cold, we lift the whole lot with as much soil as will cling to them, and transfer them to a cold house. Generally we plant them in rows right across the inside border of vineries from which the Grapes have been cut; but if these are not available we take cutting boxes to the beds, and, digging up the Schizostylis clumps, drop them in until it is full, and set them in any cold house in which they can be accommodated. Thus managed, they keep sending up spikes for an indefinite period. Many of ours had bloom-spikes on them when they were replanted

in the open air. This Schizostylis is of the easiest possible culture. It is greatly benefited by dividing the clumps. When we left ours in dense masses the flower-spikes were small and thin; but since we have taken to lifting and dividing them frequently the flower-spikes have much increased in strength and size. Ours are from 2½ feet to 3 feet high, and are more like Gladioli than Schizostylis, as usually seen in half-starved crowded rows. I doubt not that anyone giving this plant a fair trial will be equally well rewarded, for even in colder places than this it can be grown out of doors. It should, however, be covered with temporary glass lights on the approach of frost, for its flowers in a cut state are of great value in autumn and winter, and the fact of this plant supplying a colour not obtainable in quantity from any other cold-house plant of its season ought to commend it to everyone who has cut blooms to supply.—J. G., *Hants.*

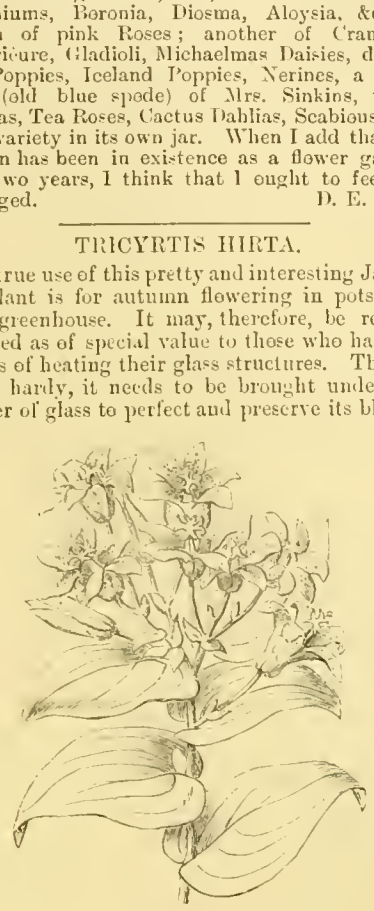
PLANTS IN FLOWER IN A SCOTCH GARDEN.

Autumn is here and winter is at hand, yet there are still flowers in the garden. Leucanthemum maximum has hardly given place to Pyrethrum uliginosum; Michaelmas Daisies are at their best; Amellus bessarabicus continues to brighten the borders with its beautiful purple stars. Iceland and French Poppies are still in quantity, and a wild Campanula, which troubles us greatly as a weed, persistently flowers where it used to be most unwelcome, but where now we have hardly the heart to condemn it for appearing. Early-flowering Chrysanthemums are a great "stand-by." Madame Desgrange, Jardin des Plantes, Golden Gem, and the very fine yellow variety, George Wermig, give sheaves of bloom daily. I have had several beds of this latter, some plants of which are left to bloom out of doors, and others are lifted with balls, potted, and flowered in the conservatory. The flowers are paler when grown inside than they are when out of doors, but come to greater perfection there. Those of Madame Desgrange, too, are of a purer white when bloomed under glass than in the open. The Dahlias were killed one very frosty morning a month ago. Mrs. Sinkins Pink still yields a fine bunch of bloom weekly from a bed two years old. Lady Fitzhardinge Pink has also occasionally fine flowers. Anemone Honorine Jobert is still in great beauty, and Tea Roses on the south wall are yet beautiful. Dinner-table decorations have never been prettier than this week, when the whole garniture was sprays of China Roses in clear glass vases on a silver plateau. Lupins are producing stray flowers, and white Phloxes are not yet quite over. It is even still possible to collect a nice little bowl of Carnations, white and flaked ones. Cloves are about over. The Hornbeam and Chestnuts (which turn blood-red here) have furnished gloriously tinted foliage, and the Hips and Haws on the Briers in the hedges are in the greatest profusion this year. Ceanothus Gloire de Versailles is still flowering on a south wall, close to a fine Madame Falcot Rose. I cut the last Lilium auratum last week, which grew on a south border surrounded by beautiful bushes of a variegated Malva, which I strongly recommend to the notice of admirers of sub-tropical bedding. Tropæolum speciosum is over now, and T. tuberosum has flowered but sparsely and late in a rich light soil on a south wall. The Gloire de Dijon Roses are as fine and as sweet-scented as in July, and there seems no prospect of these coming to an end if we but have fair weather. Stray Gladioli, the *débris* of the Dahlias, Mignonette, and masses of purple, yellow, white, and fancy Pansies, Violets, &c., go towards making a goodly show of late autumn flowers.

Under glass, Chrysanthemums are beginning to bloom. James Salter leads the way; Margot follows, and in about ten days we shall have a very beautiful show of them. Geraniums and Pelargoniums are grand. Primula obconica is never out of season. A few Orchids and an unusually fine show of Cypripedium insigne in the hothouse keep us in choice flowers; but best of all are the fine plant-yielding masses of bloom now of the Jasminum grandiflorum. A few sprays will scent a room, and keep fresh and open in water for more than a week. Up till last week I picked many bunches of Roses, none of which were prettier than a Rosa polyantha of a bright blush pink, and Cramoisie Supérieure. I have a small pale pink Nerine with thread-like petals planted at the very foot of a vinery wall, and there it flowers well and increases every year. Before me, as I write, is a table covered with jars and jugs and glasses of flowers, comprising: Chrysanthemum J. Salter, G. Wermig, Mme. Desgrange, Jardin des Plantes; white Anemones, Cypripedium insigne (a large beakerful), a silver cupful of sweet-smelling leaves, viz., four sorts of sweet Geraniums, Boronia, Diosma, Aloysia, &c.; a bunch of pink Roses; another of Cramoisie Supérieure, Gladioli, Michaelmas Daisies, double red Poppies, Iceland Poppies, Nerines, a large mug (old blue spode) of Mrs. Sinkins, white Azaleas, Tea Roses, Cactus Dahlias, Scabious, and each variety in its own jar. When I add that my garden has been in existence as a flower garden only two years, I think that I ought to feel encouraged. D. E. W.

TRICYRTIS HIRTA.

The true use of this pretty and interesting Japanese plant is for autumn flowering in pots in a cool greenhouse. It may, therefore, be recommended as of special value to those who have no means of heating their glass structures. Though quite hardy, it needs to be brought under the shelter of glass to perfect and preserve its bloom.



Tricyrtis hirta.

The plant represented by the accompanying illustration stood out-of-doors in a pot throughout the summer, and when showing buds in September, it was removed to a light conservatory, where it has been in bloom for some time. The colouring is as nearly as possible that of Disa macrantha, figured in The Garden, Vol. XVII.

K. L. Davidson.

Double white Begonias.—It is a mistake to say that the pretty variety of the above-named beautiful flowers, exhibited by Messrs. Cannell at South Kensington on Tuesday last, and described on page 402 of your last issue, is new, as it is by no means so, having been sent out at least three years ago under the name of Octavie by Mons. G. Mallett, of Plessis-Piquet, near Paris. I have grown it ever since it was sent out, and consider it to be one of the few varieties which, from delicacy of habit and want of vigour in its constitution, will do no good in the open air, and will only succeed when cultivated in a pot under glass. Another such variety with much larger flowers is Crousse's Antoinette Guerin. By far the finest double white variety I have yet seen is Lemoine's Avalanche, sent out this year, which has also the great advantage of producing no female flowers, all the blooms being fully double males.—Begoniaphile.

PLANTING HARDY BULBS.

It is a great mistake to defer the planting of any spring-flowering bulbs until the approach of winter. Bulbs put in the ground early in September will by this time have made roots several inches long, and in their case activity will be progressive, inactivity only supervening in a time of severe frost. About the middle of September I took up some Narcissus bulbs, from the majority of which roots were pushing; and it occurred to me in this last week of October, when planting others, how much greater must be the chance of obtaining a strong bloom from those planted at the first-named period. It is just as easy to obtain bulbs in the early part of the autumn as at its close, and I am convinced that if the condition of bulbs planted early in autumn was compared with that of such as are planted at the beginning of the winter, very little late planting would be done. In the case of Tulips, Hyacinths, and such bulbs as are used for filling beds on the Grass, very early planting is not practicable, owing to the presence of the summer bedders. In a general way tender plants are not effective after the second week in October, and if the bulbs are got in between the middle and end of that month they will have time to begin the formation of new roots before winter. When hardy bulbs are planted at so late a period as the present, I doubt if there is wisdom in putting them at once into the earth. There is a great difference between the dry and comparatively warm atmosphere of a stove-room and the earth, surcharged as it frequently is at this time of year with moisture, and the sudden violent change may oftentimes act prejudiciously on bulbs which have an element of tenderness in them. Of course there are some bulbs so hardy and impervious to changes of any kind, that precautions of any description are thrown away on them. The common double Daffodil is an instance of this, but take the white Trumpet kinds, such as cernuus, moschatus, &c., and you intensify their natural delicacy of constitution by subjecting them to what must be a chill. In September the natural temperature of the soil is still sufficiently high to warrant planting immediately, but later, I think, that in a general way it would be better to accustom the bulbs gradually to the altered conditions. This may easily be done by laying them out for a week on moist Cocoa fibre, or something similar. The sudden change from a quite dry condition to a wet one would thus be avoided. I have not a doubt that many failures occur in hardy bulb culture simply because they are exposed to damp and cold, the circulation being at a standstill through the absence of roots during the coldest months of the year. Spring comes with its influence on top growth before there is a sufficient quantity of roots to give it strength. The first year there may not be much evidence of injury, the stored-up energy in the bulb enabling it to bloom fairly well; but a bulb has two things to do, *i.e.*, to bloom well and make a strong growth, to lay in another store of vitality for the ensuing year. Under suitable conditions the flowering process is not in a general way exhausting, but when for some reason a good roothold has not been obtained, bloom production so lowers vitality as to leave the bulb quite the ruin of its former self. Then it requires a year or two wherein to recoup itself for an exhaustive effort, and this is a very dangerous position for delicately constitutioned bulbs, as they are rendered incapable of bearing with indifference the cold and damp, and they frequently disappear by the second year. It therefore follows that the more tender the bulb the sooner should it be got into the ground. Many a bulb that disappears mysteriously in the course of a season or two would, if well and early planted, remain to gratify its possessor for years.

Then, again, as to planting, there are various ways of doing this. You may dig a hole in your

border just deep enough to hold the bulb, and thus leave it to its fate. If your soil is well worked and drainage is fairly good this will do; but there are cases where this simple treatment is not enough. Take a clayey loam, for instance; many bulbs will perish in it which would, under identical climatal conditions and in a different soil, live and thrive. Bulb-planting is, I find, a favourite occupation with many owing to the ease with which it may be done, but if as much pains were taken in bulb-planting as are bestowed on plants in an active condition, how different would the result frequently be. Let anyone try the experiment of taking out a hole say 15 inches deep and filling it with a well-manured compost, and compare the vigour of bulbs thus planted with those treated in the ordinary slipshod fashion. The difference is very striking, not only in bloom production the following year, but in perennial vigour. In cold, stiff soils a heap of soil should be kept in readiness, and nothing can be better than the refuse from the potting bench. This, mixed with the natural soil in the proportion of one-half of each, will ensure a suitable rooting medium. It should be remembered that bulbous flowers remain generally some years in the same place, and, through the absence of roots for a considerable portion of the year, the soil is more likely to come into a close condition than when more or less occupied with fibres. There is, consequently, a greater need for that preparation which ensures a certain amount of porosity than in the case of other hardy flowers. These remarks apply with the greatest force to Lilies, which so quickly and severely feel the effects of stagnant moisture around the roots. It was, I think, Mr. Miles who once observed that the presence of a layer of brick rubble near to the roots of some bulbous flowers was life to them. I believe that in naturally unfavourable soils many bulbous flowers would succeed if 6 inches of drainage were put into a hole 18 inches deep, and in many cases the liberal admixture of pounded brick with the soil would do much towards preserving vigour. The question of depth is one that demands more consideration than it in a general way gets.

There is the nature of the plant and that of the soil to be thought of before it can be determined whether more or less deep or shallow planting is best. In shallow soils strong-growing bulbous flowers are frequently planted too shallow. Take Hyacinths, for instance. I have proved that in a light loam they bloom remarkably well at a foot under ground. It is evident that a bulb set so deep must feel drought less than one more within atmospheric influences. In cold, adhesive soils such a depth is not necessary for any bulb, and in the majority of cases would undoubtedly prove harmful. There is, of course, the question of nourishment to be taken into consideration; the lower the bulb is put into the soil the less amount of good soil can there be under it; consequently, deep planting reduces the feeding ground for the roots, and, after all, it is them that give vigour. If they can strike downwards to a depth of 15 inches in good, well-worked soil, it matters little whether the bulbs be covered with 2 inches or 6 inches of soil. In some instances, however, deep planting would be a great help. Bulbs might be planted deep enough to admit of their permanent residence instead of being taken up when the summer-blooming plants have to be got into place. In light soils I see no reason why early-blooming Daffodils, Tulips, Crocuses, Snowdrops, Triteleias, &c., should come out of the soil at all; at any rate, they might remain for several years at a time. Summer bedders will do very well in 8 inches of good soil, and if the ground were well made to double that depth in the first instance, they would be sure to get all they need. It cannot be too strongly impressed upon those who have porous soils to deal with that the thorough breaking up of the soil is absolutely necessary to the perfect blooming of hardy bulbs. Bulbous flowers generally send down the first roots they make deep into the soil, as if they wished to make sure of a safe anchorage. Thes are the mainstay of the plants, and secure them against drought. The deeper the soil, the lower down they go, and the amount of moisture at their disposal is consequently greater. A mulch of decayed manure is also wonderfully helpful, and this is the time to put it on. J. C. B.

LILIES OUT OF DOORS.

In a note on our Lilies written in July (see p. 27) I proposed adding a few particulars later in the season. Lilies in the open may now be considered over for the year, as only a few chance ones remain in flower. I will begin with what is usually considered the queen of Lilies, L. auratum, though some good judges consider L. speciosum rubrum in its best form, and others L. candidum simplex, to have at least equal right to the title. L. auratum has on the whole succeeded well with us this season, though some beds were more cut than usual by spring frosts. L. auratum rubro-vittatum was finer than we have ever had it before among our few plants, which have been in the open border since 1881; one had eight and another seven flowers. This is a truly gorgeous Lily with its broad stripe of crimson, but after some days, while the flower seems still fresh, the crimson turns to a dull, stale claret colour, and then most of the beauty is gone. The next finest of the family is L. auratum platypetalum, of which there appear to be two varieties, one variety known as L. auratum macranthum being low growing. The first L. a. platypetalum exhibited was almost without spots, like L. a. virginale, but the species includes all varieties of colour up to pictum. Two small clumps of L. a. macranthum were most beautiful and were much admired; a petal from one of these measured 3½ inches in breadth. The bulbs should be planted wide enough apart to prevent their knocking against each other in high winds; ours were not so. Our two finest of the ordinary L auratum both bloomed in the wood at the Weybridge cottage garden; the one seemed to dwarf all the flowers about it; one of the petals measured 7½ inches; therefore it was 15 inches across the flower. In another bed one grew to 9½ feet, and yet was so well proportioned, that it looked neither drawn up nor gawky. L. pardalinum and L. californicum were cut by spring frosts in some beds, and bloomed well in others a few yards off where the frosty wind had not reached them. L. speciosum rubrum and album were very fine, and so were L. Leichtlini and L. longiflorum album-marginatum, or, as I suppose it ought to be called, L. longiflorum foliis albo-marginatis. L. Szovitzianum in good soil always does well; L. Hansoni was moderately good; L. Krameri was fine and seeded freely; L. giganteum bloomed well, but was not very tall. L. cordifolium, the Japanese dwarf form of L. giganteum, was cut down by spring frosts in our Wisley Wood, as it was not sheltered from the sun which followed them. In the orchard house at Weybridge in a pot it had eight good flowers on a stem.

L. longiflorum bloomed well in some places, best in shelter, but failed in others. L. chalcedonicum did not bloom well, but the bulbs are strong and healthy. They were in full sun; I have moved them into a sheltered place. All the Martagons bloom well, and L. superbum. The question as to the relative merits of full sun or shade and shelter for Lilies, especially L. auratum, crops up from time to time in the different gardening papers. It is not an easy one to solve. L. auratum often blooms thoroughly well in complete shade and also in full sun. Rhododendron beds, as I have often before said, are the easiest places to grow it in, and the question of the necessity of sun to ripen the bulbs is settled by my friend Mr. M'Intosh's Lilies, which themselves or their children have thriven for more than a dozen years in the full shade of his Rhododendrons. I believe two great points to aim at are to prevent the bulbs getting too wet or the roots too dry, and especially to keep clear of many tree roots, which dry the soil as well as exhaust it. Rhododendrons keep their roots to themselves, and do not interfere with the Lilies, unless indeed they are grown very strong and very close.

In our little field of L. auratum in full sun, though with some shelter from wind by hedges, many hundreds bloomed well; some not more than a foot high with stems not thicker than tobacco-pipes had two fine flowers; many had one.

I have made no mention of Tiger Lilies. They always bloom well. I do not think the species without stem-bulbs, L. tigrinum jucundum, is sufficiently known and grown; it is a beautiful form for cutting. George F. Wilson.

Heatherbank, Weybridge Heath.

GARDEN FLORA.

PLATE 569.

HARDY CYCLAMENS.

(WITH A COLOURED PLATE OF C. ATKINSI.*)

Few plants are more interesting than hardy Cyclamens, especially to those who may not have convenience for growing the more tender Persian kinds. The latter have in recent years been improved in quite a wonderful way, and the hardy kinds, through good cultivation and cross-breeding, have also been much improved. With the exception of C. cilicicum, cyprium, persicum, and perhaps C. africanum, all the others are perfectly hardy, and could ill be dispensed with as far as the rockery is concerned. Dwarf or low-growing kinds, such as Coum and some of the smaller varieties of Atkinsi, are not, indeed, adapted for situations where straggling, lanky Grass would be likely to overpower them. All that hardy Cyclamens require is perfect drainage; indeed, the looser the material the greater will be the success. In loose limestone *débris* they seem to be quite at home; in such a medium they seed freely, and it is not unusual to see thousands of seedlings of Coum and Atkinsi, as well as of others, struggling for space round the parent plants. They like, as a rule, partially shaded positions; C. neapolitanum, europæum, repandum, &c., indeed, do well in the wood or wild garden under the deep shade of deciduous trees. The only difficulty in such places is keeping them moist during the growing season, but this is easily accomplished by a top-dressing of short Grass or old spent manure, which serves also as a medium in which the seeds can vegetate. Little, if anything, can be gained by sowing the seeds in pans or boxes. We have found it equally successful, and certainly less troublesome, to allow them to sow themselves. The varieties of Atkinsi make very handsome plants for greenhouse decoration in spring if grown in pans and kept in a cool frame during winter. Thus treated, they flower earlier than they otherwise would do. In planting, it is always safest to well bury the tubers, with the exception of the very small ones.

C. neapolitanum. Showing the first appearance of the flowers.

C. AFRICANUM.—This, although perhaps botanically little more than a form of C. neapolitanum, seems sufficiently distinct under cultivation to warrant its separation from that species. It is

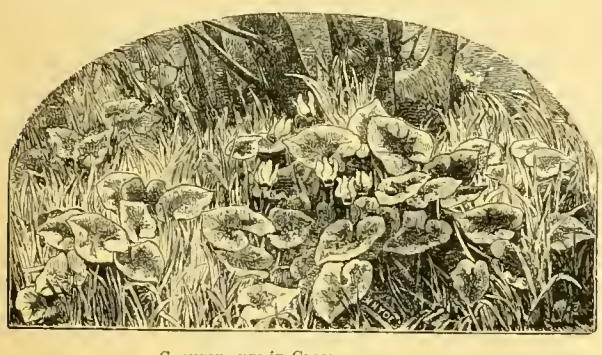
* Drawn in Messrs. Paul's nursery, Broxbourne, October, 1885.

remarkable for its enormous leaves, which not unusually measure from 6 inches to 8 inches or 10 inches in diameter, with a corresponding length, and they are beautifully marbled with white. It is questionable whether it would stand the rigours of our winters very far north, but in the south, at least, it stands well, and makes a very effective, fine-foliaged plant from December onwards. The tubers are unusually large, irregular, and covered with fibrous roots all over the surface; from the

C. neapolitanum.

upper surface proceeds a rhizome, often 2 inches or 3 inches in length, from which flowers are produced during the latter end of September and October. The lobes of the corolla are spatulate and bright rose, with a deep purplish spot at the base, and distinctly auricled where they reflex, as in C. neapolitanum. The leaves are not developed until after the flowers have appeared. They are orbicular, toothed, and cordate at the base. It is a plant which requires limestone or lime rubble in which to grow and good drainage. It is a native of Algeria. (Syns., macrophyllum and algeriense.)

C. Coum (of which the type may be seen in Curtis's *Botanical Magazine*, tab. 4) is a charming little spring-flowering species, and perfectly hardy. It, however, not unfrequently flowers at a time when some protection is necessary; this consists in placing a square of glass over the plant, or, better still, choosing a situation for it near a Pine tree, or affording some other covering so as to protect it



C. europæum in Grass.

overhead. The best plan is, doubtless, planting it out in a cold frame and allowing it to flower there. This, however, is not always convenient or available, and a square of glass or a handlight serves the purpose just as well. It may also be grown in deep pans with little trouble, and although the flowers are small, they are numerous, and make a brave show. The tubers of this Cyclamen are almost round, smooth, and produce roots only in a tuft from the base. The leaves, which appear along with the flowers usually in February and March, but often in January, are set on short stalks. They are quite round and firm and leathery in texture, dark green above without marbling and purple underneath. The flowers are deep red and without auricles. Of this species there are a few varieties—album, with white, and carneum, with rosy red flowers, being among the best. It comes from Armenia, Greece, Turkey, and other places.

C. EUROPÆUM.—This is one of the oldest, and perhaps the best known, of all the Sowbreads, and, judging from the synonomy, it seems to be a variable kind. A variety of it is said to have been cultivated by Gerard in 1569. It is quite hardy, and suitable for such positions as C. neapolitanum, though not so robust or free flowering. It is, however, worth attention, for the sake of variety. The leaves are contemporary with the flowers; the rootstock, which is irregular in shape, often throws up a rhizome, as in africanum, but much longer, and if broken up into small pieces it is capable of producing tubers, thus affording the only means of propagation we know of, except seeds. It seems to grow best in loose *débris*, and must have good drainage. It varies considerably both in the shape of the leaves and in the size of the flowers. In the southern forms the leaves are round and cordate at the base, marbled on the upper surface with white, and purple underneath. The flowers generally are bright red and fragrant. The variety Clusii has toothed leaves. The names of the slighter forms or synonyms are littorale, Peakianum, purpurascens, officinale, and reflexum.

C. IBERICUM.—To this belong the kinds represented in the annexed coloured illustration, many of which, especially the forms of Atkinsi, rank amongst the most charming of spring flowers. The varieties of Atkinsi are, we believe, the result of crosses between C. Coum and C. ibericum. While these two species are kept apart the seedlings come true to name, but when grown together or in close proximity they cross readily. Where attention is given to the raising of new forms, an essential point is a medium in which the seeds will germinate freely. We find finely sifted leaf-soil or spent manure to answer the purpose. In growing these varieties out of doors the same objections hold good as in the case of C. Coum. By far the safest plan, therefore, is to grow them in cold frames or in pots for greenhouse decoration, unless a specially favoured, well sheltered spot exists for them on the rockery. Grown in tolerably deep pans and kept in cool frames during winter, these Cyclamens make a charming show in the greenhouse or conservatory in February and March. From six to twelve plants in each pan according to size will be sufficient. The pans should be well drained, the soil rich and free, and the tubers should be almost or quite covered with coarse sand. The tubers are round and much larger than in Coum, and the roots form a tuft at the base. The leaves, which are produced at the same time as the flowers, are roundly oval, firm or leathery in texture, and have a distinct white zone on the upper surface. The flowers, which are bright red in the type, are larger than those of Coum, and without auricles at the base of the segments. In Atkinsi they vary from bright purple to rose, delicate white, and white with a bright purple spot at the base of each segment. The varieties are known under the various names of Atkinsi album, roseum, rubrum, &c. The type is a native of the Caucasus. (Syns., Coum var. ibericum, vernale, vernum, elegans, and others.)

C. NEAPOLITANUM.—This, the Ivy-leaved Sowbread, is well known, and has been long cultivated in gardens under the name of C. hederæfolium, and also often as C. repandum, which is, however, a totally different plant, both as regards leaves and flowers, to say nothing of its blooming in spring, while the Ivy-leaved species produces its flowers in autumn, the leaves developing in succession some time afterwards; it seems very variable both in shape and size of leaf, and also in the colour of its flowers. It is, however, undoubtedly one of the most useful of Cyclamens for out-door culture. Being perfectly hardy, it makes a good subject for naturalisation; indeed, in many places, notably in Devonshire and Cornwall, it is said to grow in copses quite wild, the tubers increasing until they have attained quite wonderful dimensions, bearing in good seasons over a hundred flowers. They are orbicular, slightly depressed, and roots are produced all over their surface. The leaves, which are beautifully marbled, are oval, cordate, and from 3 inches to 5 inches long. The flowers, which represent various shades of red, have a bright violet-purple spot at the base. They are also often pure white, and always furnished with distinct auricles on both sides of the segments at the base. It is a native of Central and Southern Europe, and flowers from August till October. One variety in particular called C. grandifolium is very distinct. (Syns., hederæfolium, subhastatum, ficariæfolium, &c., C. linearifolium being a monstrosity without a corolla limb.)

C. GRÆCUM.—This is often considered to be a species, but it is, we think, hardly more than a variety of the above. Its leaves, which show a great diversity in shape and marking, are developed at the same time as the flowers. The latter are variable, rarely white. The tubers are more irregular in shape than those of C. neapolitanum. It is a native of Greece, and flowers in September and October.

C. REPANDUM.—This is not so plentiful as the others are, but it is very useful in the spring garden, taking the place of C. neapolitanum. The tubers, which are small and round, have a few slender roots proceeding in a tuft from their base. The leaves, which are produced at the same time as the flowers, are oval and cordate at the base, with a wavy, deeply toothed margin. They are generally zoned with white and tinged with purple on the underside. The flowers, which are fragrant, are sometimes white, but generally bright red with a bright purple spot at the base, and the segments are truncate or flat, not auricled, as in C. neapolitanum. It is a native of Southern Europe, and flowers with us from March to May. C. romanum is another form, and others are C. cyprium, which blooms in October, its flowers being pure white with a purple spot at the base. It is nearly allied to C. neapolitanum, but differs from it in its unlobed leaves and very narrow segments. C. cilicicum flowers in October and also in November. D. K.

WORK DONE IN WEEK ENDING NOV. 2.

OCTOBER 27 TO NOVEMBER 2.

We have been favoured with a week of drier and unusually mild weather, so that our garden operations have gone on without let or hindrance. The summer bedded-out garden we have donned in winter garb, every bed being filled with hardy plants, and it now only remains to spread a thin layer of new gravel on the paths to give the final touch of neatness to the whole. "Hants" does not belong to that section of gardeners who have adopted the creed that gardens can be too tidy, and if ever his employer makes the acceptation of such a notion a condition of servitude, he will begin to think of flitting; he would like that all the rising generation of gardeners should make the same resolve, for neatness stamps the character of a gardener; just now though it is a condition that is difficult to maintain, owing to falling leaves, worm-casts, and the unavoidable dirt from soil and manure wheeling and transplanting operations. But even at some little hindrance of time from other labours, cleaning up should be done at least once a week. This has been our own rule for many years, and I question whether there has been any the less of other work done than there would have been had neatness not had

say, about a sixth share of the labour of each week. Kitchen garden work has been solely of a prospective description. Cauliflowers, of which just now there is an over-supply, have been guarded from injury by frost by breaking down the larger leaves over the flowers. Cleared decayed leaves off the plots of Brussels Sprouts to admit light and air to the buttons, a few of which are rotting owing to the work having been deferred so long. The useless underneath leaves of Scotch Kales have also been pulled off, and side sprouts have now full play for development. Cut the old stems of Asparagus away and weeded the beds, and the first frosty morning that wheeling can be done without spoiling the gravel paths, the plots will be given as rich a dressing of manure as can be afforded. There is still abundance of dwarf French Beans on our latest sown lot, and we have prepared protection for them in case of frost, which consists of Hazel rods bent over—both ends in the ground—over which thick canvas will be spread whenever appearances bespeak a frost. Runner Beans and old Pea haulm are being cleared away, and every bit of vacant ground is being got ready for manuring at first opportunity. We gathered the last of our Pears and Apples on the 29th of October, and our anxiety on this head is now transferred to the fruit room, which, in such exceptionally damp and warm weather, it is difficult to keep in that dry, airy state that is specially desirable during the first week or two after housing. However, we air as freely as weather permits, and shut up closely when raining or misty. Our soil is a little too wet to do the little fruit-tree planting that we have in prospect, but not for root-pruning of established trees. Pears grafted on Pear stocks frequently require such manipulation to keep them fruitful, and our plan is to do half the roots (one side of the tree) this year and the other half next. Trees on the Quince never require root-pruning after the third or fourth year, but they do require an immense quantity of water and manurial mulchings to keep them in good and fruitful growth; still they fully repay all that attention by the production of full crops of finely coloured fruit of the first quality. We have relieved the trees of both Apricots and Peaches of a quantity of their foliage by a gentle brush upwards with a long-haired broom, our object being to let sunlight and air to the young fruiting shoots and spurs of next year. The foliage came away with but the slightest friction, showing that its loss would be no detriment. Soon as all the foliage is off, the surface of the border will be weeded, suckers cut out, and a fresh top-dressing of soil and manure given. Potting-up of bedding plants has done, and still does, take up much of the time of indoor hands; then there is the scheming to house the greatest number in the smallest space; besides which it is an indispensable condition that no plants shall be lost owing to unsuitable positions as regards temperature; but all kinds that will bear rough usage are necessarily relegated to that category. Fuchsias, Cannas, herbaceous Lobelias, Begonias, and a few others winter well in any place, light or dark, that is free from frost. At this dull season, flowering plants of all kinds have the first consideration; and the show that Pelargoniums, Cyclamens, Bouvardias, and Chrysanthemums just now make bespeaks their worthiness to hold that position. The temperature for these flowering plants we keep at about 60°, and the atmospheric moisture inclining to the dry side, to avoid damping and mildew. Potted for forcing bulbs of Gladiolus The Bride, also a later lot of Hyacinths, and a few more Deutzias, Spiræa palmata and Thunbergiana; the latter is not so generally grown as its merits for forcing deserve. Its light, Maiden-hair Fern-like foliage and freely produced small white flowers are of the very best for cutting to intermix with flowers of larger size that require plenty of greenery to display their beauty. Excepting Grapes that are still hanging on the Vines, and that want looking over carefully twice a week to cut out any bad berries there may be, work in fruit-houses has been at a standstill. HANTS.

FRUITS UNDER GLASS.

CHERRIES.

THESE, on the whole, have had a very fair resting period, and will now remain dormant until the time arrives for starting. Sometimes they shed their leaves very early, and unless the roof can be stripped, mild weather in the autumn causes an upward movement of the sap just when it is least wanted. This, however, is not the case with us this year, and, lest it should be with others, I may observe that root-lifting or forking the soil off the surface roots and leaving them hardly covered for a few days invariably produces the desired effect not only upon the Cherry and Plum, but also upon other trees when they show signs of getting too forward. The next best process is pruning, if properly managed trees require it, but where summer pinching has been attended to and extension training is practised, this is a very light affair, even upon young trees, whilst old ones will only require spur-thinning or the removal of dead or barren branches. Spur-pruning, or thinning, is an operation of some importance, but many there are who allow their trees to go on from year to year and do not become alive to the fact that their fruit is getting smaller and smaller until it is too late to restore them to a satisfactory condition. Their only remedy, then, is entire removal and replacement with young trees, two operations which cost money, independently of loss of time; and as few gardeners are now overdone with either, my advice is, annual thinning just before the trees are cleansed in November. This process has been so frequently enlarged upon every autumn, and the best modes of destroying insects have also been given, but unless remedies more destructive than the pests themselves are resorted to, complete dislodgment from old spurs is a very difficult matter. Young gardeners who have never been overtaken by myriads of green, black, or brown aphis just as their Cherries, Plums, or Peaches were coming into flower, may make light of detailed instructions for a thorough rout. Once caught and a crop lost, they may choose their own course for the remainder of their lives, as the writer has done, and he advises thorough washing twice over in preference to painting, always preceded by careful thinning with a fine-bladed knife, to let the insecticide well into the enemy's stronghold.

PLUMS.

These and Cherries from this time forward, or as soon as the last of the Golden Drops are gathered, require identical treatment. The secret of success in Plum culture consists in strict attention to the following details: The incessant pinching of pyramids and bushes, either in pots or planted out in the borders; limited root space to prevent them from becoming gross and unmanageable; freedom from insects throughout the growing season; complete rest through the early winter months, and a low temperature with plenty of air when they are started into growth. Trees in pots, like all orchard-house trees, do best and give the least trouble when plunged out in the open air as soon as the wood is ripe—a position they may occupy until the time arrives for taking them in again for forcing. If planted out or trained on trellises, a regular system of root-pruning induces the formation of a profusion of spurs and short growths, which require very little pruning, and reduces pinching to a simple operation. The soil which suits them best is a strong, but free calcareous or sandy loam, to which old lime rubble or burnt earth may be added; but, lacking these, they will do very well without them, always provided they are well drained to favour the quick passage of water, and a moderate quantity of the new compost is firmly rammed round the balls every year. The house from which these trees cannot be removed, it is unnecessary to say, must be light and liberally ventilated, and if constructed with portable roof-lights for removal during the early winter months so much the better. Newly introduced trees are apt to grow strong at first, and for this reason they should be well formed and furnished with blossom-buds before they are taken from the open quarters. Now is a good time for new beginners to make a start, or for others to replenish their stock if they have not already done so. The varieties of Plums, many of them of second rate or inferior quality, being so numerous, none but the very best should be considered worthy of culture under glass. It is not well to start with too many varieties, but all the following are first-rate, and may be duplicated to any extent: 1, De Montfort; 2, Oulin's Golden Gage; 3, Denniston's Superb; 4, Huling's Superb; 5, McLoughlin's Gage; 6, Transparent Gage; 7, Boddaert's Gage; 8, Kirke's; 9, Old Green Gage; 10, Washington; 11, Bryanston Gage; 12, Jefferson; 13, Reine Claude de Bavay; 14, Coe's Golden Drop. These are named in their order of ripening. All do well in pots, and will give a supply of fruit throughout the Plum season. In favourable seasons a long succession can be obtained from one set of trees by removing a portion of them to the open air as soon as they have passed the stoning process; but that best of all Plums, Golden Drop, should be kept under glass, where the fruit will attain quality and colour rarely met with on open walls.

PEARS.

There are few localities in the south, west, or midland counties in which the now popular method of working Pears on the Quince, and growing them as pyramids, cordons, or wall-trained trees, does not result in the production of fruit of the finest quality. In these places, although pot culture is as old as the most primitive orchard house, this mode of growing them would be altogether superfluous work, as high-flavoured fruit can be obtained from well managed pyramids in the open air. North of the Trent, and with few exceptions throughout Scotland, as observant visitors to the congress held in Edinburgh last year could note for themselves, the falling off in size and colour is sufficiently marked to render many of the varieties almost unrecognisable by southern growers. A few collections there were from localities in which Peaches will not ripen out of doors, and these being remarkably fine I was curious to ascertain how they had been produced. In reply to my inquiries, I gathered that the trees worked on the Quince and trained on trellises under glass, mostly as cordons, had not only borne these fine Pears, but that many of the varieties had been made amenable to gentle forcing. The forcing of late Pears into use when other fruits are plentiful may not be an advantage, but it answers the end I have in view, and that is the practicability of growing a choice selection in the most unfavourable districts. Hitherto the leading cultivators have advised keeping the trees in cool, airy houses until the fruit is set, and plunging them in the open air to swell and ripen when danger from spring frosts has passed away. This practice holds good in the warmest parts of England, but I question if it would answer in the bleak north, and, glass being cheap, I would advise all lovers of good Pears to put up light airy houses, heat them sufficiently to produce our southern climate, with free ventilation, and furnish them with well-formed pyramids. In houses of large dimensions the trees might be planted out in pure loam, well mulched and watered in summer and root-pruned annually. In smaller houses, pots plunged to the rim and a little below the level, so as to form a basin for the reception of top-dressing and water, might answer better. Large pots need not be used, but the vent holes should be enlarged to ensure the free passage of water, for, much as the Quince stock enjoys moisture, it must not be stagnant, neither must it be given grudgingly. Potters in some districts manufacture a perforated pot, I believe, for Orchids, which I have used extensively for fruit trees, Pines, Melons, and other subjects which require plunging, and can strongly recommend it. If a new name were wanted for it I would call it the "tyro's safety pot," as it is almost impossible to overwater moisture-loving plants grown in it, whilst the fine fibrous roots which find their way through the holes in the

sides often save the crop when the watering of a tree is overlooked or neglected. The soil or compost for Pears in pots should be made richer than that recommended for borders by the addition of bone-dust, or, the loam being light and poor, well rotted manure may be added in the proportion of one to four of the loam; otherwise a good Pear soil produces the best flavoured fruit without the aid of animal manure, except as a mulch or in a liquid form when the trees are growing. A celebrated fruit grower says twenty-four varieties of Pears will carry one over the eight months they can be had in season. I should be content with a smaller number, as it must indeed be a fleeting variety that will not last more than ten days. But, allowing for failures and simultaneous ripening, I would select the following to succeed such sorts as Doyenné d'Eté, Beurré Giffard, B. de l'Assomption, and Williams' Bon Chrétien, which in the worst localities should go into the open air as soon as all danger arising from spring frosts is past: 1, Madame Treyve; 2, Beurré Superfin; 3, Louise Bonne of Jersey; 4, Fondante d'Automne; 5, Beurré Hardy; 6, Gansel's Bergamot; 7, Thompson's; 8, Marie Louise; 9, Van Mons Léon Leclerc; 10, Glou Morceau; 11, Pitmaston Duchess; 12, Doyenné du Comice; 13, Durondeau; 14, Hacon's Incomparable; 15, Marie Louise d'Uccle; 16, Beurré Clairgeau; 17, B. Diel; 18, B. d'Aremberg; 19, Winter Nelis; 20, Josephine de Malines; 21, Marie Benoist; 22, Bergamotte d'Esperen; 23, Beurré Rance; and 24, Easter Beurré. All these varieties are good on the Quince. Doyenné d'Eté, Jargonelle, Nos. 6, 7, 8, 9, 14, 16, 21, and 24 are made more fertile by double grafting. Trees so worked can now be obtained, or owners of full-sized pyramids of inferior sorts can change them in one year by grafting every shoot close to the main stems.

Strawberries in Pots.

These, owing to the mild weather and continuous rains, are still growing, and, judging from the fresh, healthy state of the foliage, will not settle down to rest for some time to come. If the first batch of plants is wanted for extra early forcing, they may now be laid on their sides in the open air, to give them a slight check before they are taken in; but on no account must they be allowed to become what is termed "dry," or to cause the balls to part from the sides of the pots. Of two evils—too much or too little moisture—better choose the first by leaving them where they stand, provided the roots are not striking into the ground and they are safe from the inroads of worms. In moist mild autumns we sometimes find it good practice to elevate the plants on dwarf walls or low platforms, formed of boards or shutters, placed on inverted flower-pots a foot or more in height, where they remain until frost threatens the bursting of the pots. They are then plunged up to the rims in ashes and brave all weathers, no matter how severe. Strawberry growers in high, dry, and warm gardens do not find it necessary to resort to coaxing measures, but content themselves with an occasional turn over to give the plants more light and air, and at the same time to prevent the roots from getting away from the crocks. Others, like ourselves, are obliged to steal a march on the summer by getting early runners from strong maidens put out in the preceding month of August, by using medium-sized pots well rammed with not over-rich compost, and giving them a position above the cold clay to ripen their crowns. In such cold limestone—I was going to write enervating—situations, tender varieties like The Queen and Dr. Hogg sometimes suffer if left out all the winter, not, I believe, from cold, as plants in the open quarters winter well, but from the check which follows the quick growth of these sorts when placed in pots and the season continues mild and muggy up to Christmas. These plants we find it necessary to place in cold, shallow pits, where they can have the protection of well-tilted lights when heavy rain is falling, and full exposure in dry or ordinary weather. Where pits are not at command, the Plum, Cherry, or Pear house may be utilised, as dry frost does no harm, but the pots should be plunged on the borders, not in them, in any light, non-conducting material that will keep the roots moist and progressing. At one time it was the practice to fill the shelves in cold houses through which the parching wind whistled, when the pots and balls dissolved partnership and the fate of half the plants was sealed before forcing was commenced. This suicidal system, fortunately, has been given up, and we now find professional amateurs—save the mark!—as well as professional gardeners taking a leaf out of Nature's book, and treating perfectly hardy, moisture-loving plants in accordance with their requirements. Although open-air Strawberries frequently lose the major part of their foliage during severe winters, they always flower and fruit well; but what lesson must we learn from our early varieties, now the beginning of November, in every stage of growth from setting to swelling and ripening their fruit? Many crowns no doubt remain dormant, but this persistent growth will tell unfavourably upon our early crops next season. W. Coleman.

Eastnor Castle, Ledbury.

Trees and Shrubs.

THE MONTEREY CYPRESS.

Among coniferous trees there are few that possess more merits than Cupressus macrocarpa. It is fast growing and beautiful at every stage of its growth and in every form. Its verdure is exceedingly rich, dark and very luxuriant; its branches reddish; and the long whip-like shoots impart a peculiar grace to it. Unfortunately, it cannot be absolutely depended on as hardy in every position or district in this country. Notwithstanding, however, its liability to be cut off when a bad year comes, the beauty and grace of this tree, even in its young stage, are so great that we may be sure it will always hold a place around our English country houses. When killed it must be replaced. It should, perhaps, be noted that a variety of Cupressus Lawsoniana (a much hardier plant) has been met with, possessing exactly the same habit and port as the fastigiate variety of C. macrocarpa; its colour, however, is not equal to that of the latter, although very beautiful in its own way; but the green of C. macrocarpa is peculiarly rich, and no other Cypress possesses it. It is particularly distinguished from other species of Cypress by the great size of its cones, which are nearly 2 inches long, and are borne in clusters of three or four.

Those who were familiar with the Royal Horticultural Society's Garden at South Kensington for a few years after its formation will remember with regret two magnificent plants of Cupressus macrocarpa which stood immediately under the terraces, one on each side of the waterfall. These had been brought from Chiswick, and were understood to be the original plants raised from seed sent home to the Horticultural Society by their collector, Mr. Hartweg, in 1847. For a year or two they were one of the chief beauties in the way of plants that were to be seen in the garden. Then they get darker in colour, and less healthy in their appearance; their foliage lost its denseness, and the branches got scraggy, and finally they disappeared. It was the town soot that killed them, or at least so enfeebled them, that they fell easy victims to the first untoward circumstances with which they had to contend. But these were by no means the only fine specimens of this magnificent tree which, at that time, might be seen in the neighbourhood of London. At Kew there were splendid examples, and everywhere this Cypress grew with a luxuriance and a beauty that seemed to indicate that it was perfectly suited to our climate. It had stood with little damage the cold of 1860-61, the severest winter that has been felt by this generation; and yet where are all our fine specimens of it now? During the terrible winter of 1866 the London district was utterly denuded of this tree, so was the south and the east of England. The midland counties were less severely dealt with, and Scotland and Ireland suffered but little. This was the more remarkable, inasmuch as it is a native of a warmer climate than even the south of England. The facts connected with the wholesale slaughter of 1866 are difficult of explanation. It has been observed that a plant may stand one severe winter and give way to another not so severe if it occurs within a few seasons after the first. It is as if the vital energy of the plant had sustained a shock which weakened it and left it less able to withstand another. Cupressus macrocarpa is a tree which it is the interest of everyone to preserve amongst us. It is to Cypresses what Pinus insignis is to the Pines. Both are distinguished by their fine grass-green hue, which gives them a freshness and brightness unequalled by any other Cypress or Pine. The fine slender whip-like shoots of this tree, with their rich red bark, give an attractive elegance to its motion under the breath of the wind. This species may be regarded as the representative or equivalent of our largest European Cypress (the Cupressus sempervirens) on the Pacific coast of North America. Like it, it reaches a great age and a great size; its foliage is similar, and, as in it, the fruit is large and hard, differently shaped, indeed, being oblong instead of round, but of the same character.

The Tansy-leaved Thorn.—This Thorn (Crataegus tanacetifolia) is especially noticeable just now, not only on account of its sharply-cut, distinct hoary foliage, but also on account of its large yellowish fruits. It forms a stiff-growing tree, totally devoid of any graceful character whatever; but, notwithstanding that, it is so distinct, that it should be more popular than it is The bark is of a peculiar ashen tint, which, combined with the distinct greyish foliage, causes a specimen of it to have a hoary and venerable appearance. The flowers are produced very late in the season, frequently not opening till June is well advanced, while the berries are as large as a Cherry, of a yellowish hue, and borne in the greatest profusion. This Thorn is a native of Asia Minor, and has been known in this country for about a hundred years, but, except occasionally in some old-fashioned garden, it is very rarely to be met with.—H. P.

The white Dogwood (Cornus alba).—When planted in a sunny spot this Dogwood, as it is often called, furnishes a colour rarely seen among other shrubs during the dull days of winter, and by associating it with the golden-barked Willow (Salix vitellina) some charming effects may be produced. As the most prominent feature of this Dogwood is the bright red bark, the name of alba (which refers to the fruit) appears at first to be somewhat of a misnomer. It is a shrub interesting in all stages, as the clusters of white blossoms are ornamental, and the foliage is ample even under somewhat disadvantageous conditions. This shrub is a native of the northern part of North America, and is said to inhabit the banks of rivers and lakes, while here, though it prefers a fairly moist soil, yet it by no means refuses to grow in dry spots. Another name for this species is C. stolonifera. The common Dogwood (C. sanguinea) is a British plant, and is, besides, widely distributed throughout Europe. The specific name is derived from the bright red hue that the leaves acquire in autumn before they drop, but at no time is that feature so prominent as the red bark of C. alba, to which the name of sanguinea might more fitly have been given. There is also a variety of this in which the leaves are edged with white.—T.

The common Barberry.—Interesting notes by two correspondents in The Garden (p. 370), and the sight of some magnificent plants of abnormal size and perfect symmetry laden with berries by the roadside recently, urge me to add my testimony afresh to the extreme beauty of this native plant. Not only is there a purple-leaved strain of this Barberry, but on many soils the whole of the young shoots come purple in the early spring, and continue that lively colour till towards the middle or end of the growing season, when they merge into a dull green. The more normal type also fades into a variety of brilliant tints. In addition to the extreme beauty of its fruit,

excelling, if not wholly eclipsing, every berried plant in the garden in the extreme elegance of its drooping bunches of coral berries, the flowers are also beautiful earlier in the season, and, as your correspondent "E. H." well says, the plant has a chaste, elegant appearance when in flower in the spring, and even when leafless in winter it is not unornamental. This Barberry also makes a good hedge plant either mixed with White Thorn or alone, its sharp thorns and dense habit rendering it impenetrable. The chief reason, I believe, why it is so little used for the latter purpose is a prejudice against it among farmers, amounting almost to a rural creed in many parts of the country, that the Barberry causes mildew on Wheat. Barberries are not only used to make a most beautiful and chaste coloured preserve, but the bunches of fruit are also conserved whole, and in this state form a useful dry fruit for dessert as well as for the decoration of other dried fruits. Humble as it is, the Barberry has also proved very useful for dinner-table decoration, few combinations having a more cheerful and chaste effect than one of the leaves and fruit of this Barberry laid on the cloth, while the finger glasses are also furnished with tiny bunches of its delicately shaped coral berries.—HORTUS.

The variegated Walnut tree (Juglans regia variegata).—This remarkable variety was raised from seed of J. regia laciniata. The leaves, and occasionally the bark of the branches, are pleasingly variegated with yellowish white, which contrasts finely with the lively glistening green of the rest of the foliage. The variegation did not appear until about the second year of the growth of the seedling.

The Burr Oak (Quercus macrocarpa).—This is perhaps the most ornamental of American Oaks. Nothing can exceed the graceful beauty of these trees when not crowded or cramped in their growth, but left free to follow their own mode of development. Who has not admired these trees in American Burr Oak openings? Their large leaves are dark green above and a bright silvery white beneath, which gives the tree a singulary fine appearance when agitated by the wind. The wood is tough, close grained, and more durable than that of the White Oak, especially when exposed to frequent changes of moisture and dryness.

Buddleia globosa.—I saw this plant during early summer blooming very finely in Mr. Samuel Barlow's garden at Llandudno. It was planted on a warm, sheltered, sunny border, where it grew luxuriantly and flowered freely. It will hardly stand our winters north of the Trent, and when planted out in the northern parts of the kingdom, it should be against a south wall. Even if cut down by frost, however, it will spring up again luxuriantly. To those who are unacquainted with it I may describe it as a deciduous shrub, growing 10 feet or 12 feet high. It has lance-shaped leaves of a dull green, much veined and netted; the blossoms, which are handsome, are like round balls, as large as Cherries, and deep golden. They are in perfection in May and June. It should be planted in rather dry, and well-drained soil.—R. D.

Syringa Emodi.—This Himalayan Lilac is additionally valuable owing to its flowering late in the season. It forms a large, stout-growing bush or small tree, the flowers of which are white or sometimes tinged with lilac, and borne in erect panicles. A plant studded with these spikes of blossoms is very ornamental. They are also strongly scented—indeed, too much so for close acquaintance, but at a distance the odour is not unpleasant. It thrives as well as the common kind in ordinary garden soil, and is quite hardy.—T.

Double-flowering Cherry (Cerasus serrulata).—This Cherry forms a very ornamental deciduous, somewhat erect tree-like shrub from 6 feet to 8 feet high, with stout branches sparsely furnished with laterals, which in April are thickly clothed with numerous clusters of large double flowers that remain long in perfection; on account of this and its dwarf tree-like appearance, it is the most desirable of all the double-flowered Cherries for a small garden. It is a native of the north of China, where it is called Young-To. It grows freely in any good garden soil, and is increased either by budding or grafting on the common Cherry stock. It was first introduced into this country in 1822. The leaves are obovate-pointed, quite smooth, bristly serrated on the edges, alternate on the young shoots, but more or less crowded together on the other parts, and very like those of the Bigarreau Cherry both in size and shape. The flowers are double, white at first, but afterwards, when fully expanded, tinged with red and produced in clusters on the previous year's growth.

Retinosporas.—A score or more varieties of these hardy and graceful trees are grown in nurseries in the United States, and no fewer than thirty distinct varieties of the interesting Japanese Maples. The frequent communication between America and Japan now-a-days has led to the introduction of many Japanese plants, which are found to withstand the extreme cold of the Northern States.

Pinus koraiensis—In THE GARDEN (p. 371) this Pine is described as synonymous to P. parviflora. I can hardly think that "E." possesses the true kind, for, without doubt, they are perfectly distinct. The leaves of P. parviflora are about 1½ inches long, and much more glaucous than those of P. koraiensis. The tree also cones more freely and is not so compact in growth. The leaves of P. koraiensis are about 4 inches long, and the habit of the tree is compact. The two species are both worthy of a place in every pinetum.—W. O., *Fota, Cork.*

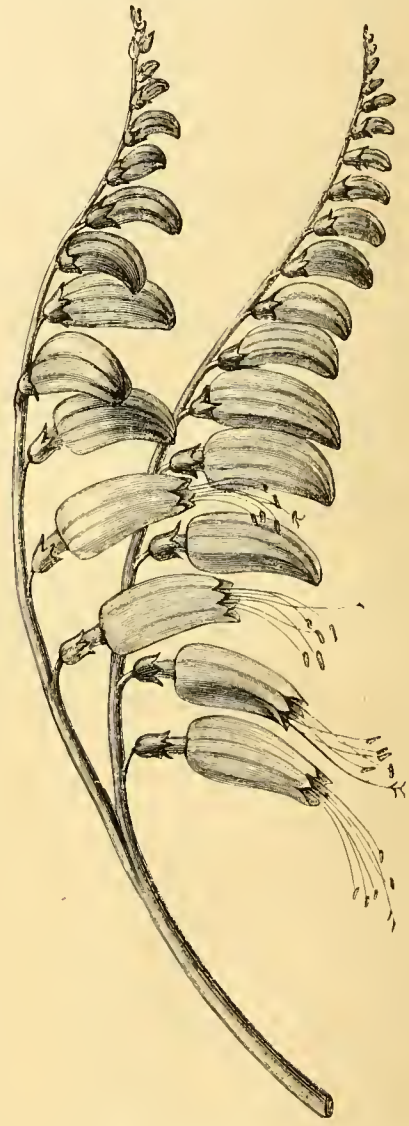
Autumn tints.—I send you a few autumn leaves—leaves of Acer Ginnala of the brightest crimson, and, more beautiful still, leaves of Rosa rugosa, of marbled green and yellow edged with the brightest red. We think the latter carry off the palm for beauty amongst all autumn leaves. Unfortunately, it is not every plant of Rosa rugosa which has such leaves. We have many plants, but only one has the leaves so highly coloured. This we cannot explain, but suspect the explanation lies in the fact that the plant in question is fully exposed to the sun all day, and perhaps there is something in the soil that affects the foliage. The leaves of Rhus typhina have also been very fine. The tree has been, as "E. V. B." beautifully describes it (in her delightful little book, "Days and Hours in a Garden"), as if a sunset cloud had settled down upon it." The leaves of Rhus Cotinus surpass, we think, those of R. typhina, but both and the Acer are, in our opinion, left behind by the Rose.—W. H. TILLETT, *Sprowston, Norwich.*

*** The leaves had, when they arrived, lost a little of their freshness, but when dipped in water they recovered much of it, and were very beautiful.—ED.

5529.—**Pruning Cotoneaster Simonsi.**—When properly managed, this fast-growing sub-evergreen is one of our best hardy wall trees. If "G. C." examines the young growths, he will find flower-buds formed in the axils of all or nearly all the leaves; spurring back removes them, when, as a matter of course, he loses the berries. Some years ago I planted a number of trees against an old stone wall facing the north, and tried the same plan, but finding I not only lost the fruit, but was in a fair way of losing the trees also, I changed my system, which is as follows: Old trees which had thrown up perhaps a dozen shoots early in the spring were pruned upon what Grape growers would term the long-rod principle, *i.e.*, every alternate shoot was cut down nearly to the ground; in some cases two out of three shoots were taken. The trees the first year looked rather thin, but they threw up vigorous growths, which were nailed in intact to flower, when the old ones in their turn were cut away. This long-rod principle has now been followed up for several years, and the wall, about 6 feet in height, is always furnished with fresh bright shoots, neither too close nor too trim, literally covered with berries. If the wall in question is too high for one or at most two years' growth to reach the top, "G. C." must try another variety: probably C. microphylla, a most beautiful evergreen wall shrub, might answer his purpose. This, however, in course of time gets rather wild, but it is not so impatient of the knife as C. Simonsi.—W. COLEMAN, *Eastnor Castle, Ledbury.*

MINA LOBATA.

THE genus Mina is closely allied to Ipomæa, from which, however, it differs in several particulars. The flowers, which are very persistent, are produced on forked racemes, and their bright colours are shown off to advantage by the deep green foliage, which is dense and luxuriant. The oldest racemes attain a length of from 15 inches to 18 inches, and produce from thirty to forty reddish yellow flowers on each fork. The flowers, which are tube-like, measure when fully developed three-quarters of an inch in length, while the uppermost coloured bud is only one-eighth of an inch long. The plant is a rapid grower; seeds of it should be sown in March and the seedlings cultivated in pots until the middle of May, when they can be planted out in the open ground. By the beginning of August they will have formed pyramids over 18 feet in height, well furnished with foliage and profusely covered with flowers, as will be seen by the annexed illustration, which shows part of a pyramid reduced from a photograph. It is a plant which likes a sunny situation and is well suited for covering arbours, trellises, &c. It was introduced to this country many years ago, but seems to have been lost. It was figured in the *Botanical Register* in 1842. In all probability it did not mature its seeds, and hence its disappearance.



Flowers of Mina lobata (natural size). Colour, reddish orange and yellow.

Messrs. Haage & Schmidt, of Erfurt, have, however, we believe, harvested good seeds of it this season, and therefore we trust it will not again be lost to cultivation. It is a Mexican species, and the only one with which we are acquainted belonging to the genus.

ROSE GARDEN.

"MANETTI THE ROOT OF ALL EVIL."

THE planting season is again upon us, and the question just now is continually being asked, What is the best stock on which to have Roses budded, or what kind of stocks had best be planted for budding next year? The question is not difficult to answer directly, but it is even easier to give a negative reply. To invert the words of Canon Reynolds Hole, the Manetti, as a stock for Roses, is the quickest, the easiest, the cheapest, and—the worst. To this statement it may be objected, that as the Manetti furnishes splendid maiden plants, often with shoots 10 feet long; that as Manetti stocks are no trouble to make, it being only necessary to cut sticks with a pair of clippers into 9-inch lengths and insert them in sandy soil to obtain 95 per cent. of workable stocks; that as plants on Manetti may be bought for less than any other kind of Rose tree; therefore the Manetti must be a very economical stock. But, all the same, it remains a most apt illustration of the saying, "cheap and nasty;" and I have no hesitation in saying that if I were offered a thousand Rose trees on Manetti as a gift, I would not be at the trouble of planting them.

The inferiority of Manetti as a stock for Roses is pretty generally admitted, but it is constantly urged as an excuse for its continued cultivation that plants on Manetti will thrive on light soils where plants on Brier will not grow—a contention which my experience at any rate entirely fails to support. Having grown Roses on six or seven forms of stocks, in soils of the sandiest and of the heaviest as well as on mixed soils of various intermediate consistencies, the plants worked on Manetti have in every case been the first to go. They grow magnificently (sometimes) the first year, wretchedly the second, and frequently fail to survive the third. Sometimes, after having appeared moribund during the season, a plant will suddenly seem endued with a fresh lease of life, and it will then be found that the scion has succeeded in establishing itself upon its own roots; in fact, the chance that any variety has of making a permanent plant when worked on Manetti is just in proportion to the facility with which that variety will strike as a cutting. To take a single instance: nurserymen will often tell one that it is no use working the Austrian Briers on Manetti—that they will not so succeed for long; and anyone who has ever wasted their time and material in trying to strike cuttings of the Austrian Briers will at once see the reason why. This is the real reason, also, for the constantly-reiterated injunction to plant with the union of stock and scion below the surface of the ground; not to keep down suckers, nor because it is good for the roots to be buried deep, but because, if otherwise, there is hardly a chance of the plant surviving for any length of time. The contention that the Manetti is the best stock for light soils seems to have been based on the assumption that its more fibrous and shallow roots would be better able to avail themselves of what moisture there might be on sandy land; but, on the other hand, in case of great drought, their roots, being fine and near the surface, are far more likely to be burnt up than those of the Brier, which are able to travel farther and deeper in search of moisture, and in case of a wet season the comparatively soft Manetti fibres are extremely liable to rot. Again, the roots being so shallow, they are sensitive to sudden changes of temperature, and a rapid alternation of heat and cold being especially conducive to mildew, it happens that Roses on Manetti get mildewed to an abnormal extent.

That this character of Manetti is not the accident of any local influences is shown by the fact that similar objections are made to it by well-known growers in such various parts of the country as Surrey, Berkshire, and Lancashire Hertfordshire, Essex, and Nottinghamshire, Oxford and Cambridge, and Kent and Stirlingshire, where, in comparison with other stocks, the Manetti has been largely tried and found wanting. A further very strong indication of its inferiority may be found in the fact that in some large nurseries, both in this country and in France, the Manetti stock has been entirely discarded, while in nearly all it is year by year further giving place to the native Brier. For it is the native wild Rose that long trial has proved to be the best stock for garden Roses in this temperate climate, and though we may well be grateful to the Italian rival that so long held undisputed sway as a dwarf stock, for having made Roses plentiful and cheap and for having broken through the system of growing Roses only as standards, yet we can well dispense with the further services of the foreigner. I say wild Rose advisedly, rather than R. canina, for there are several other species that may be employed. Of those practically useless as stocks may be mentioned, of course, R. spinosissima and R. mollis, also R. arvensis and rubiginosa; but those available are R. inodora, tomentosa, systyla, canina, and cæsia. The two last named are certainly the most valuable, R. cæsia especially, for those who prefer seedling Briers, since it always fruits in profusion, and being of compact, sturdy habit makes manageable young plants, while its native climate of Perthshire ensures it pretty complete hardiness; and R. canina's good qualities are enhanced by the great advantage of the very general distribution of the species.

The objections that are chiefly urged against dwarf Brier stocks by those who are enamoured of the fatal facility of the Manetti are, that the former are difficult or tedious to make and more so to bud; while in the case of seedlings the young plants are always smothered with mildew. To take the case of the seedling Briers first: It is obvious that if the seed be sown annually, the length of time taken by the seedlings to attain maturity is not very material, since as soon as the first crop of plants is ready to use there will always subsequently be a constant succession. It is true that in the young state the plants are very subject to mildew, but they grow out of it and seem none the worse, and by the time they

Mina lobata; showing habit of growth. Engraved from a photograph.

are ready to be budded no abnormal liability to this pest is apparent.

The best method to adopt in raising seedling Briers is to place the heps as soon as gathered in boxes of sand, to be left out of doors exposed to the weather during the winter; the fleshy part of the fruit thus rots away, and at the same time the seed swells somewhat, ensuring a more even and rapid break when it is finally sown than if kept dry during the winter. In March the contents of the boxes may be turned out and rubbed together between the hands to separate the seeds which will still be lying in hep-like aggregations, though the outer husk of the hep will have perished, and then the mixed seed and sand may be sown together on prepared seed-beds. The seedlings will come up thickly, and in November should be taken up and "heeled in" in some sheltered place under a wall or fence until the following March, when they are planted out in nursery beds. In this process two sizes should be made of the plants, as the largest will be ready to bud the year following, while the smallest will have to wait another year. The difficulty of working these stocks is unfortunately more real than any other objection urged against them, although, like all other difficulties, it may be overcome by practice. But the buds have to be inserted upon what may be called for practical purposes the tap-root of the plant; that is to say, just below the crown or collar from which all the branches spring, and as this root-like stem is often crooked and twisted, in addition to having but a thin bark, the successful insertion of buds is a matter requiring at first considerable patience and care; but that extensive trade-growers can afford to dispense with all other stocks is proof enough that the difficulty may be overcome, and the superiority of the resulting plants to those worked on Manetti is well worth a little additional trouble.

None of the charges, however, that are brought against the seedling Brier hold good against Brier cuttings, and where the slight extra trouble of raising and working the former is considered excessive, the latter may well be employed, for there is very little difference discoverable between plants on the two forms of the native stock, and though the Brier cuttings want a little more care in the actual making, yet they are ready at the same time and are just as easy to bud as the Manettis. It is sometimes said that Brier cuttings do not root readily enough to be available as a general stock, but this is not the case when they are properly made. Taking the average for the last three years, I find that the Manetti cuttings have produced something over 90 per cent., and the Brier cuttings between 75 and 80 per cent. of workable stocks, a quite sufficient proportion for practical purposes.

Brier cuttings cannot be made with a secateur, but must be knife-made, and they are preferably made with a heel, though this is not essential. Well-ripened shoots having been cut into 9-inch lengths, all the eyes except the top two or three are removed with the knife; a long nick is made in the ground with a spade and filled with white sand, and in this the cuttings are firmly inserted about 2 inches apart, and with not more than 2 inches of their length remaining above ground. In this way the rooting of a large percentage may be ensured. The time of year at which the operation may best be performed depends somewhat upon the season and the time at which ripe shoots can be obtained for cuttings; as a rule, the sooner after the middle of September that the requisite materials can be found the better, but any time till the end of November will serve. Still there is no doubt that the earlier planted cuttings yield most stocks.

All dwarf stocks should be transplanted and root-pruned in the November following (that is, twelve or fourteen months after) their insertion as cuttings, and then be heeled in during the winter, and not be planted out in lines where they are to be budded until the following spring, for it is desirable that the stocks should be not deeply planted, in order that the buds may be inserted close on to the roots; if, however, shallow planting in autumn be resorted to, the stocks will be drawn out of the ground by the frost and before long will be falling about in all directions; and if, to avoid this, the stocks be planted deeper, the buds are liable to be inserted too far above the roots and the plants will subsequently appear upon stems. This may be avoided by drawing the earth away from the stocks when budding them, but that hinders the budder, wasting his time and prolonging his work, and even if it is done, a sudden thunder-shower just after the stocks have been budded may wash all the earth back and bury and choke the buds. The exigencies of nursery arrangements may involve the necessity of planting stocks during the autumn in great nurseries; but amateurs with their comparatively small number of stocks are not bound by routine to the same extent, and by deferring the planting until a showery day in March, or even April if March continues dry, all trouble and danger are avoided, and the stocks may safely be planted quite shallow and will be growing freely in plenty of time to receive the buds, which can then without further trouble be inserted close down to the roots any time from June onwards.

Some of the advantages of the Brier as a dwarf stock are, that the Brier being less precocious than Manetti, plants worked on the former are less liable to start into growth too early and get cut back by spring frosts; and that the great hardness of Brier roots enables them to endure on cold, wet soils without rotting, while in case of drought they are able to travel to great depth and distance in search of moisture. The roots of seedling Briers generally go straight down into the soil, but those of Brier cuttings extend more laterally and are even more fibrous, so that Brier cuttings especially make stocks admirably adapted to soils of any consistency, whether light or heavy.

Of the various other stocks that have at times been employed, there are three that are still not unfrequently used for Roses, namely, a variety of R. multiflora called De la Grifferaie, R. polyantha, and a China, Madame Plantier. The last is of no special value as a stock, and the first-named is too lusty for many varieties, though it answers well for some of the climbing Teas of Gloire de Dijon race, but it is so liable to mildew, that it is not a desirable sort to have among young plants in the propagating ground, and for this reason I have discarded it in favour of R. polyantha. My experience of this Japanese species is not yet sufficiently extended (having only employed it during three years) to enable me to say how far it is available as a stock for all varieties, and it also may prove too vigorous for the weaker-growing kinds; but very vigorous sorts, especially the stronger Teas, do well upon it, and if it should prove generally useful, there will be no complaint of difficulty in propagating it for stocks, as it is the most freely-rooting Rose I know. I have put in cuttings in the open ground in September and had them so well rooted before Christmas, that in the following March some were planted in permanent situations where they were to flower, and the rest were planted in nursery rows and budded in the ensuing July ten and a half months after the insertion of the cuttings. Of course Manetti may occasionally be treated in the same way, though not to any great extent; but if R. polyantha should prove, as a great French grower has declared it to be, a first-rate stock for all sorts of Roses, it will be no mean advantage to be able thereby to save a year in case of emergency.

As at present advised, however, the answer to the question which is just now being asked on all sides, "What is the best stock on which to grow Roses?" is undoubtedly: The best stock for Roses in this country is the native Brier, of which the most valuable species are R. canina and R. cæsia, and as for the respective merits of seedling and cutting, it seems to be about six of one to half-a-dozen of the other.

T. W. G.

Souvenir de la Malmaison.—This favourite Rose furnished us with numbers of valuable blooms all through last month, which is later in the year than blooms are usually produced in large numbers. As a September Rose I do not think it has an equal, its half-open buds being then very charming. Early in the season it produced some perfect flowers, a circumstance I do not remember to have happened before.—J. C. C.

Tea Rose Sunset.—In the Salisbury Nurseries I recently saw a good breadth of this comparatively new variety in the form of half standards on Brier stocks. It has bloomed very freely and would do so till damaged by frosts. The blooms are fine and double, and may be briefly described as a marked improvement on Madame Falcot. In pots the foliage and habit are very distinct, but in the open the young shoots in the autumn are really beautiful, and used in bouquets or vases would be remarkably effective. The colour of the young leaves are, as nearly as I can describe them from memory, of a deep metallic red and most attractive.—W. I.

FRUIT GARDEN.

ROOT-PRUNING.

SEVERAL features of growth and of climate combine to give the practice of root-pruning special importance this season. The Indian-like summer weather and heavy rains have fostered strong growths, while the scanty Apple crops in some localities, under the average yield in most, and the abnormal freedom of the trees from insect pests, have all helped to develop a crop of wood of exceptional size and vigour. Growth is likewise late as well as vigorous. Seldom or never have the leaves of fruit trees been so fresh and green as in these opening days of November; hence the unripe state of not a little of the young wood this autumn-tide. Rightly interpreted, this furnishes a powerful appeal for root-pruning. Already it is almost too late to check the roots so as to heighten and hasten maturity. But something may yet be done to check or stop further supplies of sap, and thus render the wood less succulent, and consequently in less danger of becoming food for frost in the spring. As it is the spring frosts that blight and blast promising crops, and cripple and destroy our fruit trees, this simple method of making them more hard at that season, by curtailing their sap in the autumn, is one of the greatest practical importance. And this root-pruning doubtless accomplishes; for whatever theory of root structure or function may be adopted, no one can deny that the disturbance of a part or the whole of the roots, the detachment of a part or the whole of them from the soil, and the pruning off of some of them necessarily limits the supply of fluids and hastens and heightens maturity. So close is the correlation of perfect ripeness of wood to annual fertility, and so necessary is the latter to profit, that but little more need be added to enforce the practical importance of root-pruning. It is so far also one of our most potent means of protection, insomuch as it enables the tree to protect itself in two ways. It makes it hardier and it forces it to be later, and it would be difficult to say which of these is the more valuable in securing per-

petual fertility. Root-pruning is also the most powerful means at our command for limiting the size of fruit trees and moulding them into shape. Hardly had fruit trees left the open forest or field when the necessity of curtailing their size and altering their natural forms arose. Doubtless both these legitimate objects have been pushed to most absurd and unprofitable extremes. In parks, orchards, or woods fruit trees may safely have the fair run of their heads, and also of their roots, so soon as fertile habits have been established. But in gardens, and especially small ones, space is often very limited, and hence restrictions, more or less severe, must be laid upon growth. Fruit trees and bushes must either be starved, cramped, pruned, worked, or fruited into small dimensions.

Leaving the starving, cramping, dwarfing stock methods of limiting the area of fruit trees or bushes, let us note the effects of root-pruning. In nothing were the older cultivators more hopelessly beaten than in their persistent attempts to limit the size and improve the form of their fruit trees by pruning. The fact is they began at the wrong end. By their severe prunings of the tops and leaving the roots intact, the former necessarily became the more vigorous, and also the more difficult to force into or keep in any desired form. But the trees that resist and defy the powers of the knife on their tops are immediately amenable to its smallest cuts on their roots, and thus root-pruning has solved the problem of the size and form of fruit trees, and enables us with ease to regulate both at will. It has done more and better than this, and has enabled us to adjust the proper balance between growth and fertility, so that the current year's wood shall provide for the wants of the current year's crops of fruit, and also for the preparation and fulfilling of the succeeding year's fruit beds. When this perfect consummation, so devoutly to be wished by every rational root-pruner, is reached, then should the root-pruner gratefully rest from his labours. But, unfortunately, like not a few knights of the pen, the root-pruner does not always know when to stop. He not seldom goes on pruning long after all need of it has ceased, and it is this excess or abuse of root-pruning that has so often caused it to be disparaged or evil spoken of. So soon as it has succeeded in reducing the size of the trees to the desired extent, moulding them into form, and establishing their fertility, root-pruning should cease. To continue it afterwards is like swallowing medicine after the cure is perfect, or probing a wound after it is soundly healed. Neither would be more foolish nor dangerous than the knife on the roots after fertility is so often repeated as to become an established habit; for, like other habits, fertility once firmly established repeats itself with something like automatic certainty. But fruit trees may once more relapse into sterility.

One of the most powerful disturbers of a fertile habit is the loss of a crop of fruit. Thus relieved from its annual load through frost-bite, blight, or other accident, the fertile tree may again relapse into barrenness and rush wildly into wood-making. Unless this is promptly arrested by root-pruning, not one only, but many crops may be lost, for the tree, having reverted to the habit of growing gross shoots, is likely to repeat it unless once more checked by root-pruning. It is not, however, always needful to root-prune trees that cast off or lose a crop of fruit. Occasionally trees slip a crop through exhaustion; either root-pruning may have been indulged in to excess, or over-cropping been repeated so often that the vital forces of the plants have been crippled or exhausted. What such trees need is not more pruning, but lighter crops and more food. In this connection, it should be borne in mind that miscalculations in the manner or amount of root-pruning are almost sure to result in excessive fertility. The dangers of the latter may be met in various ways, as, for example, by early and severe thinning of the fruit and liberal feeding with liquid and solid manures, the latter applied in the form of surface mulches, &c. This is absolutely necessary to sustain the stamina of the trees under the abnormally heavy burdens that root-pruning imposes on them, and also to develop the bulk of the fruit to the largest possible average size and quality. Growers of fruit for sale (and who is not in these hard times?) find that none but the finest samples pay a handsome profit in the crowded markets. I have lately noticed some Pitmaston Duchess and Marie Louise Pears equal to those of Channel Islands fruit, their unusual size and excellency arising solely from prompt and severe thinning.

To leave the root-pruned tree to struggle with its whole load of fruit thus artificially augmented is just as unreasonable as to go on root-pruning it after its fertility has been hardened into a habit. The trees themselves teach us useful lessons in fruit-thinning by shooting off a portion, or a whole, of their crops when these are too heavy for their vital powers to bring to perfection. Nature, however, in this, as in many other things, is apt to run to extremes. In her attempts to strike a fair balance between the tree's back and its burden it not seldom drops its entire crop, while the observant cultivator will so skilfully balance his dual prunings, and nicely adjust the supply and exhaustive forces of the trees, so as to land a good crop alike of fruit and of wood annually, and thus preserve their health and extend their longevity. The most likely modes of securing these ends through root-pruning will be pointed out in my next and concluding paper.

RADIX.

A VALUABLE LATE PURPLE PLUM.

WILL "A. D.," or some other correspondent well acquainted with the great fruit fields about London, kindly say if it is really the fact that Mitchelson's Plum is fit for use early in September? Compilers of books and some catalogues say it is then ripe, and I am not in a position to say they are wrong; but I may assert that with me the variety grown under this name is not ripe before the end of October. Possibly, from a grower's point of view, it may be fit for market, but if it is ripe, our Herefordshire climate is sadly at fault, or otherwise I have got a later, consequently a more valuable, variety. Just now we are gathering fresh, sound fruit, the which, in the absence of frost, would keep good certainly until the middle of November. It is described in several good catalogues as of medium size, oval, dark purple; flavour very similar to that of a Damson, a great bearer, and ripe early in September. A great writer on fruit says, "the flesh is yellow, tender, juicy, sweet, and of good flavour, separating freely from the stone. In general appearance similar to the Diamond, but smaller, and does not possess the brisk acidity which characterises that variety." The above descriptions faithfully pourtray the character and quality of my fruit, fair samples of which measure 1½ in. in length and 1¼ in. in width, but I cannot get over the season of ripening, and this difference, as may readily happen when nurserymen's descriptions are taken from books, induces me to ventilate the question. A really good cooking or preserving Plum, the size of a small Diamond or a large Damson, which comes in almost with the glut, is comparatively of little value, but if it is the fact that it will keep in good condition until the middle of November, why then it is quite as valuable in the kitchen as Golden Drop, now a sweetmeat, is upon the table. Soil, season, and climate, even in this small island, have a wonderful influence over all kinds of fruit, and it is probable this Plum, which was raised near London, may ripen earlier there than it does with me; but if it is shown that the tree is very hardy and prolific on the coldest soils, and fruit fit for the dessert can be had in November, scant justice will be done until the nurserymen's lists are corrected.

Eastnor Castle, Ledbury. W. COLEMAN.

Peach Madame Pynaert.—The coloured plate of this new Peach in a recent number of the *Bulletin d'Arboriculture Belge* depicts a fruit which as regards appearance is all that can be desired. If possessed of other needful qualities it is likely to become in time a popular kind for market, as owing to its high colour it has a very taking appearance. It is stated to be of vigorous growth and so fertile that severe thinning is necessary. M. Gaujard, the raiser, observes that "the great feature of this variety is that it is so suitable for the open air, the fruit ripening about the 15th of August. As the flowers are extremely numerous, and to a certain extent succeed each other, it is very rare that a portion of them do not escape spring frosts." This is a quality which should recommend this new variety to growers in England. We want hardiness in the Peach almost as much as in any outdoor fruit, and many of our best kinds are wanting in this respect. In quality this Peach is said to be first rate. It comes very large if well thinned, and the flesh comes away easily from the stone. It was raised in 1881. M. Pynaert says that it is as remarkable for fertility as for vigour; the seedling tree is in a pot about 18 inches across, and this year bore sixty large fruits equal in appearance to that illustrated in the *Bulletin*.—BYFLEET.

RENOVATING OLD ORCHARDS.

THE thorough overhauling and renovating of old orchards is work sadly needed in many places, and now is a good time to do it. Even in orchards in fair average condition one cannot fail to observe that many of the trees are not paying for the space which they occupy, owing to the produce being specked and unsaleable. Such trees should be grubbed up to make room for varieties that produce good clean fruit. Trees growing too strongly, too, should be headed down ready for regrafting in spring. Do not cut them down so low as where it is intended to graft them, as if frost is severe it may split the bark; and, moreover, it is always best to have fresh cuts on which to graft, or, if the trees are not very large, root-pruning may be tried; but this is more adapted to garden than to orchard trees. One of the varieties that is specially suited for grafting on free-growing stocks is Loddington Seedling, or Stone's Apple. I have seen grand fruitful trees of this kind formed by grafting it on shoots about the size of one's wrist, putting fifty or sixty grafts in this way on a tree. In about three years such trees become more profitable than they ever were before, and they continue to get more so as the head of branches extend in size. I have never seen these double-grafted trees grow too strongly or fail to be fruitful if really good varieties were put on them. The plan of regrafting fruit trees on the small wood at some distance from the trunk is a decided improvement on the plan of cutting back to the large limbs. Although the grafts grow on the latter, they never heal over as they do on the small branches: consequently, at the point of junction, a portion of dead wood is left that in time decays, and the loss of limbs sooner or later is the result. The small spray-like shoots not large enough to graft on should be left to grow for a year, in order to keep up root action. During the following winter they can be cut clean away. Filling up gaps where old trees stood with young ones is an important matter, although in the case of many orchards held on leases there is no room for consideration, as it is distinctly stated that when an Apple or Pear tree is cut down a young one of the same kind must be planted. Now this is just what ought not to be done, as there can be no doubt that if changes of crops give such good results in the kitchen garden, they are far more necessary in the orchard. Though the soil may be worn out for Apples and Pears it may yet grow fine crops of stone fruits, Nuts, or bush fruits, and I have no hesitation in saying that if our orchards are to produce anything like the best results of which they are capable, they must be treated more as our vineries are; *i.e.*, as soon as they begin to fail the old trees should be rooted out and a fresh start made; it is folly to expect that a young tree planted in the shade of other trees in soil already exhausted will make

much headway. Since, however, it is compulsory to plant young trees of the same kind where others previously stood, the best course would be to cart the exhausted soil right away and substitute new soil. Large holes sufficient to hold three or four cartloads of soil should be dug, and filled in with any fresh turfy mixture; then plant the trees, stake them securely, and mulch the roots with manure. I believe, indeed, that mulching would of itself obviate many of the ills from which orchard trees suffer. If the roots can be kept at work near the surface, the growth made will ripen well and the trees will in consequence become fruitful. Trees even in good bearing condition should all be gone over with a small handsaw in order to clear away the small spray-like growth from their centres, as it is only on the outside that good fruit can be perfected. Then dust with lime and surface-dress with manure, and a marked improvement will soon be observable in the produce. J. G.

Hants.

KITCHEN GARDEN.

RIPE AND GREEN TOMATOES.

In the third recipe for utilising these given in THE GARDEN (p. 417) an important omission occurs, for which I am sorry, as it may be the cause of a loss of pickle, owing to its turning mouldy. Before the Tomatoes and Onions are finally placed in jars or bottles, the vinegar in which they were baked should have been carefully drained off. The juice extracted weakens the vinegar and injuriously affects the keeping properties of the pickle; hence the necessity for straining it off and adding fresh vinegar.

TOMATO SAUCE.—Since my last remarks were made I have been favoured with two excellent, though not original, recipes, one of which is for making sauce that will keep. Accompanying this were two bottles, one made last season and one this, according to the following instructions; and I may add that I found both excellent in every way. Take quite ripe Tomatoes, bake them in a slow oven till tender, rub them through a hair sieve, and to every quart of pulp add one pint of cayenne vinegar, three-quarters of an ounce of shallots, three-quarters of an ounce of Garlic, both peeled and cut into pieces, and salt to taste. Boil the whole together till the Garlic and Shallots are soft, then rub through the sieve again. Return it to a saucepan, and to every six quarts of liquor add one pint of Soy sauce and the same of anchovy sauce; boil together about twenty minutes, and bottle off for use, carefully sealing the corks. This, it was stated, will keep good for two or three years, or it can be used in a week from the time when it was made. Cayenne vinegar is made in this manner: Put half-an-ounce of cayenne pepper into a pint of vinegar, bottle, and let it steep for a month; it should then be strained of, and is then fit for use. I have, however, found the pepper and vinegar to amalgamate in a few days or about a week, but it is much stronger when allowed to stand a month, as just recommended.

TOMATO CHUTNEY.—Very good chutney may be made in which ripe Tomatoes form the principal basis. To every pound of Tomatoes—which should first be baked in a stone jar till quite soft, and then skinned and passed through a hair sieve—add one pound of Demerara sugar, one pound crushed mustard-seed, four ounces of salt, and one ounce of cayenne pepper, and place them again in the oven. Next stone one pound of raisins, quarter and core one pound of Apples, and slice up either four ounces of Garlic or 8 ounces of Onions, and after these have been stewed sufficiently to admit of their being easily broken up, all the ingredients should be well stirred together in the jar, adding vinegar at different times as it thickens during the cooking, which will take four hours in a moderately heated oven. This chutney keeps admirably, and a very little of it suffices at a time. W. I.

Stirring the surface of the soil.—When the surface is dry the hoe or the fork may be used freely among growing crops with advantage to loosen it up. Such work disturbs the young sprouting seeds of weeds and hurries the slug and the snail from their hiding-places, and lets in the air and the remains of the autumn sunshine. When the weather is favourable the stirring of the surface of the soil never comes amiss at any season of the year.—H.

Disease-proof Potatoes.—We do not agree with your conclusions respecting the Potatoes shown by us at the last exhibition at South Kensington; or, rather we may say, your conclusions do not touch the point which we have in view. In distributing such Potatoes as Village Blacksmith and Cetewaye, we have borne in mind that the great effort which every Potato cultivator is now making is to produce varieties least susceptible to disease; and we are of opinion that it is by the aid of two such prominent representatives of this class as those just referred to that new blood will reach the hands of hybridisers, and that the good resulting therefrom will probably be enjoyed in years to come. Ashtop Fluke is admitted to be one of the very best Potatoes as regards quality at present in cultivation. Sukreta, also having obtained the highest possible awards at Chiswick, requires no further eulogium. The outside appearance of some exhibition Potatoes is certainly attractive to the eye, but the merit of many of them ends there. We may mention that when Ashtop Fluke and International were exhibited together, the prize was given to the latter. Why? Simply on account of outward appearance, as all who have tasted International know that it is inferior in quality.—JAMES CARTER & Co., *High Holborn.*

Mushrooms amongst shrubs.—I will be greatly obliged if you will inform me whether the Mushrooms sent herewith are good for culinary purposes? Very large numbers of them have appeared this year in the shrubbery, but having grown under the shade of shrubs and trees doubts have been expressed as to whether they are of an edible variety. If this is the case (but they are considered unfit for eating because grown in shade) would it be advisable to remove the soil which has grown them, and place it in an open field for the production of Mushrooms another year?—R. T., *Windsor.*

*** The fungi sent are true Mushrooms (Agaricus campestris). Mushrooms at times grow in woods and (as in your instance) shrubberies, but in such positions they are sometimes inferior for the table and even unwholesome. One variety of the true Mushroom (var. silvicola) always, as its name indicates, grows in plantations and woods. A close and delicious ally, A. elvensis, grows under Oaks. The spawn could be removed to a pasture, as suggested by you, with a good chance of successful Mushroom growth another year. If you have the shrubbery Mushrooms cooked, you will probably find them all right.—W. G. S.

Improved vegetables.—Those who entertain the belief that the vegetables of the present day and methods of cultivation them are not equal to those in use twenty years ago must have had such delusions effectually dispelled on inspecting the truly wonderful exhibition of vegetables seen recently at South Kensington. Take Carrots, for instance; of these there were numerous samples, so wondrously fine, clean, and beautiful, as to justify the exclamation, perfection! It is but a year or two since the variety known as New Intermediate was put into commerce, and yet already it is the widest grown and most popular Carrot in cultivation. Cauliflowers, too, were everywhere good, fine, white, and solid, and yet Autumn Giant has not been with us for many years. The Snowball Turnips were like balls of wax, so perfect and so clear. Leeks seemed to have come out of moulds, so perfect and so beautifully blanched were they. Tomatoes equalled any fruit grown for beauty and form, whilst their colour was perfect and size all that could be desired. We see nothing of the old sutured Tomato now. It has gone the way of myriads of old things once good in their day, but no longer meeting the requirements of modern tastes, and if anyone will still object to show Potatoes, perhaps a look over the competitive classes of this valuable esculent as well as the large collections put up by the seedsmen at shows would assist to change the opinion so adversely held. The beautiful tubers, snow-white almost in hue and glossy in skin, in others rich in red or purple tints, are but samples of kinds which owe this beauty to good soils and careful cultivation, and would look as rough as any others if the ability of growers was not brought to bear upon their production. We had fairly good Potatoes years ago, but we have far better now; indeed, if there be one thing more than another of which British gardeners may be proud, it is of their Potatoes, and perhaps Onions.—A. D.

MARKET GARDEN NOTES.

In south coast market gardens the land is cropped to its utmost capacity at this time of year, as in early spring growers get better prices for their crops than growers inland do whose crops are later; consequently, they plant largely, not only for the supply of our local markets, but also for sending long distances, should the winter prove severe, as it was in many places last season. Amongst crops that now claim attention are Asparagus, the old stalks of which are now being cleared off, and a good dressing of manure is put on the beds. Sea-weed is largely used in this district for Asparagus; it is easily procured, and certainly suits this maritime plant well. Beetroots are being stored wherever the soil is dry enough to get on it, but excessive rains have lately made it difficult to forward such work. The leaves are cut off the roots at some distance from the crowns, as if cut quite close the roots lose colour. They are stacked closely together in a cool shed or cellar, a little sand being worked in amongst them. The darkest blood-red sorts are those mostly grown. A Turnip rooted or round Beet has also lately become popular. Autumn Giant Broccoli is being marketed in grand condition now, and if mild weather prevails it will be the staple kind for several weeks to come. A later variety with more leaves that fully protect the heads from frost, called Winter Protecting Broccoli, is largely grown to succeed The Giant, and these generally last until Snow's Winter White comes in, and unless exceptionally severe weather prevails, Broccoli of some kind is procurable continuously. Late kinds are now growing freely, advantage being taken of dry days to cultivate between the rows. Broccoli are a valuable crop, and kinds like The Champion that produce fine heads in May frequently realise good prices. Good soil, but not much fresh manure, is what late Broccoli need; if over-luxuriant before winter comes on it is apt to suffer from frost that is harmless to more sturdy plants.

BRUSSELS SPROUTS have grown very strongly, and are already fit for market, but are kept back until the demand for them is brisker. The largest leaves that are very much infested with caterpillars are being cleared off the stems and given to sheep or pigs, so as to let air circulate freely amongst the stems. Cauliflowers of the Early London type are being planted under hand-lights, or at the foot of walls or in cold frames, so as to have a good supply in spring. They are generally grown close to the homestead in the most sheltered places available, as, unlike the hardier Broccoli, they cannot stand the rough winds of the open fields. Endive is now fit for use, and late crops are being put out for spring. Blanching of the successional crops is being done by tying up the leaves or covering the heads with flower-pots or tiles, as when thoroughly blanched they sell readily.

COS AND CABBAGE LETTUCES of the hardiest kinds are being largely planted for spring on dry, sloping borders; the small Cabbage kinds are sown rather thinly, and allowed to stand until drawn out for use. Onions are now being dried in any covered buildings available; owing to heavy rains they have been kept in such a damp condition as not to be fit for storing in large quantities, and the kinds grown here are mostly of the latest keeping sorts. Autumn-sown ones are now growing freely; the beds of White Spanish that are sown thickly for drawing green are most luxuriant. Some are transplanting Giant Roccas already. Potatoes stored early now need overhauling, as disease has shown itself much more since the tubers have been lifted than it did while they were in the ground, and they soon rot their neighbours if not removed. Parsnips are now coming into use, and very fine they are; the short, thick

sorts are the best; many of those which I have lately seen on market carts are at least 18 inches in circumference. They keep best in the soil, as in case of frost setting in they can be covered with litter. Tomatoes grown on open walls are now being gathered and ripened under glass; those planted late under glass, if assisted with fire heat, will yet perfect useful crops. Spinach of the hardy kinds is in this district sown broadcast and hoed out like Turnips, and capital crops in this way are obtained. The ordinary summer Spinach is utilised for early winter use, and the hardier Prickly-seeded is allowed to grow unpicked until severe weather finishes the supply of the softer-leaved kind. Fruits taken collectively, the past season has been above the average as regards bulk of crop; with the exception of Apples, fruits of all kinds have been plentiful and cheap, especially Plums. The gathering of all, except a few of the latest Pears and Apples, is now completed, and the marketing of them is being pushed on so as to clear out all except a few of the latest keeping sorts before the American barrels arrive. Those, however, who have anything like a crop cannot complain of Apple culture not being remunerative, as anything that will pass muster for market at all is worth 5s per bushel, and choice sorts 8s. to 10s., many of the best known kinds for storing not being obtainable. Pears, though plentiful, sell well; large sorts like Pitmaston Duchess realise high prices, and ordinary market sorts, such as Beurré Bosc, fetch from 5s. to 7s. per sieve. Preparations for planting fruit trees and bushes are now being made, as home growers have abundant reason to believe that they will be able to compete successfully with their foreign rivals. The best kinds must, however, be grown, and in the best way. The late glut of fruit and consequent low prices were caused by too many common kinds that ripen simultaneously being thrown on the market. All seacoast towns still depend very much on foreign fruit for their supply, not because it is better, but because they do not get home-grown fruits of good quality and plentiful enough for their requirements. JAMES GROOM.

Gosport.

ORCHIDS.

AMATEUR ORCHID-GROWING.

I HAVE been growing Orchids as an amateur for rather more than two years, and I am anxious to hear from some experienced grower if I may consider that I have been fairly successful. I have two houses, one a span-roofed stove, 45 feet long by 18 feet wide and 17 feet high, in which the lowest winter night temperature is about 62°; the other, a greenhouse, 25 feet long and the same height and width as the other, the lowest temperature in which is about 45°. In both houses a mixed collection of plants is grown. When I started Orchid-growing neither I nor my gardener knew anything about it. I began with twelve small-established plants, viz.: Calanthe vestita, C. Veitchi, Cattleya Mossiæ, C. Trianæ, Cœlogyne cristata, Dendrobium Bensoniæ, D. nobile, D. Wardianum, Lælia Dayana, Odontoglossum Alexandræ, O. gloriosum, and O. Pescatorei. I next bought some imported pieces of Cattleya Mossiæ, Lælia purpurata, and Odontoglossum Alexandræ; the two first did very well, flowering last season and making strong growths; they have been kept in the stove except when in flower, when I put them in the greenhouse. The O. Alexandræ did not do so well; indeed, the less said about any of the O. Alexandræ that I have bought at any time, established or not, the better. My stove is too hot for them and the greenhouse too dry, and they seem to drag on an existence with weak growths and weaker flower-spikes. I have now put them under a small glass frame in the greenhouse, so that I may keep the air round them damper, which will, I hope, cause them to make stronger growth.

Another Orchid of which I bought imported plants is Cattleya Harrisoniana; this has done very well with me, and seems to be growing and flowering all the year round. I have not been fortunate this year with my Dendrobiums. I have kept them throughout the year in the stove, and I fear did not rest them enough last year, and, as a consequence, they have made weak growths, especially D. nobile and D. Wardianum, but a D. formosum giganteum which I purchased established (?) is, after half departing this life last year, now coming into flower from a strong growth. During the last two years I have continued to purchase Orchids, mostly established, until I have now over two hundred plants, many of which, considering the height of the houses and their being used for a mixed collection of plants, have, I think, done fairly well. I have flowered the following kinds, viz.: Calanthe Veitchi, C. vestita, Catasetum tridendatum, Cattleya Gaskelliana, C. gigas, C. Harrisoniana, C. labiata, C. Mossiæ, C. Percivaliana, C. Trianæ, Chysis aurea, Cœlogyne cristata, Coryanthes, Cypripedium insigne, C. Lawrenceanum, C. venustum, Dendrobium Bensoniæ, D. chrysanthum, D. crassinode, D. Devonianum, D. formosum giganteum, D. Jamesianum, D. nobile, D. thyrsiflorum, D. Wardianum, Epidendrum vitellinum majus, Lælia anceps, L. Dayana, L. Perrini, L. purpurata, Lycaste Skinneri, Masdevallia Harryana, M. ignea, M. tovarensis, Maxillaria grandiflora, Odontoglossum Alexandræ, O. citrosmum, O. grande, O. Pescatorei, O. Rossi majus, O. vexillarium, Oncidium ampliatum, O. flexuosum, O. luridum, O. Papilio, O. varicosum, Pilumna fragrans, Sophronitis grandiflora, Stanhopea grandiflora, and Vanda cærulea. Most of these have done well and are strong healthy plants, but my Cattleyas have done better than any others, and are now full of flower-spikes. Those that have done the worst are Dendrobium nobile and Wardianum, and Odontoglossum Alexandræ and Pescatorei. The only established plants that have died are a Phalænopsis amabilis (flowered itself to death) and a Disa grandiflora. May my results be considered satisfactory? M. P. T.

Orchids in flower at Mr. Buchan's, Wilton House, Southampton, include the following noteworthy kinds, viz.: Oncidium Lanceanum Louvrexianum, a kind in which the pure white front of the lip contrasts admirably with the rich violet hue of the basal part; O. tigrinum, with a large yellow lip; O. hæmatochilum, with rich crimson lip, margined with yellow; O. incurvum, O. unguiculatum, O. divaricatum, and O. ornithorhynchum, all good and useful kinds for winter-flowering. Associated with these were also the chaste O. Phalænopsis, with beautiful violet tinged sepals and petals; two species of Indian Crocuses (Pleione), viz., P. lagenaria and P. maculata, both very beautiful; Cattleya maxima, Lælia Perrini and L. Dayana, the latter a gem, suitable either for a block or small hanging basket. Here may also be seen many good forms of Odontoglossum Alexandræ and O. Pescatorei, both of which promise to produce a grand show of flowers in a few weeks' time. Amongst others might be noticed the drooping spikes of bloom of Odontoglossum Krameri, with its violet-rose-coloured sepals and petals, and yellow and purple dottings on the lip; two bold, showy kinds are O. grande and O. Ure Skinneri, both of which are now in great beauty, as are also numerous forms of the smaller O. Rossi majus, the blooms of which are very elegant and last long in perfection. The flowers of constrictum, although not large, are very gay, and are produced on large branching panicles, the sepals and petals being bright yellow, variously blotched with orange-red and brown, whilst the lip is white and irregularly spotted about the centre with rose. The showy O. Roezli, and the less conspicuous O. Wallisi, tripudians, and madrense close the list as far as Odontoglossums are concerned; the last named species is usually considered to be more a summer than a winter bloomer. The different forms of Lycaste Skinneri may be depended upon to maintain a certain amount of gaiety up to the end of the year. Dendrobiums are represented by the beautiful white-flowered D. formosum giganteum and D. Dearei; the last named species appears to thrive here remarkably well, whilst the flowers of both kinds last a long time when cut and placed in water. Other Dendrobes here are D. superbiens and D. bigibbum, both richly coloured sorts. Amongst Lady's Slippers are good forms of C. Maulei, C. Harrisianum, C. Sedeni, C. Spicerianum, and the beautiful C. Schlimi. The long spikes of bloom belonging to the Calanthes protrude from amongst the green foliage of other Orchids in quite a charming way; the sorts are the red-eyed C. vestita and a fine form of C. Veitchi called superba, whilst the evergreen, erect-flowering C. veratrifolia supplies ample foliage to set off its pure white flowers. Masdevallias also contribute largely to the general effect. M. Davisi, with yellow flowers, the gay-coloured M. Veitchi and M. amabilis, and the snowy-white M. tovarensis are all most attractive. Mesospinidium vulcanicum, the counterpart of Odontoglossum roseum, blooms freely here, as does also Cymbidium Mastersi, which, although smaller than its near ally, C. eburneum, is specially welcome at this season of the year, its flowers being pure white with a faint stain of yellow on the lip, and they yield a delicate odour resembling that of Almonds. C. giganteum is less handsome, but yet a fine species. Its flowers are yellowish green streaked with dull purple, and the lip is yellow and spotted round the edge with crimson. The Paphinias are singular plants; they delight in strong heat, and should be grown in baskets. Two kinds are in bloom here. The first is P. cristata, with flowers some 3 inches across, and sepals and petals white, streaked and transversely banded with rich brown, while the lip, which is somewhat small, thick, and fleshy, is chocolate coloured, with a white downy tip; the column, which is large, is yellowish white. The second is P. rugosa, which is similar in size and shape to P. cristata. It differs, however, in colour and markings, the sepals and petals being creamy white spotted and blotched with brownish purple; lip purplish red fringed with white. Amongst the Moth Orchids (Phalænopsis), P. Sanderiana, which somewhat resembles a rose-coloured form of P. amabilis, is now very fine, as is also a very good form of P. violacea. Vandas are represented by good examples of V. cærulea, V. tricolor, and the apparently ever-blooming V. Sanderiana; whilst the colours of the old-fashioned Zygopetalum maxillare and Z. Mackayi render them indispensable in a collection of winter-blooming Orchids.—W. H. G.

Masdevallia Crossi.—This extraordinary species is named after its discoverer and first introducer, Cross, who was associated with Dr. Spruce in his search for Cinchonas. It is a remarkable plant of slender creeping habit, and still rare in this country. In its native haunts the atmosphere is said to be miserably cold, and under cultivation it probably has hitherto been kept too warm. The flowers are produced in long, sub-erect racemes, of from ten to twenty, about two-thirds of which are open together. The individual flowers are about the size of those of an ordinary M. ignea, but much deeper in colour, those of M. Crossi being rich orange-crimson. We recently saw plants of this, bearing three flowers on a raceme, at Messrs. Shuttleworth and Carder's nursery in Clapham Park Road, where a magnificent display of cool-house Orchids may generally be found, especially Odontoglossums and Masdevallias.

SHORT NOTES.—ORCHIDS.

Oncidium varicosum.—This is just now flowering beautifully in Mr. Shuttleworth's nursery at Clapham: the very rich deep orange-yellow of its great spreading lip makes it very attractive at this dull season. Judging by the quantity of flowers yet to open, this species promises to maintain a brilliant display for some time to come.

Cypripedium Arthurianum.—In our note (p. 416) respecting this hybrid Orchid, we stated that this was raised by Mr. John Dominy. This, we learn, is inaccurate. It is the result of a cross made by the late Mr. George, then gardener at Bicton, Devon, and the seedling (for one only survived) was reared and flowered by Mr. Seden at Messrs. Veitch's nursery.

Aerides Southgatæ.—This is a provisional name given at Selborne, Streatham, to one of the largest and best of the Aerides belonging to the A. Lawrenciæ section. The plant now flowering with Mr. Southgate has two spikes some 2 feet in length, one of which bears thirty-eight huge flowers, and the other thirty-six. The sepals and petals are waxy-white, broadly tipped with magenta; the side lobes of the lip are white, the frilled mid-laciuia being also deep purplish magenta, and this rich colour extends down and all over the great spur, with the exception of the extreme point, which is green.

Orchids at Camden Wood.—Mr. Vanner's Orchid collection at Camden Wood, Chislehurst, although not one of the most extensive, is a very choice one, and exceedingly well grown. There are three houses set apart for Orchids. The flowering plants in the cool house include Masdevallia Chimæra, M. Roezli (known as the black Chimæra, which is seldom out of flower all the year round), M. Backhousiana, Chestertoni, Schlimi, bella, and macrura. Suspended under the roof is a fine display of the golden Oncidium varicosum Rogersi, several spikes of which carry over fifty blooms. The pretty O. Phalænopsis is also in bloom. The many Odontoglossums are fast pushing up their spikes, which will keep up the display during winter. In the Cattleya house the Barkerias are exceptionally well grown here, and are showing well for bloom, including the distinct and beautiful B. Vanneriana. Sobralia xantholeuca, a recently imported plant, is thriving better here than we have seen anywhere. It has six fine growths. The Phalænopsis house contains many fine plants of Schilleriana, Sanderiana, and Stuartiana, all throwing up their spikes. A fine specimen of amabilis was in bloom with over fifty flowers upon it, and a superb form of P. violacea, a large flower with rich crimson lip and lower petals. Two fine varieties of Vanda Sanderiana are flowering freely, though small plants; also Dendrobium bigibbum. Among the Cypripediums in bloom are calurum; a fine form of punctatum violaceum was in flower; also superciliare, Leeanum superbum, Dominianum, and Veitchi, all showing flower. The health of the collection throughout is all that could be desired, the pure air at Camden Wood being, no doubt, conducive to its success.

Indian Crocuses.—Of all the Orchids now in flower we find that the dainty little Pleiones attract the most attention. The sorts now in flower are P. præcox, or P. Wallichi as it is more generally called, P. lagenaria, and the lovely white blossomed P. maculata. They are easily grown in hanging pans in any warm plant stove if potted in fibrous peat and Sphagnum, and well watered or syringed when making their growth during the spring and summer seasons. A year or two ago when at Cheltenham I called at a nursery where I saw a distinct form of P. maculata very like the type, but a better grower, and it does not flower until January or February. This is a great advantage, as it enables one to extend the flowering season, since this late white and the smooth-bulbed P. humilis or its variety P. tricolor flower nearly together in early spring. Once well potted in tough fibrous compost, they may be grown on for two or three years without being again disturbed. Just as their leaves are fully grown and their roots are working freely in the pan, a little weak sheep manure-water helps them wonderfully, but care must be taken not to overdo a good thing. A pan of P. lagenaria or P. maculata with from thirty to fifty flowers is a sight well worth seeing in October or November, and these things, like Calanthes, are annual in their growth and easily cultivated.—F. W. B.

Fastening labels (*W. E. R.*).—Why not use ordinary galvanised iron tacks; they are cheaper than copper tacks and quite as efficient?

Nephrolepis rufescens tripinnatifida.—This promises to become a Fern of great merit, and to be very useful both as an exhibition and decorative variety. It is decidedly erect growing; the fronds are well displayed, and though the pinnæ are heavy, yet they are disposed in a light and graceful manner. It is one of Messrs. Veitch's novelties.—R. D.

EXETER APPLE AND PEAR EXHIBITION.

THE third annual Apple and Pear exhibition was opened in the Fore Street Market, Exeter, by the mayor and town council at 12 o'clock on Thursday, the 21st inst., and remained open until 7 p.m. on Friday, the 22nd. The weather, which has for the past few weeks been wet and boisterous, was for the two days exceptionally fine, which, with the large number of exhibits and an illuminated promenade concert from 7 to 10 on Thursday evening, attracted a good attendance and made the show a complete success. The entries, which numbered 764, consisted of 1383 dishes of Apples and 576 dishes of Pears for competition. Besides these, too, Messrs. Robert Veitch and Son exhibited 125 dishes of Apples, Pears, Filberts, Medlars, and late Plums. Messrs. Lucombe, Pince, and Co. also showed a large collection of eighty-four dishes of Apples and eighteen dishes of Pears. Messrs. Bunyard showed twenty-five dishes, and a very good collection of Apples was shown by Mr. Laing, gardener to Lord Poltimore. Fifty dishes of fine large Canadian Apples from the Colonial Exhibition were kindly lent by the executive commissioners for Canada. They were arranged on the central stage, and attracted a great deal of attention. Some Tobacco leaves in different stages of preparation were exhibited by Messrs. Lucombe, Pince, and Co., who are growing some Tobacco plants as an experiment. Among the principal exhibitors were Messrs. Bunyard, Maidstone; Mr. Watkins, Hereford; Mr. C. G. Sclater, Exeter; Mr. Powell, Powderham Castle; Mr. Scott, Yeovil; and Mr. H. Berwick, Sidmouth. In the class for twenty-four dishes Messrs. Bunyard were first. Among their best fruits were large, highly coloured dishes of Alexander, Cellini, Melon Apple, Cox's Pomona, Tower of Glamis, Lord Suffield, Lord Derby, The Queen, Gospatrick, and Lady Henniker. Mr. Watkins was second with large, well-coloured fruit of Peasgood's Round Winter Nonsuch, Blenheim Orange, Cox's Pomona, Red Costard, Mère de Ménage, Duchess of Oldenburg, Warner's King, and Waltham Abbey Seedling. Mr. C. G. Sclater, Mr. H. Berwick and Mr. Scott also staged fine collections in this class. Dishes of twelve distinct varieties were furnished by Messrs. Bunyard, Watkins, and Berwick. Good collections were also shown by Mr. D. C. Powell, Mr. H. Physick, Alphington, and others, the sorts differing but little from those already mentioned. For twelve dessert sorts Messrs. Bunyard were first; their best sorts were Lady Henniker, Ribston Pippin, Cox's Orange Pippin, King of Pippins, Worcester Pearmain, Melon Apple, Washington, Crimson Queening, Wealthy, and Cellini. Mr. C. G. Sclater, who was second, had among his fruit very good dishes of Cox's Orange Pippin, King of Pippins, Beauty of Wilts, Blenheim Orange, Court Pendu Plat, Fearn's Pippin, Cornish Aromatic, and Red-ribbed Greening—the last-named sort being highly esteemed in this neighbourhood, although described as "worthless" in the "Report of the Committee of the National Apple Congress" (see p. 218), much to the surprise of some of our local growers. Mr. Scott, Mr. Watkins, Mr. Powell, Mr. Berwick, and others also competed in this class. Amongst exhibitors of twelve sorts of culinary Apples were Messrs. Bunyard, Watkins, Powell, Sclater, and Berwick. Of cider Apples, collections came from Mr. Uglow, Sir T. D. Acland, and Mr. B. Salter, and consisted of highly-coloured and good fruit of well-known local sorts, viz., Tremlett's Bitter, Ellis's Bitter, Tom Putt, Slack-my-Girdle, Sweet Albert, Cluster, Sweet Buckland, and Sweet Bosberry. Amongst dessert sorts were Ribston Pippin, Cornish Gilliflower, Cox's Orange Pippin, and Loan's Pearmain. Sir T. D. Acland had good examples of Pine-apple Russet, Cox's Orange Pippin, American Mother, White and Braddick's Nonpareil, Cornish Gilliflower, and Ribston. The heaviest five Apples of any one sort (Warner's King) weighed 6 lb. 1 oz., and the best flavoured sort was Cox's Orange Pippin. Special prizes were awarded to fruit of Alfriston, Blenheim Orange, Golden Noble, Lord Suffield, Old Hawthornden, Warner's King, and Dumelow's Seedling; and amongst dessert fruit, to Cornish Gilliflower, Court Pendu Plat, Cox's Orange Pippin, Gravenstein, King of the Pippins, Margil, Mère de Ménage, and Ribston Pippin.

In Pears the competition was very great, and the fruit very good. Messrs. Bunyard staged fine fruit of Louise Bonne of Jersey, Marie Louise d'Uccle, Beurré Clairgeau, Beurré Diel, Doyenné du Comice, Beurré Superfin, Pitmaston Duchess, Durondeau, Beurré Bachelier, Belle d'Ecully, Grosse Calebasse, and Catillac. Sir T. D. Acland had very good fruit of Pitmaston Duchess, Louise Bonne, Madame Treyve, Glou Morceau, Beurré Diel, Beurré Bosc, Doyenné du Comice, Gansel's Bergamot, Vicar of Winkfield, Duchesse d'Angoulême, Van Mons Leon Leclerc, and Winter Nelis, some of the last-named weighing more than half a pound each. Mr. D. C. Powell showed nicely ripened and well-coloured fruit of Marie Louise, Beurré Clairgeau, and Moorfowl Egg. Mr. F. Bradshaw had good fruit of Marie Louise, Louise Bonne, and Pitmaston Duchess. Culinary sorts consisted of Uvedale's St. Germain, Catillac, Bellissime d'Hiver, and Gilogil. Special prizes were awarded to Beurré Diel, Doyenné du Comice, Easter Beurré, Glou Morceau, Josephine de Malines, Knight's Monarch, Louise Bonne of Jersey, Marie Louise, Pitmaston Duchess, and Winter Nelis. Quinces were shown by Mr. C. G. Sclater and Sir G. Clay, and Medlars by Rev. B. W. T. Wrey and Mr. F. Bradshaw.

CHRYSANTHEMUM SHOWS.

THE following are the dates of the principal Chrysanthemum shows to be held during the month:—

8, 9, and 10, Lambeth	16 and 17, Winchester
9, Royal Horticultural Society, South Kensington	,, Brighton
	,, Putney
9 and 10, Kingston-on-Thames	,, Southend
,, Southampton	,, Teddington
10 and 11, National Chrysanthemum Society, Royal Aquarium, Westminster	,, Twickenham
	17 and 18, Bristol
	17, 18, and 19, Newport
10 and 11, Bath	,, ,, York
,, Croydon	18, Hitchin
11, Hammersmith	18 and 19, Hull
11 and 12, Richmond	18, Chiswick; Taunton
,, Tunbridge Wells	19 and 20, Sheffield
,, Bury	20, Kettering
,, Portsmouth	22 and 23, Leeds
12 and 13, Huddersfield	23 and 24, Liverpool
,, Lewisham	,, Manchester
,, Canterbury	24 and 25, Birmingham
12, Reading	

OBITUARY.

THE death is announced of Mr. G. W. JOHNSON, well known as a writer on gardening, and an author. He was the founder of the *Cottage Gardener* (now the *Journal of Horticulture*) in 1848, but so long ago as 1826 he contributed to Loudon's *Gardener's Magazine*, then the only horticultural journal published. Among Mr. Johnson's most useful books is the "Cottage Gardener's Dictionary." He has for some years retired from active work. He had nearly completed his 84th year at the time of his death, which took place at Waldronhurst, Croydon, on Oct. 29.

Names of plants.—*A. B.*—Spindle tree (Euonymus europæus).—*W. E. R.*—Cestrum aurantiacum.—*C. Gregory.*—Hedychium coronarium.—*C. R. S.*—1, Cassia corymbosa (not Acacia); 2, Sparmannia africana; 3, Casuarina equisetifolia (no flowers); 4, Australian Beefwood, Abies Hookeriana; 5, Escallonia macrantha; 6, Phillyrea media.—*G. G.*—Next week.—*R. L.*—Oncidium unguiculatum.—*J. L. B.*—Diplopappus linariæfolius.—*N. B. Stanford.*—Cotoneaster affinis.—*Rev. J. W.*—Catasetum tabulare.—*J. M., Penzance.*—1, Lastrea serra; 2, Oncidium flexuosum; 3, Maxillaria picta grandiflora; 4, Odontoglossum Alexandræ; 5, Laelia Perrini.—*G. G.*—Lonicera flexuosa.—*E. F. C.*—Rhamnus catharticus.—*A. E. M. J.*—1, Marjoram (Origanum vulgare); 3, Hyssop; 5, Lavender; other species insufficient for naming.

Names of fruits.—*H. E. G.*—1, Winter Strawberry; 2, Ribston Pippin; 3, Mother; 4, Claygate Pearmain.—*E. H. (Subscriber).*—Apples, 1, Mère de Ménage; 2, Yorkshire beauty; Pears, 3, Marie Louise; 4, not recognised.—*W. K.*—1, not known; 2, Belle de Bruxelles; 3, Swan's Egg; 4, Duchesse d'Angoulême.—*M. J. T.*—1, rubbed beyond recognition; 2, Roundway's Magnum Bonum; 3, Beachamwell.—*C. J. B.*—1, Uvedale's St. Germain; 2, Marie Louise d'Uccle; 3, Nouveau Poiteau; 4, not recognised.—*No Name (parcel addressed on stiff parchment label)*—Five Pears: 1, Beurre d'Anjou; 2, Beurre Rance; 3, Charlotte de Brouwer; 4, Easter Beurre; 5, Beurre Rance.—*Salcanus.*—1, Rosemary Russet; 2, Yorkshire Greening; 3, not recognised; 4, large fruit, Tower of Glamis—small, Braddick's Nonpareil.—*G. H. M.*—3, Beurre Bosc; 4, Doyenne Boussoch; others not known.—*J. P.*—1, Beurre Capiaumont; 2, Duchesse d'Angouleme.—*Mrs. Maples.*—Pitmaston Duchess.—*C. W., Stratham.*—Calebasse.—*C. C.*—8, Souvenir du Congres; 11, Hacon's Incomparable; 12, Marie Louise d'Uccle; 13, Marie Louise. Other fruits sent will be named next week.

WOODS & FORESTS.

MEASURING TIMBER.

THE process of measuring timber when felled is very simple, yet the results produced may be different according to the article used in measuring the girth of the tree, viz., whether a thin piece of whipcord, a thick cord resembling a garden line, or a properly graduated tape or leather strap. The thin whipcord draws close into the bark or body of the tree, and does not lose much from the actual girth when doubled up into four lengths for the quarter girth, but the thicker cord loses a perceptible quantity in bending, while the tape line or the leather strap do not require bending, but show the quarter girth at once in their graduations, and give greater dimensions than either of the cords. Timber buyers sometimes object to the latter, because they do not fit into the irregularities of the bark so readily as a small cord, and, by not being doubled up, do not allow the advantage given in that way by the cord; but this objection can be met by not meeting the tape or strap quite close when girthing the tree, leaving about from a quarter of an inch to half an inch between the meeting of the fingers, which would be ample compensation. I have used Chesterman's patent graduated timber-measuring tapes extensively without making any allowance whatever, or ever having it asked for by the buyers. These tapes can be had in various sizes, either in cases or loose, to hang over the arm. For small-sized trees I prefer the short, loose tape, but for large timber I use a longer tape in a compact leather case. The case will last out a great many tapes, which do not cost much loose, and are easily inserted into the case by unscrewing and taking out the roller upon which the tape is wound. You can see how the first one has been attached; remove it and attach the new one in the same manner, push in the roller, screw up, and the thing is done. Another tape, by the same maker, may be had coiled upon a spring in a brass box, which economises much time and trouble in winding. These are made in 12-feet lengths, and may be had either of linen or steel.

In taking the dimensions when the trees regularly taper, the girth is taken in the middle of the length of the tree, but those trees that are irregular in form may require to be measured in sections, as if each section was distinct from its fellow, and each must have a separate entry in dimension book. The following is an example of a simple form of book, and one that I generally use:—

Lot.	Kind of timber.	No. on tree.	Length feet.	¼ girth inches.	Contents feet.	Total feet.	Rate per foot.	Value. £ s. d.	Remarks.
1	Oak.	1	13	26	61				
,,	,,	,,	12	19	30				
,,	,,	,,	8	13½	10				
,,	,,	,,	12	11½	11				
						112	1s. 6d.	8 8 0	
,,	,,	,,			Tops	50	9d.	1 17 6	
,,	Elm.	2	20	17	40				
,,	,,	,,	17	14	23				
						63	8d.	2 2 0	
,,	,,	,,			Tops			3 0	
,,	Ash.	3	20	16	35½	35½	1s. 6d.	2 18 3	
,,	,,	,,	9	9	5	5	1s.		

When measuring standing timber, the contents of each tree should be computed and marked in the book in going along, price per foot noted, and any necessary remarks made in the outer margin. The computation can be quickly made with the aid of the slide-rule, carried in the hand along with the book; and mistakes, if any, are more easily detected and rectified at the time by this system than by going on taking dimensions without working out the results on the spot.

In computing the contents of trees—customary measure—by the common slide-rule, the line C on the slide and the line D on the rule are the only lines used. Set the figures on the line C, which represent the length of the piece, opposite to 12 on the line D; then opposite the figures denoting the side of the square—or quarter girth—on line D you will find the cubic contents in feet on C.

EXAMPLE.—What are the contents of a piece of timber 12 feet long and 19 inches the quarter girth?

C	12	30 cubic feet.
Set		
D	12	19 quarter girth.

Customary measure does not give the real contents of the tree, but this can be easily ascertained from the slide-rule by selecting another gauge point on the line D. I have not seen any rule with this gauge point marked upon it by the maker, but I discovered it for myself, and mark it upon the rules I use by driving the point of a pin into the wood of the rule at 10·625 on the line D. To work out the problem, set the length of the tree, in feet on C, to 10·625 on D, and opposite the quarter girth on D; find the true contents in cubic feet on C.

EXAMPLE.—What are the true contents of a piece of round timber, 12 feet long and 19 inches the quarter girth?

C	12	38¼ real contents.
Set		
D	10·625	19 quarter girth.

Showing a difference of 8¼ cubic feet between the true measure and the customary measure of "the trade." The most convenient size of rule for carrying comfortably and using with facility in making computations is the 3-feet four-fold rule. The space on the D line between 10 and 11 is graduated into four divisions. To mark the gauge point 10·625 on that line, place a mark half-way between 10½ and 10¾, and the thing is done. A. P.

Planting trees.—In tree planting attention should be paid to soil and climate. The Oak prefers a clay soil; the Scotch Pine a northern aspect with a sandy loam. As a rule Conifers are most suitable for elevated grounds and poor soils; soft-wooded trees for low-lying, swampy lands; hard-wood trees only grow well in good soil and moderate elevation. Plantations require a great deal of attention and care, and should not be formed by direct planting, but by transplanting young trees from the nursery. Judicious pruning greatly enhances the value of the timber, and it is most important that when branches are removed care should be taken not to split the branch from the body of the tree, and should in all cases of larger timber trees be cut about 12 inches from the trunk of the tree. If the branches are cut off close to the trunk of the tree, the wet gets in, discolours the heart and often causes the whole of the trunk to decay, and the timber is then of no value. In young trees the branches may be cut close, as in this case the sap soon forms into a kind of bark and saves the tree from decay. When planting young trees 4 feet to 6 feet apart is a fair distance. Trees that are planted with a view to their early removal by thinning are called nurses in the eastern counties, and for this purpose Firs are generally preferred. These are planted for the assistance of the growth of timber, which is a great help in keeping them free from branches.—FORESTER.

The Black Walnut.—In his address before the recent American Forestry Congress, Dr. Loring, in speaking of the Black Walnut, said: "This tree, culled from western forests to meet a limited though important demand is really becoming scarce on the northern side of the Ohio Valley; but on the southern, along the foot hills and in the valleys of the Appalachian range, it is abundant and almost untouched. It grows rapidly in the Western States, even beyond the Missouri, and is destined to be the source of wealth to the future tree grower."

FORESTERS AND GARDENERS.

I TRUST that "Yorkshireman" has read the article (p. 399) on "Measuring standing timber"; if so, he will see that the writer does not agree with him that valuing standing timber is an easy matter; but, on the contrary, anything like facility in estimating accurately in this way is only acquired by extensive and careful practice. One would almost think that "Yorkshireman" has been a gardener himself, from the way he extols the gardener's intelligence at the expense of foresters. I do not contend that it requires the possession of genius for a man to be a capable forester, but I do say that years of experience are needed to enable a man to discharge economically and satisfactorily the duties connected with the management of large areas of woodlands. Foresters, unlike poets, are made—not born. I do not wish to imitate the boastful language with which "Yorkshireman" concludes his article, but I may say, in all humility, that I have had the management of several thousand acres of woods for some years, and have sold annually some thousands of pounds worth of timber, and have employed all the various workmen whom he so pithily enumerates, and that, in my opinion, any intelligent gardener may not *soon* understand all the "many details," or *soon* learn them.

Who is to pay the "intelligent gardener" while he is learning these details of wood-management? And if the foreman in the woods can carry on the work during the gardener's probation, why appoint a gardener at all? Any woodland owner if in want of a forester advertises invariably for a man possessing some years of experience. He does not think that the requisite knowledge can be gained in a few weeks. I have no doubt that there are many gardeners who would gladly become foresters if they had the opportunity, for not only are foresters on large estates better paid, but they are free to a great extent from the daily worries and harrassing anxieties of the gardener, and have only one master to please, and not two or three.

I have had largely to do with the valuing of standing timber in the three counties of Northumberland, Durham, and Yorkshire, and my deliberate opinion is, that no man can do it well and quickly without a great deal of practice and close and continuous observation. When a youth, assisting my father in large valuations, I have had frequently to climb trees or cut them down to settle a disputed point as to the girth of a tree in the middle. The only way for a novice to learn what trees lose in girth between the butt end and the middle is to estimate a tree standing, and then fell and test his measure; and not one or two trees only, but some scores in various places. I pity a forester or any other man who has had no practical training in the work he has to superintend, for workmen are quick to find out and take advantage of the ignorance of a master, and cause him to have many a humiliating moment.

The question is purely one of opinion, and it is with much diffidence that I put forward mine in opposition to that of an experienced and capable man, as "Yorkshireman" undoubtedly is, but I feel strongly that our woodlands will not be better managed by adopting such a plan as "Yorkshireman" advocates.

W. B. H.

Pruning Oak woods.—Not only is pruning unnecessary—for, if thinning is done gradually, allowing the Oak trees to draw each other up to such height as may be required, the lower branches will of themselves drop off—but it is actually injurious, as every timber merchant or village carpenter knows. And the boughing of Oak trees materially affects the value of the timber when felled, though the tree, when pruned, may be only twenty or thirty years, and, when cut, 150 years old. When the boughs are thrown off by Nature, as they are most perfectly under careful management, the bark gradually closes over the part from which the bough dropped, and it becomes impossible to define the former position of the bough, nor would any sign of it be found when

the tree is cut; but, should the tree be pruned, an unsound knot, or a sore in the tree, is at once formed, allowing the water to penetrate the trunk where the branch was cut off. This will rot, and a black dead piece of wood will be found in the centre of the tree when it is cut. The bark will, no doubt, usually close over the wound made; but this will take some years, and, before it is closed, the mischief will be done, and, in old trees, it not unfrequently happens that the perfect closing over the wound by young wood causes a species of dry rot.—R.

WOODLAND MANAGEMENT.

Anyone observing timber trees in woods and in hedgerows as he passes by rail through any fifty miles of England can hardly fail to be struck with the absence of anything like method in the timber management. He may find some exceptions to this general rule in some few woods which are of sufficient magnitude to return a regular yearly income. But, even in these cases, the knowledge of the subject is almost invariably inferior to that displayed in the culture of land for ordinary purposes. Two distinct systems are followed, both equally injurious to the general good—in one district everything is cut down; in another, everything is left to stand. Here the trees are injured by indiscriminate crowding—good, bad, and indifferent, in which case the good are the sufferers. On the other hand, whole districts are dismantled of their fairest ornaments, and neighbouring crops are left to starve from the destruction of their natural shelter. In both instances the largest profit which can be derived from land by the judicious admixture of agricultural and timber crops is lost to the individual proprietor, and, of course, through him lost also to the country.

Farming and timber growing are considered by some to be antagonistic interests; but, if common sense were allowed to arbitrate between them, the two would be closely and firmly allied friends. This injurious war of interests is clearly apparent in the two systems to which we have already alluded. In one district, some large landed proprietor, devoted to farming only, cuts down every stick on his estate. The tree that is venerable from age, but useless as property, and the straight-growing sapling, which is yearly bringing the highest value the land is capable of, share the same fate. A clean sweep is made—a cultivated desert created. Angry indeed is the neighbouring lord, who expresses himself not in words, but in trees. In this case, the noblest specimens stand inconspicuous in a crowd of the mean and the worthless. And thus the systems act and react on each other, converting our pleasant England into a starved waste or a badly regulated wilderness. "We want more light." A new system must be commenced, by which the annual value accruing from timber may be secured to individual proprietors as income, and through them to the country.

The value of an estate well covered with timber is worth more by many thousands of pounds than one destitute, or nearly so, of trees; yet trees, for the most part, are allowed to grow haphazard. Though loved for their beauty, they are treated with supreme neglect. I venture to assert—and I could furnish half a dozen examples of what I say in any one of the midland counties—that the mismanagement, or rather non-management, of timber on the lands of many large and rich landed proprietors is such, that they would not dare to have their cereals or other crops cultivated in the same style. Such neglect would excite public attention.

The cause of this state of things is not far to seek. I have alluded to the high farming crotchet which sacrifices everything to agricultural produce. This is, however, not the only cause. Timber is nobody's business. Sometimes it is looked after by the proprietor himself, or it is left to a land agent, a bailiff, or a tenant. Of these, the first has too much on his hands to do the work; the second considers agriculture to be the real interest concerned; the third at present is a foe avowed and deadly. All three are generally indifferent foresters. What care they for the eulogiums of Evelyn, Loudon, or Brown?

Another fruitful source of evil is, that timber is generally regarded as so much ready money, not as a regular income. It is felled on emergencies, not at stated periods or on a systematic plan. No regular succession of trees is kept up. Some landed proprietor gets into difficulties—there is a big cutting down. His successor is well-to do, and loves trees—there is a big planting. How often do we find trees submitted to the axe at their most growing age, whilst on a neighbouring estate the proprietor will preserve Elms, that, being past their prime, are yearly shattered by the winds?

Another result of the want of a recognised system is, that in all other businesses there is capital to fall back upon. No sort of property can be managed well unless the requisite amount of labour is expended upon it at the right time. There must be something beyond the profit of the business itself, or profit itself will be the loser. The principle is, however, not applied to trees.

We must not omit the evil that results from a want of uniformity in the views which govern this kind of property. There are certain rotations of crops both in horticulture and in agriculture, and tenants who succeed each other go on recognised principles, and seldom entertain theories widely different from each other. Their profession is land management, which is an understood thing; but with timber the work is done all manner of ways, and the least profit which can be produced from the timber-growing soil may fairly be expected. W. J. W.

THE CANADIAN POPLARS.

The Poplars and Willows are amongst our most common native trees and shrubs, says Mrs. Trail, in her "Plant Life of Canada." We have a great variety of species of both, from the lofty Cottonwood of the Western peninsula on the shores of Lakes Michigan and Huron, to the dwarf Willows that form the chief portion of the vegetation of the far northern boundaries of Hudson's Bay.

Little valued as timber in the thickly-wooded lands of Eastern and Western Canada, where hardwood trees abound, such as the Walnut, Maple, Beech, and others, yet in the more distant divisions of the Dominion, where timber trees are less abundant and in the prairie bottoms where the Poplar and Birch form the only trees, the Poplar rises in value and is used not only for firewood, but for building purposes where better timber is not easily obtained, unless at a very great cost. In remote places far from the means of transport, and where, for the present, saw-mills are not in existence, the Poplar supplies the place of a more durable wood. The Romans called the Poplar "The Tree of the People," and it was used to decorate the public walks.

The Cottonwood—Necklace Poplar—(Populus monilifera) is the finest of all the Poplar family. It is a noble-growing forest tree, confined in Canada, chiefly to the more westerly portion of the Dominion. Between the great lakes seems to be its particular locality. It loves the margin of lakes and rivers and moist ground, indicating a rich vegetable soil, well repaying the cost of clearing the land of the trees, which are of great height and girth; though the wood is very light when dried, yet it is difficult to burn on account of the abundance of sap while green. On this account the settlers do not attempt to fire the felled trees until a year's seasoning has rendered them easier to burn—so I have been told by an intelligent old Scotch settler who moved westward some years ago into that part of Canada where the Pine is scarcely seen, and the gigantic Cottonwood and other hardwood trees abound. The wood of the Poplar is used for turning and carving, and is made into shavings for thin boxes for millinery goods, and for druggists' purposes, and any work that requires very light, easily worked wood.

The foliage of the Cottonwood is smooth, heart-shaped, with prominent nerves, serrate, slightly hairy teeth; the fertile catkins are long, with fringed scales; the seeds are clothed with white cottony down, from which the familiar name given to the tree is taken. This is the largest and most important of the Poplars. The specific name, monilifera, or Necklace-bearing, is applied on account of the appearance of the fertile catkins, which are very long, and have the large fruit-pods scattered irregularly along them, giving somewhat the appearance of a necklace.

*** This is the common Black Italian Poplar so much planted in this country.—Ed.

Tacamahac—Balsam Poplar—(Populus balsamifera).—In favourable situations, in low ground near the shores of lakes and rivers, on gravelly banks and low bottoms, the Tacamahac is found all over the eastern and north-easterly portions of Canada, filling the air with its balsamic fragrance. It is not one of the largest of our native trees, but where growing in free space it forms a fine bushy leafy head. The foliage in shape resembles that of the Pear tree—large, smooth, ovate, pointed, and serrate, whitish and abundantly net-veined beneath.

It is not advisable to plant the odorous Balsam Poplar in the vicinity of gardens on account of its tendency to throw out suckers from the roots, or increase by seeds, which thus become untidy and troublesome to clear away. The catkins of the Balsam Poplar are from 2 inches to 4 inches long, curving, tail-like, and covered abundantly with the white silky down attached to the seeds.

After showers, the leaves emit a fine aromatic odour. The great peculiarity of the Tacamahac is seen in the resinous leaf buds which are formed early in autumn and are covered with a fragrant yellow gum which is of a most healing nature. It is used as a styptic for fresh-cut wounds by the natives, also as an ingredient in a healing, stimulating ointment for bruises and sores. The crushed leaves are also applied to strains and bruises. The buds gathered in spring and steeped in spirits form a liniment in quality closely resembling the old well-known "Friar's Balsam," and it is equally excellent as an application for fresh wounds, being styptic and very healing.

American Aspen (Populus tremuloides).—The Aspen may be seen in all low wet flats, forming thick groves of slender growth with greyish smooth bark, which whitens in more open situations. The wood is of little value; it is white, watery, and brittle.

On entering one of these Poplar flats, or swales as the country people call them, a sensible change in the air is perceived; the dew seems more heavily condensed, and a chilliness is felt even in warm summer days, while the slightest breath of wind sets every leaf in motion, fanning the air to coolness.

The Aspen is a short-lived tree, subject to a black canker caused by an insect which destroys the bark, and gives an unsightly aspect to the larger trees which are usually found growing on waste lands by roadsides, where they spring up spontaneously.

Large-toothed Aspen (Populus grandidentata).—The leaves of this species are large and coarsely toothed at the margins, especially when young; very pointed and downy underneath, of a greyish tinge of green above. Like the common Aspen, it springs up in old neglected clearings and waste places. The long, drooping, silky catkins appear before the leaves expand. The growth of the tree is rapid, but becomes unsightly in age with black rifts and scars; the juices of the tree attract the small black ants, and the wood-peckers help the work of decay either for the juices contained in the tree, or for the insects that take refuge in the bark. The wood is considered of little worth. The buds of the Poplars begin to form early in the autumn and slowly advance, till in March and April they may be seen swelling the gummy varnished cases which protect the immature leaves and catkins, the bluish silken down peeping out as if to try the temperature of the early spring before unfolding. Among the low dwarf Willows, the leaf buds often appear so green, that at Christmas one might expect to see the bushes clothed with verdure. One is apt to think these premature efforts of the trees are put forth, while the sap is yet active, preparatory to the rest that takes place during the winter months, and yet it is a question if indeed the vegetable life is not always active, though the effects are not apparent.

Oak fence posts—Will any kind reader who has experience of these say if they last longer when the top is inserted in the ground? I am told this is the practice in the midland and eastern counties. In Sussex the woodmen do not seem to know of it, and say the lower end in the ground is the best way.—J. H. G.

No. 782. SATURDAY, Nov. 13, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

GARDENING ON THE GRASS.

SMALL lawns look best when their centres are open; the beds (if any are required) should be near the margins. Gardening on the Grass is a phrase adopted by horticultural writers to describe a phase of lawn decoration, which, though not new, is distinct from the practice of laying down geometrical figures on the Grass. It associates well with the picturesque grouping of trees and shrubs, and does away with that formal division line of border, which prevents the Grass from growing up to the stems of the shrubs. There is also a good deal of economy in it, and, on the whole, I think not very much, if any, sacrifice of effectiveness. If more attention was given to trees and shrubs, and less to short-lived exotic flowers, better and more tasteful ways of grouping and arranging them would be adopted. Instead of long straight lines of borders filled with mixed plants often lacking in effectiveness, either from unskilful grouping or from occupying the same position too long, enclosing meaningless masses of shrubs, there would be a choice selection of suitable foreground shrubs, each in itself a picture from having room in which to show its true character. The Grass would grow up to their stems, and fill in the interstices between so that not a foot of bare soil would be visible anywhere. Gardening on the Grass simply means adding an irregular fringe of flowers to soften the line between shrubs and Grass, altogether different in scope and extent from the old-fashioned mixed border. To give a better illustration of what the idea means, let us assume that we have a lawn of moderate extent to deal with. On all sides there is a more or less irregular margin, breaking up here and there into glades and recesses, which partly enclose snug nooks and corners which may be made available for Ferns or other plants requiring shade and shelter. Early-flowering bulbs, such as Snowdrops, Crocuses, Daffodils, &c., may nestle amid the outer fringe of shrubs, the line wavering occasionally to avoid all appearance of formality, patches of Snowdrops and groups of Daffodils sometimes advancing into the open in front of the shrubs (skirmishers, a military friend calls them). In some of the openings among the shrubs patches of the taller Lilies might start up, such as auratum and the old white, but beautiful, Lilium candidum or Madonna Lily. After the bulbs had blossomed and disappeared other flowers would come on, and in this kind of lawn decoration everybody might plant the flowers they love best, but as each species will appear alone, as it were, none but those possessing considerable merit should be employed.

The Pæonies, both the herbaceous and the tree or Moutan section, are well adapted for this work, and there is now very pleasing novelty in colour among the flowers of the newer varieties. The Rose, the Fuchsia, the German Iris in considerable variety may be had. The Fuchsia is specially attractive when it gets well established, growing into single wide-spreading bushes out of the turf; and there are many other things that will occur to everybody who gives any thought to the matter that will well reward us for bringing them out into the open. But overcrowding must be avoided. We may of course, if we wish to get up a good-sized clump quickly, put several plants into one hole to form one group, and though by so doing we originate a struggle for life, no great harm will be done, as outwardly on all sides they will find breathing room. This plan of lawn decoration will be interesting as furnishing scope for the display of taste, and affording opportunities for studying the effective grouping of movable objects, as mistakes can easily be rectified without incurring much expense, and this is the season for doing such work. The margins of shrubberies can be opened up. Choice shrubs distinct in character can be fitted in, such as the Lawson Cypress, the Golden Yew, variegated Holly, Spiræa ariæfolia, Thujopsis borealis, T. dolabrata, Biota semperaurescens, Thuja Vervæneana, Taxus adpressa, Cryptomeria elegans, Venetian Sumach, Magnolia Lenné, Tamarix, &c. The bulbs and other things can be planted after the border has been turfed over. E. HOBDAY.

INDOOR GARDEN.

WINTER-FLOWERING PLANTS.

PERPETUAL-FLOWERING CARNATIONS.—Where buttonhole flowers are required daily and in considerable quantities, no more suitable or more serviceable flowers could be named than perpetual Carnations, especially if the more sweetly-scented varieties are cultivated. As a rule, much the most sturdy and floriferous plants are grown by those who supply the markets and the trade generally. It is not because, as many at first imagine, they possess the most dwarf varieties, but simply owing to their having command of the most suitable structures in which to grow them. They must have good light positions not far from the glass, and this trade growers are enabled to give them. We have to winter ours in a high span-roofed house running from north to south, and although we are usually successful in preparing a good batch of dwarf plants, these, when housed, soon commence to grow spindly, the bloom being correspondingly weak. They have a stage to themselves and are not crowded, otherwise they would soon become useless. If the central or front stages of a lean-to house facing the south could be devoted to Carnations, there they would succeed best during winter, and well repay any trouble taken with them. In every case strong young plants are much superior to old ones. Ours are usually struck early in spring but if we had to rely on our own plants for providing cuttings, propagation would be done in the autumn. Why so many fail to effect a good strike in spring is owing to the cuttings being too soft and weakly. Not only do such cuttings refuse to strike well, but even those rooted and grown on rarely attain such strength as do those obtained from plants that have been wintered in a position where they get the full benefit of sunshine and light. Those, therefore, who cannot favour the whole of their plants with the best positions ought at least to grow a few for affording cuttings. It is not tops, but good side shoots slipped off when about 4 inches long that are the best. The former may be the stouter, but they do not branch so well. Cuttings, such as I have tried to describe, will root as freely in a close propagating frame or in propagating boxes as do Verbenas, though not quite so quickly, but the weakly ones damp off wholesale. Where spring propagation fails it is advisable to strike the requisite number of cuttings in August or September, or a few old plants may be planted in a shallow frame placed over or containing a bed of good sandy soil; any number of side shoots can thus be layered. This is undoubtedly the best method of keeping up a good stock of the invaluable Souvenir de la Malmaison. We have layered this in the open ground, in fruit houses, and in frames, and in every instance with good results. Well matured side shoots also strike in gentle heat at any time during spring or autumn, and the first flowering stems of these young plants produce several fine blooms. A gritty loamy soil suits all Carnations, and they should have clean, well-drained pots. Our youngest Malmaisons are flowered in 6-inch pots, and the large old plants in 9-inch pots. The strongest of the commoner perpetuals are flowered in 9-inch pots, and the remainder in 8-inch pots, and these being well filled with roots are none too large. All should be kept carefully staked up, or they soon become unsightly, the strength of the plant being diverted to the production of side shoots instead of being expended upon strong upright-flowering stems. Very bushy plants we have sometimes supported with sprays of Birchwood, much as Kidney Beans are usually treated, but, on the whole, we prefer the more laborious system of staking. Crowded weakly plants are especially liable to become infested with greenfly, and for this the best remedy is frequent fumigations with Tobacco paper. In hot and dry positions red spider also makes an appearance, the broad-leaved Malmaison being a frequent sufferer in this respect. A syringing of sulphur water checks and destroys this little pest, and does not disfigure the foliage. Nothing in the shape of forcing ought to be attempted, as this would soon end disastrously. Nor should there be any need to hurry on the blooming. Strong only once stopped plants are, when housed in September, commencing to bloom, and a genial greenhouse temperature, say ranging from 45° to 55° by day and rather less by night, will, other treatment being favourable, encourage them to bloom perpetually. They should be watered carefully, never being allowed to become dust-dry nor saturated, and when the pots are well filled with roots occasional supplies of weak liquid manure greatly assist them. Miss Joliffe, blush pink, is the dwarfest and most floriferous, and by many this and Malmaison is preferred to all others; the former is sweet-scented, and not much liable to burst its calyx. A. Alegatière, scarlet, is fairly dwarf and free-flowering, but there is little scent. Belle Rose is still a favourite; it blooms continuously, and no fault can be found with its size, shape, or scent. Purity is the best white, and is very sweetly scented. La Belle produces handsome white blooms, but it is of weedy habit. A good continuous blooming yellow variety is not yet forthcoming. Pride of Penshurst and Mrs. G. Hawtrey are both very beautiful, but they more nearly approach the border varieties than the perpetuals. They are not winter, but spring bloomers. The old Clove Caroation being a great favourite here, we cultivate a lot of it in pots, and in spring are rewarded with a good supply of this spicily scented variety. A good batch of potted-up plants of the hybrid Pink Mrs. Sinkins also affords an early supply of much-appreciated white flowers. W. I. M.

Arum Lilies in autumn.—In the summer of 1885 we had a large Arum growing in the bed of a conservatory, but it became too large for its place and it was dug up, divided into thirty pieces, and planted in the open. Immediately after this all the large leaves died down, but fresh ones soon sprang up from the roots. By last autumn they were nice dwarf plants, and they were lifted in October and put into boxes 1 foot square and 10 inches deep. Some of them flowered this spring, and in May they were all placed in the open air in the boxes. They were well supplied with water and soon became good plants. In October many of them began to show flowers, and just now they are developing many massive blooms. Fresh buds are also being produced, and they promise to flower well in the shortest days. They are greatly valued now, as the spathes are so very ornamental either on the plants or when cut and placed in vases, and of all the flowers we possess I think they are the most striking at the present time.—J. MUIR, *Margam.*

Pelargonium Guillion Mangilli.—"W.I.M." has not exaggerated the merits of this semi-double zonal Pelargonium: it is one of the most useful kinds we have, and its value is not nearly so fully recognised as it should be. Of the semi-doubles, I know of none that flower so freely and continuously; in this respect it nearly equals the much-valued Vesuvius. If well fed and liberally watered there seems to be no limit to its blooming powers. To see this Pelargonium at its best, however, it should be grown along into good-sized specimens, as, like all the doubles, it blooms most profusely when on a basis of old wood. Good-sized plants of it under the influence of a spring sun are grand, and these are allowed a rest in summer: shaked out partially and repotted in July, they will come in again well in winter. What we much need is a semi-double white, identical in all other respects with Guillion Mangilli. There has been considerable improvement lately among these double whites, but not one of them can be said to perfectly fulfil the requisite requirements of a

winter-blooming Pelargonium. In any case, Guillion Mangilli should be included in every collection of winter-blooming Pelargoniums.—J. C., *Byfleet.*

NOTES OF THE WEEK.

Iris stylosa in the open air opened its first flower on Oct. 30th, the earliest date of blooming that I have observed as yet, after thirteen years of cultivation.—G. J., *West Surrey.*

Oncidium Jonesianum.—We have received two fine spikes of this beautiful new Oncidium from the garden of Mr. Ybarrondo, Aigburth, Liverpool. The spikes are grand examples of good culture, and must have been cut from very fine plants to have produced such strong racemes of flowers. We are informed that they flowered from a specimen bought from the first importations. One spike bears twenty-one flowers, which are more than we have hitherto seen on one spike; the other spike carries twelve flowers. The variety, too, is superb, the white lip being richly spotted with rich crimson.

Heliconia aurea striata.—The very handsome Musa-like plant, H. aurea striata, is much less grown than it deserves; the bold, bright green leaves being striped with orange, render it very effective. We recently saw a distinct and handsome sport from this in the Pine-apple Nursery, called lineata, in which the leaves in addition are striped and splashed with creamy white and rose. We believe that both forms require strong heat and a moist atmosphere to develop their beauties.

Cymbidium giganteum.—Although this fine bold-growing plant has been an inmate of our Orchid houses for nearly half a century, the preponderance of green in its flowers has prevented its becoming a favourite. A variety which we recently saw in bloom at Selborne, Streatham, cannot fail, however, to commend itself to all lovers of the rich, rare, and beautiful. The scape is from 2 feet to 3 feet long, bearing numerous large flowers, the sepals and petals of which (instead of being nearly green) are chocolate streaked with lines of purple, whilst the large yellow lip is profusely spotted and blotched with rich crimson. In addition, the flowers are delicately fragrant, and last a very long time in perfection.

Chrysanthemums.—Not more welcome is the Rose to our gardens in June than is the Chrysanthemum to them in November. Lovely as Chrysanthemum flowers look at exhibitions, they are infinitely more interesting at home. Take, for example, the large conservatory at Selborne, now containing some 500 plants. What can be more striking? They are tastefully arranged, both as to position and colour, which is well diversified, amongst Japanese kinds. The following are a few of the best, viz.: Le Chinois, purplish violet, florets twisted; Mons. Astorg, silvery white, with soft violet centre, florets drooping; Mdme. Lacroix, sulphur-white, passing to pure white, florets drooping; Rosa Bonheur, deep rosy purple, a superb variety with large drooping florets; Criterion, rich clear amber, florets drooping; Mdme. de Sevin, rosy purple; Comte de Germiny, nankeen, heavily streaked with brownish yellow, florets long, broad, and curled; R. Ballantine (sometimes named Source Japonaise), beautiful light violet, with incurved florets; Mdme. Bertier Rendatler, orange shading with yellow, florets twisted; Cullingfordi, crimson-scarlet. These, besides such favourites as Elaine, Lady Selborne, Baronne de Prailly, The Cossack, and James Salter, seemed to be the most attractive. Amongst incurved flowers the following were very fine, viz., Lord Alcester (sometimes called Princess Imperial), pale primrose; Mrs. Bunn, medium-sized, bright golden yellow; Lord Wolseley, bronzy red, very fine; Golden Empress, pale yellow; Jeanne d'Arc, blush white, tipped with rose; Mrs. Heale, white, tinged with rose; Alfred Salter, lilac-pink; Nil Desperandum, dark orange-red flower; Prince Alfred, rosy carmine, large and fine; Mr. J. Laing, a medium-sized flower, but very handsome, yellow tinged with orange; Baron Beust, chestnut-red, tipped with yellow; Hero of Stoke Newington, rosy pink; Princess of Teck, white, tinged with pink—all good, as are also some fine Queens and Beverleys. At Croydon Lodge, the residence of Mr. Stephenson-Clarke, where a large orchard house is filled with these and other good sorts, amongst which we noticed many of those previously named, and likewise some others, distinct and handsome, the best of which were Album striatum, white, striped with purplish crimson; Album plenum, creamy white, very fine; Apollo, buff, with drooping florets; Bouquet Fait, rosy pink; Jeanne Délaux, same as F. A. Davis; Mastic, yellow, tinted with red; Purple Prince, rich purplish violet; Maiden's Blush, creamy white, tinged with flesh; and Meg Merrilies, very large and quaint. Amongst Anemone-flowered kinds the best were Mrs. Pethers, lilac, with a rosy centre; Empress, very large blush with lilac centre; Emperor, blush, with pale yellow centre; King of Anémones, dull crimson; Gluck, golden yellow; and Georges Sand, bronzy red. Amongst incurved varieties the most striking were Duke of Edinburgh, rosy lilac; Prince Alfred, rosy carmine; Gorgeous, a golden yellow American kind; Lady Talfourd, silvery purple; Prince of Wales, large purple; Refulgens, bright maroon-purple; and Gloriosum, another bright yellow of American origin. To these may be added such kinds as Golden Eagle, Guernsey Nugget, and Queens and Beverleys, which are in most collections exceptionally good.

At The Woodlands, Tooting Common, the residence of Mr. H. Doulton, Chrysanthemums are all treated upon the cutting-back principle, and very effective they are as decorative objects, being dwarf, well supplied with foliage, and the flowers excellent. Amongst the best were the following: Fanny Boucharlat, creamy white, tinged with pink, petals flat and drooping; Agréments de la Nature, florets narrow, twisted golden yellow, tinged with reddish brown; Soleil Levant, flower large, florets quilled, pale yellow; Source d'Or, flowers drooping, orange and gold; and John Laing, reddish brown, tinged with rose and yellow. The following incurved varieties were extra good, viz.: Jeanne d'Arc, blush white, with rosy purple tips; Jardin des Plantes, deep golden yellow; Princess of Wales, purple; Nil Desperandum, deep orange-red; Lord Wolseley, bronzy red.

In Mr. Bonner's garden at Bridge House, Tooting, Chrysanthemums are not so largely grown as at any of the places just named, but they are nevertheless exceedingly well managed; on some which are allowed to become large the buds are partially thinned; these yield an abundant supply of flowers of just the size suitable for placing in vases for room decoration, a purpose for which the large flowers, however well they may look in a conservatory, are quite unsuited. Elaine, Lady Selborne, James Salter, George Gordon, Curiosity, and Fair Maid of Guernsey are useful varieties for this purpose. Amongst Japanese kinds with large flowers the best were Soleil Levant, pale yellow, florets quilled; J. Délaux, dark velvety brown with long spreading florets; M. Plauchenau, bright rosy pink; Criterion, bright amber; Golden Dragon, bright yellow, with long curled and twisted florets; Margot, rosy violet, with creamy centre; Val d'Andorre, rich chestnut, shaded with orange; Duchess of Albany (Jackson) orange-buff; Japonais, bronzy yellow, florets very large and incurved; and Dr. Audiguier, crimson-amaranth. The best incurved flowers were Barbara, bright orange-amber; Empress of India, pure white; Mr. Brunlees, Indian red, tipped with gold; Princess of Wales, rich purple; White and Pink Venus, and Baron Beust, chestnut-red tipped with yellow.

Masdevallia racemosa Crossi.—This little gem is so seldom heard of in flower, that I am glad to note that three plants may be seen in bloom in Messrs. Shuttleworth and Carder's nursery at Park Road, Clapham. It is not only distinct from all other Masdevallias, but is extremely beautiful. The flowers are of the brightest orange-red, flushed and lined with scarlet. They are about the size of those of M. amabilis, and borne in racemes, as many as twenty flowers being shown on the dried specimens collected in the plant's native habitat. There is no other known Masdevallia at all like it, and it is not surprising that it is so highly prized.—G.

Crystal Palace Chrysanthemum Show.—The termination to a brilliant flower and fruit show season held at the Crystal Palace was appropriately a large Chrysanthemum exhibition, which was held on the 5th and 6th, being the first show of Chrysanthemums this season about London. There was a large assemblage of exhibitors representing the best growers in the country, and the valuable prizes offered enticed competitors from all parts, headed by Mr. Gibson, of Morden Park, who seems to be invincible this year. He won the £10 prize for forty-eight blooms, besides various other prizes; and among other successful exhibitors were Messrs. Drover, Fareham; Mr. Edwards, Balham; Mr. Munro, Twickenham; Mr. Neville, Twyford. The pot plants made a great display, particularly the groups, occupying 100 square feet. Messrs. Cannell, Swanley, had a large display, including several new varieties, among which the following were awarded first-class certificates: Elsie, William Holmes, Cincinnati, Jane and Miss Cannell. Certificates were also awarded to Mr. Flight for Mrs. J. Wright (Japanese); and to Messrs. Laing for La Marguerite and Mdlle. Elise Dordan. It has been a busy and excitable week among growers and exhibitors of Chrysanthemums. About London there has been several shows held on almost each day, and very excellent were those at Kingston, Lambeth, Richmond, Stoke Newington, and Croydon, but our limited space precludes reports of them. A prize list of the Crystal Palace Show is given in our advertising columns.

Oncidium andigenum.—I herewith send a flower of a very rare Oncidium. I flowered it this year, and, not knowing the plant, sent it to Professor Reichenbach, who replies, "It is O. andigenum, and is very rare; in fact, yours is the only plant in Europe." The growth and bulbs are very similar to those of O. concolor, for which it was bought.—J. M. Bannerman, *Wyastone Leys, Monmouth.*

*** The flower sent is very beautiful, somewhat similar to a large flower of O. Phalænopsis; the lip, however, is different in shape. The sepals and petals are creamy white, irregularly blotched, and dotted with dull crimson; lip large, three-lobed, the side lobes very large, creamy white suffused with pink, and blotched at the base with deep velvety crimson, and dotted and freckled with the same colour; front lobe spotted with rich crimson, and bearing at its base a rich orange crest; column purple.—Ed.

NEW MOUNTAIN ARALIA.

(OREOPANAX EPREMESNILIANUM.)

A series of beautiful photographs was lately sent to us by M. Comte d'Epremesnil, representing various views in his garden at Thibermont, near Dieppe, and among them was one from which the opposite illustration was engraved. This is a new shrub recently introduced from South America, but as it there inhabits the mountainous regions, it is hardy enough to withstand full exposure on the north-west coast of France, and the Comte d'Epremesnil presumes that it would be perfectly hardy in the milder parts of these islands. It is probably quite as hardy as the common Aralia Sieboldi, which even in and about London grows to tree-like dimensions, and is rarely if ever winter-killed.

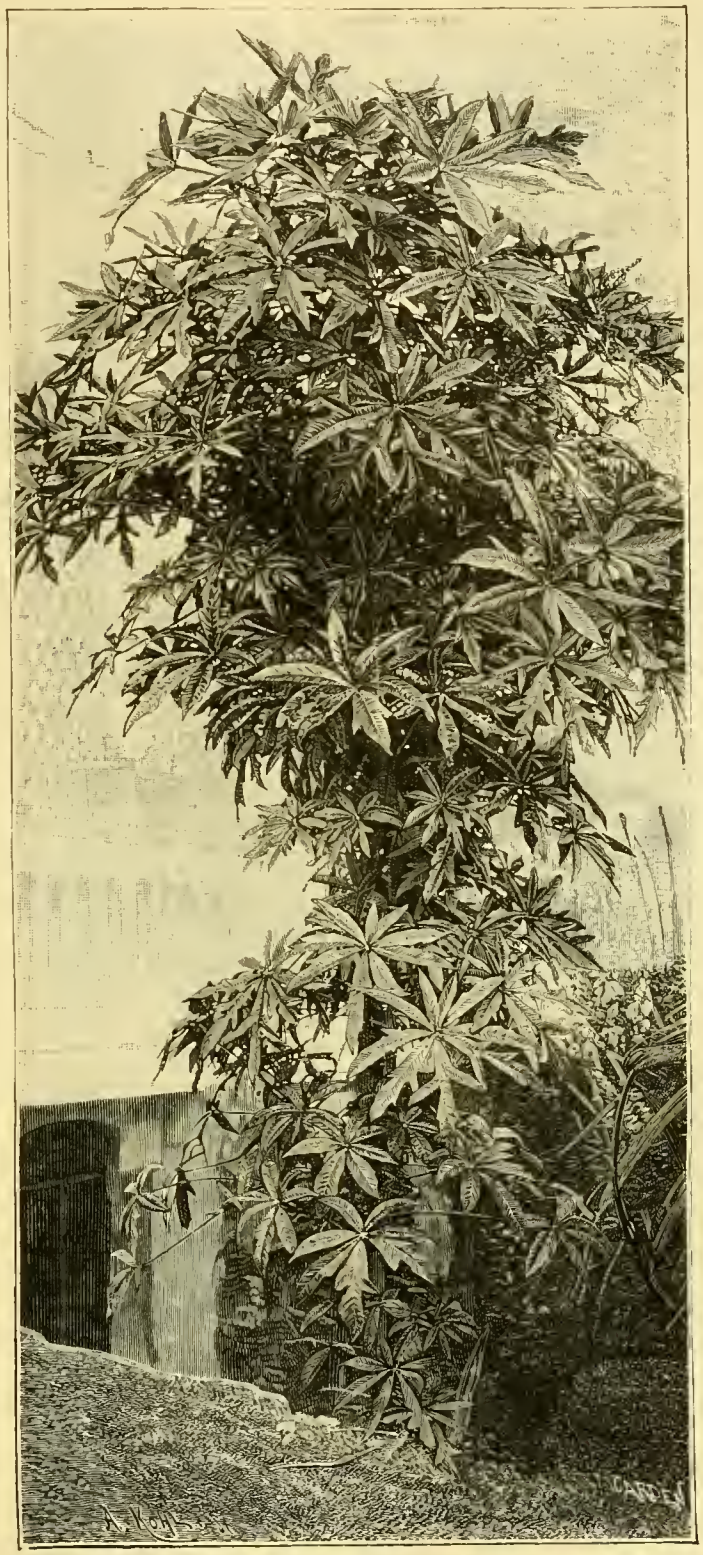
None of the true species of Oreopanax have found their way into English gardens as ornamental plants, although in the countries bordering the Mediterranean, and especially Cannes, Nice, &c., several kinds are commonly seen in cultivation, being in favour because of their handsome bright green foliage. O. Epremesnilianum, as the illustration well shows, is a noble shrub, somewhat resembling in growth the well-known Aralia Sieboldi, but grows taller. The leaves are large, digitate, the divisions lobed, and they thickly clothe the branches down to the ground. Another handsome Oreopanax is O. Andreanum, which has undivided oval leaves, sometimes lobed, thick in texture, and covered with a thick reddish felt; its flowers are in an erect terminal spike. O. peltatum is very Aralia-like; so also is O. Thibauti, which was first distributed as an Aralia.

NOTES ON RECENT NUMBERS.

Pernettyas.—The very beautiful and distinct varieties of P. mucronata raised by Mr. Davis, of Oglesgrove, ought to be extensively cultivated wherever Rhododendrons will grow. Considering that several of them were certificated at South Kensington in 1882, they certainly do not seem to be as generally known as they deserve; yet the various colouring of their berries, white, pale rose, deeper rose, rich crimson, and almost black, adds greatly to the attractiveness of this always desirable species. They seem to fruit even more freely than the type, and are just now literally smothered with berries, growing in light and slightly peaty soil. The plants appear to thrive better when allowed to run together into a mass than when kept apart as single specimens, and in this way they make very attractive clumps at a season of the year when anything bright is welcome in the garden. They are also effective if potted up, to make a foreground to a group of Chrysanthemums where the stems of the latter may have become rather overlong, and either indoors or out the clustered berries never fail to attract attention.

Tropæolum tuberosum.—There is no doubt that this plant will survive an ordinary winter on a light soil without being lifted and kept dry till spring, but as a number of tubers are found round the original tuber, something after the fashion of Potatoes, the mass of growths that push through in the spring make such a tangle as to prevent the flowering from being very satisfactory when the bulbs are not taken up and separated. As to the soil for this plant, it certainly succeeds with us in shallow soil exposed to the full sun. Our best plants are always those grown on the iron pillars of a verandah surrounded by gravel walks; a spadeful of gravel is removed from the base of each pillar and replaced by a spadeful of light rich compost in which the bulb is planted. The pillars are about 10 feet high and are soon covered, the plants being about a yard through near the base and tapering to the top, while they continue a mass of bloom throughout the summer, and their bright yellow and scarlet flowers are gay yet, not having been injured by 5° of frost on the 3rd inst. Possibly, however, "Greenwood's" plant was not in so different a situation as would appear at first sight, for in an exceptionally hot and dry season like the past, a soft-rooted plant in heavy clay may quite conceivably have as restricted a root-run as a plant grown in a few inches of soil upon gravel; and we are told that the plant in rich soil bloomed badly. The general tendency of planting Tropæolums of all sorts in very rich soil seems to be not so much to reduce their flowering as to induce an excessive luxuriance of foliage under which the flowers are hidden from view.

Wild Roses in America.—The excellent article from the "Arnold Arboretum," on p. 414, is of special interest in drawing further attention to some of the most attractive of the single Roses as garden plants. The Rose first mentioned, however, must either be a different variety from that grown in England as R. kamtschatica, or else is another striking instance of the effect of locality upon the appearance and habit of a Rose, for our R. kamtschatica, though of much stronger and coarser growth, so far from having flowers larger and paler than those of R. rugosa, produces them only about half the size and of a considerably deeper colour; while the succeeding fruit is also smaller, less brilliant, and less freely produced. A form of R. arvensis, too, with pale rose-coloured flowers, sounds like a local variety, as in England this species is the purest white, and is also the most constant of the native Roses in habit, form, and colour, being the only one of which, I believe, there is not recorded any appreciable variation. The Rose described under the name of R. multiflora is evidently the charming R. polyantha, formerly called R. luciæ, a sub-species of multiflora, and beyond all question one of the most delightful of climbing Roses. The suggestion that it might become the parent of some fresh climbing Roses is already partly carried out, for Lacharme this year distributed a red-flowered variety, which is certainly a climber (the result of a cross with General Jacqueminot), and is highly spoken of as a garden Rose. Oddly enough, none of the former hybrids, commonly known as the Polyantha Roses, between this species and the Tea-scented varieties have displayed the slightest tendency to a climbing habit. It is also interesting to note that in America, as it is said to have done in France, this Rose has proved itself a valuable stock upon which to work other varieties; and it is not impossible that R. carolina, which is almost a bog plant, might be useful as a stock to grow Roses on in very wet places. One of the chief attractions of R. setigera (or rubifolia) is not mentioned, for its leaves are like those of the Blackberry, not only in form, but also in the brilliant autumn tints which they assume, a desirable characteristic which is maintained happily in its varieties, Baltimore Belle and Queen of the Prairies.



Oreopanax Epremesnilianum in the open air in the garden of the Comte d'Eprémesnil, Thibermont, Dieppe.

Cypripedium spectabile.—The objection that is brought on p. 415 against the showy Orchis, namely, that it seldom survives a second season in the garden, is sometimes urged against this showy Lady's Slipper, although quite inexcusably. If it is planted in a dry situation exposed to east winds it will certainly very soon succumb; but if it is given a cool place where it is sheltered from cold winds and frost in spring, after the plant has once started into growth, it soon becomes permanently established. For instance, planted among Rhododendrons in deep, cool peat, and planted rather deeply as a precaution against both severe frost and drought, this Cypripedium produces its lovely rosy and white flowers year after year, and with annually increasing strength. Other plants that succeed in similar situations are those mentioned in connection with the life-like portrait of Pyrola rotundifolia on p. 429, and either among Rhododendrons or under the shade of Fir trees, the Linnæa borealis, with its delicately pencilled and deliciously fragrant little bells, the dainty Trientalis europæa, as well as Epigæa repens with its white flowers and subsequent berries, may be easily established and naturalised.

Anemones as annuals.—The plan recommended by "Veronica" of raising Anemones from seed is undoubtedly invaluable as a means of obtaining a supply of cut flowers, and the amount of flowers that may be got from a seed-bed would appear incredible to some people who had never tried growing Anemones in this way. Perhaps the

superiority, or otherwise, of the transplanted seedlings, according to the severity of the winter, may be explained by the fact that they, owing to the disturbance of their roots, have their growth checked—that is to say, have their water supply greatly reduced—and are thus rendered less liable to injury by frost; while the plants left standing, continuing to grow freely and being full of water, are badly damaged in the event of hard weather, but should the winter prove mild, make naturally stronger plants than those which have been checked by removal. The same thing is observable in many other plants, notably among Rose trees, for the preservation of which, transplantation is frequently recommended. Some gardeners annually dig up their Tea Roses to prevent their injury by frost; but, of course, the blooms the following season are not so fine as on established plants, and most people now wisely prefer to risk their trees being slightly damaged for the sake of obtaining the most beautiful blooms.

Cyclamen europæum is still bright on the rockery in spite of the gales and floods, and one cannot but wonder that it is not more generally grown. The delightful plate of hardy Cyclamens in The Garden last week ought to make everyone want to grow these fascinating flowers, which come so early and stay so late. They may be easily established in Grass under trees, or anywhere where Primroses will grow; but if such places are not available, they grow admirably on the rockery or among old stumps in rooteries. Of course, they are largely grown in some gardens, but many people do not seem to be aware of the hardiness and adaptability to wild-gardening of the charming, but atrociously miscalled Sowbreads.

T. W. G.

NOTES.

The ever-blowing Rose.—In the *Botanical Magazine* of Curtis (t. 284) is a very characteristic portrait of this old and once popular Rose. Why is it now so seldom seen? I remember looking at this plant—quite a good sized bush of it in a pot—which used to flower in the window of a shoemaker of the village wherein I was born. It was the only one in the place until one after another begged slips and suckers, until many other windows could boast of nice little plants of this crimson China Rose, or Rosa semperflorens of the botanists. It is curious to note how almost imperceptibly changes take place in gardening language. The popular name, as applied to this dwarf and floriferous species by Curtis, brings to my mind that the verb "to blow," as synonymous with "to bloom," is fast disappearing. "Blow-house" was also another and earlier name for the more modern greenhouse; but the word is now rarely used in any form, since even the humble itinerant costermonger's "all a-growin' and a-blowin'" has well-nigh disappeared. Rosa sempervirens was first introduced from China by Mr. Gilbert Slater, of Knot's Green, near Leytonstone, in the year 1791. Quite a small plant, in a 5-inch pot, forms a sweetly pretty Rose for a sunny window, which will be rarely without a flower or two throughout the year. As indicated above, its culture and multiplication are of the most simple kind. I consider it as one of the most interesting of all the old Roses for pot culture.

Flowers of November.—Open-air Chrysanthemums in plenty, and Veronica Andersoni, both blue and purple flowered, are fresh and beautiful. On a sunny border is a good tuft of a small creamy-white autumnal Crocus of which I do not know the name, but it somehow gives us a foretaste of spring-time as its pale stars open in the sun. Only yesterday we had two splendid half-open blossoms on the great-flowered Magnolia. The yellow stars of the winter Jasmine are opening quite rapidly, and show best where contrasted with dark-leaved Ivies, or as seen near the vermilion-fruited Pyracantha, or some of the large-berried Cotoneasters on the walls. One of our Flag Irises, I think I. atro-purpurea, has thrown up a strong spike of flowers thus late in the year, and happening to mention the fact to Mr. Walker, of Whitton, he tells me that many of his plants have done the same. I cut the spike two days ago, and placed it in water in the stove where I now see its rich satin-like petals unrolling themselves as if it were spring-time to them. Senecio pulcher, Nicotiana affinis, late-planted Gladioli, Schizostylis coccinea, Stocks, Wallflowers, Primroses and Polyanthuses are all in flower, while such shrubs as Arbutus and Escallonia macrantha are fresh and ornamental, as they usually are at this season near the sea. The old Monthly Rose is nearly always in flower, but there are good blooms not only on that finest of all late Roses, Souvenir de la Malmaison, but some buds of Baroness Rothschild, sent by a friend, are really now fresh and beautiful blooms in water indoors. So far, November has been kind and genial.

Unheated plant houses.—Every good garden might be made infinitely more interesting by the simple addition of an unheated greenhouse or conservatory. But we must start clear, so to speak, with a well-built house, and no attempt at artificial heating whatever. Then there must be discretion used in the selection of the plants to be grown. Nothing tender must be attempted, and, as far as possible, planting out must be the rule. Of course, pot plants may be grown on the side stages, but the best effect and most luxuriant growth will be gained by planting out all the large-growing things. In such a house Camellias and Indian Rhododendrons, Bamboos, Lilies, Ghent Azaleas, Japanese Aralias, and the finely cut-leaved Maples may be grown. All sorts of hardy bulbs in pots, such as Crocus, Hyacinths, Tulips, Squills, and Narcissi, may be potted and brought in from the open air to bloom inside. There is no dearth of beautiful hardy plants suitable for every month in the year. Just now a few pots of the best Chrysanthemums would afford colour among the graceful leafage of the hardier Palms (Chamærops), of Japan Bamboos, and of New Zealand Tree Ferns, all rising from a carpet of fresh green Selaginella. There are hundreds of plants not quite hardy in the open air during our most severe winters which would be healthy and luxuriant all the year in such a house as is here described, and if it were joined to the dwelling, either direct or by way of a corridor, it would form an agreeable smoking place or lounge, while not giving a tenth of the trouble or expense attending a heated conservatory.

Little things.—It has been said that genius simply resolves itself into a capacity for expending infinite trouble and thought on what to ordinary people appear the merest trifles. That it is so in the garden everyone will allow, for the best of all gardeners are not only acute observers, but nervously particular as to little things. There is a story told of a celebrated nurseryman, who on being told by a customer that his foreman had no "go" in him, replied, "You have mistaken his value, sir. I have plenty of go myself, but my foreman has the equally valuable quality of seeing when things are likely to go wrong, and is prompt in checking error or waste; he is the safety-brake of the whole concern." The art of gardening, like all other arts, depends for its success on a multitude of trifling operations being performed in the right way and at the right time. It is far easier to learn how to paint a picture, or to build a sound and beautiful house, than it is to form a good garden. Not only does a good gardener know what to do, but his observation and experience teach him what not to do, which is an equally valuable possession. I happen to know a little of the difficulty now experienced by gardeners in obtaining good situations, but employers tell me it is equally difficult to obtain well trained men. Especially difficult is it now-a-days to obtain a good all-round man. You can easily procure a good Orchid grower, a Grape and Peach grower, or a first-rate kitchen garden foreman, but it is not so easy to get a man well up in the practice of hardy flower culture. Ladies more especially have taken up hardy flowers; therefore most of our fine old country houses are gay with them for nine months out of the year. Young gardeners especially should take up this branch, as it is sure to be of use to them. Learn to grow Grapes as big as Green Gage Plums, and Peaches the size of Melons, and the tenderest and most succulent of vegetables to boot. All these things are necessary, or at least acceptable, but they will not of themselves satisfy those who are fond of hardy flowers also.

Cape bulbous plants.—Mr. McEwan, of Cape Town, South Africa, points out in the pages of a contemporary that the climate of Western South Africa is so different from that of the eastern side, that cultivators who wish to be successful with South African bulbs should clearly recognise this wide difference, and act accordingly. The western bulbs, such as the majority of Ixias and some Gladioli, naturally have to endure a cold, wet, winter season, and burst into flower during the hot days of spring. The winter on the eastern side, on the other hand, is a dry one, and the bulbs, such as Gladioli of the G. carneus section, bloom after the rains of November. Hence, the first question on the receipt of a parcel of Cape bulbs should be, from which side of the South African continent do they come? By-the-by, I wish Mr. McEwan would give us a chart of the Cape flora, showing the rainfall, and climate, and *locale* of the most ornamental native plants. Perhaps, however, some information and meteorology of the Cape will be annexed to the new "Cape Flora," now in course of preparation at Kew. Such information, if carefully prepared for easy reference, would be an incalculable advantage to lovers and cultivators of Cape plants. Ixias we can now manage fairly well in a dull and humid, although mild, climate. Our plan is to plant deep in December, so as to keep back the growth as much as possible, and so treated they bloom beautifully in April and May. As the leaves wither in June, they are taken up and stored in dry sand until planting time.

Nutrition *versus* fertility.—Mr. Meehan, an English gardener, who has made himself a name as one of the leading botanists in the United States, tells us that "to American botanists is mainly due the credit of the discovery that whether a plant be male or female, or a flower on the plant be male or female, is a mere question of nutrition." While granting to the full the principle here laid down, I should like to point out that Caleb Threkeld, M.D. (the author of "Synopsis Stirpium Hibernicarum," a small octavo relating to the plants, wild and naturalised, near Dublin), pointed out this fact so long ago as 1727. As bearing out this theory of nutrition *v.* fertility or sexual variation, Mr. Meehan quotes an experiment made by Prof. Hoffmann, who "sowed seeds of numerous kinds of dicecious plants closely together, so as to give little food to each plant, and seeds of the same plants thinly, so as to give each plant nearly all the food it could use." Where the seeds were sown thickly, Hoffmann counted 283 males to 700 females, while in the well fed or thinly sown lot there were only seventy-six males. This is

the knowledge of 1886, and so we will now hear Threkeld, who wrote his quaint observations in 1727. In the synopsis, under Cannabis mas (Male Hemp), he says: "The male Hemp has the seed, the female only flowers, yet both are procreated from the same seed. The more attentive husbandmen observe that in a fat soil you have generally plenty of male Hemp, in a lean soil more of the female, or where sown too thick and so wants nutritious juice it is female." Of course, Threkeld here transposes the sexes, but his observations are quite as much to the point as are those of Prof. Hoffmann. The question of nutrition *v.* fertility opens up some very interesting potentialities, and its effects of the most practical nature are every day evident in every garden.

Queen Chrysanthemum.—Once again we have a golden harvest of Chrysanthemums in our gardens. Elaine must have first place, although some of our visitors like the tossed fluffy appearance of some good blooms on a standard plant of Lady Selborne. James Salter is also a good pink of the last named type. What a beauty is Madame de Sevin, with a fringe of drooping florets of a bright deep lake colour, and having a contorted centre of narrow lilac florets resembling a catherine-wheel! Source d'Or, a rich orange or amber Japanese, with reflexed florets, is distinct. So also is Mons. Astorg, a fine white in the way of Elaine, but with larger flowers. Lord Beaconsfield, crimson with amber reflex, is also much admired. Bouquet Fait is large and good; so also William Robinson, which resembles the last in form, but is of a soft amber or buff tint, quite different from aught else I know. Several seedlings now on their second year's trial promise well. Mandarin, a new Japanese sent to us by Mr. Boyce, is very distinct and good; and we are expecting great things of roseum superbum, which was splendid last year, the flowers opening out into February long after even Princess of Teck had left us. For cutting, some bushes of Mdme. Desgrange, Sœur Melanie, and Elaine yield plenty of good white flowers. If the weather keeps mild, there will be a good bloom in the open air and on walls. L'Ile des Plaisirs is a good rich crimson-brown Japanese variety, which contrasts well with lighter sorts; and M. Richard Larios is also a showy variety, now in good form. It is scarcely too much to say that chill November is robbed of half its foggy terrors by the genial advent of our winter queen. Veronica.

Rose hedges and bulb protection.—While experimenting at Oakwood two notions have occurred to me which I think are worth recording. The first is a new hedge. We tried a small one in front of the cottage, and this succeeding, we have now made one about 100 yards long of Japanese Rose (Rosa rugosa); the beauty of its flowers, fruit, and foliage, the last while green and afterwards golden in autumn makes it ornamental, while the quick growth of the plant and many and close thorns make it useful. The plants of our last hedge consist of seedlings taken out of a seed bed not more than 2½ yards square. This hedge has a backing of cut Furze; I expect in three years it will be a well grown hedge. Notion No. 2 is a substitute for snow as a protection for some bulbs and plants. Snow, as is well known, owes its efficacy to the air among it. I have tried many experiments to get something that would take its place. Finding that plants sowed themselves on our gravel walk, and came up better than in the seed beds, I used a surface of fine-sifted gravel with good results, and now believe that for bulbs which it is undesirable to plant very deep, and yet which must not be frozen, a covering of from 3 inches to 4 inches of sifted gravel stones about an inch long would hold air enough to prevent frost getting down into the ground and be easily removed in spring. With some precious bulbs and deciduous plants I have put a surrounding of bricks edgewise, filling up the enclosed space with these gravel stones. Smaller stones may be better; this is a subject for experiment.—George F. Wilson, *Heatherbank, Weybridge Heath.*

Flower Garden.

THE JAPAN WINDFLOWER.

In the last issue of The Garden (p. 429), Mr. Frank Miles inquires as to the typical species and varieties of Anemone japonica, and I should like to reply to his queries, as a very slight return to him for some very suggestive and pleasant letters which he has been good enough to write to me as a gardener from time to time. As he surmises, Anemone japonica was one of the late Robert Fortune's introductions. Before me is the first number of the first volume of "The Journal of the Horticultural Society of England," published in 1846, in place of the expensive quarto "Transactions," which, as I believe, were soon afterwards discontinued. This plant enjoys the peculiar honour of being the first on the list of a series of descriptive notices of "New Plants, &c., from the Society's Garden," and it is thus set down therein:—

The White Japan Anemone (A. japonica alba).

1. Anemone japonica, Siebold and Zuccarini (Fl. Japonica, vol. i, p. 15, t. 5; "Botanical Register," t. 66, 1845).
Received from Mr. Fortune, from Shanghai, June 20, 1844.

Its flowers are described by Lindley as being "nearly 3 inches in diameter," and as consisting of "a considerable number of bright purple leaves (*i.e.*, sepals) of a somewhat obovate form, and about half an inch wide; most of them undivided, but a few have irregular lobes at the side; those on the outside are smaller, greenish at the back, and covered with silky hairs." Lindley says further: "It is a greenhouse plant of considerable importance in consequence of its flowering in autumn;" but his prophecy as to its being "abundantly multiplied from seed" has only partially proved true in a way we shall presently describe. It may be as well to mention the fact that this original note of Lindley's is dated August 29, 1845.

In part 4 of the same volume (*l. c. supra*), under date September 2, 1845, we find a list of novelties exhibited at Regent Street from the society's gardens, including a notice of "Anemone japonica, from Mr. Fortune, from the north of China;" hence this date may be safely taken as that of its first public appearance at a London exhibition.

Now Mr. Fortune left England for China in the spring of 1843, that is, about six months after the news that peace between that country and England had been concluded. In the autumn of 1842, after exploring in Hong Kong, Canton, and elsewhere, he sailed for Shanghai, which place, as he tells us in his "Sketch of a Visit to China" (Jour. Hort. Soc., vol. i., part 3, p. 213), he reached soon after November 13, on which date he sailed. "The land," as he himself writes, "is a deep rich loam, and is, without doubt, the finest in China, if not in the world." "In a country like this," he further writes, "which is everywhere flat and cultivated, it was not expected that I could find very many wild plants. Two, however, were met with which have since attracted a considerable share of notice in England. I allude to Cryptomeria japonica and Anemone japonica. The latter was found when in full flower amongst the graves of the Chinese, which are round the ramparts of the city. It blooms in November when other flowers have gone by, and is a simple and beautiful ornament to the resting-places of the dead." He afterwards tells us he saw many cultivated plants in the flower-shops and nurseries, the former being at this season filled with Chrysanthemums.

So that our good friend Mr. Miles (p. 429) is, so far, perfectly right in his surmises, and even if Fortune afterwards met with this plant in Japan, it seems abundantly evident that he originally saw it and introduced it to the Chiswick Garden from the burying-grounds of Shanghai. So far as I know, Mr. Fortune did not meet with the white variety, nor have I ever met with evidence of there being varieties of this species in China or Japan, but it is more than possible—indeed, highly probable, for reasons hereafter to be adduced—that such varieties really do exist there. I have already mentioned Lindley's prophecy as to its "abundant multiplication from seed," so that it need not surprise us to find attempts at hybridising the plant having been made at Chiswick very soon after the actual introduction of the plant itself from China, and not from Japan, as the "dictionaries of gardening" will have it—at least, the three or four that are beside me as I write. It should be remembered that a nearly allied plant, viz., A. vitifolia, a white-flowered species, had been introduced to English gardens from the valleys of Upper Nepaul as early as 1829, and the late Mr. George Gordon made use of it in his hybridising experiments in connection with the more recently introduced A. japonica. This was previous to the year 1850, since in *The Gardeners' Magazine of Botany* for that year, p. 17, we find a coloured figure and description of one of the hybrids

which had been originally exhibited at a Regent Street meeting on September 4, 1849. The entry in the published journal of the society reads as follows: "A hybrid variety of Anemone japonica, produced between that sort and the white Indian A. vitifolia. The result was an improvement in the shape of the flowers, but they were much paler than those of the Japan Anemone."

The coloured plate in the *Magazine of Botany* is named A. japonica hybrida and it is a tolerably good figure by Holden of the plant now-a-days grown in gardens under the names of A. japonica hybrida, or rosea, or intermedia, or pallida, as the case may be, but A. japonica hybrida is undoubtedly its oldest and best name. Lindley, again, alludes to these early hybrids of Gordon's in *Gardeners' Chronicle* for 1855, p. 451, and from it we learn that the two parent species were reciprocally crossed, and that both species yielded seedlings, but while those from the A. japonica seed were strong and beautiful (as A. japonica hybrida really is), those from the seed of A. vitifolia "had the tenderness and ragged flowers of the male parent [*sic*] and were worthless." Having proved that the typical A. japonica was introduced from China, and that A. japonica hybrida is a garden hybrid between the type and A. vitifolia, we may now venture to inquire as to the origin of A. japonica alba, or A. Honorine Jobert, as it is more generally called. Now, in the *Gardeners' Chronicle*, as quoted in THE GARDEN, Vol. VI, p. 498, M. Otto Froebel distinctly affirms that the plant is not a hybrid between A. vitifolia and A. japonica, as had been stated, but that it originated from a large tuft of the old A. japonica with red flowers, from which a root-branch arose with pure white blossoms. This sport originated in the garden of a M. Jobert, at Verdun-sur-Meuse, about the year 1858, and it came into the possession of Messrs. Froebel in 1860. So we have tolerably sure grounds for saying that this white form is, so far as its European history goes, a sport or reversion from the original red or purple plant as introduced to Chiswick in 1844.

Now comes the peculiar period in the history of these two varieties of typical A. japonica. We will turn to Vol. XVIII. of THE GARDEN, p. 328, wherein the late Mr. J. C. Niven, of Hull, distinctly states that he, when at Kew, raised a seedling from the Indian A. vitifolia (A. japonica growing in close proximity) with soft rose-coloured flowers, to which, as he says, he gave the name of A. japonica hybrida. Mr. Niven does not mention the dated historical detail cited above, so that we must consider it unknown to him, and credit him with having raised by chance a hybrid at Kew which Gordon had reared at Chiswick years before. In this article Mr. Niven mentions that A. japonica Honorine Jobert is said to have been a sport from A. japonica hybrida; but his own belief is, that it was really a seedling from it—an opinion we now know to be erroneous, since it is, as above affirmed to be, a root-sport from the typical A. japonica itself. But more anon. In the same volume of THE GARDEN, p. 245, we find "J. S. W." maintains that A. japonica alba is identical with A. Honorine Jobert—a conclusion now generally believed, although on p. 298 "D. T. F." maintains that there are two white varieties, and he affirms that A. Honorine Jobert is far superior to another white which he does not name, but which possibly may have been A. vitifolia, which, while somewhat resembling A. Honorine Jobert, is assuredly inferior as a garden plant.

Then comes a note from "A. D," p. 421 (Vol. XVIII.), who, in accepting Mr. Niven's statement as to A. japonica hybrida, rosea, or intermedia, agrees with "J. S. W." that A. japonica alba and A. Honorine Jobert are identical; but he complicates the question a little by assuring us that "last autumn (1879) plants of rosea sported to alba, and are now (Oct., 1880) producing white flowers. Hence, we have evidence that both A. japonica and the variety hybrida have produced the variety called alba, or Honorine Jobert, in gardens. Again, on p. 454, "D. T. F.," in spite of what has been said by "A. D." and others, avers that A. Honorine Jobert is a superior variety to that called A. japonica alba, and also says that "he has watched the sporting of the rose-coloured variety (hybrida) with white," but that the latter is inferior.

I am afraid some readers of THE GARDEN will think this a long history, but one must sometimes be a little lengthy in order to be clear and exact. In this paper I have tried to clear up the whole question of Anemone japonica and its garden forms. We may summarise the whole matter thus:—

1. Anemone japonica, so-called type with purple-red flowers, introduced from China by Fortune to Chiswick in 1844.
2. The above plant, crossed with the Indian vitifolia by Mr. Gordon in the Chiswick garden, produced A. japonica hybrida in 1849.
3. A. japonica alba, or Honorine Jobert, was a root-sport from the above A. japonica, and was first observed in France in or about the year 1858.
4. Both Mr. A. Dean and Mr. D. T. Fish agree that they have seen A. japonica hybrida yield a white-flowered sport.
5. I am of the opinion that there are only three forms or varieties of A. japonica, viz., the type (reddish purple), A. japonica hybrida (pink or rose), and A. Honorine Jobert (pure white), but if Grant Allen's scale of colour variation be the true one, then the white form ought to be the original wild type in Japan or China, and if so, one could the more readily understand both the purple and the rosy varieties reverting to white, as they assuredly appear to have done.

No doubt Anemone japonica is really found in Japan, as stated by "D. K." (p. 172), and the original description or figure seems to be that in Siebold's "Flora Japonica," but the fact remains that Fortune originally introduced the plant from Shanghai, and infers that both it and Cryptomeria japonica were wild, although the context goes to prove that they were both cultivated on graves, and both may originally have found their way from Japan to Northern China. If it be true (and I could give much evidence to prove the fact) that flower-colour was originally green or yellow, passing to blue through all shades of pink, rose, red, and purple—then, of course, we must consider the white varieties, not as albinos, but as the more primitive or typical forms of a species. It is practical and convenient to consider the plant first seen or introduced as the typical one, but, as I imagine, no one learned in plants would for a moment uphold that it is so in Nature, although we so find it in books.

The two varieties figured in THE GARDEN at p. 172 are A. japonica alba (Honorine Jobert of the French) and A. japonica hybrida, the plant certainly raised by Mr. G. Gordon, and possibly also by Mr. Niven when in charge of the herbaceous plants at Kew. The most cursory glance at the figure shows that the white form is by far the most typical of the two, and I should not have the slightest hesitation in deciding on this white plant as being the typical, *i.e.*, oldest form of the species, and that it has originated from root-sports under cultivation only makes it the more probable that these were simply cases of reversion to an ancestral white type, which I have no doubt will some day be found to exist in China or in Japan. Mr. Miles' pertinent queries have cost me some little time and trouble, but I wish we had more amateur gardeners of his insight and calibre. These stately Japan Windflowers are so beautiful and long-enduring when well grown, that no trouble taken on their behalf, or in the interest of those who grow them, can be wasted. Some of our Kew correspondents have ample records at their disposal as to the history of these flowers, and I hope they or others interested will help us further in this matter.

VERONICA.

DAHLIAS IN NOVEMBER.

ON the 1st of November our beds of single Dahlias were almost more fresh and gay than they were at midsummer. In many respects the flowers are improved. They are larger, more brilliantly coloured, and last longer. The hot dry weather which prevailed in the summer rushed the single Dahlias out of bloom into seed pods at a speed to run them almost wholly out of bloom unless persistently picked off almost daily. Never do I remember the flowers to have been so numerous or short lived. Even after cutting, the fever in the blood seemed to pursue the blooms in vases or glasses into cool rooms, and cause them to fade almost as soon as gathered. But now, as "A. D" points out, p. 401, the flowers last much longer. Nor is the additional durability of cut blooms in the autumn or winter at all confined to Dahlias. It may also be seen in the plants so far removed from each other as the Rose and the white Brugmansia. The durability of autumnal or winter Roses must have been noted by all familiar with them. Nor does this arise from mere change of temperature, as the external surroundings of late Rose blooms in heated rooms, and their transference from the cool external air to these is all against their durability. What may, for lack of a better phrase, be called the ebb tide of life is probably the chief cause of the longer endurance of autumnal or winter blooms. The Brugmansia suaveolens is well known as one of the most fugitive, as well as fragrant of blossoms. During its heytide of growth and vigour in summer its blooms will hardly last fresh for three hours after cutting; now they will stand for twenty-four, thirty-six, or even forty-eight hours. Returning to our Dahlias, the Pompons have almost bloomed themselves out, and the few large bloomed varieties are in a similar plight, though both are producing young shoots in late summer-like profusion, while the single and the Cactus are still in their full glory. The Cactus has more blooms open on this first day of November than it has had at any time throughout the season. Has anyone grown the Cactus Dahlia in a suitable, that is something like a summer temperature under glass, and with what result? It has much the character of an evergreen ever-blooming plant, and, as a rule, shows no sign of resting from its twin labours of growing and flowering until frost cuts down its promising harvest of perpetual verdure and beauty. Permit me to thank Mr. J. T Poë (see p. 406) for his useful method of starving and pinching the Cactus Dahlia into bloom. I have also found that the older the tubers, the more severely divided, and the poorer the soil, the more bloom in proportion to the shoots. Mr. Poë's mixture with the white Japanese Anemone is as perfect, from an artistic point of view, as it is likely to be in checking or suppressing the over-hasty habit of shoot-growing that hides up the perfect blossoms of the Cactus Dahlia beneath the leafage and buds of their successors.

HORTUS.

Michaelmas Daisies.—The three best of these which have come under my notice are A. ibericus, Madame Soymier, and grandiflorus; to my mind these have better qualities than most others. A. ibericus, which comes either from the Pyrenees or the Caucasus, I am not sure which, flowers early—

about September—grows from 1 foot to 2 feet in height, and has large and well shaped bright blue flowers, in which there is just a tinge of purple; compactness, good colour, and evenness of flowering are its good qualities. Madame Soymier is, as far as I know, an accidental sport from lævigatus; it is a very dwarf plant and a most profuse bloomer; the flowers, which are small, are of a bluish purple colour. A. grandiflorus is one of the latest to flower; even here we must pot it in order to enjoy its flowers, which are large and of the brightest possible violet. It is not so coarse as A. Novæ-Angliæ or Novi-Belgii, and the foliage, too, is of a better shade of green.—MAX LEICHTLIN, *Baden-Baden.*

CLIMBERS ON TREES.

THE grace, verdure, beauty, and sentiment of the Ivy on the Oak have passed into poetry and proverb. It cannot, perhaps, be exceeded nor even matched in natural beauty and prodigality and grandeur of artistic effect, unless by the wild Clematis or Traveller's Joy. The latter, when it reaches its white fluffy state of winged seeds, hanging in downy-like masses from far-reaching boughs, reigns supreme along our hedgerows and through woodland glade, and forest. Magnificently effective as both Ivy and Clematis are universally admitted to be, it seems singular that so little has been done to artificially drape trees and shrubs in our hedgerows with a greater variety of creepers or climbers.

For example, in the two families of plants already named we have almost every conceivable size and colour of foliage, flower, seed, or berry; and yet how seldom one finds the variegated-leaved Ivies, or the smaller bloomed species of Clematis, such as the Virgin's Bower or C. Flammula, with its varieties, and such species as Viticella, azurea, to say nothing of the finer garden hybrids, draping trees and shrubs in pleasure grounds or home woods. And yet the Virgin's Bower, with its marvellous sprays of white star-like blossom drooping from tree to tree or branch to branch, with its delicious Hawthorn-like perfume, is simply perfection. The larger-flowered Clematis might be objected to as being on the whole, too tender or too large-bloomed for the draping of trees and shrubs. Not a few of the latter, however, are worthy of a trial tentatively, a few sprays of C. Jackmanni escaping from the shoots of the silver-leaved Maple being an example in point worthy of repetition to any extent. But no objection can be urged against the smaller-blooming species, nor the rich varieties and species of Ivy we possess, with leaves of all sizes and of every hue of colour from the deepest golden to the purest silvern. What could afford a more welcome surprise than a few branches of either escaping from the verdant branches of a Pinus insignis or a dense mass of Yew boughs? But some will exclaim that the Ivy would check the growth or undermine the health of such plants. It might, were it left in undisputed possession; but the object is not to smother the trees nor shrubs of value either with Clematises, Ivies, or other climbing plants, but simply to use the latter as drapery for the former; and thus used, little or no harm need be done to the trees by the draping plants. And there are many other classes of climbing plants that could hardly injure the plants they were grown upon. Among the latter, perhaps the most valuable and brilliantly effective are the different species and varieties of Virginian Creeper and Grape Vine. The old Virginian Creeper (Ampelopsis hederacea) rambles freely among shrubs or climbs up trees, and the new species, Veitchi (A. tricuspidata), is yet more chaste and beautiful. The latter is a true climber, grasping hold of stems or branches like Ivy, while the other holds on or climbs by its tendrils. The foliage is also widely different, though the leaves of the latter vary so widely in size as to constitute a marvellous variety in itself. Either of these plants form the richest drapery to shrubs and trees, and I have frequently directed attention to the brilliant combinations which they form with Hollies, Yews, and other plants. And then we have for perfume as well as colour the different climbing Honeysuckles; Caprifolium, in several species and variety, and Lonicera fragrantissima and others, as well as Wistarias, Jasmines, &c., all in their many species and varieties more or less adapted for the draping of trees and shrubs. Nor must other and more fragile plants be omitted. Perhaps the richest draperies ever seen by the writer—and they were both exhibited on a deep dense background of Yew—were formed of the old Canary Creeper in the one case, and in that of the other by the more brilliant-coloured Tropæolum speciosum. Even the old Convolvulus major and the all too seldom seen Eccremocarpus scaber can make a brave display of colour and drapery on low trees and shrubs. But these are mere samples, as it were, of the rich stores of suitable materials that lie ready to our hand. With Roses, Brambles, Deadly Nightshade, Bryony, Pyracantha, the more delicate type of Barberry, such as the common, Darwini, Wistaria, &c., there is no doubt but that our home woods, hedgerows, and shrubberies might easily be lightened up with some features of interest and beauty at a trifling cost without permanent injury to either trees or shrubs. D. T. F.

BLUETS.

(HOUSTONIA CERULEA.)

MANY are the good plants from the Northern States of America that have enriched our gardens of late years. The little Bluets, shown nearly

Bluets (Houstonia cærulea). Engraved from a photograph for THE GARDEN.

full size in the engraving, is a gem for a cool spot in the rock garden in sandy peat, where it thrives and grows apace, and goes on flowering nearly all the summer. The typical form has flowers of a pale blue colour, but the white variety is most frequent in cultivation in England, and is rather the prettier plant.

Dahlia Anne Harvey.—It may be interesting to some of your readers to know that Dahlia Anne Harvey, which lately received a first-class certificate from the Royal Horticultural Society, is probably one of the oldest of the section to which it belongs. I found it in Cornwall some years ago in the cottage garden belonging to an old lady who took great pride in her plants, and who grew them very well indeed. After growing it for two years I sent blooms of it to you, and you spoke favourably of them at the time. In 1883, I think, I sent the stock of it to Mr. Ware, of Tottenham, and he catalogued it the following year. As far as I could learn, it had been in the same garden for over twenty years, and I have no doubt it would never have gone any farther had not the present healthy taste for good things, which do not commend themselves to the eye of the florist, but which are nevertheless acquisitions to the garden, set in. It is a robust grower, though not tall, and the dark crimson colour and velvety look of the blooms make it a very striking variety.—JOHN C. TALLACK, *Ascot.*

Tricyrtis hirta.—You gave this plant such a bad character a year or two ago in THE GARDEN, that I am tempted to send you a spray of its flowers which I have just picked from an open border, and I think you must admit that as a hardy plant in flower on November 1 that you hardly did it justice when you said it was useless in English gardens. I think, too, that you will acknowledge that there are many Orchids grown in a costly manner not half so beautiful as this Tricyrtis. I find this plant to thrive best in a rather dry and poor soil. In a rich soil it grows so strong, that the flowers are late in opening, and then early autumn frost spoils them.—J. C. C.

*** The spray sent bore twelve large and handsome flowers, but, as we remarked in our last week's issue, it should be grown in pots, and placed in a cold house in the autumn in order to preserve its flowers from such weather as we are now experiencing.—ED.

Tree Carnation La Neige.—I have pleasure in forwarding a bloom of the above for your opinion. It is somewhat past its best, as you can see the stamens have begun to decay, but I think it is bound to rank as one of the very best pure white Tree Carnations. The habit is remarkably dwarf, the plant being only about 16 inches high and extremely free flowering, considering the size of its blooms. You will observe how nicely the calyx retains its normal condition.—JOHN KNIGHT, *The Oaks, Epsom.*

*** The flower sent is certainly of very high quality, being pure white, and measuring about 8 inches in circumference, whilst the calyx is stout without any sign of splitting.—ED.

TREES AND SHRUBS.

PRUNING SHRUBS.

ALL fast-growing common things, such as Laurels, should be pruned back annually to keep them within bounds. Too often they are left to encroach upon other and better things near, until both are injured. Laurels are often planted as nurses, and they are, by reason of their rapid growth and dense, warm habit, well adapted for this work, But their growth must be watched and a check applied when necessary, or they will monopolise the whole space. In all cases where the work is done regularly and no large limbs have to be removed, the work may be done either in autumn or winter; but if the saw has to be used it will be better to delay the pruning till March, doing it just as the sap is rising. The reason for this is, if large branches are cut off in winter and a severe frost comes the stumps may die. I have more than once seen old shrubs killed through being headed down in winter, but this does not apply to any knife-pruning which may be necessary, as merely shortening back the young shoots does not expose the vital principle of the plant to injury like the drastic measure of cutting off its head. All evergreen shrubs, including the dwarf Coniferæ, such as Arbor-vitæs, Yews, Cypresses, &c., which require putting into shape with the knife, may be seen to now, and special attention should be paid to the regulation of the leaders, and to the pruning back of any common plant that is encroaching upon a choice specimen. By keeping in check the common things and encouraging the Hollies, Conifers, and other trees and shrubs of slow growth and ornamental character to develop, a marked improvement might be effected in many places. Deciduous flowering shrubs should as a rule be pruned as soon as they have done flowering; if pruned now, some of the best blossoms will be cut off. I am referring more especially to such fast-growing things as Lilacs, flowering Currants, and Syringas. In pruning the dwarf Conifers, and in fact all Evergreens, always prune back to the base of a young shoot, which

will ferm the leader and still leave a good surface of foliage, and avoid that ragged stumpy effect which an unskilfully pruned shrub presents. If the pruning is done properly no cuts or wounds ought to be obtrusively visible.—E. H.

—— From the beginning of November until the end of March is the season when this operation is most generally practised, and although no hard and fast lines can be laid down as guides to cutters, there are some points which should be strictly avoided. The shears should never be used in cutting any tree or shrub unless they form a hedge. To save time in cutting and make the specimens appear neat, many fine, free-growing subjects which would assume naturally growth of the most graceful and pleasing description are clipped round and round until they become so artificial in appearance that one would never think they had grown at all, but were made to a design by some mechanic. It is this style which should be avoided above everything, and in the place of the shears let the knife only be used. With this, a tree or the outer branches of it can soon be reduced in size, and by cutting the branches which protrude, the inner ones will still be left with their points entire, and it is these which will sustain the natural-like aspect of the tree. In many cases bushes grow so near the edge of walks that they soon become an obstruction, and a common way of dealing with these is to clip them back annually until they form a thick and high hedge-like erection on the very edge of the walk. Now, these "little hedges" here and there never formed part of the original design of the garden. They are modern innovations of a most objectionable form, and they should never be allowed to exist. It may be they are valuable kinds of trees, and the fear of cutting them hard in has led to their assuming perpendicular faces on one side, while the other may be growing naturally and in curious contrast to it; but all owners of such may rest assured that if the knife was used judiciously, the upright face cut away, and the overhanging part made to recede, the tree would quickly assume a pleasing natural form, and the whole aspect of the garden would be much less stiff and formal than when disfigured with dots of hedges.—J. Muir.

Cotoneaster Simonsi.—In reply to the inquiry (5529), I may say that it is useless growing this plant against a wall, pruning it back close, and expecting it to bear berries. The plant is unfitted for a wall; it is not evergreen. Cotoneaster microphylla had better be used. This is evergreen, berries well, and if a plant of Jasminum nudiflorum be planted to grow with it, the contrast of the yellow flowers of the one with the crimson berries of the other will in about a month, or before, be a perfect sight of plant beauty. Simonsi is a beautiful plant planted where it can have room to grow, without being spoiled by pruning. I have a large number of Simonsi planted in this way. A knife has never touched any. They are now covered with scarlet berries, and when frost comes the foliage changes to the most beautiful tints of scarlet, yellow, brown, black, and green of all tints; but there must be full exposure, no shading by trees, and a south or south-west aspect.—K. K., *Tuddyforde, Devon.*

The Acers, or Maples.—These are all highly ornamental; natives either of Europe, North America, or the temperate parts of Asia, including China and Japan, and, with the exception of a pinetum, nothing could be more interesting than an aceretum, for among broad-leaved trees, few families display greater variety or grow more rapidly under ordinary treatment than the Maples. Some of them, such as Acer macrophyllum, eriocarpum, neapolitanum, and the common Sycamore, form rapid-growing, large, and lofty trees, while others, such as A. monspessulanum, opulifolium, and Opulus, are only round-headed low trees. The beautiful Acer Lobeli assumes a pyramidal form, somewhat resembling that of the Lombardy Poplar, while Acer cretieum and heterophyllum are nearly evergreen or quite so in mild seasons; again, others have fine variegated foliage, or leaves of as deep a hue as that of the purple Beech, or so dissected as to resemble some of the smaller Ferns. The leaves of many of them, too, just before they fall in the autumn either change to a bright crimson, golden yellow, or chestnut-brown, clothing the trees in brilliant colours, which only the American Oaks can rival.

PINUS INSIGNIS.

I GIVE here the dimensions of a young Pinus insignis which was blown down by the severe gale on the 14th of last month. It was one of a batch of seedlings raised in the spring of 1877, and finally planted out in a good situation in November, 1879. The height of the tree is 30 feet, and the circumference of the stock at the base 28 inches. We have several hundred trees of the same age, which, although in very exposed situations, stand remarkably well, many being on our Devonshire hedges, which are banks of soil 5 feet or 6 feet high, and 3 feet to 4 feet wide; but, in order to ensure their withstanding wind in a young state about October, a man goes through the whole of them with the secateur and thins them considerably, reducing the small inner branches so as to make them appear similar to a well-grown plant of Pinus Laricio. If this were not done they would become so dense, owing to their rapid and luxuriant growth, that they would not be able to stand our south-westerly gales, which have a twenty-five miles clean sweep from Dartmoor. Our young stock is transplanted every year, and yet they grow rapidly. This ensures first-rate balls of roots, and incurs no danger at planting time. Last March I planted several 10 feet high in very sunny and exposed situations, which stood the hot summer weather with impunity, and had no attention as regards watering, yet they are as good a colour as those planted several years before. John Garland.

Killerton, Exeter.

Laurustinus hedges.—One of the prettiest features belonging to gardens on the south coast at this time of year is the hedges by which they are surrounded. They frequently consist of the common white-flowered Laurustinus, that shows dense masses of white flowers just as other flowers are getting scarce. The hedges are formed with plants, put in about 1½ feet apart, and being kept trimmed into shape from the first, they soon form effective hedges. The growth made is short and stubby, and consequently the flower-heads are innumerable. There is a great difference in the dates on which such hedges flower in different seasons. Last year, owing to cold weather setting in early and continuing late, their blooms were not fully expanded until spring; this year, thanks to a more genial autumn, their flowers are already fully expanded, and they give quite a summer look to the gardens, in which there is still a good display of tender summer flowers, such as Dahlias, Heliotropes, Pelargoniums, Chrysanthemums, and even already spring-flowering Primroses and Violets. The Laurustinus is also freely used in mixed hedges that are also popular here, consisting of such plants as Escallonias, hardy Fuchsias, Euonymus, and old-fashioned Cabbage Roses, all mingled together with good effect. By cutting them with a knife instead of with shears, such plants as these answer all the purposes of a hedge or screen, and add considerably to our store of flowering plants, as, where gardens are limited, even their hedges may be made effective.—J. G., *Hants.*

Elæagnus rotundifolia.—This is a most interesting species. We have a plant of it here from 4 feet to 5 feet in height, which is annually covered with pretty scarlet and amber-coloured berries. It is perfectly hardy, having stood out in a western aspect without any protection since the autumn of 1872. The undersides of the leaves are silvery, which is more distinct on young foliage than on that which is older. The berries, which hang on long stalks like Cherries, are produced on the last year's wood; it has never produced berries here before, probably from the fact of its not being sufficiently established. It seems to be easily propagated by means of layers, and is a shrub which should certainly be in every garden.—T. T.

Spiræa bella.—This beautiful species forms an open and rather loose-growing shrub, from 3 feet to 4 feet high, which throws up strong shoots annually from the ground, that in the following season produce laterals, terminated with loose corymbs of pretty deep rose-coloured flowers in May and June. The leaves are alternate, on longish foot-talks, ovate, acutely pointed, sharply serrated, light green, and smooth on the upper surface, somewhat glaucous beneath, with the peduncles and principal veins on the under side pubescent. The stems are somewhat diffuse, flexuose, reddish, and branching; branches, loose, slender, spreading, and downy. The fruit is ripe in September. It is a native of Nepaul and Bhotan, where it is found in ravines and mountain-woods, at an elevation of from 5000 feet to 9000 feet. It is perfectly hardy, grows freely in any common garden soil, and is easily increased either by cuttings or by means of suckers, which, if separated in the autumn, soon make nice plants. It was introduced in 1820.—G.

Calophaca wolgarica.—This forms a pretty, slender, spreading, deciduous shrub, from 2 feet to 3 feet high when on its own roots, but when grafted standard high on the Laburnum, it forms a very singular and beautiful object, either when covered with its yellow blossoms in June, or with its fine reddish pods in August. It is a native of Siberia, where it grows on dry gravelly hills near the rivers Wolga and Don. It was first introduced in 1780. It grows well in any good garden soil, and is increased either by grafting it on the Laburnum, or by means of seeds, which are produced freely in most seasons. The leaves are alternate, pinnate, and terminated by a small acute spine-like point, and a pair of lanceolate stipules at the base; the leaflets are small, orbicular, and entire, with a small acute spine-like point; they are smooth on the upper surface, velvety beneath, and mostly in seven opposite pairs. The flowers are pea-shaped, bright yellow, and produced in axillary pedunculate racemes, containing from seven to ten flowers. The legumes or pods are oblong, somewhat cylindrical, with a sharp bristle-like point, and stalkless; when young they are beset with soft hairs, mixed with stiff glandular bristles, and are of a bright reddish colour; the seeds are ripe by the end of August. Its synonyms are Cytisus wolgaricus and pinnatus.

Missouri Silver Leaf (Shepherdia argentea).—This shrub forms a striking and very elegant, silvery-looking, compact shrub of slow growth, but which, under favourable circumstances, will attain a height of from 6 feet to 8 feet. It is a native of North America, particularly along the banks of the Mississippi and Missouri Rivers and their tributary streams; is easily increased by the underground suckers, and grows well in any good garden soil that is not too dry. It was first introduced into this country in 1818. The leaves are alternate or opposite, ovate or ovate-oblong, rounded at the ends, glabrous on both surfaces, greyish green above, but quite silvery and dotted all over with rusty brown scales beneath; they are from 1½ inches to 2 inches long, and from 1 inch to 1½ inches broad, and are produced early in the season. The shoots and lesser branches are of a deep rusty brown colour, and furnished at the base of each of the lower leaves with flower-buds. The flowers, which are produced in April, are small, yellow, axillary, aggregate, and unisexual, or each sex upon a distinct plant. The female flowers are bell-shaped, equal, flat, and smaller than those of the males, and produced on short peduncles in racemes at the end of the branchlets; while the male ones are lateral, aggregate, and in groups that resemble a catkin. The berries, which ripen in September, are scarlet, transparent, acid, and about the size of the Red Currant, but richer in taste. They are much relished in America, where they form one continued cluster on every branch and twig of the plant, and are called Buffalo Berries, and Rabbit Berries, and (by the American Indians) Beef Suet. The Shepherdia argentea is well adapted for small places, or for the front of the shrubbery; but as the sexes are pro-

duced on different plants, it requires to have a plant of each sex placed near each other, or, what is better, so close as to form but one bush, or no fruit will be the result.

PENDULOUS CONIFERS.

Nearly all Conifers have a semi-pendulous or drooping aspect when young, as is well exemplified in the case of the Deodar Cedar and others, but afterwards as they attain age and size they lose it, and assume their usual or natural forms. The number of really pendulous Conifers is therefore by no means so numerous as might be expected. One of the most striking of the pendulous varieties among the Larches is the Godsall Larch, which, when grafted standard high on the common Larch forms a striking and pretty object on a lawn. Lawson's pendulous Larch is another form of the common Larch which in general appearance resembles the pendulous American Larch; this kind when large forms a drooping tree with horizontal or extended branches, the lower ones of which frequently reach the ground. It is a native of the Tyrolese Alps. The pendulous American Black Larch (Larix pendula) is the Hackmatack of the American woodcutters, and is found in the coldest districts from Canada to Virginia. The wood of the Hackmatack is superior to that of the common Larch for lightness, strength, and durability. Smith's Inverted-branched common Spruce is a very singular variety, in which the leading shoot staightens itself in the old wood, after the manner of the Deodar Cedar; the lateral branches on old trees are as drooping as those of the Weeping Willow; it is superior as regards its drooping habit to all the other pendulous forms of the common Spruce. Abies canadensis gracilis is a very distinct variety of the Hemlock Spruce, with long, slender, little-divided, and drooping branchlets, furnished with very small leaves; it is a very distinct and desirable variety. A. L. S.

The Siberian Salt Tree (Halimodendron argenteum).—This is a capital sea-side shrub, but thrives equally well in any good soil, and if a little salt be given old plants of it occasionally, it greatly improves their growth. This plant is propagated by means of seeds, by cuttings of the roots, and by grafting it on the Laburnum or the arborescent Caragana. When the latter, however, is used for the stock, it is apt to throw up suckers close to the ground, and, therefore, it is not so good for the purpose as the Laburnum, which does not do so. The name is derived from "halimos," maritime, and "dendron," a tree, in reference to the plant growing naturally in salt fields and saline steppes near the river Irtysh, or Irtish, in Siberia. It was first introduced in 1779. It forms an irregular, much-branched, deciduous shrub, from 4 feet to 8 feet high, when planted in the open border on its own roots; but when grafted standard high on the common Laburnum, it forms one of the most graceful drooping plants that can adorn a lawn or shrubbery. The leaves are alternate, abruptly pinnate, with two pairs of small leaflets, clothed with a whitish silky down, deciduous, and with the petioles and stipules spinose. The flowers are of a fine rosy purple, sweet smelling, pea-shaped, tolerably large, and produced in great abundance on two and three-flowered peduncles, from the end of May to the middle of July, or even later, if the season be moist. The young plants, however, flower but sparingly at first; but when they attain size and age they bloom profusely. The pods are inflated, or bladdery, hard, ovate, brown, and contain but few seeds. Its synonyms are Robinia Halodendron, Caragana argentea, and Halodendron argenteum.

The Nepaul Beam tree.—The subject of adapting the size of trees to the extent of the grounds in which they are to be planted is one which is very generally neglected, notwithstanding its great importance; for almost everyone who plants a garden of a few rods in the neighbourhood of towns, finds in eight or ten years afterwards that a few of the coarser-growing trees have attained to such a size as to smother everything else, and to render it altogether impossible either to have smooth turf or healthy flowers. Now the Pyrus vestita is one of those small trees which are most suitable for planting in such places, not only on account of the beauty of its foliage, but also on account of its growing rapidly till it attains a height of from 15 feet to 20 feet, and becomes comparatively stationary for some years, forms a splendid small tree from 20 feet to 30 feet in height, which flowers in May and June. It is a native of Kumaon and Upper Nepaul, at elevations of from 9000 ft. to 12,000 ft., and was introduced in 1820. The leaves are very large, ovate-acute or elliptic, acutely crenated or coarsely serrated towards the points, on rather long foot-stalks; and when they first appear, which is very late in the season, they are clothed with a thick white coating of wool, but as soon as the warm weather advances they throw off their fleecy coat on the upper surface, and at length become smooth and of a glossy green. In the autumn, before they drop off, they assume a fine pale yellow colour. The branches are whitely tomentose when young, but smooth when old. The flowers, which are numerous and white, are borne in branched terminal woolly racemose corymbs. The fruit is round, tubercled, glossy, and about the size of a common marble, and greenish brown when ripe in October. The following are the synonyms under which it is often sold: Pyrus crenata, lanata, and nepalensis.—G.

Rose Garden.

ROSE STOCKS.

I am glad that "T. W. G." has spoken out so freely on the subject of the Manetti stock, and I hope many will see in his remarks the cause of their failure in Rose culture. I have observed the behaviour of the Manetti in a variety of cases. When treated in the ordinary way it has generally proved a failure. My own experience of it (and I have experimented with it in various ways) is, that it is worthless unless the plants are worked where they are to remain. Thus dealt with, they keep longer in vigorous condition than they do when treated in any other way, but I have never lifted any from nursery quarters and transferred them to another site without losing a considerable number in the third or fourth year. It appears to me that they resent removal.

With regard to seedling Briers, I think that "T. W. G." sets a higher value on them as stocks than they deserve. No one could look upon a plantation of seedling Briers in a rather poor soil at the end of July and come away impressed with them as suitable stocks for vigorous Roses, especially if the weather should have been hot and dry a fortnight previous. They are then invariably smitten with such an attack of mildew, that it is very certain the energies of the plants must be terribly crippled; and although, as "T. W. G." says, they grow out of it, plants so affected at the beginning cannot, under any circumstances, prove to be sufficiently vigorous to sustain robust growth. The germs of such a troublesome disease do undoubtedly lurk about them, and are carried with them to their new homes. It is clear to my mind that the seedling Brier is nearly as great a failure as the Manetti. I am supported in this opinion by the fact that during the past fifteen years many thousands of Roses worked on the seedling Brier have been distributed all over the country; yet there is the same outcry of Roses dying every year as there was before seedling Briers were introduced, and I do not think we want any better evidence of their unsuitableness.

It is, I think, time that rosarians generally began to acknowledge the fact that there are many Roses that are not influenced in their growth after the first two years by any stock, whatever its character may be, a remark which applies to the Tea-scented varieties as well as to Hybrid Perpetuals. Take, as an instance, that old favourite Rose Devoniensis; did ever anyone see this Rose growing better on an alien stock than on its own roots? Amongst Hybrid Perpetuals I may mention La France as a variety not influenced by any stock on which it may be worked for a longer time than I have mentioned. I therefore maintain that we gain nothing by using any kind of stock, except in the case of standards, but that is no reason why a suitable stock for Roses should not be forthcoming.

Own-root Roses hardly, perhaps, belong to the subject under discussion, yet they are closely connected therewith, and on own-root plants I claim to speak with a certain degree of authority, as I have been a raiser of them for many years. I can now point to some beds of them that I planted twenty years ago; these are as luxuriant now as at any previous time, and show plainly that we can do without stocks altogether; by doing so we get rid of the annoyance of plants dying in a year or two after they are planted. Out of 130 plants which it took to fill the four beds just alluded to, I cannot remember that I lost more than one plant, yet many of them continue to make shoots upwards of 6 feet in height, and thus the beds are a perfect thicket of shoots made during the past summer. Many lay stress on the statement that Roses do not thrive on their own roots, but my experience is that those which are weak growers as own-root plants are equally weak the second and third year when worked on stocks. As to the merits of own-root plants, the plain fact is this: People have not patience enough to allow them to get established before they condemn them. I am aware that one cannot get a large plant from the most vigorous growers under four or five years, and that there are some which never attain a large size; but then as a set-off, when they reach that stage they still increase, and one is in no trouble about a severe winter killing them, as the crown will be safe if the branches are injured; and as to plants budded on any stock, more than half the number are dead or dying by the time when own-root plants have got to a useful size. Every year's experience with own-root plants shows that, in the case of weak growers, they will grow equally well on their own roots as when worked on a stock, and that instead of dying altogether they slowly acquire more vigour, and last a lifetime if fairly well treated. Who can say as much in favour of budded or grafted plants? J. C. C.

ROSE JOTTINGS.

In many gardens the Rose is the dominant flower; in some it monopolises a good deal of the space and time at the disposal of the amateur cultivator, and to the enthusiast who can only afford one hobby, I should certainly recommend the Rose if he is in a position to do it justice. But the Rose must be treated liberally, for the large, full, globular flowers with thick fleshy petals cannot be built up on a starveling diet. The site must be well drained, as stagnant water means death in a cold winter. A good depth of loamy soil is essential to obtain the best results, and the manure-heap must not be stinted. The manure should be suited to the land, giving the cool, moist manure to the light land, and the drier, warmer stable manure to the cold, heavy soils. Night soil, if the land is light and poor, is a good application when it has been mixed with earth for a few months. Very heavy clays in their raw state are not suitable for Roses, as they hold so much water and are so cold, and we must bear in mind our cultivated Roses are, for the most part, of Eastern origin. But heavy, cold clays may be so improved by draining, burning, and manuring as to produce Roses of the very best quality, and it is easier and cheaper to do this ameliorating work before the Roses are planted than to find we have made a mistake and be compelled to do it after a failure. The Rose, with rare exceptions, does not take kindly to formal gardens, though a standard Rose may be used occasionally to form a central object in a bed; but when this is done the tree must be a healthy one and the variety a free bloomer. Gloire de Dijon fulfils this con-

dition exactly, but the number of varieties suitable is limited.

Standard Roses must have a sheltered situation. When blown about by the wind they are in a most unhappy condition. Though a few standard Roses may be admissible as centres and backgrounds, the bulk of the plants should be dwarfs, and as many as possible should be on their own roots, either rooted from cuttings or budded low down on the Brier, and the stock completely buried in planting. If this is done, the plants will in a couple of years be firmly established on their own roots. If the Manetti is the best stock for poor soils, it is not the best where the ordinary Dog Rose will grow freely, and if the wild Dog Rose is plentiful in the hedges or woods in any district, the hint supplied by Nature should be taken. The best way of improving light soil is to cover it 2 inches or 3 inches thick with clay, leave it exposed all winter, and in the spring fork it lightly in. By sheer force of gravity the clay will gradually work downwards; therefore, it would be a mistake to bury it deeply. There are many ways of arranging

Groups of Roses, and if full and free, they never come amiss anywhere. They do not associate well with formal figures, but well furnished masses on Grass are always beautiful, and in such positions we can get close up to them to cut a bud or examine and admire their beauty without treading the soil over their roots into a quagmire. An informal group, 6 feet or 8 feet or more in diameter, planted full enough to hide the soil in the Rose season, with the turf growing up to the stems, would be a much pleasanter object to look upon than many of the plantations are now. For such groups to be admissible on the lawn, dwarf Roses alone should be employed, and they should consist of the free-growing, vigorous varieties only. John Hopper, Jules Margottin, La France, Gloire de Dijon, Souvenir de la Malmaison, General Jacqueminot, Dupuy Jamain, Charles Lefebvre, Baroness Rothschild, Marquise de Castellaine, and Paul Neyron are some of these. And a full, thick bed of Tea Roses in a warm sheltered corner is a pleasanter sight than any number of Pelargoniums; but the soil must be made suitable and the plants set almost close together. The following are a few good varieties: Anna Ollivier, Catherine Mermet, Devoniensis, Etoile de Lyon, Homère, Jean Ducher, Madame Falcot, Madame Willermoz, Souvenir d'un Ami, Innocente Pirola, and Niphetos. November is the best time to plant all Roses except Teas; the latter should be kept under shelter till April. Teas on their own roots are hardy enough, as by mulching with dry litter or Moss they will be perfectly safe. It will be better to defer the planting of all Roses till March rather than plant in badly prepared beds; still, the late planted Roses do not overtake the early ones, at least during the first season.

Rose exhibitions.—I have gone through the grounds of most of the great exhibitors, and I have looked over nice collections where a green box was unknown, and where the idea of exhibiting, otherwise than as they grew or in great armfuls as they were cut, never cropped up. The exhibition list is a field of battle for which some natures have a strange love. There is a thrilling kind of joy in winning prizes at an exhibition of Roses—I should say somewhat akin to the triumph felt by the gladiator in ancient Rome when he stood ever his vanquished and prostrate foe. I have often watched the flushed face and the bright eye of the successful exhibitor as he hung over his boxes of flowers (before he had been spoilt by repeated victories) after the battle had been fought and won; and I have contrasted his joy with his nervous, restless manner on the morning of the show just before the judges went round. But when the battle had been fought and won, what then? Why, many go home to empty, flowerless beds, and must live—like the beauty who has won many conquests and yet remains single—upon the contemplation of past victories, for the present has but little to give us, and the future, though full of hope, is yet far away. Rose shows have undoubtedly done much for the Rose, but by far the most delightful gardens to visit are those where the Roses are grown for their own beauty and sweetness, and to cut for the rooms, and to give away in large bunches to friends. And in the full flush of the Rose season, the more we cut them, the more they flower; for the back buds break away and the young shoots that emerge therefrom come laden with buds, which quickly expand into globes of beauty and sweetness. Disappointment and discomfiture often await the exhibitor, and none but the strong fight the battle to the end, yet it is good for all of us to have difficulties to grapple with and overcome, for thus only can really successful progress be made. The best Roses for exhibition are not, as a rule, the best garden Roses, but still there are very few winning stands but which contain not a few of the most prized varieties for general purposes. Take, for instance, the beautiful old Gloire de Dijon; it is not often left out of the winning stands, not because it is perfect in shape, but because it is so reliable and never fails. La France, Charles Lefebvre, Glory of Waltham, and many others are good garden Roses, and also useful on the exhibition table. Some people have an idea that it requires the expenditure of a good deal of money to set up a collection of Roses, even in a small way, but this need not necessarily be so. The land certainly must be well done; it will probably cost as much to prepare the land as to buy the Roses, but even then in a small way the expenditure will not be ruinous. Of course, if a person wants to begin Rose growing in a large way at first, he may very likely be called upon to disburse largely, but anyone, if fairly intelligent, may begin with a small, useful collection of some thirty or forty varieties. Study their habits, read about them in the papers, and learn to bud and graft, and to love them, and with that love will come the necessary knowledge to enable him or her to grow good flowers, and, after a few struggling seasons, to win prizes with them. I had the pleasure of riding by rail one day last summer with a man of this class, who had struggled up from the bottom round of the ladder. I could see by the green boxes he was looking so carefully after that he had Roses in them, and was on his way to a show, and I could see that he was an amateur. My friend said he had taken prizes at the Crystal Palace and other large shows, not, of course, in the premier classes, but in the twelves and twenty-fours, and occasionally at a local show going in for thirty-six, but that was the utmost limit. And, he said in reply to my question, that he never spent after the first year more than a sovereign in any one year for new Roses, but he was very select in his purchases; he never bought a new Rose till it had been proved to be suitable for his purpose. And, as regarded his time, he never counted that anything, as he put the benefit to his health derived from his hobby against his time and work. He said his Roses often caused him to rise several hours earlier in the morning than he should otherwise have done, and he found himself the better for it. He began, like others I have known, in a small way with some four or five dozen plants, and then he procured some Brier stocks, and at the proper season amused himself with budding, and then only bought such new Roses as took his fancy. E. H.

Rose Cheshunt Hybrid.—This Rose merits all that has ever been said in its favour. It is one of the best of growers and freest of flowerers. Many treat it as a dwarf bush or as a standard, but it is as a wall plant it displays the greatest amount of merit. As a climber it possesses all the good qualities of Gloire de Dijon, and as a pair they are unique. Cheshunt Hybrid begins to bloom in early spring, and never ceases until winter sets in. It is the *alpha* and *omega* of bright-coloured Roses, and should be largely introduced and grown as a wall, pillar, or as an arbour Rose in the open. In small gardens, where varieties are limited, and good varieties only should be found, this variety should stand first on the list. Nothing could be more satisfactory than the profuse way in which it flowers; the successional blooms are as bright as those produced in the first instance, and their size, form, and fragrance are all first-rate. It is generally classed as a Tea-scented variety, the blooms of which are cherry-carmine, large, full, and, as has been stated, finely shaped. It is excellent for cutting in large quantities, and should be included in every collection of Roses.—J. Muir.

Garden Flora

PLATE 570.

ANTHURIUM SCHERZERIANUM AND ITS VARIETIES.

(WITH A PLATE OF A. S. ROTHSCHILDIANUM.*)

In the large number of varieties of A. Scherzerianum that have originated under cultivation, and in the extent of the divergence from the type or progenitor which is shown in the most prized forms of this Anthurium, we have very striking evidence of what may be done by careful cultivation and selection towards the improvement of garden plants. It is only twenty-five years since this Anthurium, now commonly known as the Flamingo plant, was introduced into Europe from its home in Costa Rica, and probably only within the last ten years has its improvement been properly worked at, and yet we have already a great many varieties, both in size, form, and colour, all differing considerably from the plant as known and figured twenty-five years ago. In the *Botanical Magazine* (t. 5319) will be found a representation of what A. Scherzerianum was then. Here the spathe is little more than I inch long, and the spadix is about the same length, whilst the stalk is only 6 inches high. Compare this with the variety known as Ward's variety, in which the stalk is sometimes 3 feet high, and the spathe 6 inches long by 4 inches broad. In colour, also, the change brought about by cultivation and cross-breeding is most marked. In the type the colour is bright scarlet, but we have now crimson, white, straw-coloured, white and pink, white and scarlet, and so on. We are unable to state whether or not all the plants of A. Scherzerianum now in gardens are descendants from those first introduced, of which that figured in the *Botanical Magazine* is one. At Kew, where Aroids of all kinds are yearly received from South America, we have never seen fresh imported specimens of this Anthurium, although other old garden plants are frequently included. It is probable that after the plant had once been established in gardens its multiplication by the usual method would render fresh importations unnecessary, and we may therefore consider it likely that all the forms of A. Scherzerianum now known in gardens have originated under cultivation in Europe.

The cause of this diversity in size and colour is no doubt due very largely to changed conditions, to high cultivation, and to seminal variation, more particularly to the latter. It is a fact of great importance in horticulture that plants with a tendency to vary under cultivation may be made to develop various and distinct characters much quicker and with greater certainty if they are propagated through several generations from seeds than if sporting through high feeding and changed conditions is relied upon. The thousands of varieties obtained from some of our most popular garden plants have, with very few exceptions, sprung from seeds produced by cultivated plants. Darwin quotes numerous instances of this in his various works, and we have every-day evidence of it in the plants which we annually raise from seeds. The whole secret of procuring new and improved sorts of garden plants

* Drawn in Messrs. Veitch's nursery, King's Road, Chelsea, May 21, 1885.

ANTHURIUM ROTHSCHILDIANUM VARIETIES

rests on this important fact in relation to seeds produced by cultivated plants, for, as Darwin shows, every variation, seminal as well as other, is directly or indirectly caused by some change in the surrounding conditions. We must also remember that the nature of the plant acted upon governs the result. No amount of change will have any apparent effect on some plants, whilst others often vary considerably with even a slight change of conditions. In its relation to the origin of the varieties of A. Scherzerianum, hereinafter to be described, the above facts are interesting as throwing some light on what we have here to relate. We have seen that this Anthurium when first introduced was small-flowered — smaller perhaps than it was after it had become established and its wants understood. In 1874, or about twelve years after the introduction of the type, we get a variety with pure white spathes, and shortly after this the famous large-spathed form, known as Ward's variety, was obtained; then the curious little variety called pygmæum, with a narrow, curled spathe, and the spadix raised on a kind of stalk nearly 1 inch long. This was followed by one with two spathes at the base of each spadix, and named semiplena. Out of these five distinct varieties all kinds of forms—some curious, others beautiful—have been obtained, till it seems probable that the Flamingo plant will be represented by as many varieties as have sprung from Gloxinia speciosa, the parent of all the Gloxinias in gardens. A curious instance of reversion to the type was afforded by an attempt to cross the varieties Rothschildianum and album—the latter being the seed parent—this having resulted in a progeny of red-spathed typical Scherzerianum. A. Rothschildianum was obtained by fertilising the type with pollen from the white-flowered form (A. Williamsi), about twenty per cent. of the offspring being white with red spots, whilst the rest were pure Scherzerianum. When the white-flowered variety was made the seed-bearer, every one of its seedlings were red-flowered.

The following list comprises all the named kinds of A. Scherzerianum about which anything is known. The differences between some of those bearing distinctive names are, in some cases, so slight, that it would be as well if their names were dropped altogether. The type is already described above. From this we go on to the larger spathed kinds till we come to—

Specimen plant of Anthurium Scherzerianum; spathes scarlet.

A. S. Wardi.—In this the spathe is 6 inches long by 4 inches wide, of a deep scarlet colour, as also is the large curved spadix; the stalk is stout, and in large, strong plants as much as 2 feet 6 inches high. There may be minor differences between this and the following, but not sufficient to justify their bearing such distinctive names as Hendersoni, maximum, Cypheri, giganteum, grandiflorum, and Woodbridgei. The last-named received a first-class certificate from the Royal Horticultural Society in 1882, but it is scarcely different from the others, except, perhaps, in being a trifle narrower spathed.

A. S. Palmeri.—This bears a spathe 6 inches in length, but narrow, with a tapering point, and somewhat curled.

A. S. pygmæum is a small form with narrow leaves about 9 inches long, and a spathe rather thin in texture, the point tapering and recurved, and of a bright red colour. Its most remarkable character is in the stipitate (stalked) spadix, the flower-bearing portion being separated from the spathe by a stalk-like expansion nearly 1 inch long. It was obtained by the Messrs. Veitch and received a first-class certificate in 1880.

A. S. semi-plenum is a form with medium-sized spathes, distinguished by the smaller supplementary spathe opposite to the larger one. It is a curiosity which might be used in crossing with a view to obtaining a variety with several large spathes to each spadix. It originated in the nurseries of Mr. B. S. Williams.

A. S. Williamsi.—This is a small plant with white spathes and a yellow spadix, the latter being sometimes stalked, curled, and pale yellow. Though not an ornamental plant, it has been useful in crossing with the red-spathed varieties. Sometimes this kind develops small, spoon-shaped bracts or spathes all along the yellow spadices, resulting in a monstrous, inelegant appearance, but interesting as showing that each of the flowers on the spadix may have a bract to themselves. A red-spathed variety showing the same peculiarity once originated in the nurseries of Mr. Patterson, of Carlisle, but this does not appear to have been perpetuated. With Williamsi we should include the white spathed Verveneanum and album, which hardly differ, except slightly in size, from Mr. Williams' plant.

A. S. Rothschildianum.—M. Bergman, gardener to Baron Rothschild at Ferrières, was the first to obtain a cross between the red and the white-spathed varieties, the former being the seed-bearer. Out of twenty-five seedlings, all except four were like their female parent, while the four had large white spathes spotted with red, the spadix being yellow, as in the white-flowered parent. Since M. Bergman's success others have raised similar mottled forms from the same cross. Mr. Heal, who has been conspicuously successful as a hybridiser of plants, has made this mottled Anthurium plentiful, and in addition to that raised by M. Bergman he has also obtained several other well-marked forms of the same character, three of these being shown in the plate. The tendency to vary has been well shown among the mottled-spathed varieties as raised by Mr. Heal. We know those who consider these spotted-faced Anthuriums ugly, but there are on the other hand many others who admire flowers of this character. The plant named Madame Emile Bertrand is nothing more than a Rothschildianum with rather small red dots.

A. S. andagavense is curious in having the back of the spathes scarlet spotted with white, and the front white with red blotches.

A. S. mutabile.—This is an interesting plant, owing to its singular habit of changing colour, hence the name. The spathes on first developing are white, but as they grow older they gradually change to a scarlet colour. In this we have a character similar to what occurs in A. Lindeni and A. Roezli, the former bearing large white spathes, which change to rosy carmine as they get older, and the latter, also white-spathed, becomes green with age.

A curiosity, with a scarlet leaf on the flower-stalk in addition to the bract, was once to be seen in the Exeter Nurseries, but this has apparently been lost or the character was not permanent. Another with a branching spadix has

been seen. There is the same tendency to variation in the size and form of the foliage of this Anthurium.

The cultivation of the Flamingo plant and its varieties is not difficult. Such examples of it as that recorded as having 165 flowers expanded at one time do not fall within the capabilities of all cultivators, but anyone who has a moist stove or an East Indian Orchid house may grow good specimens of it with ordinary care. Annual repotting is necessary, the abundance of water the plant requires soon causing the soil to decompose and become mud, so that it must be renewed every year. August is the acknowledged best time to repot this Anthurium. The soil should be carefully washed from the roots, and the plant should be repotted in a roomy pot, half filled with drainage, and in a compost of peat, Sphagnum, and charcoal, such as would be used for Odonteglossums. Loam is sometimes recommended, and we have seen loam answer well, but it was exceptionally good and free from iron. The plant should never be allowed to get dry. Good varieties are propagated by division of the tuft of growths, but seedlings are always interesting, and there is always the chance of a good variety being obtained in this way. The seeds are enveloped in orange-scarlet pulp; they take about twelve months to mature. They should be sown in Orchid soil and plunged in a hotbed of 80°. W.

WORK DONE IN WEEK ENDING NOV. 9.

NOVEMBER 3 TO 9.

FOR the week ending yesterday our rainfall register totals up 2·06 inches. On the evening of the 4th rain began to fall, and there was but little cessation till the morning of the 7th; consequently it has been next to impossible to do any work that necessitates treading on the soil, and, besides a little trenching in kitchen garden, our open-air operations have been confined to road-mending, leaf-raking, and to sweeping and rolling pleasure-ground walks. Being thickly surrounded with trees, the leaf harvest always takes up a lot of time, but in this dear fuel district they enable us to materially lessen the coal and coke bills when used as bottom heat in forcing pits, and are just as valuable for protecting from frost plants that are being wintered in turf pits, such as shrubs for forcing and Strawberry plants, also for mixing with stable litter for hotbed purposes, and, not least, for storing to rot down as vegetable mould for potting purposes, so that if all their merits were summed up, it is questionable whether there is any garden labour more profitably bestowed than that of leaf-storing, to say nothing about the neatness that is thereby assured. Put leaves in pits intended for starting our first lot of Strawberry plants. Oak is the description we prefer, as the heat is long lasting, and never intense, from the moderate bulk—about 3 feet depth when trodden down—that is required to gently excite the roots of Strawberries into growth. The plants we never plunge in the leaves, the warmth being ample if simply stood on them, as is also the heat; the leaves give off sufficient top heat without heating by hot water, unless when the weather is exceptionally severe; even then, mat coverings on the glass enable us to dispense with fire-heat. The bad weather has afforded plenty of time to examine Potato stores, to pick out bad tubers, and to sort them into using and seed sections; the latter we have laid thinly on shelves in a frost-proof cellar. Fruit rooms, too, have had a considerable amount of attention; every bad fruit has been picked out, and all of it arranged, with just a little regard to displaying it to the best advantage. Pears are, unfortunately, ripening in quantity, a common occurrence at this season. The fact is, we have far too many varieties that ripen in November, and too few good kinds for December and the first two months of the new year. Those now contemplating planting would do well to note this, and be content with fewer autumn and early winter varieties and have more late kinds, such as Doyenné du Comice, Winter Nelis, Josephine de Malines, Glou Morceau, Knight's Monarch, Ne Plus Meuris, and Bergamotte d'Esperen. Except the very early varieties, Apples keep a longer time, so that restriction of varieties is not so essentially necessary. Work in the houses has consisted in finishing potting and moving bedding plants, clearing Gardenias of soft brown scale, which with us seems almost as difficult to exterminate as did the mealy bug a few years ago, but persistence with weak paraffin oil washings is gradually working a cure. Put in the forcing pit a few Roman Hyacinths, early Tulips, Kalmias, Andromedas, and Arum Lilies; potted up crowns of Lily of the Valley and Harrison's Musk; tied up the flower-stems of Carnations, and to Cyclamen flowers that have got drawn from overcrowding and a little too much heat, we found it necessary to put a stick, and with a loose tie of matting secure them to it, to induce an upright growth of flowers. Chrysanthemums are now at their best, and we have arranged them in the coolest houses we have to prolong their flowering season. A few plants of late flowering varieties are still in the open air, as we are wishful to have them in full flower at Christmas. Preparatory to commencing forcing, the earliest vinery is being thoroughly cleansed—walls, glass and woodwork—inside and out, and the Vines painted over with a strong lather of Gishurst and soft soap. The border (an outside one) has been top-dressed, and is now being covered with leaves and litter in bulk sufficient to keep out frost, but not with the intent to artificially add heat to the soil, this being really unnecessary, even if not positively injurious, to which latter view my experience of the last few years certainly tends. Pruned trees in second Peach house; loosened Figs from trellis and cleared away all the dead foliage, and till more room can be had in vineries that are now full of Grapes this house will be filled with the hardier kinds of bedding plants. I say hardier, because on no account will heat be applied to the house till it is time to commence forcing. Filled up Grape room with remainder of Hamburgh Grapes from an intermediate house. Vineries full of ripe fruit have required much attention to cut out bad berries; a little fire-heat we keep on constantly, and this enables us to ventilate freely in all weathers, and dry, warm air is the first essential to the preservation of fully ripened Grapes.

HANTS.

Work in the Hardy Fruit Garden.

Our principal work during the past week has been the completion of root-pruning and the rearrangement of fruit trees against walls. Peaches, Apricots, and Cherries are now disposed of, and although they received very heavy waterings through the summer and we have had an abundance of rain, the lower stratum of soil resting beneath the 4-foot pathway was not a whit too wet for the roots of these moisture-loving trees. The soil in this garden being very old and full of humus, our principal care is the removal of all surface dressing and old mulching, quite down to the solid staple, at the outset. This is wheeled away to the vegetable quarters and Strawberry beds, to which strong stimulants are at all times acceptable. The trenches round the trees are then thrown out down to the drainage, every root is shortened back to within a length of one's fingers of the past year's pruning, and the trench is firmly rammed with new compost, to which a portion of the best of the old is added as the work proceeds. As nothing more will be needed until the Peach trees are unnailed and washed early in January, all the wall paths are surfaced with an inch or two of old lime rubble. A poor mulch, some may say; but calcareous matter is just what they require; the winter rains wash it down to the roots, and we secure a clean path throughout the winter. Apricots are treated precisely the same; but Cherries, which have developed gumming proclivities since the seasons became so wet and cold, on north borders especially, I now raise bodily, and after adding more drainage replant on the surface. This treatment, although the past spring was very trying, seems to have produced the desired effect, for the growths this season are clean and bright, and old sores in the forks of the branches, bound up in stiff loam and cow manure, are healing. The soil for these trees is less rich even than that given to the Peaches and Apricots; it is also lighter, and contains a much greater percentage of old mortar. While treating of Cherries, I may state that I have given up the summer training and in a great measure the pruning of the intermediate shoots, which are now allowed to grow out from the walls. All leaders, to save them from injury, are nailed in full length on the extension principle as they grow, and the best of the breastwood is laid in where space admits at the winter dressing. Old trees which have been spurred in from year to year are a little troublesome at first, but by keeping the main branches thin and removing a few of the worst, space can always be found for a quantity of full-length growths, where formerly they were cut away and not unfrequently the spurs gummed and perished. The above remarks, I ought to say, refer to sweet Cherries, of which thousands, I believe, are hastened to death by a too free use of the knife annually. The knife is a useful and indispensable implement, but, like another invaluable article—rich manure—it is often found in the wrong place, doing more harm than good amongst our already sufficiently tortured trained fruit trees. In this neighbourhood, as in Kent, we have large Cherry orchards containing trees the age of the oldest inhabitant. Sound slightly elevated ground, open to the elements, suits them best. Eltons, May Dukes, and Bigarreaus bear good fruit from year to year, but they do not gum. And why? Simply because root and branch keep pace with each other, and they are not poisoned with manure. A more simple lesson than this it is difficult to imagine; and yet we cling to the hard-beaten path of routine; we manure when every cell in a tree is gorged; we prune when the knife should be kept in the sheath.

BUSH FRUITS.

Once more these humble, but invaluable, trees require attention. Currants and Gooseberries may still be planted on fresh well-worked ground, staked and mulched, but not pruned. In old gardens we sometimes see veterans doing feeble duty, and inquire why they are not gathered to the bonfire. The reply is, "Oh! that is a favourite quarter or margin, and we cannot afford to destroy them." Gooseberries and Currants of home manufacture, as it happens, superior to anything I have yet been able to purchase, can be propagated by any labourer, and all one has to attend to is annual lifting until they are old enough to bear fruit. Then if the favourite margin is cleared in October and all the bush-sick soil from a broad deep trench is wheeled away to take the place of good ordinary stuff from the centre of a vegetable quarter, an exchange is made at little expense, and successors to the veterans go ahead without feeling the moving. Bush fruits like generous treatment, but strong manure does not lead to such satisfactory results as many imagine. Give a good depth of soil, and if it is thought too poor, place a layer of garden refuse in the bottom of the trench, raise the level to allow for settling, and mulch the surface. A few cuttings of the most approved varieties should be put in annually to keep up the stocks. If not wanted they cost nothing, and there are few parishes in which cottagers might not be helped from the squire's garden. Gooseberries, also Red and White Currants, should be divested of all their lower buds before they are put into the ground, otherwise they will throw up suckers, which rob and delay the formation of bushes on clean single stems. Black Currants, on the other hand, are not at home on single stems, but produce the greatest quantity and the best quality when allowed to stool freely from beneath the surface of the soil.

RASPBERRIES.

Now is a good time to make new plantations of these, also to thin out the canes, replace faulty stakes, and make old ones ready for the winter mulching. The formation of new beds should precede the dressing of established plantations, and for this reason: The young canes which have been left for stock should not be taken up until the fresh ground has been deeply trenched and heavily manured ready for their reception. Then, having firmed and levelled the ground, set out the rows, and driven short stakes, on a dry day lift without disturbing the old stools, and plant immediately. Unlike the Gooseberry and Currant, the soil for these moisture-loving plants cannot be made too light and rich; therefore good spit manure, leaf mould, peat, road scrapings, and burnt refuse, one or all, may be freely incorporated. Cold, heavy loams do not suit it, but deep draining, burning with wood the clayey subsoil, and the addition of plenty of the above-named materials will ameliorate almost any soil provided it is not brick clay pure and simple. These preparations may appear superfluous, but when it is borne in mind that a well-prepared bed under proper annual management will last a quarter of a century, it will at once be seen that the light is well worth the candle.

Planting.—There are several modes of planting and training, all of them good in their way, but not equally well adapted to all gardens. At this place where we are literally devoured by birds, we contrive to make our plantations in squares or double rows for the convenience of netting, and while not overlooking the wants of the roots in positions where the framework for carrying the wire and nets will not stand out too prominent. When Raspberries are planted in single rows, the canes, with all their root buds carefully preserved, may be placed 2 feet apart, or even closer, and the young wood thrown up during the following summer may be trained upright to wires, or, better still, to a double or V shaped trellis, formed by driving stakes in pairs nearly touching each other at the bottom, and 3 feet apart at the top. To these pairs of stakes 6 feet apart in the rows, two stout wires on each side tightly strained longitudinally are secured with small staples; the lowest are 18 inches from the top of the planting ridge; the highest are secured near the tops of the stakes. The canes the first season, about the end of March, unless very strong, are cut down nearly to the ground, a few buds being left to assist those beneath the surface at the outset. If well mulched and watered, strong fruiting wood rises up through the centre of the trellis, but no attempt is made to tie to the wires until endangered by high winds in the autumn. When ripe all the strongest are tied out right and left; the weakest are cut away, and a heavy mulch completes the winter dressing. By adopting this plan the fruit-bearing canes drawn out each way get plenty of light and air, the greater part of the fruit hangs down in the shade, and the rising generation of young ones occupy the centre. When planting in squares consisting of a number of rows, I allow from 5 feet to 6 feet one way, 4 feet the other, and plant in triangular triples. Three clean, straight Larch stakes receive about two canes each, and here also the young wood rises through the centre of the triangle formed by the stakes, which are 1 foot apart at the base, 18 inches at the top, and 4 feet in height. Raspberries, be it bornes in mind, should never be disturbed by spade or fork after they are once planted, but liberal supplies of dressing they will take annually.

Varieties.—Few people, even in large gardens, care to grow more than one or two varieties. Carter's Prolific stands first in Kent. The old Fastolf is excellent, so is Cutbush's Prince of Wales. Baumforth's Seedling produces fine large fruit of a deep red colour, but I have not yet discovered where it differs from our old friend Fastolf. If a yellow is wanted, the old Antwerp may be selected.

STRAWBERRIES.

Our early plants of Vicomtesse Héricart de Thury and La Grosse Sucrée still keep throwing up strong trusses of flower, which set and swell well, and, aided with a little protection, might have ripened a quantity of fruit in October. A frost on Wednesday—4°, the first of the season, and just sufficient to cut the Dahlias—may perhaps put an end to this desultory bursting of crowns, otherwise our precocious friends will be found wanting when their tribute is expected. To the same cause, extreme mildness and dry warmth in the ground, we may attribute the persistent growth of runners and weeds, not only in August-planted beds, but also in old ones. These we are again clearing out, and giving the surface roots about 2 inches of rich mulching recently removed from the Peach trees. Young plants from which a little fruit is expected next year will require firming with the foot as a preliminary to the application of the top dressing, which should be rich and carefully applied without burying or breaking the foliage. On light, warm soils I have found old cows' manure and marl laid in ridges between the rows in the autumn, and levelled down after a sharp frost, a most excellent fertiliser. On the cold calcareous land with which I now have to deal, old Mushroom manure, containing one-third of turfy loam, suits the plants best. Having a liberal supply, it is cast freely over the beds, and the rougher and looser it lies the better they like it.

Composts.—Where root-pruning and planting receive proper attention it generally happens that stocks run low by the end of the season. Vines, Peaches, fruits of all kinds under glass must have their annual quantum of the best, and when it has done duty in this department, being highly charged with stimulating matter, it forms an invaluable store heap for use amongst hardy subjects. Light and heavy loam from old pastures should now be cut, not too thick, and stacked in long narrow ridges ready for use in the spring. If heavily clothed with herbage it should be closely mown, as too much Grass induces fermentation and sourness in the stack. When newly-cut turf is to be used at once in the renovation of Vine borders, fermentation is often an advantage; not so when slow decomposition of the fibre should be the first consideration. The better to secure this a dry harvest time must not be overlooked; a few drain pipes running horizontally through the body of the stack and a cap of thatch will complete the most careful precautions. Peat, in many places an expensive article, not unfrequently receives more care than it requires. Where small quantities are required at short intervals, a few sods may be kept on hand under cover, but the bulk keeps best and retains its virtue longest when stacked and thatched in the open air. Sand, charred materials of all kinds, crocks, and pots cannot be kept too dry. Road scrapings and parings from the sides, well charged with grit and manure, make a most excellent fertiliser, safe, sound, and equal to half the specialities cultivators have the privilege of buying at a high figure, but coming easy, it is too much neglected. Like turf, this should be well stacked up in solid ridges to drain and dry, and time should be allowed for it to pulverise and put off its caustic character before it is used. Successful growers of bronze and zonal Pelargoniums know its value. Manures, in the same way, cannot be too firmly stacked and beaten up with the back of the spade, not only so economise space and maintain neatness, but also to seal up ammonia and keep in their fatness. Manure from the nearest spent hotbed or lining does very well for ordinary purposes, but when one wants a small quantity of superior quality for potting and top-dressing, a good stock from the feeding stalls should always be on hand. Green or raw manure is quite as injurious as over-doses of strong liquid, but when thoroughly ripe and used in moderation it forms one of the most valuable articles in the horticulturist's laboratory. W. COLEMAN.

Eastnor Castle, Ledbury.

King of the Pippins.—What Apple have we in November, December, and January equal to this? It bears year after year with the greatest certainty; the fruits are of good size, handsome, firm in the flesh, and rich in flavour. It is ready for use now, and will remain good during the next three months. It is suitable either for kitchen or dessert.—J. MUIR.

FRUIT GARDEN.

ROOT-PRUNING.

As in most garden operations, there are, of course, many degrees and modes of root-pruning. For example, total uplifting and replanting is the most radical method of all, but this is so different and so much more severe than any of the other methods, that it is shunted off the line of root-pruning by practical men. There remain, however, several methods of performing this most vitally important operation, and these differ more in degree and method than in their principles or results. There is the original mode still practised by some which may be described as both a leap and a series of cuts in the dark. To give the authors of this method justice, however, they were really less in the dark than many of their critics supposed. Admitting the correlation of top and root in regard to vigour, distance, and also direction of growth, they made a series of cuts with sharp mattocks or spades where the roots were supposed to be, and doubtless not seldom succeeded in severing the strong ones; but, of course, they also often missed these and played havoc with the best. Such leaps in the dark in root-pruning are now abolished, and the first step and condition towards root-pruning consists in baring and more or less freely exposing the main roots of the trees. Hence the practice of root-pruning is now based on the safe principle that seeing is believing; but there is another and yet more important result arising from the practice of seeing rather than guessing our way in root-pruning. The mere baring of the chief roots and the detachment of the surface ones from the earth is of and in itself one of the most important and powerful methods of root-pruning. This is a feature of the practice that has been but little thought of or taken into account by many. But it cannot be too emphatically stated that the preliminary steps towards what is mostly considered root-pruning constitute a pruning process of more or less severity, for it is impossible not to destroy a good many of the smaller, more fibry, and, in consequence of these qualities, most powerful feeding roots in the process of baring the main ones, however cautiously or skilfully spade or fork may be handled, and, besides, the effects of root-disturbance can hardly be distinguished from those of root-pruning. Detached roots, or those merely mixed with or pressed against the soil, possess no feeding power. It is not till the vital force takes the initiative and grips hold, as practical men express it, of the earth that the roots become endowed with the power of absorbing, manufacturing, or conveying the food of plants to any useful purpose. They may absorb and convey water, but that is a widely different thing; hence all separation of roots from the earth cuts off for a time, or greatly reduces, the supply of food, and is therefore equivalent to a certain amount of root-pruning.

Much experience and a good many experiments also go a long way to prove that roots merely detached and not pruned are often longer in re-establishing their working connection with the earth than those that are pruned and immediately replanted. The practice of inlaying plants by the heels is fruitful in examples of the above curious, and to many unexpected, phenomena; and yet it may probably be accounted for on the simple principle that the concentration of force not only augments its energy, but quickens its speed. Be that as it may, it may be laid down as an axiom in root-pruning that the root-disturbance involved in baring the roots is equivalent to a considerable amount of pruning.

From the stage of exposing the roots there are at least two modes of procedure. The most common is that of searching for and pruning back the thickest and strongest roots—that is, in the

language of practical men, those with fewest fibres and strongest fangs. These vigorous roots are mostly found running in two directions and at every possible angle between the two. They may, however, be roughly described as vertical and horizontal. The former may be pruned back to within a yard of the tree with perfect safety as a rule, and it is to these chiefly or only that the most experienced root-pruners turn their attention. It is these vertical fang, fibreless roots that favour the production of much wood, and render yearly fertility a vital and physical impossibility. But more caution is needed in regard to the horizontal roots, and it may not seldom prove inexpedient and even dangerous to sever all of these within a yard, or, in case of larger trees, two or even more yards, of the bole. In exposed situations the whole of the horizontal roots may be needed to brace up the tree against prevailing winds in the absence of the powerful vertical holdfasts already removed. In all cases it is safer to root-prune too little than in excess, for it is easy to repeat the process, but difficult, if not impossible, to restore the vigour of a fruit tree crippled through excessive root-pruning. Unfortunately, the trees in such condition are mostly twice punished—first, by over-pruning, which is bad enough; and secondly, by over-cropping, which may prove even more disastrous and destructive in its results.

One of the simplest and easiest methods of avoiding the risks of either is the adoption of the tentative mode of root-pruning, by which the process is completed in two or even three operations instead of one. If the results of the tentative method are less rapid, they are assuredly equally or more permanent, and the risk of serious accident or loss is reduced to nil. And should any tendency manifest itself in the tree to grow out of fertile ways, nothing can be easier than to correct it by resuming root-pruning. In fact, in some climates and on some soils the safest practice is to continue tentative root-pruning annually, as skilfully managed it must cause little loss or any serious diminution of the crop.

The most common and simple method of carrying out root-pruning tentatively is to prune one-half the roots at a time. In bleak and exposed positions, one-third might be safer, and after the entire area of the roots has once been operated upon, the three-year's system would prove almost equally effective in perpetuating fertility. But under average conditions half the roots may be pruned at one operation with safety, for it must be borne in mind that though the operation should be thorough, as far as it goes, only a half of the roots or a little more, in the first instance, are operated upon at one time. Now, in all the other modern methods of root-pruning the trees suffer a compound loss. The surface roots are twice pruned, or subjected to its equivalent as far as their arrestment of function is concerned, through their detachment from the soil. During the process of removal, however carefully performed, not a few of the feeding roots are broken off, that is pruned or bruised in the process. By tentative root-pruning, a half, two-thirds, or, if thought desirable, three-fourths of these are left intact, for it is almost as easy to divide a root run into four quarters as two halves. Returning, however, to what is on the whole the best plan, that of root-pruning a fruit tree by two little goes instead of one great one. The first question is, how shall we divide the area of the roots? Here we have two certain guides—the points of the compass and the direction of the roots. Experience has almost established it into an axiom that wherever there is most sun-heat thither will the larger and stronger roots be most thickly gathered together. This discovery, like not a few others, tended for a time to lead root-pruners into a wrong practice, though not on a wrong scent. The roots were there, but it was a mistake to cut or disturb them all at once, as there were frequently very few more to be found. Hence, by far the best method is to divide the roots' area into two semi-circles, east and west, and operate on either of them first as is most convenient.

The diameter of the half-circle must be regulated by the size of the tree to be operated upon. A clear yard from the bole in the case of the usual run of pyramidal or bush trees is a useful rule, but this may be extended to two in the case of larger ones. Within these ranges most trees may be dealt with. Beyond this space a deep trench from 2 feet to a yard is dug out a spit or more wide, according to its depth; and, as a rule, the whole of the roots found in the trench here are cut off. Some root-pruners, however, make a point of following the best ones out and preserving their fibres and doubling them back to be replanted. The trench reveals the character of the roots and affords space for dealing with them. It requires to be wider at the side opposite the bole of the tree, as the whole of the root mass should be tunnelled underneath up to and right beyond the bole. From beneath the bole every vertical root is cut through to within 2 feet or a yard of the surface. On some soils and by some practitioners the severing of the side and base roots is held to be sufficient root-pruning. But the majority of practitioners are not satisfied with such rough and ready methods. Vertical roots cut off under a ball are apt to push strong root-buds and start afresh on the same tack and once more find their counterparts in sterile shoots on the tops of the trees.

To prevent this and other evils the more careful root-pruner clears the soil away from the roots under operation, uncovers, prunes, and rearranges them at pleasure; the vertical roots are cut out almost entirely back to the bole, or, if not too stubborn and there is a scarcity of roots, as is often the case with Pears, they are bent upwards in a horizontal direction. All the best roots are either displayed horizontally or slightly pointed upwards in the fresh filling up. The roots are also pruned back in such manner that their vital extremities, in and through which the most important functions of nutrition are performed, may be almost equally distributed all through the root runs, instead of crowded together on their outer extremities, where the root rivalry is often the strongest and the competition for food the keenest. The redistribution of the roots, the mode and matter of filling up are of almost equal or more importance than the mere root-pruning. It must suffice now to say that the distribution of roots should be regular and equal, as near as may be, the soil under and among them laid firm and made as solid as practicable, without applying sufficient weight or violence of any sort to rupture or bruise the roots, and that in all cases where the soil appears worn out or exhausted more or less fresh soil—the more the better—should be added to the old. If these matters are properly attended to, each plane of earth from base to summit will have its healthy root with one special and separate feeding ground free, for a time at least, from the intrusion of any and all others.

Closeness to the surface of the main roots.—Like most other novelties, this has been carried to extremes, and, unless in cases in which it is intended to have a permanent mulch over the soil, nothing will be gained by bringing the roots nearer the surface than 3 inches.

Best means of consolidating the roots after root-pruning and replanting.—There is no consolidator equal in gentleness, force, and closeness to water. All these are supreme merits in the case of newly-removed, freshly-pruned roots. A liberal supply of water, heavily applied, runs the earth home into every nook and cranny, and only those who have tested it by experience can have any idea how firmly and solidly such mixtures of earth and water settle home over and among the roots. After this deluge comes a top-dressing of a few inches of dry soil or a mulch of litter, and the operator's work is completed and that of the roots begins forthwith. What, no stakes! No, none, as a rule, for not the least indirect benefit of tentative root-pruning is that half, or even more, of the roots being mostly intact, these suffice to support the trees without stakes, unless in localities where special winds prevail from any given quarter. But even these may mostly be baulked if duly noted beforehand.

For though some broad rules have been laid to guide root pruners as to whether they shall make their first essays on the roots on the north, south, east, or west side, yet may they safely box the compass in search of any mixture of points, cardinal or otherwise, that shall best fortify trees to stand upright without bending or flinching through their interim of weakness that succeeds to their root-pruning. All this, however, has but a scant bearing on wall trees. The stability of these being ensured, they may be the more freely root-pruned and even wholly transplanted with safety. With stone fruits, however, considerable caution is needed, as gumming not seldom closely follows the cut of the knife on their roots; and for Peaches and Nectarines especially careful lifting and replanting are often preferable to root-pruning, as generally understood by the phrase that is more or less cutting.

Fortunately, a simple mode may often be found to limit by almost one-half the root-pruning of such trees whose extraordinary vigour renders it indispensable. As their roots necessarily run to the north and south of the boles, if the roots on the south side are lifted or lightly pruned, this will mostly suffice to moderate their growth on the lines of fertility.

Doubtless this seems somewhat contrary to the old notion that every root had its branch, every fibre its twiglet to support. Though modern scientists would be the last to deny the close correlation that links together root-work and top-growth and produce, yet wider knowledge of the functions and freedom of vegetable life as a whole seems to prove that the bark, wood, and vessels of plants are so permeable to fluids in all directions, that wherever a demand arises for fluid or force, fluids enough and to spare shall be forthcoming sooner or later. Much of the distance and the difference between sterility and fertility may be covered or made up in the time of waiting for supplies. All root-disturbances, whether of lifting or pruning, call a halt in the speed or a lightening of the loads in the vital delivery company that rest not from their labours throughout the season in their distribution of supplies from lowliest rootlet and fibre to the loftiest twiglet and bough. The cultivator, however, may so control these through root-pruning and otherwise as that the products shall be in accordance with his wants and wishes. Radix.

LIFTING LARGE PEAR TREES.

Having tried an experiment in reference to the above subject, I am desirous of recording the result for the benefit of any perplexed amateur. Now, there are six large Pear trees against a wall in my employer's garden full grown, well trained, and facing the west. The girth of the largest is 3 feet, thus giving your readers an idea as to the size of them. They have scarcely ever borne any fruit, saving occasionally a few on each, and each year they have thrown out strong, vigorous shoots; so, last November, I dug a trench about 4 feet from the trunks of four of them. I then cut the large roots (with needed help) and lifted them close to the surface, forking the soil round and among the roots, and mulching them with plenty of horse manure to protect them mainly during winter. They were allowed some time to settle down, and then were nailed close to the wall, as they were before. Some time after the operation a manager of one of the best nurseries in England came to look at the gardens, and, of course, said the trees would die. However, I am pleased to say that all four are living; two of them have thrown out their foliage beautifully during the past summer, and one has had a very nice Pear on it. Two of them are not doing quite so well, because they were served very bad in the lifting, having three or four large tap roots directly under the trunk and possessing but few fibres.

Thus far the experiment is a success. I need scarcely add that they have had a large quantity of water during spring and summer. The

fact is, the trees were too deep. No doubt there are many of your readers who have trees of the nature I have described, but do not know the cause of failure. Now, if they will pursue the course as above stated, I see no reason why they cannot share a like success.

I must again emphasise the fact that trees so lifted must have abundance of water during spring and summer. T. H. Heath.

The Mansion, Totnes, Devon.

HARDY FRUITS.

The most important work at the present time amongst hardy fruits is root-pruning, renovating, and planting. Judging from the fine samples of Apples and Pears which have this year been produced, it is quite evident that considerable progress has been made by growers in many parts of the country. Kent, it is generally admitted, stands first, but why the fruit from that county takes the lead, at first sight it may be difficult to imagine, as there cannot be so very much difference between the climate of that and some other counties. The cause, then, must be sought in some other direction, as there are thousands of spots in different parts of the country equally well adapted to the culture of the Apple, which may be considered indigenous to our soil. From Devonshire wonderfully fine Apples are obtained, and more than one spirited grower is proving on the exhibition table that Hereford is capable of producing fruit worthy of her name. But what are the trees which produce these fine bright examples like, and how are they managed? Surely they cannot be the wretched Moss-covered, Lichen-clad, Mistletoe bushes which gave more than one great writer the horrors some short months ago. Certainly not, although these are capable of and in many places are undergoing a course of renovation which will yet pay for the thinning, grafting, and scrubbing; the draining, top-dressing, and cultivation bestowed upon them. Cultivation is the word. The men of Kent first in the field. The Devon and Hereford men, while not despising old friends of the past century, plant trees of every conceivable form by thousands and cultivate. They drain, they subsoil, and trench deeply. They disdain the old wilding stocks, and kernels raised haphazard, in their own districts, and select the most approved sorts for market or private use. These may be on the free stocks for standards; or on the English Paradise or the French Paradise for pyramids and bushes. Mr. Watkins, of Withington, near Hereford, I believe, grows his fine fruit on young standards, but the majority of cultivators now give preference to low-growing trees on the dwarfing stocks, root-prune, mulch, and feed well during the time they are swelling up their fruit. To a great number of fruit growers of the present day these dwarfing stocks, to which we are indebted for such fine fruit, are comparatively new, but this is a delusion, for the editor of the "Parks and Gardens of Paris" tells us they were used in France nearly 200 years ago, and the writer of an old book published in 1706, teaching his patron how to plant his four acres of garden, speaks of the Paradise as the generally acknowledged stock of that country. If the churchmen of those days, for the writer was a Carthusian monk, then, as now, went in for the best, and recommended the Paradise stock, which has held its own for centuries, there must be something good in it; but how it happens that it has made such slow headway in this country the wonderful crops it is now producing deeply involve in mystery. At last, thanks to observant writers, and competitors, who were driving us out of the orchard, if not out of the garden, the two dwarfing stocks are now propagated and worked by the million, and find a place in every garden, be it large, or a tiny bit at the back of the cottage, throughout Britain. So far so good; but lest the owners of these miniature gardens should think planting puts an end to their labours, and that they only have to admire and reluctantly gather the produce, I beg most earnestly to warn them of their danger, and to say they must cultivate.

Apples on the French stock never grow strong, but form a mass of roots, which do not go down very deep, and the crops they carry are enormous. If left alone they very soon become stunted and weak, and having such a small root run the soil becomes exhausted, when the fruit speedily falls away in quantity and quality. Mulching with good rotten manure and an occasional soaking with diluted liquid, or pure water, are two very important points in good culture, and will keep the trees progressing for years; but something more is wanted; they must have a taste of fresh compost. The quantity need not exceed a few spadefuls, neither must it be largely composed of animal manure, as this will be wanted for mulching. The best material I have met with is good turfy loam, fresh and free from the pasture, or, lacking this, the wayside. Scrapings from a limestone road laid up to become dry make an excellent corrective; burnt earth or clay, charred prunings, and garden refuse make the best of all fertilisers. When trees on this pompon stock have been well planted in good friable soil that has been trenched 2 feet in depth, they should be worked round with a spade or fork at the end of the second or third year, not perhaps so much to check growth as to shorten the points of the roots and make them ramify in the new soil. After this it is possible the roots will take care of themselves until the fruit by its size intimates that fresh food will be acceptable. Some leading nurserymen who disapprove of this stock for orchard planting must, I think, admit that it is well suited to the formation of miniature cordons for training on low walls, against trellises, or horizontally in large or small gardens where space is limited. It is also the stock for choice or tender sorts like Calville Blanche, and some American varieties, when potted for orchard house culture.

The English Paradise is a much stronger grower, but still a dwarfing stock, and, not excluding the Crab, is more extensively used than any other. Like the first, it has a wonderful effect on the scion, which in a year or two becomes very fertile and bears fruit of fine calibre. Some fruits of Peasgood's Nonsuch from this stock now before me, as handsome as a Lord Palmerston Peach, weigh from sixteen to nineteen ounces each, and other varieties are proportionately heavy. It also makes much stronger roots, takes a deeper grip of the soil, generally throwing out one or two rather strong anchor roots, and for this reason the trees should be worked round and well root-pruned at the end of the second year. Once root-pruned, bushes or pyramids make steady and profitable progress up to a good size; but no matter how large the orchardist may wish them to grow, size of tree should not be the outcome of neglected root-pruning. If any amateur cultivators there be who within the past few years have taken up, to them, the new dwarfing stocks, but have not examined the roots since the trees were first planted, now, this month of November, is the time to overhaul them. If strong, two or three-year old trees may be worked round until the balls are not more than 18 inches through; each strong root must then be shortened with a clean cut, when the new compost previously prepared must be made very firm about them. Next to planting, root-pruning, and training in a skilful manner stands the important operation of

Mulching.—On naturally rich, but heavy soils, especially in cold districts, the material used should be light and warm, of moderate thickness, mild or stimulating, according to the condition of the roots and the prospect of fruit in the coming season. Warmth being such an important factor, the winter mulch should be sufficiently heavy to keep out frost, and to prevent the escape of moisture early in the spring. The summer dressing, on the other hand, whilst preventing evaporation should be light, or loose enough to favour the absorption of sun-heat when the sap is in motion. The names of the materials used are numerous—one might say endless—and may consist of almost anything through all the grades of manure to long stable litter, from rough lime rubble—a capital non-conductor—to Cocoa-nut fibre. On warm or thin soils, manure from cow-sheds and piggeries is often used by experienced cultivators, but it is possible to have too much of a good thing; therefore, to prevent the book gardener burning the roots of his trees, it may be well to remind him that these powerful stimulants should never be used—and then sparingly—until they have been piled up at least a twelvemonth. Then, a stimulant being needed, it is a good plan to chop the manure down, spread it thinly round the trees, and cover with short litter, or, this being objectionable to the eye, a covering of charred garden refuse will answer equally well. To those who require a milder mulch and wish to steer clear of danger, let me commend the partly exhausted Cucumber or Mushroom bed—at all times free from the seeds of weeds, good retainers of moisture, and, at the same time, sufficiently pervious to sun-heat, which will draw the roots to the surface—the best of all feeding grounds.

My object, when I commenced this paper, was to direct the attention of the owners of small or villa gardens to the importance of lifting, root-pruning, and planting; but, having already exhausted my space, my remarks upon the last subject must be limited. Root-pruning and planting being kindred operations, almost invariably confined to the autumn months, it generally happens that the two are carried on or closely dovetailed together. In order to plant and grow successfully, the first thing to be considered is the preparation of the soil. This, as I have before stated, should be well drained to free it from stagnant water, and trenched at least 2 feet deep. If old pasture or cultivated garden ground, stirring the soil will give the trees a good start without the aid of manure, which should be kept in reserve for mulching. Light soils can be worked in all weathers when rain is not falling, but deep, heavy loams, which are most suitable for Apples, should be trenched and levelled before they become cold, wet, and plastic. Assuming, then, that these operations were performed last month, and the newly broken ground has had time to settle, it will be necessary to set it out by drawing drills running from north to south, 5 feet apart for the French Paradise and 6 feet to 8 feet for the English. Lines in the opposite direction 4 feet apart may run either at right angles or diagonally, according to taste, the main point being the disposal of the trees in rows running from north to south. At each intersecting angle a stout stake should be driven quite down to the solid subsoil and sawn off 2 feet to 3 feet above the ground-line. If the ground is high and likely to be affected by drought, holes may be taken out for the reception of the roots; if, on the other hand, it is low, cold, and damp, planting on the level and mounding with soil from between the rows will answer best.

Planting.—A sufficient quantity of fresh compost similar to that recommended for use at the root-pruning having been prepared, no time should be lost in getting the trees into position on their arrival from the nursery—that is to say, if the plantation is to be formed with newly-bought trees. Many prefer securing them a year in advance, and a very good plan it is, as a great number of them take up very little space, and a summer's acquaintance enables one to decide how they shall be arranged. Moreover, trees of home manipulation from the maiden are made to assume forms best adapted to the grower's requirements, and, being on the spot, they can be transferred from the little nursery to their permanent home early in October. All, however, have not the time, the convenience, or the experience; consequently the nursery is the only resort; and, with the exception of a saving of time by buying a year or two beforehand, the nurseryman's quality will be found all that the most fastidious can require. I have said no time should be lost in getting nursery trees into the ground, but this will depend entirely

upon the weather, as it is better to lay them in and wait even till spring than ruin some soils by treading in the wet. When unpacked, each tree should be examined to see that the union is satisfactory. All straggling or mutilated roots at the same time must be cut well back to sound wood, and if, as sometimes happens in November, they look dry, insertion in puddle will arrest injury if they have not been too long out of the ground. But what is "puddle?" many an amateur's help-meet will inquire. Well, puddle for very small trees can be made by filling a large bucket half full of adhesive soil and reducing it to the consistency of thick paint by the addition of water. Into this the roots of each tree should be dipped if not particularly dry when planting is performed in dry, ungenial weather. It is a brief operation and often does away with the necessity for watering when the roots are dormant and the season late. From this remark it must not be inferred that I ignore water; quite the reverse. I approve of it for every purpose where pure liquid is required, and look upon good pond or river water as the finest consolidator of soil about the roots of newly planted trees, when and wherever they are disturbed before the leaves fall. After that period good friable compost placed about the tender roots of small trees will keep them moist enough through the winter. When placing the trees against the stakes it is always wise to keep them well up as opposed to deep planting, and to give them an occasional shake to work the fine particles of new soil in amongst the roots. Moderate firming with the foot, followed by frost-proof mulching and a loose tie or two to keep them upright, will settle the work for the winter. W. Coleman.

Eastnor Castle, Ledbury.

SIZE *v.* QUALITY IN FRUITS.

One of the reasons why size has great weight with planters is the fact that even in private gardens now-a-days fruits must have what may be termed marketable value, as surplus produce is sold from nearly all gardens in the kingdom, and those responsible for such sales soon find that small fruits, no matter how good they may be in flavour, are in little request; while large ones, even if the flavour is only second-rate, realise good prices. No gardener would for a moment compare Gros Colmar Grapes with Grizzly Frontignans, or Lady Downes and Alicante with Muscat of Alexandria, but they have to consider what will best sell, and what will make a good display on the table. The eatable value is kept in the background; consequently it is only where flavour is made a speciality of that we find it valued as it ought to be. Let us take Pears as an illustration as to what effect mere size has on some people. In this locality the Pear crop has been good this year, and really fine-looking Pears sell readily, but small ones are of little value. Pitmaston Duchess is probably the most popular market Pear grown, and at a rough guess I should say that our crop of it from one tree realised as much as that from any four trees of the Seckel or any of the other high flavoured, but small Pears. People will hardly look at such fruit, and although for my own eating I always select a small russetty-skinned Pear, yet I must plant large kinds for market, simply because they pay. It is the same with Apples; little ones that used to be popular are now out of date, and even for dessert people want a good-sized, high coloured Apple. One of the most popular of dessert Apples is the Red Quarrenden, the merit of which lies in its high colour; as an edible fruit it is surpassed by many that are not worth half as much in the market. In the case of Strawberries, Sir J. Paxton is more largely grown than any other kind, not because it is the best, but because it is a fine-looking fruit, bears carriage well, and proves at the end of a journey to be in good condition; it therefore sells well. Similar cases might be cited, but these, which are of everyday occurrence, show that growers are not blind to the defects of the system which compels them to sacrifice quality to good appearance. It is demand that creates the supply, and those who have to cater for it must endeavour to meet it, or find their occupation gone.

Hants. J. Groom.

RASPBERRY CULTURE.

When in the west of England during the past summer I called upon an old gardener, and found that he had wonderful crops of Raspberries; the fruit was not only numerous, but also very fine. The sort grown is a favourite one among the Kentish fruit growers, viz., Carter's Prolific, a red variety. The soil in which the plants were growing is composed of about three parts of a light loam, and to this is added annually a good dressing of decayed horse manure. The loam—a fertile one—is fully 2 feet deep, and in such a soil the roots go down deeply, and it is not to be wondered at the plants grow strongly and produce heavy crops of fine fruit. A plantation is allowed to stand for about six years—not longer; after that the fruit becomes small. The best and finest crops are when the plants are about three or four years old. When a new plantation is to be made the ground is deeply trenched and freely manured; then the strongest suckers are selected from the old stools, which are lifted about the end of September, and they are planted out in rows 6 feet apart from plant to plant, with a space of 5 feet between the rows The second year numerous shoots spring up from the base of the plant, all of which, with the exception of the four most promising, are cut down close to the ground. Two of these are trained to stakes placed in a slanting direction on one side of the bush, and the other two in like manner on the opposite side, so that an open space is left in the middle for the young suckers that follow to grow up in. The plants are kept clear of weeds during the summer, and if a numerous company of suckers spring up they are thinned out, and about twelve of the strongest left to each root. This greatly accelerates the growth of those that are allowed to remain, and also improves the size of the fruit. If any more shoots are put up after the bushes are so regulated, they are at once removed. About the end of November the dead stems are cut away, the growths of the current year examined and all cut away, excepting eight or ten of the strongest. They are then pruned, about 8 inches of the top of each being cut away, and they are then tied out as above described. New plantations are made when the plants are about four years old, and by the time the old one is spent the new one has come into bearing. A good dressing of manure is put on in the early part of the winter, after the prunings are cleared away and the soil forked over, taking care not to do it too deeply to injure the roots. The Kentish Raspberry growers long since found out the advantage of thinning out the suckers. They cut away all the weakly ones, leaving a few of the strongest only. The result is, that the fruiting canes go on bearing longer than they otherwise would. But, good as the sorts already grown are, there is yet ample room for improvement in our Raspberries, more especially in the direction of continuous bearing. A new variety named Lord Beaconsfield is highly spoken of. It is a red variety, particularly fine, and its robust habit withstands the drought better than any other; the fruit is very large, and borne in the greatest profusion. Baumforth's Seedling is a new large red variety of fine flavour and very productive; but in ordinary kitchen gardens Raspberries are far too much crowded. R. D.

FRUIT EXHIBITIONS.

There have of late been several large exhibitions of fruit, notably of Apples and Pears, and doubtless many useful lessons have been learned, not only as to what kinds it is desirable to grow, but what is of equal, or perhaps of more, importance, what sorts to avoid. Fruit catalogues are so overstocked with sorts, that I am sure those who have not had a good many years' experience must feel considerable difficulty in selecting any given number of trees which they may require. At exhibitions many take down the names of fruits in the winning lots, or any dishes in other classes that especially take the eye, and as the show is called a hardy fruit show, visitors are under the delusion that all the fruits which they see set up are grown in the open air, whereas in many cases they have been grown in orchard houses. Many of our most successful exhibitors know that a dish of Calville Blanche, or of any other kind, though useless for ordinary culture, often turns the balance in their favour where the competition is closely contested, and many a *bona-fide* open-air grown lot thus gets put second or third, instead of first, solely through exhibiting a dish or two grown under glass. I have no wish to depreciate the culture of Apples or Pears in orchard houses, but I think it ought to be distinctly understood that a dish of orchard house grown fruit would disqualify a collection in which it was put, for it does a good deal of harm and no real good, as there is abundance of sorts that can be grown to perfection in the open air. No amount of cultural skill will make tender sorts that even in sunny France require a wall come to perfection in many parts of England; in fact, even in the case of the hardiest kinds it takes considerable time and experience to find out the sorts that really succeed best in certain localities. The fact that young trees in nursery lines bear good fruit is a sign of progress; indeed, in good fruit years one may see fine crops on trees barely large enough to be sent out as bushes, pyramids, or cordons. One point exhibitions have clearly demonstrated, and that is, that in the southern parts of the kingdom the highest coloured fruit is to be found, and my impression is that although Kent has so long enjoyed a monopoly of fruit culture, Sussex could beat Kent on many points, especially if dwarf trees were the rule. Of course the strong soil of Kent and its large forest-like trees yield quantity, but quality must henceforth be considered, and the warmer soil and maximum of sun heat that the more southern counties enjoy ought to mark them as especially suited for hardy fruit culture. James Groom.

Gosport.

KITCHEN GARDEN.

ROOTS FOR WINTER.

During summer and autumn, when gardens are full of everything required, a scarcity in the way of roots may be tided over by substituting something else. But in winter, when all kinds of vegetables are valuable and many sorts scarce, a good supply of sound roots is most useful. In fact, with plenty of roots, the absence of many kinds of green vegetables will hardly cause any serious comment, as cooks use roots very largely in many ways, and in less pretentious hands they also supply all in the way of vegetables that is necessary for days together. Perhaps, however, the full value of roots is never more appreciated than during a long spell of frost or snow, when greens cannot be readily got at, or are destroyed by the severity of the weather. Stored roots are then safe and at all times accessible. As soon as they are under cover, one may rest assured that, come what may, the root supply is right. Many, however, lose some of the best of their roots from being too long in storing them, and others fail from storing them badly. In storing timely and properly lies the secret of successful keeping. No root which requires protection and storing should be left in the open air after the beginning of November.

Potatoes head the list of important winter roots. I know of many cases in which late crops have not been taken under cover yet; the wet weather experienced in some districts made it impossible to lift them; but the moment they were movable they should have been lifted, and where quantities were housed during fine weather, those still out should not be put along with them, as a good deal more decay will take place amongst the latter than the former. We know some growers who store many tons in their outhouses at this season, and they keep remarkably well there until new Potatoes come again, and I would never desire a better place in which to keep them than a cool shed.

They are emptied down in a light position first; then they are turned over with the hands a few times at intervals of two or three days; the bad ones are picked out each time turning takes place; then they are put into a heap and covered over with straw to exclude light. If well picked over before being covered up, disease will give but little or no trouble, and one turn over about mid-winter will be all they will require until spring, when they have to be turned over now and then in order to break the growths off the tubers. There are few growers who have Potatoes to store who do not possess a shed or some kind of outhouse that will keep out wet, and this and the straw covering are all they require in order to keep them in prime condition. The great advantage of storing in sheds is that they can be so conveniently got at for use, and any signs of disease or premature growth can always be observed and checked in time.

Leeks.—These do not generally come under roots for winter use, but it is more the root portion of stem below ground than the tops that are used; and where have we got a more useful winter vegetable? Leeks are extremely hardy and will bear almost any amount of severe weather, but those which are full grown now may decay before the winter is over, and they will keep better if lifted and placed with their stems amongst ashes in some odd corner than left in the soil. They should be put in moderately close, but not so much so as to rest on each other, as that would cause some of them to decay. When long periods of severe weather are likely to occur, a quantity of them should be taken under cover. Those who only know Leeks as subjects for the stock-pot should try them as a substitute for Asparagus, or for any other vegetable.

Onions.—Here we have another winter root, or rather bulb, of the greatest importance. It is in daily demand, and to keep up the supply from now until May the bulbs must be stored with care. In many cases bulbs which are to be kept for a long time are tied on to ropes, and they keep very well in this way suspended from the ceiling of some dry room, and under this treatment any decay in them can readily be detected. A thin band of hay or straw about 2 feet or so in length does very well as a basis on which to tie them, and from three to four dozen bulbs may be put on each. It is useless, however, to tie up bulbs that will be used immediately; all such may be placed in a heap in any cool room. A damp place will cause them to become mildewed, and a too warm one will make them sprout, but a dry shed or loft will generally suit them well. Large Onions never keep so well as small, firm ones; therefore, the whole of the latter should be kept for use in spring.

Carrots.—Although these do not take the place of greens, they are nevertheless indispensable, and a daily supply of them must be kept up. They are more difficult to grow than store, as the Carrot maggot often plays sad havoc with large roots; therefore, small sound roots are to be preferred to large wormy ones. They should all be lifted on a fine day; the tops should be cut off them, and then they should be stacked in a heap in a cool, dry shed in moderately dry sand or leaf-soil. They may be sorted before storing, putting the best by themselves to keep until spring, and the worst for immediate use.

Turnips.—These are very hardy, and need not be taken in until December. The stems should be cut off, and then the bulbs may be placed in a heap in any shed, with a quantity of hay, straw, or Bracken thrown over them to exclude frost and drying winds, as the latter cause them to shrivel. The white Turnips should be taken in first, as the Swedish variety and the yellow ones are hardier, and will bear a little frost.

Beetroot.—This may be treated like Carrots, only the leaves must not be cut in closely or the small side roots cut off, the main object being to preserve them intact and avoid allowing any of the juice to escape. If well and carefully stored the roots will remain good until next May.

Parsnips.—These are very hardy, and are better in the ground during winter than out of it, as when dug up they are liable to shrivel and lose their flavour. During severe weather a quantity of them may be taken up for convenience sake, as it is sometimes a difficult matter to dig them out of the frost-bound ground.

Salsafy and Scorzonera.—These are much alike as regards keeping qualities. Neither of them is quite hardy, but both will bear a few degrees of frost. We generally make two liftings of them—one now and the other in March. Those lifted now are stored with the Carrots, and the March ones are put past to prevent them from starting into growth again in spring. During frost they are mulched over with litter, and we generally find that these turn out fresher in spring than those stored in November.

Cambrian.

MILDNESS OF THE SEASON.

A few months ago tillers of the soil complained, and not without reason, of a cold, sunless, tardy spring. A spasmodic, but on the whole fairly good, summer followed, and many are now inquiring what is to be the outcome of this mild, unseasonable autumn. Fruit growers have no reason to complain, for trees of all kinds are splendidly furnished with fruit buds; the wood appears ripe, but not too forward, and the prospect for another year is all that men who do not go out of their way to quarrel with the future can desire. Vegetable gardeners, on the other hand, find many of their cut-and-dry arrangements slightly upset, but with them even the balance is not all on the wrong side, for while lamenting the bolting and bursting of the Brassica tribe, and the persistent growth of Lettuce and Endive, they are still able to pick dishes of delicious Peas for daily use. French Beans and Scarlet Runners slightly tinged with frost on low ground are still in bearing, and that grand Broccoli, Veitch's Autumn Protecting is turning in splendidly. Forewarned, forearmed. Steps should now be taken for protecting the heads, not only by tying the ample leaves with matting to keep out frost and wet, but also by preparing deep cold pits or open sheds for their reception as they are lifted from the borders. Cabbage and Cos Lettuce intended for early spring are now hearting, and if left alone will very soon be of little use. Lifting and transferring with good balls to west walls and sloping banks in a high, airy and shaded part of the garden will retard and preserve many of them. Others less forward may be placed in cold pits to save them from the destruction which severe weather will bring. Meanwhile, seeds of Cos and Cabbage kinds should be sown thinly in boxes, and kept close to the glass in spent Cucumber frames for filling up the gap which the August-sown plants this year will leave in the spring. The best sorts of Cabbage Lettuce for sowing late are Hardy White Dutch and Lee's Immense Hardy. Of Cos varieties, the Black-seeded Bath and Hicks' Hardy White are suitable. If only a tithe of these come to the dibber, they will come in at an acceptable time, or Early Paris Market, sown early in January and again in February, will fill up the gap now threatening. Good salads all the year round are now imperative, and the only way to cope with Nature when she plays pranks, as she has done during the past twelve months, is to make intermediate sowings of one or two suitable kinds and treat the plants as half-hardy annuals.

Eastnor Castle, Ledbury. W. Coleman.

Comparative yield of Potatoes.—It may be of some interest to your readers if I give my experience this year of the comparative yield of Potatoes per acre in our home nursery. The various sorts have been all treated alike; they were planted in April on ground which had been occupied by trees for the previous two years, and manured with good rotten mixed cow and horse droppings. The plots of ground were measured and the yield of Potatoes carefully weighed. It will be seen that Covent Garden Perfection heads the list and that Champions are at the bottom. Very few diseased Potatoes were to be seen in any of the varieties, but the Champions were the worst, and also contained the most small. At the wholesale prices current in this district the Covent Garden Perfection is worth (exclusive of small) £24 per acre. The weights given below do not include small Potatoes: Covent Garden Perfection, 1714 stones per acre; Magnum Bonum, 1682 do.; Vicar of Laleham, 1267, do.; Magnum Bonum Hybrid, 1240 do.; Champion, 1183 do.—W. B. H.

MARKET GARDEN NOTES.

Leeks.—When looking through a large market garden in my neighbourhood a few days ago I was much struck with the fine development seen in the Leeks as compared with what could be witnessed at this time last year. Then, owing to the dry summer, the Leeks were so small as not to be worth marketing; now they are very fine. I have not seen such fine development before, to the best of my recollection, and I attribute this to the adoption of the practice of sowing the seeds in the open ground, and thinning them out instead of in seed-beds, and the transplanting them as heretofore. I imagine that this practice, which is new in my neighbourhood, grew out of the failure of last year's crop from the drought. Unless it is a growing, dripping season when the young Leeks are put out in the open ground, they are a long time getting a good hold upon the soil, and if dry weather sets in failure results, the Leek being a succulent, moisture-loving plant. Leeks are proving a remunerative crop; a workman carefully digs them up with a fork and women collect the roots, take them away and trim and wash them, and then they are sent to market. They make a delicious dish when properly cooked.

Coleworts have been planted extensively this season. Bunched greens have become quite a popular London vegetable. The seed is sown in drills, and when large enough the plants are thinned out, and those removed put into spare ground. Coleworts have done well this season. It is a kind of tradition among the market gardeners that Coleworts require frost upon them to make them tender; already many are fit to pull, but no frost has come upon them. Land cleared of Tomatoes, Beet, and other crops is being planted with young Coleworts, and lines of the hardy Fulham White Cos Lettuce are being put out between them. It is rare weather for the young Lettuce plants to get a start. About here the common green Colewort is the one preferred; it is more compact in growth than the selection from it known as the Rosette Colewort, and it is preferred by the market gardeners.

Fulham Cos Lettuce.—I should think this is a hardy selection from the old London White Cos. What we know as the Paris White Cos is an improvement on the last-named. The Fulham Cos is a very fine and pure one, and the market gardeners always leave a few of the very best types to seed, and by so doing they can ensure a good stock of it. Very large breadths are now being put out. The seeds were sown in frames at the end of August or early in September, and if they can get a good start in the autumn, the plants stand the winter in a very satisfactory manner, and the Lettuces turn in early in the spring, being a few weeks in advance of the early spring-sown plants. My own observation teaches me that the best crops are had when planted in full exposure. Like the Leeks, the plants grow vigorously and to a great size on well-manured, light, stony land.

Vegetable Marrows.—It is only recently that some of the crops—the latest of them—have been cleared away. The vines were very persistent, owing to the mild, open weather and absence of frost, and they bore fruit up to the last till settled by the London fogs and damp. The crop of Marrows proved exceedingly plentiful.

Brussels Sprouts.—Great quantities of Sprouts are now being gathered and sent to market. The plants everywhere have made a vigorous growth this season, and the Sprouts are both numerous and very fine. They are cut away from about 6 inches of the stalks, and so those left swell all the more rapidly in consequence. At present there is every appearance

of a great glut of green stuff this winter, but much will depend, of course, upon the character of the winter. The green crops are soft and succulent, and if severe frost followed close upon rain, a great deal of damage would be done.

STOCKS FOR BUNCHING.—I saw, the other day, some large seed-beds of white, scarlet, and purple biennial Stocks ready for planting out. They are largely grown in market gardens for bunching, and there is a brisk demand for the flowers. R. D.

Books.

CHRYSANTHEMUMS AND THEIR CULTURE.*

PERHAPS no florist's flower has been taken in hand so strenuously of late years as the Chrysanthemum. The reasons are not far to seek. No flower answers more obediently to good, but not difficult or costly, management than this; none is capable of a more bewildering variety of delightful form and colour; none can be grown to equal perfection in a town atmosphere. When other flowers have vanished, then the Chrysanthemum, white and golden, pink and crimson, buff and ruddy brown, comes to brighten the dark months, and to the Chrysanthemum shows there are no counter attractions. The recent publication, within a short space of time, of two books upon the Chrysanthemum testifies to its deserved and increasing popularity. Mr. Burbidge's larger and excellent work has been in our hands some little while, and has now been followed, and, we may say, supplemented, by a handbook by Mr. Molyneux, the famous champion grower—a reprint, in book form, of a series of chapters contributed by him to the pages of a contemporary.

This is one of the most thorough and accurate treatises we have ever read; it is, indeed, an exhaustive sermon upon the author's own text. "It is by rigid attention to the smallest matters that the greatest successes are won." As Mr. Molyneux has in six years won eighty-six prizes, including seventy-four firsts and the champion cup for the last four years in succession, his counsel upon every one of the details of his own method of cultivation must be peculiarly weighty. Points of special importance or possible obscurity are further explained by excellent sketches, such as those of a good and a bad cutting, of shoots bearing respectively the "crown" and the "terminal" bud, with dotted lines showing how to disbud properly, and of a plant similarly explanatory of the "cutting down" operation. Absolutely nothing is omitted, from the preparing of the plants for cuttings (p. 1) to advice about the refreshment of the exhibitor awaiting the verdict, with toilet and dinner (p. 106)!

The chapters upon propagation and the treatment of young plants are most valuable. We have always believed that not only with this plant, but with all plants, much more than is commonly supposed depends upon the very earliest stages of growth, and that the seeming "coming all right" afterwards of feeble beginnings is delusive. Mr. Molyneux's experience of Chrysanthemums causes him to hold strongly that "upon the treatment they receive in the early stages their future welfare depends," and he therefore makes this part of the book somewhat elaborate and minute. A page upon the special management of weak varieties is very helpful, for some of these, *e.g.*, Criterion, afford distinct and very beautiful flowers, but are apt to fail under ordinary conditions. We are surprised, however, to find the splendid crimson M. Henri Jacotot included in this class, for we have found it unusually sturdy and free-flowering. A lighter soil and less stimulant is the summary of Mr. Molyneux's receipt for the management of these weaklings. The question of soils is fully and lucidly treated, the kernel of the matter being given in the shrewd observation that "the soil, while it contains food, must be regarded as a store for additional food that is required and given from time to time, the store or larder all the time remaining sweet." Accordingly, a considerable proportion of charcoal is recommended as an ingredient of the compost. It is to be noted that Mr. Molyneux disapproves of the use of cow manure. The chapter upon feeding and top-dressing is replete with useful suggestions, such as that about the intermittent use of soot water, and the advantages of a change of diet from week to week. We are inclined, however, to think that Mr. Molyneux's practice of giving liquid manure before the flower-buds form may be found risky by growers less experienced than himself. Some of the finest varieties, such as Jardin des Plantes, are easily rendered blind by stimulants given a few days too soon, though others, such as Elaine, seem to delight in strong food from a comparatively early stage. We think, too, that the statement that "the pinks, lilacs, and darker shades are rendered much richer" by the use of sulphate of ammonia is too general, and may mislead. Our own experience is that the finest reds, such as Cullingfordi, are easily ruined by it. Excellent hints are given concerning plants and blooms for market, and a record of the heights ordinarily reached by the principal varieties will be found useful. Indeed, every chapter and every page is crammed with solid information.

We cannot, however, help saying that in thus praising this book we praise it from its own point of view, which is by no means ours. We are most emphatically of opinion that the popular admiration for huge, coarse flowers is a degraded and lamentable taste. The mob demands them and exhibitors supply them, and we shall not easily escape from this vicious circle; but the mere demand for such productions is not a proof of their intrinsic excellence, as Mr. Molyneux and others think. The average Briton's idea of a beautiful carpet pattern used to be magenta Roses 2 feet across on a ground of loud blue, and there was much demand for such fabrics; but the taste was not thereby proved to be perfect and final. We agree with Mr. Molyneux that comparatively few varieties of Chrysanthemum will make beautiful plants if allowed to run up to their natural height and retain all their buds, though some, *e.g.*, Bouquet Fait and Lady Selborne, are far lovelier grown in this way than in any other. But we maintain that the truly artistic grower will delight in a plant abundantly furnished with branches, leaves, and flowers perfect in form, though of medium size, and that such a plant is not unnatural, even though fashioned to some extent by the grower's art; and a Chrysanthemum of the right size, according to our notions, is a flower which adorns its plant, a dwelling-room, or a lady's dress. Two, or at the most three, 9-inch flowers on a gaunt plant fulfil none of these conditions. Such monsters are good for a Chrysanthemum show, and for nothing else in the world. But the object of a show should be not to demonstrate how much bigness and how little refinement a flower is capable of, but to teach folk of high and low degree how best to make their gardens and their homes bright and fragrant. Mr. Molyneux, in his enumeration of the qualities which constitute "a good bloom," puts size first and colour last, an order which we should precisely reverse. We also remark that he omits even from his list of decorative varieties three of our most especial favourites, viz., the old Julie Lagravère, a plant of indomitable constitution, yielding clusters of small velvety flowers of an unsurpassable ruby crimson; L'Ile des Plaisirs, or Early Red Dragon, a dwarf Holly-like bush, almost a species for distinctness, which wreathes itself with a mass of satisfying red-brown; and Tokio, unique among Chrysanthemums for the grace of its long and slender flower-stems crowned with delicately fringed and almost scarlet blossoms. But then not even the champion's skill could induce these plants to supply him with 9-inch blooms for his green board. About one part of the book—the descriptions and illustrations of the dressed bloom, the implements for dressing, the cups and tubes, &c.—we say nothing. We have our thoughts, but they lie too deep for words.

But we are now, we own, taking Mr. Molyneux's book out of its own plane, so to speak, for judgment. Considered from the standpoint of the florist proper, the big-bloom man, the winner of "points," by whom and for whom it is written, it is a specimen of such sound and thorough workmanship as we seldom meet with, and will surely be indispensable to all such cultivators of the Chrysanthemum. G. H. E.

* "Chrysanthemums and their Culture." By E. Molyneux, Swanmore Park, Bishop's Waltham. (171, Fleet Street, E.C.)

Public Gardens.

GARDENS FOR THE PEOPLE.

LONDONERS, with their wealth of parks and gardens and squares, have been slow to realise the immense boon to health and happiness which an increase of open spaces would be to our overcrowded population. Indeed, it is remarkable that, with our appreciation of modern Paris, the example set us by the boulevards is only just beginning to make itself felt. The example, however, has been followed, and the Thames Embankment, Northumberland Avenue, and that more recent achievement, Shaftesbury Avenue, go far to show a zealous desire to escape from what may be called the Oxford Street age. Lord Brabazon, so well known for his untiring zeal in the cause of the poor, has for a long time recognised the pressing necessity of utilising every available plot of ground for their good; and with this aim he has, as president of the Metropolitan Public Gardens Association, been instrumental in throwing open a vast number of spaces throughout the whole of London, and has thus contributed in no small measure, not only to the health and happiness of our less fortunate fellow-citizens, but to the well-being of the whole population. The fourth annual report of the association, which has just been issued, tells a story which it would be well if many would take to heart. It shows how recreation grounds are a necessity, not only as the means of mere breathing space, but also as harbours for the thousands of helpless children who without them are the victims of our now almost unmanageable traffic. We do not propose to go into a detailed account of the good work done and being done by this admirable institution. It will be enough to point out how through its agency many a disused burial ground has been converted into a quiet recreation ground for old and young; how many a waste spot has been levelled and turned into a cricket field; how many a West-end square has been secured during the dead season for the use of the gardenless poor; and how benches and drinking fountains have been supplied and trees planted here, there, and everywhere. There is, however, one feature of this association to which we would call special attention, and it is that, among the many urgent wants it attempts to meet, the giving of employment to the unemployed is not forgotten. The report is, in fact, an unanswerable reply to those who say that nothing is being done for the unemployed, and on this ground alone Lord Brabazon's philanthropic efforts cannot be overrated, nor the association of which he is the head be too warmly supported in its beneficent and far-seeing aim.—*Saturday Review.*

Societies and Exhibitions.

ROYAL HORTICULTURAL.

NOVEMBER 9.

CHRYSANTHEMUMS were the prevailing exhibits on this occasion, and numerous new sorts were submitted to the committee. Several new or rare plants added to the interest of the meeting, and the following first-class certificates were awarded :—

CLERODENDRON NUTANS.—A beautiful old tropical shrub, shown by Mr. Head, of the Crystal Palace Gardens, Sydenham, who brought it from India several years ago. It is quite distinct from other cultivated Clerodendrons, being a much-branched shrub of dwarf compact habit, with long and rather narrow leaves. The flowers are large, pure white, produced in drooping racemes from the tips of the young shoots. The calices are reddish purple, and the flowers are followed by indigo-blue berries. Flowering habitually, as it does, at this season, its value is enhanced.

PONTEDERIA CRASSIPES DELICATA.—A lovely water plant, common enough in botanic gardens, but very seldom seen in flower. The plant is at once known by the swollen leaf-stalks, which cause the plant to float. The flowers are borne in an erect spike; they are about 1½ inches across, of a delicate pale mauve, and adorned with a deeper blotch of the same colour on the upper sepal, and spotted with yellow. This beautiful aquatic was shown by Mr. Ross from Sir George Macleay's garden at Pendell Court, Surrey.

PRIMULA CAPITATA MAJOR. — A large-growing variety of this superb Himalayan Primrose. The flower-stems are over a foot in height, terminated by a dense head of flowers of the richest purple. Shown by Mr. G. F. Wilson, Heatherbank, Weybridge.

ANGRŒCUM AVICULARE.—A singular, rare, and very beautiful Orchid. It somewhat resembles A. arcuatum. It is of dwarf growth, and the plant exhibited by Sir Trevor Lawrence bore two spikes, each about a foot long, and bearing about sixteen flowers set in pairs on the spike. The flowers are white and transparent, and the tail-like spurs are over 4 inches long. It is apparently a free-flowering species.

AMARYLLIS LADY MAYORESS.—A grand new variety of the reticulata race of hybrids; flowers in autumn and winter. The present variety is a cross between the old A. reticulata and Leopoldi. The flowers of the hybrid possess the reticulated and delicately rose-coloured flowers, while from Leopoldi it has gained large size of flower and fine shape. It is a valuable addition to autumn stove plants. It was shown by the raisers, Messrs. J. Veitch and Sons, Chelsea.

CHRYSANTHEMUM COQUETTE DE CASTILE.—A new Japanese variety raised by M. Délaux. It is remarkable for the delicate colour, which is a pale peach-pink, a tint rarely seen among the multitude of sorts now grown. The flowers are large and full, the florets narrow, long and reflexed. The sort was shown in excellent condition by Mr. W. Holmes, Frampton Park Nursery, Hackney, every plant in the group of about a dozen being only about 2 feet high, and carrying luxuriant foliage and very fine blooms.

CHRYSANTHEMUM GLORIOSUM.— A Japanese sort, with large flowers, with a dense mass arranged, long and narrow florets of a clear golden yellow colour. Shown by Messrs. Veitch.

CHRYSANTHEMUM WHITE CERES (Japanese).—Flowers large, long, shaggy, pure white. Shown by Messrs. Veitch.

CHRYSANTHEMUM PHŒBUS (Japanese).—Flowers of a bright yellow, medium size, and full. Shown by Messrs. Veitch.

CHRYSANTHEMUM EYNSFORD GEM.—A single Anemone-flowered variety with blooms about the size of a crown-piece, centre bright yellow, florets deep rose-purple; an extremely pretty sort. Exhibited by Messrs. Cannell, Swanley.

CHRYSANTHEMUM ADMIRAL SIR J. F. SYMONDS.—A very large flower, semi-double, the large yellow disc being conspicuous; the flowers are long and densely arranged around the centre, and are bright yellow. Shown by Messrs. Cannell.

CHRYSANTHEMUM JANE.—A single-flowered and beautiful sort, of moderate size, snow-white florets and bright yellow centre. Certificated as a "decorative" variety. From Messrs. Cannell.

CHRYSANTHEMUM LA FRANCE.—A Japanese variety of a wonderfully rich colour—a kind of crimson-purple: the flowers are of medium size, dense and of good form. From Messrs. Cannell.

Among other plants of interest shown were some new Orchids from Messrs. Veitch. One of these was the new hybrid Zygopetalum leopardinum, which is supposed to be a cross between Z. maxillare and Colax jugosus. The flowers are about the same size as those of Z. maxillare; the sepals are greenish, heavily spotted with reddish brown, while the lip is of a bright purple, mottled with white. Masdevallia glaphyrantha, another new hybrid, is probably a cross between M. infracta and M. Barlæana, it being most like the latter parent. A beautiful hybrid is Calanthe hybrida grandiflora, a cross between C. Turneri nivalis and C. vestita lutea, the flowers of which are large and pure white, borne in much the same manner as Turneri. Messrs. Veitch also showed Begonia John Heal, a new winter-flowering plant with flowers of a bright carmine, which remain on the plant for nearly three weeks, and then gradually wither without dropping. Oplismenus albidus, shown by the same firm, is likely to become a useful carpeting plant in stoves. It is a variegated tropical Grass of trailing growth, and retains its colour throughout the year. Mr. R. J. Measures, Cambridge Lodge, Camberwell, showed a very fine specimen of Lælia præstans, representing a first-rate variety. The plant bore five flowers, each 4 inches across. He also showed flowers of Cattleya Gaskelliana and a twin-flowered spike of Cypripedium insigne. Mr. Tautz, Studley House, Hammersmith, sent a plant of Cypripedium Leeanum superbum, a very handsome hybrid from C. Spiceri-anum, and considered to be one of the very finest Lady's Slipper Orchids grown. Messrs. Heath, of Cheltenham, showed specimens of Ixora Besti; but November is hardly the season to judge of the merits of Ixoras.

NEW CHRYSANTHEMUMS were plentiful, collections being shown by Messrs. Veitch, Cannell, Bull, and Ower. The cut blooms from Messrs. Cannell were exceptionally fine, comprising new semi-double and single sorts, which may yet prove as popular as the doubles. The sorts we singled out of the Swanley collection as the best were Neatness, Scarlet Gem, Eysford Gem, Rose Favourite, Jane, Coquette de Castile, La France, Mrs. Cannell, and Thorpe Junior. Among Messrs. Veitch's sorts were Paul Dutour, Jupiter, Ruy Blas, Mr. H. Elliott, all good. Among Mr. Owen's new sorts the best were Distinction, Mr. Glover, and Mrs. Naish; and among Mr. Bull's were Lady Avenal, W. Clark, and Madame Ghys. A bronze Banksian medal was awarded to Mr. Clark, Twickenham, for a very fine lot of Cyclamens, the first group shown this season. Among the sorts was an extremely dark one called Albert Victor, one of the finest darks yet raised

Fruit.—The following were among the principal exhibits: A new Grape named Miss Clark came from Mr. E. Woodall, St. Nicholas House, Scarborough. It is said to be the result of crossing Black Hamburg and Gros Colmar. The bunches shown much resembled the latter variety, but it is said to ripen a month earlier when grown together under the same conditions. The committee desire to see bunches of it again later together with foliage. The bunches shown were excellent examples of good culture. Another new Grape was shown named Winter King. It is a noble-looking black variety, which the committee consider like Gros Maroc. It was shown by Mr. Bowman, Hylands Park, Chelmsford. Mr. Ronpell showed some excellent fruits of Apples, Cox's Orange Pippin being unusually fine. A cultural commendation was awarded to Messrs. Lane, Berkhampstead, for a very fine display of their Apple Prince Albert, which is one of the very finest kitchen Apples we have. Messrs. Veitch showed fruits of the new Apple Bismarck, a noble fruit, large and handsome; and Messrs. Rivers sent a gathering of the Wyedale Plum, said to be the latest and best of all culinary sorts.

NATIONAL CHRYSANTHEMUM, ROYAL AQUARIUM, WESTMINSTER.

NOVEMBER 10 AND 11.

THE large and really grand show of Chrysanthemums held at the Aquarium this week afforded further evidence of the fact that a central Chrysanthemum society has hitherto been a need among growers and exhibitors of this popular flower. Local societies are plentiful enough, but these for the most part are so hemmed in by restrictions, that growers in out-of-the-way places cannot exhibit. But with this newly-constituted national society the case is different. Anyone can compete, and it is this open competition that is finding favour among exhibitors, who value the honour of prize-winning in classes open to all comers more than when the show is purely local. This national society, though it cannot, apparently, quite make up its mind to renounce its local origin (that of Hackney and Stoke Newington), becomes each year less local in its shows, for now one sees exhibits from the provinces and less from London growers. The society is also making itself important in other ways than holding shows. It now boasts of a floral committee—a tribunal before which new varieties may be placed for adjudication. It, moreover, publishes an official catalogue of sorts, which is excellent, notwithstanding the quibbles that have been raised concerning it in various quarters; and its latest work has been the affiliation of provincial local societies, which now numbers over a score. In short, the society has aimed in making itself the representative Chrysanthemum society, and it is fast gaining that position.

The schedule on this occasion was lengthy and comprehensive, and the prizes offered were substantial, amounting in the aggregate to upwards of £200.

The Chrysanthemum classes numbered thirty-six, and in addition to this there was a fine exhibition of fruit, vegetables, and fine foliaged plants.

Incurved Varieties.

The chief class in this section was that for forty eight blooms, for which the three prizes offered were £10, £7, and £4. There were eight collections, but far surpassing all was that from the well-known grower, Mr. Gibson, Morden Park, Surrey. Every bloom was good, and the selection could not be better, but the exhibitor made a sad mistake. He staged four blooms of one sort; whereas the limit was but three of a sort. Through that blunder he was disqualified, and lost the valuable prize. The following is a list of the sorts he showed :—

Empress of India	John Salter
Princess of Wales	Nil Desperandum
Golden Queen	Barbara
Golden Empress	Hero of Stoke Newington
Queen of England	Jardin des Plantes
Princess Teck	Nonpareil
Jeanne d'Arc	Golden Eagle
Princess Beatrice	Refulgence
Mabel Ward	Lord Wolseley
Lady Hardinge	Yellow Perfection

The second best collection, from Messrs. Drover, of Fareham, was consequently placed first; Mr. Wm. Wildman, second; and Mr. Salter, third.

The best collection of twenty-four blooms was from Mr. Wildman, and consisted of—

Empress of India	Nil Desperandum
Golden Empress	Prince Alfred
Lord Alcester	Alfred Salter
Guernsey Nugget	Queen
Jeanne d'Arc	Venus
Eve	Antonelli
Novelty	Barbara
Mrs. Dixon	J. Salter
G. Glenny	Refulgence
Princess Beatrice	Lady Slade
Mr. Bunn	Mrs. Shipman
Lord Wolseley	General Slade

The president of the society, Mr. Sanderson, took the second prize; and Mr. Strong the third.

There were nine collections of eighteen blooms, that from Mr. Kidd, West Hill House, Dartford, an excellent display, being first. He had the following sorts :—

Princess of Wales	Prince Alfred
Empress of India	Golden Empress
Lord Wolseley	Lord Alcester
J. Salter	Mrs. Heale
Mr. Brunlees	Jeanne d'Arc
Isabella Booth	Nil Desperandum
Baron Beust	Prince of Wales
Princess Beatrice	Eve
Mrs. Shipman	Cherub

The class for a dozen blooms was also large, there being ten lots. The first, from Mr. Doughty, consisted of Queen of England, Golden Empress, Empress of India, Jeanne d'Arc, Mrs. Heale, Mrs. Shipman, Lord Alcester, Princess of Teck, A. Salter, Prince Alfred, Hero of Stoke Newington, Lady Hardinge.

Among fourteen sets of six blooms, Mr. Hill, of Hythe, sent a fine collection for the first prize, which consisted of Empress of India, Princess of Wales, J. Salter, Jeanne d'Arc, Nil Desperandum, and Princess Teck.

The first prize in the class for six blooms of any variety was taken by Mr. Springbett, with Princess of Wales; Mr. Salter, with Lord Wolseley, was second; and Empress of India was third.

Japanese Varieties.

There were six classes devoted to this popular section, and throughout some extremely fine blooms were shown. The principal class was for forty-eight blooms in not less than twenty-four varieties, the prizes being £10, £7, and £4. There were seven competitors, whose exhibits made a great display. The chief prizeman was Mr. Gibson, who had a grand collection of large and highly-coloured blooms and a first-rate selection of varieties. These comprised the following, and of several there were duplicates:—

Mad. C. Audiguier	L'Adorable
Japonais	Hiver Fleuri
M. Lacroix	Mons. Astorg
Maiden's Blush	Fair Maid of Guernsey
Grandiflorum	Roseum pictum
Golden Dragon	Margaret Marrouch
Baronne de Prailly	Jeanne Delaux
Comtesse de Beauregard	Duchess of Albany
Boule d'Or	Meg Merrilies
M. L. Brunel	Thunberg
Elaine	Comte de Germiny
Album striatum	White Dragon
Criterion	Val d'Andorre

Very fine collections were shown in this large class by Mr. Ridout, of Reigate, and Mr. Bettesworth, of Cheshunt, who were second and third respectively. Of the best twenty-four blooms, the finest were those from Mr. Child, of Esher, whose collection was made up of—

Comtesse de Beauregard	Mad. Audiguier
Baronne de Prailly	Mons. Astorg
Val d'Andorre	Thunberg
Meg Merrilies	Mad. Lacroix
Fair Maid of Guernsey	Yellow Dragon
Peter the Great	Galatea
Album plenum	Criterion
Duchess of Albany	Mad. de Sevin
Album striatum	N. Davis
Japonais	Hiver Fleuri
Elaine	Augustine
F. Boucharlat	La Triomphante

There were seven collections in this class, all good but the class for twelve blooms was more numerous, there being twelve competitors. The dozen which Mr. Moore showed for the first prize were—

Baronne de Prailly	Comte de Germiny
Mons. Astorg	M. Delaux
Val d'Andorre	F. A. Davis
Criterion	Fair Maid of Guernsey
Thunberg	Soleil Levant
Triomphe de la Rue du Chatelet	M. J. Laing

The best six Japanese blooms of a white sort were some some grand examples of Fair Maid of Guernsey from Mr. Duncan, followed by Mdme. Lacroix, also remarkable flowers, and Elaine. The best six blooms of any coloured sort were of Yellow Dragon, the second best Japonais, and the third Jeanne Délaux.

Reflexed varieties were a fine class, the seven collections of twelve all being first-rate. The best, from Mr. Moore, consisted of—

Mrs. Forsyth	Golden Christine
Cloth of Gold	Felicity
Peach Christine	Dr. Sharpe
Phidias	Cullingfordi
Garibaldi	

Large Anemone-flowered sorts were also well represented by six sets of twelve kinds, Mr. Moore being first again. His sorts were—

Laing's Anemone	Acquisition
Mrs. Pethers	Lady Marguerite
Sunflower	Fleur de Marie
Gluck	King of Anemones
Georges Sand	Minnie Chate
Empress	Princess Louise

Anemone Pompons were shown best by Mr. Whitley from a London garden at Southwark. His sorts were—

Regulus	Miss Nightingale
Antonius	Mrs. Wyness
Mdme. Chalonge	Marguerite de Coi
Astarte	Mr. Astie
Rose Marguerite	Magenta King
Perle	

Pompons.—This pretty class was represented admirably by a few of the exhibitors of twelve sorts. The best collection contained—

Black Douglas	Dr. Sharp
Marabont	Tousssaint Maurisat
Adele Prisette	Mons. Hoste
Prince Victor	Mdme. Marthe
Golden Circle	

Pot plants.—These, of course, made the principal display, and, on the whole, they were excellent. There were nine classes set apart for them, the chief being the two for groups of Japanese sorts only, and for other sorts exclusive of Japanese. Twenty sorts were the minimum number to be shown, and the allotted space for each group was 60 feet. A very fine lot of uniform medium height won the first prize over the Japanese sorts. This was from Mr. Edwards, Balham Nursery, while the corresponding first prize group was from Mr. Stevens, St. John's Nursery, Putney. The trained specimens were of the usual stamp, excellent in their way, and particularly noteworthy were the six trained Pompon plants. These were from Mr. Reeve, Hadley House, Barnet. Each plant was fully 5 feet across, the trellis being mushroom shaped. The sorts were Rose Andromeda, Golden Cedo Nulli, Sœur Melanie, Fanny and Marguerite de Coi. Mr. Monk's nine trained specimens were good, and the same exhibitor's six trained plants won the first prize. A special silver medal was awarded, and very deservedly, to Mr. Holmes, Frampton Park Nursery, Hackney, the society's hon. secretary, for a magnificent group of mixed varieties, every plant being admirably grown, and most remarkable was the dwarf growth of the whole collection, the average height being 2 feet, yet the blooms were large and fully developed.

Fruit.

The various classes for fruit were well filled, the quality throughout being really first rate. This high form was specially found in the *Grape* classes, the chief of which consisted of twelve bunches, in not less than three kinds. Here a new exhibitor from Ticehurst fairly bore off the honours by sheer weight, having no less than six bunches of Gros Colmar, very fine indeed; three huge Barbarussa, capitally done and weighing 14½ lbs.; and three excellent Black Alicante. The second prize went to a much more varied and interesting collection from Elvaston, but the honours were chiefly won by some grand Gros Colmar, the three bunches showing size of berry, colour, form, and finish such as rarely are seen, and well merited the special cultural certificate awarded. Other bunches were Muscat of Alexandria, Golden Queen, and Mrs. Pearson, whites; and Alicante, Lady Downes, and Mrs. Pince, blacks. The capital lot of bunches from Gunton Park comprised Mrs. Pince, rather loose and lacking colour; Black Morocco, Gros Maroc, and Lady Downes, these latter three being very good. There were seven lots shown, and some fine bunches were left out in the cold. Of *Black Grapes*, in a class for three bunches the best again were from Ticehurst—very fine handsome tapering Gros Colmar; some good, but shouldered bunches of the same kind were second; and good Alicantes third. Three remarkably fine and well-finished bunches of Barbarossa were in the class which comprised nine lots. Of *White Grapes*, the best were Muscat of Alexandria, from Gunnersbury Park, medium-sized, but finely finished. Others of the same kind took the other prizes. A capital lot of Golden Queen had to stand out.

Of six dishes of Pears, eight lots were shown; some splendid fruits were found, though not a few others were past eating. Gunton Park was again to the fore, as in the past, with these fruits; grand samples of Marie Louise d'Uccle, with Beurré Diel, Beurré Bosc, Glou Morceau, Marie Louise, and Doyenné du Comice, making up the collection. From Beckenham came very fine Pitmaston Duchess, Beurré Clairgeau, Beurré Diel, Duchesse d'Angoulême, Beurré Superfin; whilst a nice lot from Cheshunt was third. *Dessert Apples* were mostly shown in good form and rich in colour. Among ten collections from various parts of the country, that from Horsham was the best; the chief sorts were Ribston, Blenheim, and Cox's Orange Pippins, Golden Russet, Court Pendu Plat, and King of the Pippins. The next best lot came from Welford Park, one of the best Apple gardens in the kingdom, and comprised Adam's Pearmain, Cornish Aromatic, Gravenstein, Blenheim of rich colour, and Cox's Orange Pippins, with a very handsome yellow kind; Lady Alice Eyre, a seedling from the old Golden Reinette, and of excellent quality. Petworth supplied rich colour in the Nanny, Scarlet Nonpareil, Ribston, and Blenheim Pippins, &c.; Fearn's Pippin, Mabbett's Pearmain, and Worcester Pearmain were very good in this class. Nine lots of

Kitchen Apples were shown by nine. In the best lot were superb fruits of Cox's Pomona, Waltham Abbey Seedling, Emperor Alexander, Warner's King, Loddington Seedling, and Gloria Mundi, coming from Linton Park; whilst Welford Park followed with superb Brabant Bellefleur, Mère de Ménage, Stirling Castle, Blenheim Pippin, &c. The third lot, from Loughton, included good Annie Elizabeth, Echlinville, Alfriston, and Peasgood's Nonsuch. Thus there were no less than thirteen diverse kinds in the eighteen dishes. A special silver medal was awarded to Mr. G. Bunyard, Maidstone, for a grand collection of 100 dishes of Apples, which included all the best kinds, rich in colour, and very fine.

Vegetables.

Four collections of *Potatoes* were in competition in the class for twelve dishes, the best coming from Edgecote, Oxford—clean and handsome; whilst in the class for six dishes there were five collections, Petworth and Ealing having the best lots. Of white kinds, London Hero, Schoolmaster, Duke of Albany, Chancellor, Reading Giant, Sutton's Seedling, and Favourite; and of coloured kinds, The Dean, Beauty of Hebron, Edgecote Purple, Reading Russet, and Prizetaker were the best.

Special prizes.—Messrs. Sutton and Sons' prizes for six kinds of vegetables brought eight lots, the samples being exceptionally good. Esher was a specially good first with Autumn Giant Cauliflowers, Prizetaker Leeks, Snowdrop Potatoes, Intermediate Carrots, Rousham Park Onions, and Perfection Tomatoes. In other collections were fine Cauliflowers, Chancellor Potatoes, Brussels Sprouts, Red Celery, &c. Five prizes were awarded. Messrs. Webb and Sons, Wordsley, offered prizes for a similar class, six lots competing, the best coming from Coleshill gardens, and including very fine Student Parsnips, Carrots, Autumn Giant Cauliflowers, Magnum Bonum Potatoes, and Snowball Turnips. Messrs. Sutton and Sons staged 100 dishes of Potatoes, including seedlings and good named kinds, all the samples being excellent.

A list of prizes is given in our advertising columns.

Verbenas and red spider.—I shall be thankful if some of the readers of The Garden will tell me what to do under the following circumstances: My stock of plants of Verbenas is badly covered with red spider and other pests. I have watered them with soot water, and should like to know if that will keep them free from red spider and rust. I have heard that it will do so, but should like to know what others think of it. What temperature should Verbenas be kept in during the winter months?—B.

R. R., Nairn.—"Thompson on the Vine." Blackwood and Son.

Names of plants.—*Messrs. B., King Street.*—Rubus rosæfolius.——*T. M. F.*—Judging from a single flower, your Orchid appears to be Cymbidium Dayanum.——*J. M., Ballinakill.*—Pretty forms of Scabiosa atropurpurea; it is an annual.——*H. A. Page.*—Oncidium serratum.——*W. S., Doncaster.*—Specimens sent without numbers are Adiantum fulvum, Pteris serrulata, Pteris serrulata cristata, Selaginella pubescens.——*E. G. L., Weedon.*—1, Chrysanthemum latifolium; 2, Chrysanthemum Leucanthemum; 3, Urospermum Dalechampi; 4, Aster Novi-Belgii var.; 5, Silphium terebinthinaceum; 6, Silphium perfoliatum.——*Miss P., Bristol.*—Oxalis rosea.——*A. R., Windermere.*—Specimen quite undistinguishable; send flower again.

Names of fruits.—*W. Whait.*—1, Pitmaston Duchess; 2, Chaumontel; 6, Napoleon; 7, Doyenné du Comice. We name four only each time.——*W. B. H.*—Pitmaston Duchess.——*R. T.*—All the fruits were too much decayed to identify.——*Scot.*—1, Seckel; 2, Passe Colmar; others will be named next week.

WOODS & FORESTS.

NOTES.

SAWMILLS.—The way "Omega" and others magnify and harp on the importance and duties of the estate sawmill makes one think that if they lost that string, their bow would be almost useless. On the large estate where I first became familiar with sawmills, we had two large ones for the woods and one in the woodyard. The two in the woods were chiefly employed in cutting up rough slabs, rails, and posts for estate purposes, and no one concerned themselves much about them except the two old men and their assistants who looked after them. Their management is of the simplest description. Here we have a steam mill for sawing our timber, and, in addition to our own wants, we do a good deal of colliery work, so that our duties are perhaps more complicated than on most estates. Still, we have had no labourers having their ribs broken that I remember for twenty years back or longer, but, be that as it may, I am puzzled to understand how sawmills can be conducted without labourers, even at whatever risk there may be. In "Omega's" case I can only conclude that the "many handy and good labourers he has seen with ribs broken, arms hands, and thumbs and fingers off through attempting to work the circular saw" has compelled him to do the manual work himself belonging to his sawmill, and to turn the more important duties of forester over to his men. His picture of mutilated limbs, however, will not do, for no such universal disasters happen in any well-regulated establishment. In addition to our own mill, there is another not far off that probably saws up 20,000 feet of our timber annually for a great variety of purposes, and when the owner called the other day and heard "Omega's" catalogue read out, his remark was that the sooner "Omega" took refuge in assurance against the Employers' Liability Act the better, as in anyone else's case the consequences would have been ruinous, workmen not now-a-days usually submitting with impunity to have their limbs mutilated to the extent that seems to have been the case with "Omega's" men. As regards "Omega's" definition of a forester as a "person to superintend general estate management," I have to reply that he is not a person on whom such duties devolve where a forester proper is kept. That is well known, but if it be necessary to magnify his position in that way, well, then, the gardener is by far the most likely man for such an important post, and there have been, and are, gardeners who could be named on whom the post of general estate agent has been conferred from ducal estates downwards, and who have performed their duties in the most satisfactory manner, quite fulfilling the estimate formed of them from their skill and knowledge as gardeners. I could, on the spur of the moment, enumerate about half a dozen gardeners I know of who held, or do hold, such positions. In conclusion, I am sorry I do not convince "Omega" by my writings, but if he would only meet my objections by something else than mere platitudes and assertions, I might try, although his particular conversion on the subject is not the whole end and aim of my writings.

PRICES OF TIMBER.—"Young Forester's" letter on this head is interesting as showing how prices and demand vary in different parts of the country. He has little or no call for "small Oak" in Monmouthshire; whereas, in this part of Yorkshire, poles from 2½ feet upwards are the only kind saleable till we get up to trees fit for wagon sides, which are in fair demand, and that must quarter 13½ inches 18 feet up. Trees between the two are practically unsaleable in any quantity. We have to set such timber out in the falls if they happen to be dying or going the wrong way, but they have accumulated on the hands of purchasers to such an extent during the past few years, that, in order to give purchasers a chance of getting rid of them, we have ceased for the present to mark any trees above 8½ feet, unless dead or ill-placed, always excepting wagon-side trees when to spare. As regards these large trees for wagons, hitherto the best and soundest Oak only has been employed, but of late Memel or red deal has been introduced in place of Oak, with what results I cannot say, but makers speak favourably of it as being nearly as strong as Oak, while much cheaper and lighter. As by far the biggest part of the large Oak in this country goes for wagons, it may be guessed what effect the introduction of foreign timber is likely to have on the home-grown timber market in that direction. The Memel is delivered at about 1s. per foot sawn, I am told; whereas home-grown Oak of good quality has been fetching 1s. 6d. per foot in the wood for the same purpose, and was much dearer than that a few years back. The effects of foreign competition on the home timber trade is simply ruinous. I make no comment on the merits of free *v.* fair trade, but simply record facts. Unless labour becomes cheaper by about fifty per cent, and everything relating to estate management is lowered proportionately, it will be of little use expatiating on the profits of timber growing. Fanciful management is out of the question. Planting on the cheapest methods is all that can be afforded now. Rather than plant good land, I would turn it into a rabbit warren, which I am sure would pay better with good rabbits at 3s. per couple in the market.

As to Ash mentioned by "Young Forester," good Ash is very saleable, and so is small rough in Yorkshire. I knew a buyer pay too much, as I thought, for a fall of small poles for the sake of the small Ash and Sycamore poles in it running from 2 feet to 3 feet; such stuff is sold for shaft wood and a variety of purposes.

WHAT HAVE WE TO SELL?—This is the question very much affecting the home timber trade. Abroad, both in America and Europe, almost every tree in the forest is of a saleable description, and what refuse is left is turned to account for various purposes that we are strangers to here. Charcoal is made extensively from the refuse, much of it is used for firewood, and the large tops and boughs are manufactured into a variety of articles for export and home use. In England at the present time it may be said that only the measurable timber is disposed of, cordwood and underwood seldom fetching a remunerative price now. Sometimes the cordwood is burnt on the spot, as the readiest means of getting rid of it, while underwood is left uncut. The measurable timber consists in England principally of Oak, Ash, Sycamore, Birch, Larch, Scotch Fir, and, in more limited quantity, of Beech and Elm, &c.; and in the north, of Spruce Fir. In almost all falls of home timber set out, the worst timber only is, of course, removed, unless in cases where the whole wood is felled; hence great quantities of it is of little value and could not be sold if it was not put along with the best. This practice is, however, injurious to the trade, and when it is stated that much of the bulkiest timber, which should fetch most, is rough and often foxy or gone in the heart, it will be understood how difficult English timber-merchants find it to compete against the importer of foreign deals and logs already cut to order. These faults of the home-grown timber are chiefly due to our methods of forestry management, and cannot be remedied so far as old forests are concerned, but they should teach us a lesson for the future. Almost all timber is best when the tree is at its prime. For "old Oak" there is a certain demand, but it is nothing compared to the demand for strong, sound timber. Old Oak is unfit for all purposes where strength is requisite, being "tender," as experts in the timber trade say, and fit only for furniture, wainscotting purposes, and such like. Numbers of old Oak trees which have been sold of late years have turned out almost useless when cut up, having become decayed in the heart from old wounds and decayed tops which admitted water. I know of a fall of old Oak, which last year could not find a buyer at any reasonable price, examination having shown that many of the trees had become hollow and rotten at the base inside; and such purchases are extremely risky. In short, it may be said that the greater portion of English timber set out for sale is too rough and too branchy, owing to the manner in which it is grown, and does not fetch near as good a price as it would have done had it been cleaner and straighter, if even of much smaller dimensions. Dear as carriage of timber is by road and rail, buyers will come one or two hundred miles to buy exceptionally clean and well-grown timber, while rough samples may be going a-begging at the door.

GARDENERS AS FORESTERS AND VALUERS.—"W. B. H." does not specify the "details" of woodcraft a gardener cannot soon learn, as I feared, and of course it is in his power to magnify them prodigiously, but now-a-days, fortunately, people do not take things for granted, and until the unlearnable "details" are forthcoming we may safely disregard them. We have the present condition of the forester's charge throughout Great Britain to go by, and the verdict has been universally given against their management. Nobody is "to pay" the gardener for "learning him" forestry. He is fitted at any time to take the charge and have knowledge to spare. As to valuing, I admit the array of instruments mentioned the week before last is calculated to frighten novices; but as neither "W. B. H." nor myself, nor any practical forester ever employs them, having much simpler and equally sure methods to go by, I am surprised at him bringing such an article to his aid. Even the method described this week (p. 443) is too cumbersome where thousands of trees and feet are valued. "A. P." says his example of a valuing book is one he generally uses, but it is as old as the hills, only never carried into the woods with any forester for general use. The idea of going through the wood and making entries in ten separate columns and valuing each tree or every few trees separately is too absurd to be entertained for one moment. No purchaser would listen to such stuff, except, may be, in the case of a few trees of special size and quality, but would go over a large fall of timber, calculate the contents, and offer so much per foot or per lot, and as the forester would have to settle in that way also, what is the use of all the labour described by "A. P."? Last year, for example, we valued 6000 trees and poles in one wood by the simple process of counting the trees and poles separately and the different kinds, taking a careful average of a certain number of trees in certain parts of the fall afterwards to find the contents, and then putting on the price. There is no other way of valuing large quantities in a reasonable time than this. Just imagine "A. P.'s" ten-column memorandum book in such a case, or valuing with the "instruments" mentioned the week before. In every case of valuation done in this manner that I have known the measure has turned out at the end as near the mark as when done by most elaborate methods. Not long since a case occurred which I had to do with, in which 10,000 trees and poles of very varying dimensions and nearly 100,000 feet of timber was involved (a case of damage to woods from a certain railway company's premises), and the whole of the timber was valued by the proprietors' agents on the counting and averaging principle, and afterwards by the agents of the company, who employed competent men. On comparing notes afterwards it was found that the estimates on both sides were so near, that the proprietors accepted, the question of the amount of damages being settled afterwards. As to measuring tapes, Chesterman's self-winding steel tapes mentioned by "A. P." are just toys—as far as timber measuring is concerned. They are principally used by ladies and gentlemen, who carry them in their waistcoat pockets. Nothing beats the common woodman's tape, a few feet long, usually carried loose by men. Compared to the string, with its doubling and double doubling, and measuring and after calculation, the tape is just a ready reckoner, and nowhere is the string used now that I am acquainted with.

YORKSHIREMAN.

Profits of tree-planting.—It has been calculated that the tree thinnings of an acre of land worth

only from 5s. to 10s. per acre, but planted with a mixture of Larch, Beech, Pine, Hazel, Birch, and Oak—the latter with a view to the growth of navy timber or trees of large size for building and other purposes—will at the end of from ten to fifteen years, according to local circumstances, repay the average expenses of planting, rent, and management during that period, together with compound interest at five per cent.; and the profits of future falls may be estimated as follows: In thirteen years, or at twenty-three years' growth, £24 10s. per acre; in thirteen years more, or at thirty-six years' growth, £39 per acre. After that period a triennial profit of about £12 per acre, until the Oak is fit for the many purposes for which timber of first-class quality is required, when the final clearance may be expected to fetch from £200 to £250 per acre. NORTHERNER.

THE CONDITION OF ENGLISH WOODLANDS.

"W. J. W.," in his opening paragraph (p. 444), has hit upon and well described the way in which ordinary English wooded land is dealt with. Bringing to the front such an unsatisfactory condition of affairs would not at any time be inopportune, but just now it is especially to the point, as the season when the havoc described is wrought or the neglect perpetuated is now upon us. Whatever may be said about the importance of planting and the necessity of those being engaged in it having proper qualifications, there can be little disagreement of opinion that judgment in exploiting what has already grown is far and away more important. I, however, attribute a good deal of the condition of our timber supply to mere thoughtlessness. In making shift for the moment's necessities without looking at what the future effect will be is one class of thoughtlessness, and this may be committed either in cutting to raise money or in making wholesale clearance on behalf of the agriculturist. "W. J. W." speaks of the young and straight growing sapling sharing the same fate as the matured tree. This is too often the case, but a little thought is all that is required to save it. From a forestry point, it is the very class of trees upon which we have to depend as coming behind the present crop. From a money-making point, it is the least desirable thing to cut, as a score of such saplings would not realise the price of a single fair-sized tree. On the other hand, it is useless to let rubbish grow on merely because it is young, as it may really have no chance of becoming good timber, and may be seriously damaging what would, if opportunity be given it, grow into valuable timber. The decision of where these points meet is one of the most important questions in practical forestry, and if more carefully looked into, would do much to lessen the evils attendant on the plan of cutting without thought, which has been too long current. If the conditions were more understood, I take it that there is not such a wide divergence between clearing a crop of timber when ripe and keeping a place fairly wooded for ornament. If we take the Elm as a typical tree—and it is certainly one of the most useful as well as ornamental—there is no reason why an individual who has his thoughts about him should not periodically cut what from the timber side of the question should be felled, and still preserve the ornamental character of the property. It will, of course, sometimes prove necessary either to sacrifice a group of trees when they come to maturity, or, on the contrary, let them go on the road towards decay. In such instances the judgment and the taste may clash, but the removal of one group may bring out another which had previously held an incospicuous place. These may be looked upon as minor matters, but it is doubt and fear upon such points which help to contribute to the sum total of the condition of things of which "W. J. W." speaks. I have mentioned thoughtlessness as shown in a too free use of the axe and saw; and doubt and fear, or in other words, caution, being two causes which account for our English woodlands being as they are. To a great extent I so regard it, and there seems no good reason why a material modification should not take place without the elaborate machinery being set in motion of which we now and again hear. It must not be overlooked that it is the judgment in proper selection which is necessary to bring about a change for the better, and this is a very different thing to the technical knowledge required in raising, and also in subsequently felling and dealing with the selected trees. The knowledge of how to select can soon be acquired. The great thing is to get attention directed to it, and this is week by week being done in the columns of this paper, and although diverse opinions are often expressed, they cannot, on the whole, fail in giving fresh tone to what is on all hands admitted to be a neglected subject.

D. J. Y.

THE MANAGEMENT OF WOODS.

As "Yorkshireman" is looking at this subject with a gardener's eye, it is only to be expected that he will attach as much importance as possible to such parts of a forester's duties as most nearly approximate to those of a gardener. It is on the relative value of this that I differ from him. That knowledge gained as a gardener would be useful to any individual who undertakes the management of woods I do not deny, but it would be merely in one branch of the subject. What an estate carpenter would gain in his own work would be another branch, so that a gardener and a carpenter would be on a par by being qualified in different branches, but neither would be competent to undertake a forester's work merely because in pursuing another business they happened to gain information which could be turned to account. Beyond the special department of each, neither gardener nor carpenter would be able to go, unless by "accidental association" they had from time to time been gaining knowledge of how a forester's work is done, and of what it consists. My only reason for particularising a carpenter was, because he was the first class of workman connected indirectly with forest work (in the same way as a gardener would be) occurring to my mind. Unless "Yorkshireman" maintains and can prove that gardeners are superior in mental calibre to every other class of individual who happens to be engaged upon an estate, or are employed upon any branch of work which would give an insight into wood management, his argument entirely fails. Assume that two young men of equal intelligence aspire to become foresters. One enters the garden; the other starts life as an estate carpenter. The first gets an insight into plant growth, and the second gains a knowledge of dealing with the wood when it is grown. Unless each avails himself of the advantages of what I have called "accidental association," he would be entirely unfitted to undertake the management of woods; but granting that each has equal ability and application, I fail to see why a carpenter could not as readily pick up a sufficient knowledge of plant growth and planting as a gardener could the necessary knowledge about dealing with and disposing of the grown product. Let "Yorkshireman" satisfactorily disprove these points, and then I will admit that he has made out a case why gardeners are to be preferred to every other class for employment as practical foresters. I do not say this at all disparagingly as to the legitimate branches of a gardener's work, but merely to properly assess his value as a wood manager.

D. J. YEO.

Timber measuring.—I cannot quite agree with "A. P." in all his remarks on this subject. What I use in measuring timber is a good strong whipcord, which I think cannot be surpassed. I strictly object to tape. For instance, in measuring a lot of felled timber in a wood a difficulty often occurs in getting it around the pieces; and, again, if you are able to get a tape around, it will not stand the test. All disputes as I have been in or heard of, the whipcord has gained the day. As regards taking dimensions of a tree, "A. P." is perfectly right. The book, of which he gives an example, seems to me to be very suitable. In order to get at the real contents of standing timber (a very difficult matter), I take length and girth, then make my remarks as to quality, and leave the calculations till I have time to make inquiries as to roads, &c. It is most important to allow for bark in measuring standing or felled timber. I allow 1 inch in trees that are 12 inches, and half an inch under 12 inches in girth. For my own part I condemn the tape for buying or selling, as I consider it very unfair. Certainly it is useful with standing timber, but it always makes timber more than what is really in it. I cannot perceive how "A. P." can bring the real contents of a tree 12 feet by 19 inches to 38½ feet. Perhaps it would be better for him to give an example in figures, so as to show it more plainly.—YOUNG FORESTER.

NOVEMBER NOTES.

In some respects the present season is a remarkable one, and not the least observable thing is the tenacity with which most trees have retained their leaves. At the beginning of the month there was very little diminution indeed in the bulk of foliage, and up to the time of writing there are comparatively few trees bare. Among common timber trees the Scotch Elm has been one of the first to lose its leaves. In a few cases the English Elms are nearly bare, but in the majority of instances they still (Nov. 5) retain their foliage. Amongst those which are virtually bare may be mentioned the Ash. The Sycamore, too, has within the last few days shed its leaves very rapidly, and the Horse Chestnut comes within the same category. Between these last mentioned trees and the Oak there is a very wide difference in the way in which they lose their summer garb. With the Ash, Sycamore, Horse Chestnut, and others of the class the process seems generally only a matter of a few hours, but with the Oak it is much more protracted. At the present moment, Oaks as bare as they could possibly be in the dead of winter are to be met with, and though comparatively few in number, others which constitute the bulk still have their leaves adhering, but of a russet colour, whilst others again retain the dark green of summer, so that spring-time will be upon us again before the whole of the Oaks have finally rid themselves of the past season's covering. In a lesser degree the same may be said of the Beech. With regard to the smaller trees, many of the Hawthorns have lost their leaves, but the greater portion still have them more or less intact. The difference in this respect between trees of the same species is often very marked, as while some are virtually leafless, others have lost few or none. Situation no doubt has something to do with this, but not everything. Age probably is also a factor, and soil is not without its effect. With us the common Maple was one of the first trees to show the tints of autumn, and now its leaves are disappearing fast. The Hazel often goes to make up a good deal of woodland masses, and this is in its last stage so far as retaining its leaves goes. Very few have really fallen, but the first touch of frost will work a great change. Perhaps a tree which shows the continuity of the seasons as well as any common to our woods and hedgerows is the Goat Willow. At the time of writing the leaves of this tree are as green as at any time during the summer, but the young buds which produce the catkins of the early spring are very noticeable. Speaking of deciduous trees in general, it is a little surprising that the strong winds we have lately experienced have had so little effect upon the leaves, but there is no doubt that the mildness of the season will partly account for it. The fall of the leaf being looked upon as the signal for commencing operations in the woods, the first change in the weather sufficient to clear the bulk of the trees will be enough to cause active work to begin. So far as the woodman is concerned, a few gentle frosts will be acceptable, and there will be but little done until they come. WILTS.

Fence posts upside down.—This plan is never followed here—at any rate, not systematically—and if a post gets set upside down, it is more from accident than intention. The idea, I believe, originated from the theory that moisture would not have the same effect upon the tissue of the wood when it was inverted as would be the case when fixed in its natural position. There may or may not be something in this, but with ordinary Oak fence posts it would be quite counterbalanced by the inconvenience of having the smaller and generally more sappy part of the post fixed in the soil. As the result of a good deal of experience with Oak posts, I should prefer having them sawn and fixed in the same position as the trees grew, especially when the logs from which they are cut taper considerably, which they are pretty sure to do. When posts are cut parallel throughout, which seldom happens, the experiment could be more easily tried.—D. J. Y.

No. 783. SATURDAY, Nov. 20, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
The Art itself is Nature."—*Shakespeare.*

A NORTHERN GARDEN.

In this part of Northumberland the winter, so far, has been exceptionally mild. My garden, near Benwell, is on the very summit of an eminence about 400 feet above the sea level, and it includes the site of a camp and the greater part of "Condereum," the third station on the Roman Wall. In addition, therefore, to the usual inducements to dig deep we have the interesting incentive, that in so doing we occasionally turn up Roman coins, Samian ware, inscribed stones, and other antiquities. To-day (Nov. 17) I took my usual morning stroll round the garden, and though the general effect was the reverse of exhilirating, I was yet surprised to find so many plants still in flower, and apparently little injured by frost. The Cactus and single Dahlias yet showed blooms and were a mass of flower-buds, but never, I fear, to open. The colours of the Chilian Beet, some with stalks of deep crimson and with leaves of metallic lustre, others with stalks and mid-ribs of gold on leaves of yellowish green, were gorgeous. Roses were still budding and flowering, so were Anemone japonica alba, Geranium Endressi, Helianthemum flavum, Fuchsias, Aubrietias, and Antirrhinums. That diminutive gem, Lithospermum prostratum, which began to flower last March has, up to this date, never ceased to cover a rock with its pendent deep green sprays dotted over with charming Gentian-blue flowers. But the choicest gem of the winter garden is the Acæna microphylla, which, planted on the edge of a Vine border in exceedingly rich loam sloping towards the sun, is now a mass of the deepest carmine, far finer in colour than any Alternanthera. What a splendid autumn and, in fact, winter bed might be made of this plant if put into a circle of 6 feet or 8 feet diameter, edged with 2 feet of the deep green Saxifraga atropurpurea, or the same bed might be first filled with Daffodils, Hyacinths, or Tulips, edged with Crocuses or Scillas, and then surfaced with the Acæna and Saxifrage; or the Acæna might be planted as undergrowth to the ordinary summer-bedding plants, and be in perfection after they were removed. I never saw the Saxifrages look so beautiful as at this season of the year. S. rosularis, cochlearia, Stnrmeriana, lantoscana are now encrusted with a pearly sheen, which gives them the appearance of frosted silver. I returned home, therefore, feeling that even at this dull, foggy, dreary season the garden in winter has its charms for the observer of Nature.

John P. Mulcaster.

Benwell Park, Newcastle-on-Tyne.

A new Thorn.—A few weeks ago fruiting specimens of a Thorn were shown by Messrs. Veitch, at South Kensington, under the provisional name of Cratægus tatarica—a name given on account of its having been received from Tartary. Since this Thorn was exhibited it has been found to be C. pinnatifida, and, as the fruits of Messrs. Veitch's specimens appear to be larger than those of the type, it is considered to be a new variety, and has been named by Mr. Brown, of Kew, C. pinnatifida major. As previously stated, this is a valuable new shrub, remarkable for its handsome leaves, which are from 2 inches o 3 inches long, deeply lobed, and tinged with vinous purple. The fruits, which are about the size and shape of Cobnuts and borne in clusters of from two to five, are deep orange-red in colour. The flowers are said to be but little different from those of other Thorns. It is perfectly hardy in the Coombe Wood Nursery, where there is a large specimen of it. It is a native of North China and Amurland, and the type was named years ag'.

THE FIRST CHRYSANTHEMUM.

Mr. F. W. Burbidge has sent us flowers of the Chrysanthemum named Dr. Sharpe in order to enable us to compare its flowers with the drawing of the first Chrysanthemum flowered in this country, and which appeared in the *Botanical Magazine* in 1795. The coloured drawing and the living flowers are so much alike in every way, that there is no doubt that Dr. Sharpe is the identical sort which was flowered by Mr. Colvill in his nursery in the King's Road, Chelsea, just ninety-two years ago. The drawing beautifully represents the peculiar shape of the flower, the toothed florets of the expanded bloom, and the quilled flowers in the half-opened state. The colour, too, is excellent, for even after ninety years the richness of the purple-crimson is not in the least faded. This fact is most interesting, as it plainly shows that a plant may be cultivated for a hundred years and yet not become altered in any way. This Dr. Sharpe variety may, however, not be identical with the wild type of C. indicum, as it may have been introduced from Chinese gardens, where the Chrysanthemum had been grown for ages in great variety. What Mr. Curtis said about this plant in the tenth volume of the *Botanical Magazine* may be interesting to some of our readers. He says: "New as this plant is to us, it appears to have been cultivated in China for ages. Linnæus, who describes it in his 'Species Plantarum,' refers us to a figure in the 'Hortus Malabaricus'; this figure, and the description accompanying it, agree generally with our plant, but the flowers are more double, much smaller, less clustered, and do not correspond in point of colour, yet there can be no doubt that our plant is a variety of the same; it is there described as growing in sandy situations and having green petals. Rumphius, in his highly interesting work, the 'Herbarium Amboinense,' is much more minute in his information; he observes, that these plants were originally brought from China, where they flower in May and June; that there are two sorts principally cultivated in India, the white and yellow-flowered, and a third sort, differing only in the colour of its flowers, which are red (the variety, as we suppose, here figured) began to be known among them at Amboyna; the flowers there do not expand well, owing to their being produced at the rainy season, and they decay without producing any seed. He tells us further that it is cultivated chiefly for pleasure; that the natives and the Dutch plant it only in the borders of their gardens, in which it does not succeed so well as in pots; and that if it remains more than two years in the same spot, it degenerates, becomes less woody, and often wholly perishes; that the Chinese, by whom it is held in high estimation, pay great attention to its culture; they set it in pots and jars, and place it before the windows of their apartments, and that it is not unusual for them when they invite their friends to an entertainment to decorate their tables with it; on those occasions, he who produces the largest flower, is considered as conferring the greatest honour on his guests; besides these three varieties already mentioned, they have a fourth, which is more rare, whose flowers are of a greenish ash colour, all these varieties growing in separate pots, they place in certain quarters which they particularly wish to decorate, and the effect they produce is highly pleasing. In the cultivation of this plant they spare no pains; the shorter it is and the larger its flowers, the more it is esteemed. To make it dwarfish, and at the same time productive of flowers, they check its growth; for, if suffered to grow rude, it assumes a wild nature, and produces little but leaves. When it is coming into flower, of the three blossoms which usually terminate each branch, they pluck off two, and thus the remaining flower grows larger; by this, and other management, they cause the flowers to grow to the breadth of one's hand. He enumerates still a fifth sort with white flowers, which is extremely rare, and smaller than the others, called *Tschuy say si*, that is the drunken woman; its flowers morning and evening flag, and hang down as if debilitated by intoxication; in the middle of the day they become erect, and follow the course of the sun; but this (most probably a distinct species) is not exported from China. Finally, he remarks, that the Chinese and Malays are so attached to these flowers, that they even decorate their hair with them. Thunberg, in his 'Flora Japonica,' enumerates the Chrysanthemum among the natives of that country, and describes it as growing spontaneously in Papenberg, near Nagasaki, and elsewhere, observing, that it is cultivated for the extreme beauty of its flowers in both gardens and houses throughout the whole empire of Japan, and that the flowers vary infinitely in point of colour, size, and plenitude. This Chrysanthemum appears to be a hardy greenhouse plant, and it is highly probable that, like the Camellia and Aucuba, it will bear the cold of our mild winters without injury. As it flowers so late, there is but little prospect of its producing seeds with us, but it may be increased by cuttings and division of the roots."

A MOORLAND GARDEN.

Cookridge Tower, belonging to Mr. A. W. Sykes, is situated on one of the highest pieces of table-land within a radius of five miles of the borough of Leeds. It is some 13 acres in extent, but owing to its half-woodland and half-moorland character, which to nearly its fullest extent has been taken advantage of, it really becomes, from a gardener's point of view, a larger and more important enclosure than one might at first imagine it to be; in fact, the whole area may be termed a series of woodland, rock, pleasure and fruit gardens. The house overlooks a large lawn, unbroken by walks or beds; and here may also be found a well-stocked rock garden, and a cosy hollow, whence stone has been quarried, has been transformed into a charming retreat by ornamenting it with aquatics, and its banks and ledges with Lilies and other large flowers, which do well in such a sunken and sheltered situation.

One of the chief features of the grounds is the great sandstone rocks which crop above the surface, somewhat isolated and weatherworn. Happily, these, though quite near the house, were saved by somebody's forethought from the delver's wedges and hammers, and the owner, by a happy idea, has thrown them into bold relief by surrounding them with pieces of well-kept greensward. There is no other touch of art near them, except a few Primroses under a part, which hinders the close approach of the mowing-machine, and a bit of Houseleek here and there.

In harmony with the semi-wild character of the other parts the drive is minus Grass or any other edging, and there you see an irregular mingling of Ferns, Vincas, Forget-me-nots, Primroses, and similar flowers. There are but few beds, and absolutely no bedding. The beds may be termed rock beds, as in them, among a few Moss-grown stones, a selection of the rarest alpines is thriving in the happiest possible way. I never saw alpines more flourishing under cultivation than in these grounds; doubtless the altitude of 600 feet is something in their favour, and then the resources of the place are almost all that could be wished for. There is a spit of capital loam, leaf-mould, in all stages of decomposition, practically in unlimited quantity, and the same may also be said of peat. In some parts at a depth of 18 inches a bed of fine sand is found. In addition to these natural advantages, the owner, in order to help and protect his favourite plants, has had them planted in the best spots, clearing away as much of the wild vegetation as seemed desirable.

Rhododendrons form quite a feature of this place. The ponticums have been freely planted for backing up the lawns and banks of rarer sorts. It may seem odd, but here, as with Mr. Milne-Redhead, these common sorts suffered more than the hybrids during last winter. Surrounding the larger lawn are grand specimens, which in the flowering season produce some striking effects. In a

field, however, as seen from the rougher rambling walks in the lowly wooded parts, small groups and single specimens have been placed with rare judgment, and to see them in flower among short timber, and surrounded by the varied hues of knee-deep Bracken, Ling, and Heather, is a picture little short of perfection. It hardly need be said that the natural soil and subsoil already mentioned exactly meet their requirements, and doubtless influenced their being planted to such a large extent.

Alpine and herbaceous plants.—Plants of these not often seen in many places are here represented, and it may be interesting to state that the sweet soil and atmosphere, and the comparative immunity from fogs with which we in the valleys have to contend, appear to have a magical effect on plant life. The Himalayan Primulas grow like Cabbages, and those of the European Alps seem equally happy. The finer single and double Primroses, even the old double crimson, so rare and fickle, grow into big tufts in one season. Gentians have not been long planted, but in a year or two they have made rapid progress. Verna and bavarica thrive wonderfully; the curious Paris quadrifolia, so difficult to establish, here finds a happy home. Saxifrages are largely employed in the stony places, and even those many of us find fickle grow away without check, notably squarrosa, the rarer forms of oppositifolia, Burseriana, the diapensoides class, Megasea purpurascens, and other Himalayan species, such as Fortunei, which are often believed to be tender. Just as much may be said for the genus Campanula; the Bellflowers, from the tallest to the most humble, are scattered about, and from the fragile hederacea to the Chimney species, they almost too soon fill their allotted spaces. When it is seen that such moisture and shade-loving species as Ourisia coccinea, Linnæa borealis, the Cortusas, Serapias, Cypripediums, Fritillaries, Reeds, and such like are equally accommodated with such sun-loving and drier-rooting subjects as the Drabas, Arenarias, New Zealand Veronicas, Wall-rues, and the tribe of alpine Wallflowers, it is evident that mixed collections can be made to flourish in the same garden, though it may be under different conditions. I was delighted to see on my last visit, not long ago, how the charming purple Milk-wort was spreading, also Gaultheria procumbens and nummulariæfolia, the Chickweed Winter-green (Trientalis), the Soldanellas, and rarer Andromedas. I was also impressed with the fact that many things which often die in more low-lying gardens during winter seemed to stand the cold better at Cookridge than elsewhere. Some of these, I may mention, were Gunnera scabra, the Platycodons, Phlox pilosa, Onosmas, Arnebia echioides, Sempervivum Laggeri, some Sisyrinchiums, Egyptian Yarrow, the brevifolium set of Stonecrops, and others which do not occur to me just now. I believe I am not far wrong when I state that Galax aphylla, Adonis pyrenaica, Dianthus glacialis, and the Androsaces are generally conceded to be test subjects for culture in our climate, and I am glad that it has been my lot to see them happy. The Edelweiss here has none of the half-decayed or biennial character which it so often has. Umbilicus spinosus has not suffered in the least from the past two winters. When it is stated that cut flowers are in great request, and that the range of glass is limited almost entirely to growing fruit and Orchids, it may be supposed that hardy plants have mainly the cut-flower material to produce.

Rock gardens.—One of these is on a space cleared of wild vegetation, and selected for its nearness to the dressed parts of the grounds, as well as for its adaptability by reason of the stone there cropping up in large and small blocks above the surface. Something has also been done in the way of arrangement, but very little in changing the surface level, and the heaping-up idea was nowhere carried out in the preparations for the plants. The consequence is, that all are set in the natural soil cleared from old roots, and mostly at the old level. In some places moisture largely accumulates in rainy weather. There are positions of dryness and a maximum amount of sunshine as well as of shade, with all practical intermediate degrees of both. From the manner in which the surrounding and dwarfer trees and shrubs have been left or thinned out, and the wild and beautiful undergrowth preserved to the edge of this rock garden, it has a cosy and half-natural effect. Tall things in the way of Sunflowers, Elecampane, Speedwells, &c., have been set in groups in the more open parts of the scrub, and a coppice here and there has been planted with the finer varieties of Heaths. The lower and twiggy trees have had rambling Roses and other climbers placed in prepared soil at their feet, so as to climb into and drape their branches; but as this result can only be obtained after a considerable time, the desired effects will yet have to be waited for. Such bold subjects as Irises, Grasses, Saxifraga peltata, &c., associate admirably with big rocks just standing above the surface. The second rock garden is formed in a hollow; well-grown shrubs and trees close by, but not overhanging, benefit the things grown by keeping high winds well overhead. A series of beds which used to be planted with the usual high-coloured tender plants have been changed into rock beds; they are situated in a good-sized recess of the large lawn, and, being in the line of sight from the windows with one of the big sandstones standing out clear on the Grass, they harmonise and otherwise have a solid, but pleasing effect. In these beds, where but few stones are employed, the plants do remarkably well. Thymes, Mountain Avens, the dwarfest Gentians and Primulas, Saxifrages, alpine Pinks, Andromeda tetragona, dwarf Gromwells, Bellflowers, and Sempervivums, and such like not only prove themselves capable of adorning the most frequented parts of the pleasure grounds equally with tender bedders, but the pleasure and interest which these thriving alpines afford never wane throughout the year.

Lilies.—In addition to numerous ordinary sorts of Lilies, which are mainly grown in the open air, some fine specimens have been grown in pots here this summer. The spotless and distinctly-coloured flowers of Batemanniæ, which has a stem nearly 5 feet high, numbered eight flowers on a stem. Auratum macranthum was in grand form. The pale-rayed, but otherwise pure white, flowers were fully 9 inches across, though reflexed; the petals were quite 4 inches broad, and, overlapping each other, their massive effect may be imagined. Auratum rubrum vittatum was highly coloured in the band; flowers 8 inches across, and three on each 3-foot stem. Auratum pictum showed an unusual form—almost fantastic in the shadings, each flower being 6 inches in diameter, and five flowers on each of the 5-feet to 6-feet stems. Ordinary auratums were grown to 7 feet, and ten to twelve flowers were on each stem. Leichtlini was good; the flowers had been screened, and the fine yellow showed up the distinct spotting of chocolate-brown in a better way than is usually seen.

J. W.

NOTES OF THE WEEK.

Gardeners' Royal Benevolent Institution.—We are informed that Baron Ferdinand de Rothschild, M.P., of Waddesden Manor, Aylesbury, has kindly consented to preside at the forty-fourth anniversary festival of this institution, to be held on Friday, the 1st of July, 1887.

Luculia gratissima.—This fine old-fashioned, but somewhat neglected, stove plant is now flowering freely in Mr. Williams' nursery at Holloway. It is usually thought to be a shy flowerer, *i.e.*, until it has attained a considerable size, but the specimens at Holloway are not more than about 2 feet high, and yet, as we have said, they produce sweet-scented flowers in abundance. Some of them are seedlings, and some have been obtained from cuttings.

The Chinese Date Plum.—Some very fine fruits of Diospyros costata have been sent to us by Canon Ellacombe, gathered from a tree growing against a south wall in his garden at Bitton, near Bristol. The fruits are similar in shape and of about the same size as those of well-grown Acme Tomatoes. They are orange-coloured, and produced three and four on one shoot. Those sent are not ripe, but Mr. Ellacombe says they will ripen if kept. He calls it "Tchi-tchi," presumably its native name. D. costata is a variety of the better-known D. Kaki. It is a native of China, where it forms a small tree. It was introduced nearly a hundred years ago. Mr. Ellacombe does not state his opinion as to the edible qualities of the fruit, but we remember tasting some of D. Kaki, grown in Mr. G. F. Wilson's orchard house at Weybridge, a year or so ago, and these were pleasant to the taste; they were not so good as Apricots, but a fairly good substitute for them.

The green Narcissus (N. viridiflorus).—Mr. Peter Barr sends us a flower of this rare little bulb, which he says is the first flower from his plants this season. It is certainly a curiosity, but no great beauty. The flowers are star-shaped, about an inch across, and of a dull olive-green colour. It has the tiniest of cups, and the whole flower is so unlike that of a Daffodil, that one would hardly believe that it is a near relative of the Emperor and other stately Daffodils of that stamp.

Vitis humulifolia.—The rain deluges which we have lately had have effectually washed the colour out of the few flowers left in open-air gardens, but I notice that the berries of this pretty Vine look all the brighter for the continual washings and buffetings to which they have been lately subjected. This Vine wants a good, hot summer, and if planted in poor soil and in a sunny aspect, it is really lovely when in fruit, but in shady places it does not ripen its berries. Its leafage, too, is good. There is no difficulty as to its growth. I find that in grows freely in the poorest soil, and that its turquoise-coloured berries are more beautiful when checked in growth by a hard root-run than when planted in a rich Vine border.—James Groom, *Gosport.*

Variegated Phytolacca.—We have received from MM. Forgeot and Co., of Paris, a specimen of a new variegated-leaved form of Phytolacca, which they name P. purpurascens foliis variegatis. Its leaves are beautifully variegated, being green and carmine in the centre, and broadly margined with creamy white, while the large fleshy stem is light red. The raisers state that it is a hardy and vigorous perennial, growing about 6 feet high, and that it will prove invaluable for the embellishment of open-air gardens.

Oreopanax Epremesnilianum.—The Comte d'Epremesnil writes: "I have just seen with great pleasure in the last number of The Garden the beautiful engraving of the Oreopanax Epremesnilianum; but a mistake has been made in referring to the garden of Thibermont, near Dieppe, as the place where this plant and others grow in the open air. It is in the garden of the Villa des Cocotiers, Golfe Juan, Alpes Maritimes, that all the Palms and plants of different kinds of which I have spoken to you are found. I think it is indispensably necessary to rectify this error as soon as possible. I should not like to mislead anyone who might suppose that all these plants grow in the open air near Dieppe."

Schizostylis coccinea withstands the wind and wet bravely; in fact, it affords about the only brilliant bit of colour to be found out of doors just now, and as long as sharp frost keeps off we can get plenty of its spikes, the flowers on which open beautifully after they are cut. Gentiana acaulis has been full of bloom lately, and looks like keeping on until its usual spring display takes place. How so many complain about its not growing freely I cannot imagine. I find that if planted in firm soil and left alone it soon forms a dense mass. A good thick edging of this Gentian in full bloom is a sight not readily forgotten.—J. G., *Gosport.*

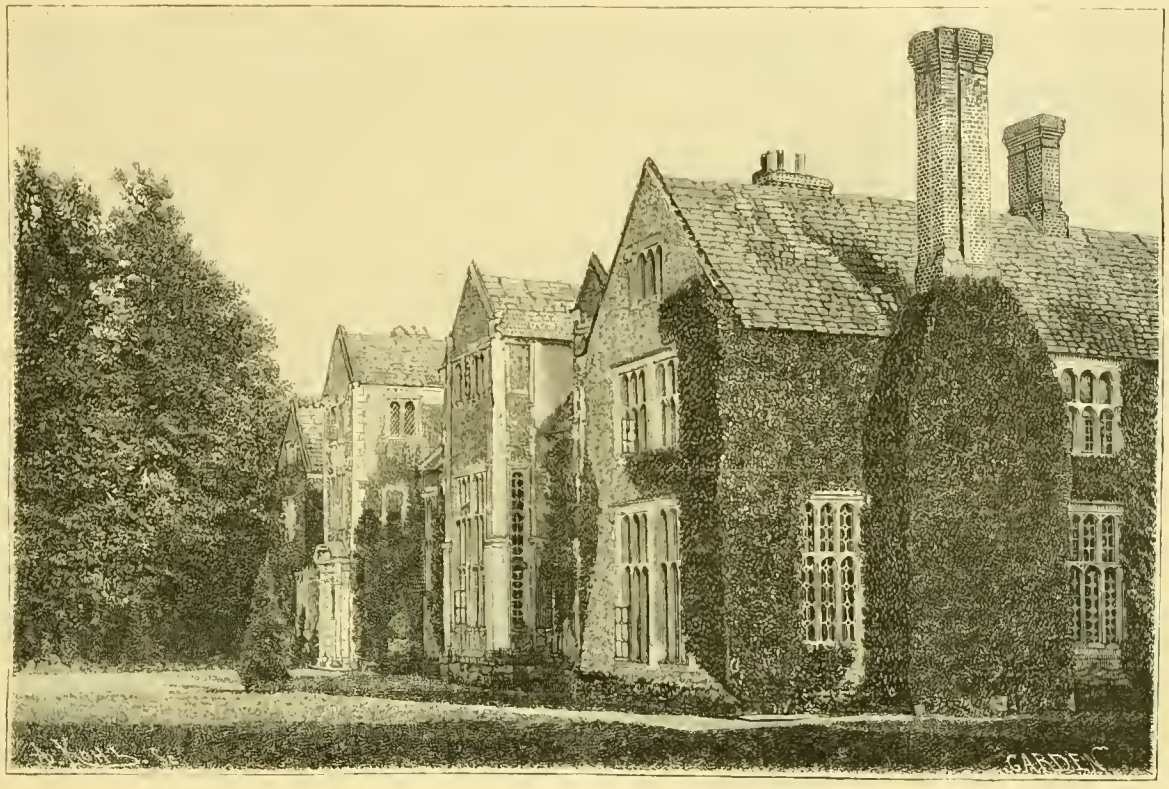
Rosa arvensis.—Is this Rose to be bought anywhere? If any reader of The Garden would send me a sucker I should be glad to give the old White Rose or York and Lancaster in exchange. Also, can anyone tell me where the old Apple Rose is to had?—M. P. Forster, *Lesbury, Northumberland.*

How to eradicate Horse Radish.—Will someone do me the favour to inform me whether there is any method by which I can destroy the growth of Horse Radish in my kitchen garden, which is completely overrun with it? I have tried digging it out, but though I went a considerable depth, the plants only appear to grow the stronger.—Constant Sub.

LOSELEY.

Loseley, near Guildford, the seat of Mr. William More Molyneux, is a fine example of a stately English home, and of the noble style of national architecture of the time of Queen Elizabeth. The building is of the local Bargate stone, with quoins and wrought masonry of freestone, brick chimneys and slated roof, the whole toned by weather and Lichens to a harmonious silver-grey colouring. The house is on three sides surrounded by wide, level lawns, with groups of large trees at a pleasant distance. These fine stretches of Grass are for the most part happily unspoilt by the usual cutting-up effect of flower beds and injudicious planting, and the grand grey house rises from the level sward with its quiet dignity unmarred by any petty frivolities. The lawn on the south side has not been so fortunate, and is a good deal spoilt by a small sunk rectangular garden of no beauty, with beds set out in heraldic patterns. The entrance road from the south-west passes up a steep hill through a double avenue of magnificent Elms, and the view from the last named lawn, looking full into the mass of these superb trees is a sight that a tree-lover can never forget. The fourth side of the house, beyond the offices, is bounded by a large walled kitchen garden. This garden on the south side is not visibly walled, but a steep turf bank rises to a level bowling green, the subject of one of our engravings. A flower border filled with good hardy plants conceals the coping of the wall which descends to the moat on this side. Each angle of the wall is accentuated by a small picturesque building—in some cases a large pigeon house, but in the view engraved, a pretty summer tea-house. The kitchen garden is an ideal one, both for utility and for enjoyment. Its large walled space ensures shelter, and as its extent is needlessly great for vegetable and fruit growing, it comprises, in addition to the bowling green, ample Grass walks and lawn-like spaces, broad borders of hardy flowers, shady alleys of ancient Filberts and fantastic old Apple trees. The house stands on rising ground in a park of fair size, ornamented with groups of fine Oaks, Elms, and Spanish Chestnuts. An old plantation of well-grown Scotch Fir, which comes to perfection in the light sandy soil of the district, makes a pleasant variety. To the north, within a mile, rises the Hog's-back, the westerly section of the chalk range that runs due east and west through a large part of the county of Surrey.

This fine house was built by Sir William More, an ancestor of the present owner, in 1562 and succeeding years. His son added a western wing, which has since been pulled down. Queen Elizabeth was a frequent visitor at Loseley.



Loseley, Surrey. Engraved for The Garden from a photograph.

FRUIT GARDEN.

GRAPES IN THE OPEN AIR.

I must differ from those who assert that the Grape is not suitable for open-air culture in this country. So far from placing it last on the list of hardy fruits suitable for open walls, I would give it, so far as the cottager is concerned, the place of honour. I have, of course, only in mind the warmer counties of this country. Of Grape culture in the north and in the midlands I have had no experience, but I do know that over a large area very good Grapes may be grown by giving them the attention they need. In ninety cases out of a hundred they do not get this attention, and that is why failures occur. I do not understand why, but the love of the Grape seems to have died away in places where, a quarter of a century ago, every cottage was more or less wreathed in Vine foliage. It was pleasant to see the cottager sitting under his Vine-clad porch, and to look at the yellow or blue-black Grapes clustering on the end or covering the front of the dwelling. Whether bad seasons or mildew is the cause of this decadence, or whether outdoor Grapes are passing through one of those phases of neglect which at some time or other overtake every cultivated plant, I know not; but it is certain, from being one of the most popular of hardy fruits, Grapes are now the least thought of. The fault so frequently committed is that of leaving too many shoots. Our climate being uncertain, we need to expose every leaf and bunch of fruit to the full influence of the sun during a great portion of the day. In a general way, growers appear to think that they have a tropical sun to deal with, which is able to force enough heat through a tangled mass of leaves and shoots a couple of feet thick to ripen Grapes buried under it.

The other day I saw a cottager vainly trying to repair the effects of neglect. The lateral shoots of this Vine had formed a drooping mass of foliage, from which here and there peeped out a bunch of green Grapes, and which through the summer had never got the full benefit of the sun's rays. But a short distance from here I saw another Vine, the condition of which compared with the former was as sunshine to shade. Every shoot had space enough; the laterals were cut in regularly, and thereon hung in good condition quite a bushel of Black Cluster Grapes. These Grapes were ripe, though the summer has been remarkable more for drought than heat. The only serious drawback to outdoor Grape culture is mildew, which I will admit is a fearful scourge, and one more difficult to deal with in the open than under glass. There may be years when the most determined efforts will fail to completely eradicate it, but it can always be kept in check; there need be no serious loss from it. What the French Vine growers have done with many acres we may surely do for one single Vine. A short time ago I killed the mildew on a wall 100 feet long in about an hour by syringing with soft soap and sulphur. In this instance the foliage was badly infested, but by taking proper measures at the right moment this pest need never obtain a hold. From long observation I am convinced that there is just one time when mildew appears. No rule can be laid down; it entirely depends on the certain atmospheric conditions which, unless in exceptional seasons, are sure to prevail for a sufficiently long period to favour parasitic development.

This critical and dangerous period must be watched for, and the plague spots attacked the moment they appear. Mildew comes first in minute isolated spots. This is the sowing of the seed, which, left alone,

yields a bountiful harvest of disease, loss, and annoyance to the Grape grower. It is almost inconceivable the rapidity with which mildew under the most favourable conditions spreads. To-day it is seen in the shape of a few isolated minute patches; in a week's time there is not a leaf in which the circulation is not lowered by this parasite. One must act on the stitch-in-time principle if the deadly foe is to be fought with success. A very small amount of sulphur applied at the right moment will often save a Vine from injury, and it is seldom that mildew comes twice in the same year. In the case of badly infested Vines two dressings will generally be found necessary, for mildew, like all the enemies that assail plants, is difficult to exterminate when once it has obtained firm hold. It is only fair to say that this difficulty is intensified in the open air by reason of heavy rains, which often come and wash off the sulphur before it has time to act upon the fungus. It is, however, rare that we do not get a spell of fine weather sufficiently long to enable the remedy to do its work thoroughly, and advantage should be taken of the appearance of lengthened fine weather to apply it. When sulphur is applied in the open air, it is a good plan to use some soft soap with it, at the rate of 2 oz. to the gallon. This will enable it to resist all but very heavy rains.

Great importance is often attached to making the soil rich for outdoor Vines. This is, I think, a mistake, as much strong food causes a rank growth, which is often unable to ripen as it ought to do. In naturally rich moisture-holding soils I would apply no manure, for if the ground is well worked the roots will be sure to find as much food as they want. It has often been a source of wonderment to me to see what a small amount of soil the Vines in many of the vineyards on the Continent have to grow in. In many instances they have not more than 6 inches of workable soil, this resting on a hard pan of stony matter, into which, however, the roots in all probability find their way in time, and which helps them to stand against the drought which one would naturally suppose must be severe on the steep slopes on which they grow. The wood made under such circumstances is not very strong, but it becomes thoroughly matured, exposed as it is to a scorching sun, which not only acts on wood and foliage, but on the roots, by thoroughly warming every particle of soil around them. The fact that the Vines grow and live healthily for an indefinite period under such circumstances shows that much rich food is not needful, and we may conclude that in a level and naturally damp country it is harmful. I have in mind a Vine which grew on a wall, and which was one of the best samples of outdoor Vines I ever saw. It covered the end of a largish dwelling, and for many years annually bore a good crop of well coloured black Grapes. This Vine, it happened, had been in good hands from the time it was planted, and had, therefore, received all proper care in pruning, summer-pinching, &c.

The noteworthy point about it, however, was that it grew in the poorest soil possible to find, and that it got no manure. The natural soil was pure sand to the depth of 2 feet or more, and this on the surface became so hot that it almost burnt the hand in a time of heat. It was about the worst soil for garden crops that I ever knew, not only on account of its inability to retain moisture, but because, when the surface became quite dry to the depth of a couple of inches, nothing short of a tolerably lengthy period of rainy weather could wet it through again. A good summer shower, such as in ordinary soils did real good, was only of use in refreshing the foliage, for none of it got to the roots. The dusty surface did not allow it to pass through, and the first hour of hot sun evaporated it. I mention this to show how little moisture the roots of the Vine in question got. The less moisture the warmer the soil, and I have no doubt that to the warmth the roots enjoyed in summer, in addition to the care bestowed on it, were due the lengthened vigour and excellence of the crops it bore. Just when this Vine was in its prime it changed hands; the new owner neither knew nor cared about Grape culture, and the last I heard of it was, that it was but the shadow of its former self. Whether it succumbed to an attack of mildew or to neglect generally I do not know, but the fact is, that when skilful hands no longer tended, decrepitude took the place of vigorous fertility. I need scarcely say how necessary it is that Vines grown on open walls should get the full benefit of all the sunshine they can get. The position should be, if possible, full south, and where such a situation cannot be commanded, I would say, plant a Plum, a Pear—anything but a Vine. Vines may be planted at any time after the fall of the leaf, but the best time is, I think, early in spring. With respect to the preparation of the soil, there is not much to say. The important point is to thoroughly work it to a depth varied according to its nature. The more porous the soil the greater depth of it will be necessary; but if I were going to plant Vines on a heavy loam, I would keep the roots within a foot of the surface, if possible, so that they might feel the influence of the sun. In the case of soils of this description I have no doubt that an addition of brick rubble, mortar rubbish, or something similar would be beneficial.

Amongst hardy fruits none lend themselves better to artistic trimming than the Vine, and the shoots may be arranged so as to impart an ornamental appearance when at rest. A well-trained Vine is at all times pleasant to see. The simplest form of training is, however, the best, and that which I would preferably employ consists in leading two horizontal branches near the ground from the stem and allowing shoots to rise from them at regular distances to the desired height. This arrangement better allows of easy supervision than any other; the position of each fruiting shoot is better seen, and the necessary work of stopping the laterals, thinning the shoots, &c., is facilitated. It also allows of the renewal of youthful vigour by taking up a young shoot now and then. It is simply a modification of the "long-rod" system, as carried out frequently under glass, applied to outdoor Vines. A most important point is the regulating the shoots, so that every shoot and leaf and bunch of fruit get the direct influence of sun and air. No success can attend an absence of methodical training. If the shoots are so crowded that they overgrow each other, they are mutually robbed of that which is life to them. The best of soils and most favourable of situations cannot, unless in exceptional seasons, counteract such a defect. Even in sunny France training is considered of most vital import, and the renowned Chasselas Grapes of Thomery owe their excellence as much to systematic, careful culture as to favourable climatal conditions. The Vines there are as carefully tended as those under glass with us. The stopping of the shoots and thinning out of laterals must, from the time the bunches show, be vigilantly attended to. A common practice is to allow the shoots to run away for a month or two, and then, when they have become crowded, cut them away wholesale. This is very bad practice, as it involves a loss of time by depriving the bunches of air and sunshine, and causes a check by depriving the Vine suddenly of a number of growing shoots. Every shoot allowed to extend and cut off in this way takes away from the quality of the leaves which must be left on. Every shoot should be pinched back at one leaf from the bunch, and lateral shoots must be taken out as soon as they appear. This throws the sap into the leaf, so that it acquires great substance, and one well-developed leaf is worth half-a-dozen that have grown in partial shade and deprived more or less of air.

Thinning out the berries of outdoor Grapes is not often practised, but it has, of course, the same effect as in the case of indoor Grapes. This should be done as soon as they are large enough to handle; allowing them to remain until they are as large as Peas will not do. It frequently happens that the shoots of a Vine have plenty of room for the first few years after planting, and then gradually become too crowded. In such cases some of the rods should be cut away. When the shoots are young, 15 inches apart will be enough, but later on they will require double that distance. When a Vine from any cause has come into a bad condition, the old wood having a knotted appearance and the fruiting shoots coming weakly, a good plan is to cut away some of the old stems every year and take up a young rod in their place. This alone will frequently give new life, and is often found successful with Vines under glass. The growth of the new wood gives an impetus to root action, and in the course of two or three years a new Vine will have taken the place of the old one. It will soon be seen whether such a measure is likely to have any good effect; if not, then dig up and plant anew. With respect to kinds, we really appear to be in the dark ages of outdoor Grape culture. Even in the days when this form of hardy fruit culture was more popular, only two kinds were known to the million, *i.e.*, the Black Cluster and the Sweetwater.

The French have very nearly 500 hardy Grapes, not one of which has ever been fairly tried in this country, and this number is continually being increased by raisers who are endeavouring to combine reliability with greater precocity. Surely some of these would suit the warmer districts of this country. Who will do the good service of making a special feature of outdoor Grape culture, with a view of testing the numerous Continental kinds in respect to their adaptability for our climate? Some of the kinds I have been acquainted with in France and Germany seemed to me considerably earlier than those commonly grown here. There is one called the August Traube (August Grape) grown in the south of Germany, especially in the Margraviate of Baden (a district bordering on Switzerland), remarkable for its exceptional precocity. I have not the slightest doubt that this Grape would ripen well in this country. A Grape that will ripen in Germany early in August ought to ripen with us six weeks later. I remember, too, very distinctly a Grape that in my boyhood grew on our dwelling, and which no gardener who saw it could tell its name. It came almost as large in berry as a fair sized Hamburgh; the colour was equally good, and it carried a good bloom. This Grape always ripened, and could easily be disposed of to fruiterers in the neighbouring town. I should much like to meet with this Grape again; perhaps some of your readers may recognise it from the description here given. There is no doubt that a series of cool summers with more or less sunless autumns have had a deteriorating effect on outdoor Grape culture, but we are not justified in assuming that this is to be the normal state of our climate. Seasons good or bad are apt to move in cycles, and when we once more emerge from this depression we are likely to be again favoured by a return of old-fashioned summer weather. I would remind those who hold pessimist views on this matter that the question of whether Grapes can be grown in the open air has been practically settled on the Marquis of Bute's estate at Cardiff. I am informed that in spite of adverse seasons the vineyard planted some years ago with, I believe, Continental kinds selected by Mr. Pettigrew in France has flourished, and that good wine has been made from them. I am also told that this vineyard is going to be extended. This does not indicate that our climate is very unfavourable to the Grape, but rather that, given a favourable situation, the right kinds, and skilful culture, outdoor Grape culture may be made a success.

If Grapes will ripen on an open hillside, they will do so on a wall, and, having in remembrance the crops of Grapes on the cottages of the pleasant little villages of Surrey, I do not hesitate to assert that it is care and skill rather than climate that is at fault. No fruit that I can see has taken the place of the Vine; no fruit has been or ever will be so popular with cottagers. The Pear is uncertain; so in a great measure are Plums and Cherries; and Peaches are out of the question in all but professional hands. The Vine is almost sure to bear fruit, as it rarely gets cut by the spring frosts, which bring the average yield of many other hardy fruits down so low. Moreover, the pruning is as simple as that of a Currant or Gooseberry bush. Let those plant Pears or Plums that will, but I cannot think that they will average higher as regards profit than Grapes. Comparing the returns during a decade, I am convinced that the advantage would be on the side of the latter. Pears are only of use for dessert—they are not used for jam; Plums and Cherries are more generally called for, but with them there is apt to be a glut or none. Any greengrocer in a populous neighbourhood will purchase fairly ripened Grapes, and they are often in

request for wine-making. There is never any difficulty in disposing of them at a fair price. I have often known a cottager clear over 20s. from his Grape Vine in one season. J. Cornhill.

VIGOUR AND FERTILITY.

This subject, according to a contemporary, has been revived in a somewhat new aspect. It will be remembered that in the discussion that took place in The Garden some time back, I contended that vigour promoted fertility in the case of both fruit and flowers, and *vice versâ*, Mr. "D. T. F." and others holding the contrary opinion. The following, from Mr. Thos. Meehan, in your contemporary, seems to favour my view:—

In coniferous trees the female flowers, ultimately the cones, are only borne on branches which have plenty of light at command and are endowed with vigorous vitality. When these branches become overshadowed, or weak from age, they are given up to male flowers only. In Indian Corn and similar plants the ears are located where the most favourable conditions for nutrition exist, the male flower, or tassel, forming merely the "tail end" of the stalk. Numerous facts of this character have been collected closely connecting the female flower with full nutrition, and the male flower with a more limited supply in the primordial stages of their existence.

European observers continue to record facts sustaining these views. Among the latest is a paper by Hoffmann in the *Botanische Zeitung* for 1885. He sowed seeds of numerous kinds of dioecious plants closely together, so as to give little food to each plant, and the same plants thinly, so as to give each plant nearly all the food it could use. Where they were thickly sown he counted 283 males to 700 females. In the well-fed lot there were but seventy-six males. In our own country the common Ragweed (Ambrosia) is a good illustration of this fact. In a Potato or Corn-field where the plants grow very strong and vigorous, the proportion of female flowers is largely in excess of the male, and it is not uncommon to find plants with nothing but female flowers under these circumstances. But in fields where grain has been cut, and the Ragweed comes up in thick masses late in the season, and nearly starving each other, male flowers are very numerous, and some are wholly male. Female flowers are always few on each plant.

The above paragraphs seem to be pretty much the same as saying that vigour promotes fertility, as in the case of the subjects exampled by me, viz., the Grape, Nectarine, and Currant, &c., there cannot be perfect fruits without seeds. Whoever may be right, the fact is interesting that the theory that vigour promotes fertility is quite opposed to one of the most cherished convictions of gardeners, as exemplified in "D. T. F.'s" late contentions on the subject, for that poverty produced fertility as well as roots on a plant is an article of faith of gardeners of long standing. The two theories are directly opposed to each other, and it would be disappointing to discover that cultivators had been all along acting on quite wrong principles. It can hardly be forgotten yet that I referred "D. T. F." to Currant and Gooseberry bushes during the past season as affording good evidence of vigour promoting fertility both in the number of racemes and berries produced, and I would almost have expected him to act upon my suggestion and report the result; but he has not done the latter, and I may be excused for taking his silence as favourable to my view. I did repeat my observations, which only confirmed all I had written more and more, as in all the cases observed, whether they related to single shoots or whole bushes, the most vigorous examples bore the most fruit. J. S. W.

Preserving Filberts.—I have found well-matured nuts to keep best in their leafy shells and in a jar placed in a dry, yet cool, place. No doubt very much depends upon the sort of fruit, the soil in which grown, and the cultivation bestowed. Then it seems not easy to keep home-grown nuts beyond Christmas. On the other hand, we find imported nuts to be good all through the winter, perhaps all the year round more or less good. That may arise from the diverse nature of the ripening periods, or perhaps from the greater warmth more thoroughly ripening the nuts. The Barcelonas have a high reputation for sweetness, freshness and soundness, due no doubt to the thorough ripening received. Thus it would appear reasonable that small nuts should keep with us good or bad just as the position has enabled the fruits to become thoroughly ripened or otherwise.—A. D.

MARKET PEARS.

A market gardener in my neighbourhood grows Pears largely for market, and he states that he has done better during this season than for some time past, although the crop of leading varieties was greater generally than for the past few years. He commences to market with the Portugal or Chalk Pear, a variety that I cannot trace, and a Pear that must be eaten as soon as gathered, as it will not keep; it is like the Windsor in appearance, but smaller, and it is a very heavy cropper. This variety, the first sent to market, brought him 6s. per bushel. Then followed the Hessle or Hazel Pear, a variety that grows into a fine standard, and succeeds in almost any situation, and perhaps it is as extensively grown as any other variety, especially in the north midland and northern localities. This year the Hessle almost everywhere gave a tremendous crop, and so Hessles sold somewhat cheaply; a good sample fetched 4s., 5s., and even 6s. a bushel; the inferior ones only 2s. 6d. This Pear is of excellent quality in some districts. Next came in order of time Williams' Bon Chrétien, which in its season fetched from 5s.—the smallest—to 20s. per bushel, according to the sample, the very finest realising the latter price; good average samples fetched 10s. per bushel. Then followed Beurré de Capiaumont, a dessert Pear of good quality that ripens at the end of September and in October; the tree is of hardy, vigorous growth and an abundant bearer; 2s. per bushel was considered a good price; some of the very finest samples fetched a little more. Next came Calebasse, which is regarded as a dessert Pear of inferior quality, coming better on some soils than on others—a somewhat irregularly long russetty Pear, the flesh crisp, juicy, and sweet. My informant not only had a large crop, but the fruit was both good and clean, and for the very best he obtained as much as 24s. per bushel; the inferior fruit fetched 5s., and the best 18s. and 20s. per bushel. Beurré Diel is now being marketed, and which is known to be a dessert Pear of the highest quality. On large standard trees it cannot be expected that the fruit would be as fine as on young and vigorous pyramids, but 10s. per bushel is considered a good price. Lastly, in the order of time, comes the old Bishop's Thumb, an old-fashioned and excellent dessert Pear, hardy in growth, a great bearer, and doing well as a standard. There has been a very heavy crop of this variety this season, and only low prices can be obtained. R. D.

ROOT-PRUNING AND GUMMING.

"Radix" (p. 450) seems to manufacture his vegetable physiology as he goes along—a very good plan where the practice inculcated is not quite orthodox itself. Gumming, he tells us, "not seldom follows" root-pruning, which will be news to most fruit growers. I fear "Radix" confounds gumming with canker, a totally different disease. On looking up authorities on the subject I read that gumming is simply a form of extravasion due "to excessive vigour, in which the sap is formed more rapidly than the circulatory vessels can convey it away," and that "there is but one course of treatment to be pursued—root-pruning, and reducing the staple of the soil." If this be true, "Radix" must have got on the wrong side of the hedge with his root-pruning theories. Robert Thompson and all other sensible authorities take the same or a similar view, and I think most Peach growers know well that gumming is always most to be feared in gross limbs not sufficiently matured and hard cut back at the autumn pruning, and that the symptoms can be sensibly abated by root-pruning, which checks the flow of sap, or provides channels in the shape of growth to give the sap a free run. There are no surer means of extinguishing the disease than these if they are resorted to in time. I never knew nor heard of gumming being actually caused by root-pruning, nor do I think "Radix" ever did either. I put his assertion on p. 458 down simply as one of those little free and easy statements that he is rather fond of making and indulging in. Then he goes too fast when he declares that "experience has almost established into an axiom that wherever there is most sun-heat thither will the larger and stronger roots be most thickly gathered together," an assertion which shows how profoundly reflective "Radix" must be and the extraordinary amount of study he has brought to bear on his subject. If the above statement was true, there would be no need for root-pruning at all, because as the sun-heat is always most felt at the surface of the border, the roots would be "gathered together" there, and not down many feet deep in the cold, uncongenial subsoil at the bottom, where "Radix" tells us to hunt for them. Tho fact of the matter is, "Radix's" practice, theory, and assertions are so hopelessly mixed and at variance one with another, that one may be excused for thinking the idea of giving them coherence never so much as entered his mind. Hugh Miller wrote that some writers cast off their thoughts in writing as joiners did shavings with a plane, and that the products in each case were of about equal value. Anti-Radix.

NOTES.

Winter berries.—Although as a fact Holly berries are less abundant than is usual here with us, yet there is a fair sprinkling of both red, yellow, and orange-tinted kinds. A visitor here the other day remarked that it is only the green-leaved Hollies which berry or fruit really well, and that induces me to ask if the gold or silver variegated Hollies ever do bear fruit abundantly, or otherwise? The yellow-blotched Aucuba fruits nearly as freely as the green-leaved varieties. I saw a fine flat tazza of bronze—a Japan incense-burner, I think it was—filled with the berried branches of Euonymus europæus, both red and white kinds; Cotoneaster frigida, Leycesteria formosa, Snowberries, and winter Cherry, the whole being set off by a few dark, bronzy Ivy leaves, the crimson-tiuted sprays of Veitch's Japan Creeper, Smilax, and the blood-coloured and golden foliage of deciduous Azaleas. Apart altogether from their flowers, lovely though they be, the Azaleas of the Gheut and mollis, and those of the A. calendulacea groups, are well worth growing, for the sake of their beautiful autumnal foliage, which is of all tints, from golden yellow, pink, red, scarlet, bronze, and crimson. I saw a fine bush of Pyrus Maulei growing on a sunny wall yesterday fairly covered with its golden red-cheeked, Quince-like fruits. Wherever it fruits well it is very ornamental, and a bit or two of its scented fruit is a great improvement to an Apple pie.

Smilax.—When the garden is gay with Scilla or Narcissus in spring, with Iris, Roses, and Pæonies in summer, or with the flowers and rank leafy growth of autumn, the Ivy and the Smilax on the old walls are apt to be overlooked amongst the colour and perfume or the plethora of many leafy things. There is no fear of that now, however, and I have just been admiring a mass of white Chrysanthemums which are blooming in front of a group of Smilax, and remarking how much better they seem than other groups equally good, but backed only by the dead wall. Everybody who winters in Rome or Florence will tell you delightful stories of the Violets and Cyclamens, and more especially of the dark bronzy-leaved Smilax, as seen there clustering over old walls or tree trunks, or near to the ruins of former greatness. We may never obtain in our northern gardens quite the luxuriant vigour that the sunny south gives to these elegant things, yet in mild seashore localities many varieties of Smilax, and especially S. aspera, are quite at home. The point is to plant them well at first in sandy loam, old lime rubbish, and to cover them well with stones, through which their young Asparagus-like shoots are not slow to

appear. Even if a very sharp winter cuts them down to the ground level, they soon sprout up again when so protected. The best kinds should always, at any rate, find a place in cool conservatories, where they are perfectly safe, and yield lots of graceful leafy wreaths for cutting as required from time to time. A wreath of Smilax endures fresh and fair week after week in water that is often changed. A dish of Smilax leaves and snowy Christmas Roses is delightful during the chilly wintry days.

Tritoma grandis.—From early in August until now (Nov. 15) we have never been without the glowing erect spikes of the Torch Lilies. The one now in bloom came here under the name of T. grandis, and is a moderate grower, barely half the size of T. nobilis, but very showy, and especially valuable for its late-flowering habit. A good clump planted in a sunny corner among sand and stones would be a very welcome addition to the best of gardens during November. T. media is a plant often sent to me as the T. pumila of the Bot. Mag., a plant I have been in search of for years, and as I now see is throwing up its spikes as usual, and during mild open winters this kind often goes on blooming until T. caulescens throws up its thick spikes in April. So far, I consider T. Saundersi as one of the clearest in colour, and best of all the early autumnal kinds, just as this T. grandis is the latest and best of the November-flowering varieties. I am afraid, however, that names mean but little as yet amongst the plants of this group. We have just been dividing and replanting some masses of the common kind, and find this the best season, as new roots are now pushing out in all directions, and these will be much strengthened by fresh, deep, rich soil.

Stone covering for bulbs.—Mr. G. F. Wilson's note on bulb protection (p. 448) is a very interesting one, and the adoption of the principle which it inculcates may save many a choice and valuable new bulb if adopted at once before a real cold snap sets in, and which may now at any time happen. It is not a new idea, but none the worse for that by any means. The first time I ever saw stones used as a protection for choice bulbs was in a corner near one of the once famous Orchid houses on the West Hill at Wandsworth. The late Mr. Sigismund Rucker had some large groups of Crinum and Amaryllis bulbs planted out in a sunny position, and when I saw them first they were quite warm and cosy beneath a cartload of pebbles or boulders. I believe Mr. Pilcher pointed out this wrinkle to me, and perhaps, if this meets his eye or anyone who knew Mr. Rucker's place and remembers these Crinums, he or they will be kind enough to tell us more about them. Here we adopt another plan. We surround the collar of any rare plant with stones and then fill in the interstices with dry, coarse sand, or with coal ashes or turf mould (*i.e.*, peat earth). Even a spadeful of coal ashes thrown around or over a rare plant or bulb often makes all the difference between life and death. Dry tan is good, but better than almost any other protective substance is the "pob" or "choves"—this being the refuse from the flax or jute mills of Dundee or Belfast. Those who cannot obtain it, however, will find stones, as Mr. Wilson recommends, practically perfect.

Late flowers.—The generally acknowledged fact that late flowers of Dahlias, Gladiolus, Mignonette, and Daisy-flowered things of many kinds keep fresh longer now than during the hot summer weather may, I think, be accounted for in some degree by there now being a lack of heat to develop the pollen and stigmas, so that these very late blooms do not become fertilised as do those of the earlier part of the year. Even during the height of summer if the anthers and stigmas of flowers are removed before fertilisation takes place, such flowers last fresh and fair much longer than otherwise would be the case. Double flowers last fresh longer than single ones for the same reason, and the main reason why some Orchid flowers endure fresh for weeks is simply because they are secure from fertilisation. Of course, I freely grant that development generally is much more slowly carried on now than during summer, but no matter what it is which prevents the flowers becoming fertilised that will also tend to prolong their beauty. The florists long ago recognised this fact, and gummed the anthers of their pet flowers so that the pollen was locked in as it were, or they snipped away the apex (or stigmatic surface) of the styles for the same reason. It is very easy to test the truth of the above so far as Orchids are concerned. The flowers of some Lycastes, Phalænopsids, or Dendrobes will endure fresh for three or four weeks if unfertilised, but if fertilised artificially they scarcely keep fresh as many hours.

Underground.—I think it is the late Mrs. Ewing, when writing "Mary's Meadow," a work which all little gardeners should read, who tells us that every stick or label as seen in winter seemed to her to bear the word "resurgam" on its face, no matter what words were really written there by the gardener. After all it is so, for every bulb is a buried treasure, a joyous hope, a new story, a promised delight, to reward us for waiting patiently through the chilly days of snow, and fog, and rain. It used to be a popular notion that bulbs of all kinds were at rest during the winter, and that they grew up quite suddenly in the spring. Now we know that if most bulbs have any resting season, it is as soon as the leaves fade away. Snowdrops and Siberian Squills rest in May, Ixias and some Irises of the I. reticulata section in June, Narcissi and Daffodils in July, Lilies in August or September; hence we find that they remove best at those times, and not during the winter-time months after their new root fibres are at work underground. This year bulbs began to root very early, and we are now feeding them by a top-dressing of fine well-rotted manure and wood ashes, which every shower helps to carry down to the thousands of hungry little mouths below ground. A bulb is in some ways a miracle we may never fully understand, but we may, at least, save it from starvation at this season when it is doing its best for our delight in spring.

Flowers and gardens.—It is useless asking which are oldest in the world—whether flowers or gardens—since it is sufficient to remember that the first man was set to dress and keep the first garden of which we can read in books. But one cannot help wondering in what part of the world cultivation originated. Was it in India? Was it in Egypt? Was it in Mexico or Peru? Professor Monier Williams, who has translated some Indian poems, informs us that Kálidása, the Hindoo poet, who wrote the beautiful drama of "Sakuntala Regained by the Ring," B.C. 56, tells us that the King Dushyanta when out hunting first saw his bride by chance in a hermitage garden as she and her maids were watering the flowers. No one who has not seen it would believe the actual delight evinced by the more cultured Hindoos and Persians at the mere sight of beautiful flowers. A Persian, towards evening, will take his mat and walk quietly and alone in his garden until he comes to some favourite flower. Then he unrolls the mat and sits down cross-legged before it, lost in contemplation. At the appointed hour he will pray before it, and then roll up his carpet and go indoors ere darkness comes. To-morrow, the next day—so long, indeed, as his favourite flowers endure, he will do the same. Mahometans generally are very fond of flowers; even Mahomet himself must have loved them, as his oft-quoted tribute to the Narcissus shows. "He that has two loaves of bread, let him sell one and buy flowers of the Narcissus, for bread is for the body, but Narcissus is for the soul."

Veronica.

Trees and Shrubs.

FORKED TREES.

So long as trees are young and small there is little harm in having them forked, although, in my opinion, they are not so handsome as trees with single leaders, but when they become old forks are very objectionable. We have many large trees here, and some of them fall now and then at all seasons, but it is when we experience a hurricane such as that which we had in October, 1881, or on the 15th of last month, that they suffer most, and then I find that forked trees are the first to be blown down. Sometimes the fork begins at the root, and such trees are generally split in two or one half falls away while the other remains, or if the fork is some way up the stem there is sure to be a breakage. A casual passer-by might think nothing of this, but anyone who comes to look into such trees after they are broken down will see how very much the fork favours destruction; the water which finds its way into the fork soon penetrates the wood, and this in time decays so much, that it cannot resist a storm and the wreck of the specimen follows. This is not confined to any kind or class of trees, as lately Ash, Oak, and Elm, as well as some valuable Pines, have suffered from this cause, and I have no hesitation in asserting that forked trees should find no place in modern gardens. Where trees are large and the forked portions have each assumed the proportions of trees it is difficult to thin them out to one, but the evil ought to be checked at an early stage of their growth, and if any tree which shows an inclination to fork was taken in hand at the beginning and the leaders confined to one, many fine specimen trees and shrubs which come to an end prematurely would become permanently beautifully. It might be difficult in all cases to prevent forest trees from forking, but those in parks and pleasure grounds would well repay any little attention required to prevent them from forking.

J. Muir.

Margam, Port Talbot, S. Wales.

Magnolia scent.—"W." speaks (p. 391) of Magnolia grandiflora as follows: "It is one of those shrubs which have a bad name because of the baneful emanations proceeding from them." Will "W." favour your readers with his authority for the statement that "baneful emanations" proceed from this noblest of all hardy wall plants? The delicious scent of the flowers is no doubt powerful, but I was quite unaware that it was considered "baneful," or even injurious. We would not have a large vaseful of its flowers in a room; the scent is no doubt too strong for that, but so is the odour of May flowers, such as Gardenias and Tuberoses. This is very different from the scent being "baneful."—W. H. Tillett.

Azalea mollis in autumn.—A large number of seedling plants here of this Azalea differ a great deal as regards the tints of their decaying foliage. Though growing under the same conditions, some retain their leaves much longer than others, while in the case of the decaying foliage their peculiarities are strongly marked. For instance, some will remain quite green till the leaves are just on the point of falling; others die off a dull brown, some a rich golden yellow, while a bright crimson tint is also well represented. Some of the yellow and red shades are very conspicuous, being among the brightest of autumn tints, but even these all pale before some of the North American Vacciniums. These seedling Azalea mollis differ as

widely in the case of their flowers as in their foliage, varying as they do from pale straw to reddish salmon, all the various intermediate shades being represented. The raising of seedlings is an easy matter, for under favourable conditions seeds are ripened in considerable quantities. Ours were sown in a bed of sandy peat and sheltered by a frame, as, owing to the minute character of the seeds, it is desirable to maintain the ground in a uniform state of moisture as far as possible, and this is best effected when sheltered by a frame. When the seedlings are large enough to handle, they are pricked off into other beds of sandy peat, and quickly make rapid progress.—ALPHA.

Jasminum nudiflorum.—This Jasmine seems to be unusually early in flowering this season, for generally but a few scattered blooms, if any, are borne during the autumn months. We have some in full flower now, and, from what I hear, ours are by no means the only flowering plants. Though it is usually trained against a wall, this Jasmine also flowers when allowed to grow as an open bush, and, as soon in the shape of some specimens here, should rank high among autumn-flowering shrubs. All that is necessary in order to cause them to retain their bush form is, in the spring, after the flowering season is over, to shorten a few of the more vigorous of the shoots. I have seen these bushes employed with advantage in the decoration of a cool greenhouse during the winter, as with the protection thus accorded them they continued to flower for a long time.—T.

Golden Tree Ivy.—Among golden-leaved shrubs the yellow-foliaged form of the Tree Ivy is one of the brightest, and retains its colour throughout the year, sufficient, in fact, to be a conspicuous object at all seasons, while now when many of its associates are bare of leaves it is very attractive. This Ivy is not variegated in the ordinary manner, but the exposed portions of the leaves are heavily suffused with gold, and as sunshine is necessary in order to ensure the greatest depth of colouring, this fact should be borne in mind when planting. The tree or bush Ivies are all desirable shrubs: others, besides the kind here mentioned, being the common form and a variety of Hedera Rægneriana, which combines the large deep green leathery leaves of that kind with a shrub-like habit.—H. P.

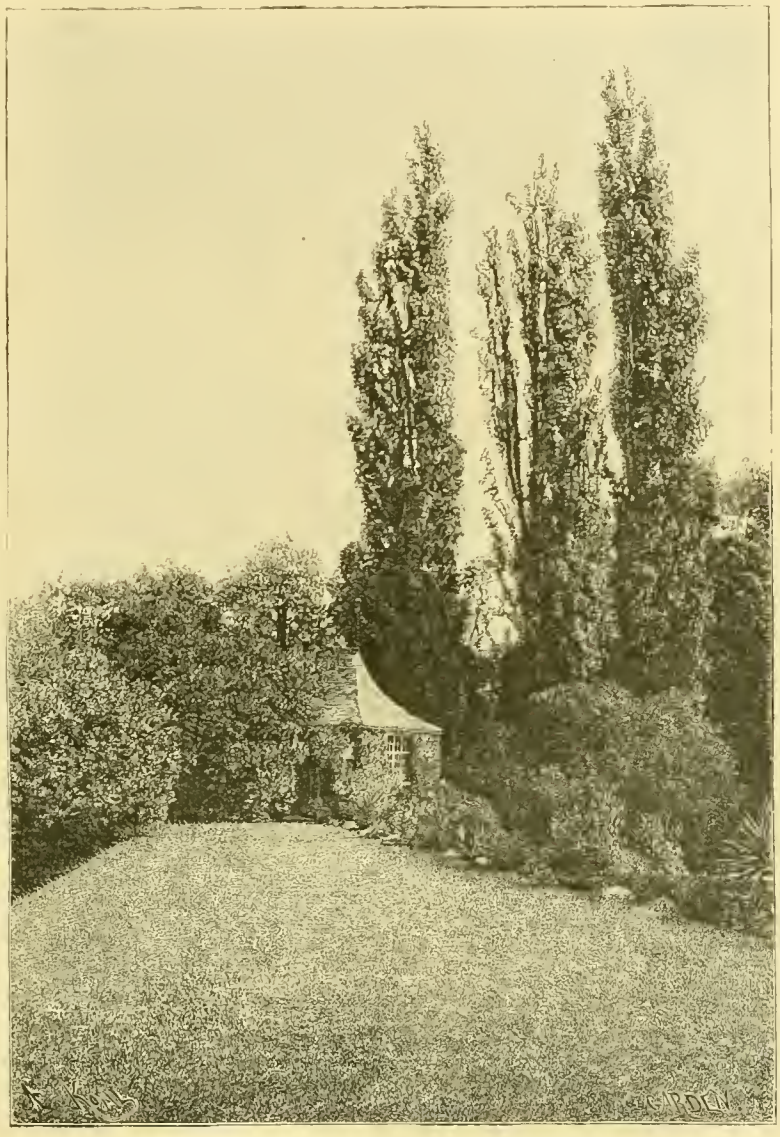
Winter colour of Conifers.—From many years' observation I have remarked that a large proportion of species belonging to the genera Thuja, Biota, and Cupressus, although perfectly green during the summer months, generally assume more or less of a reddish brown tinge in autumn and winter, and return to their usual green colour during the spring months. Some of the varieties, such as the columnar Biota orientalis elegantissima and the globular Thuja aurea, are generally quite brown in winter, but during the spring months they assume the ordinary green tint, while in summer they take on a rich golden hue. Towards autumn the golden tint disappears, and is succeeded by the ordinary green colour of the original species, and finally they return to the brown, or winter tint. The cause of this remarkable anomaly I attribute to want of sunshine in winter. The Cupressineæ tribe from the western hemisphere do not exhibit the same marked difference which is generally noticed in the eastern species, still in some instances a very slight brown or dull green tint is often observable. The higher brown tints are chiefly seen in varieties which, I suspect, have been produced in nurseries or gardens, and are evidently hybrids between eastern and western species.—J. M.

TREES FOR AUTUMN EFFECT.

Now that deciduous trees and shrubs are once more beginning to attract the attention which they so well deserve, and which was diverted from them when Conifers became such favourites, instead of the monotonous sombre green of the Pines and their allies, we may expect to see more frequently the delicate tints of early spring furnished by the swelling leaf-buds or opening blossoms, the manifold shades of green during the summer months, and the brilliant colouration assumed in autumn by many of the fine deciduous trees from North America and Eastern and North-eastern Asia, which were much more generally known at the commencement of the present century than they are now.

If planters would but note the wondrous autumnal changes in the foliage of many deciduous trees and plant accordingly, they could easily create beautiful effects in gardens. With care, too, the summer tints might be made to thoroughly harmonise, so that at all times the individual beauty of a tree might be enhanced by judicious contrast. Trees with totally different habits might also be chosen, so that, even when leafless, the tracery of the branches would be a source of artistic enjoyment. My remarks are, however, confined to autumnal tints and to trees and shrubs which are most noticeable at the present moment. Many of these are somewhat uncommon, all are strikingly handsome, and even the common ones deserve to be more generally known and appreciated than they are.

For truly gorgeous colouration in autumn some of the American Oaks bear off the palm. Perhaps the most beautiful is the Quercitron Oak of the Eastern United States (Quercus tinctoria), the fine, deeply-lobed foliage of which in autumn exhibits a lovely combination of dark glossy green, crimson, and reddish brown, the green occupying generally the central portion of the leaf. Quercus rubra (the Red Oak) and its varieties are especially noteworthy; in these the redder tints of the decaying foliage are more unalloyed with other shades, so that in the sunlight the leaves brighten up and glow as if they were on fire. Q. alba (the White Oak) is a noble tree with large leaves, brownish red being the prevailing shade in autumn. The Chestnut Oak (Q. Prinus) and its varieties, with their large, Chestnut-like leaves, are hardly less beautiful than the Quercitron and Red Oaks, and assume autumnal colours, in which bronze and reddish purple predominate.



Loseley. Bowling-green and summer tea-house. Engraved for THE GARDEN from a photograph.

Totally different in colour and habit of growth are the Hickories, two of the most showy in autumn being the Pig-nut Hickory (Carya porcina) and the small-fruited Hickory (C. microcarpa), from the Eastern United States; both have Walnut-like foliage; the large leaves of the first die off a uniform rich golden yellow. The Yellow Wood (Cladrastis tinctoria), from Kentucky and Tennessee, is one of the handsomest of the flowering trees of the Locust kind; in early autumn it is clothed with large, pinnate leaves, of a fine orange-yellow shade. The Bird Cherry (Prunus Padus), particularly when planted in open ground, has leaves tinged with rosy red when dying, and one of the prettiest effects I have ever seen was a fine group of Bird Cherries with a background—a few yards away—of dark, glossy, evergreen shrubs.

The June Berry (Amelanchier canadensis), although not possessing the delicate tints of the last-named, wonderfully enlivens the autumn shrubbery with its red-brown leafage. The Red Mulberry (Morus rubra), from the Eastern United States, is very conspicuous in October on account of its sulphur-coloured, prettily-lobed leaves; it is a small tree, and, with a background of dark green such as that afforded by the Evergreen Oak (Quercus Ilex), is most striking. The Blue Beech (Carpinus americanus) is a small tree from 10 feet to 20 feet high; its decaying leaves exhibit a charming combination of green, golden yellow, light red, and crimson. The South European Acer Opulus furnishes us with a mixture of purplish, orange-scarlet, and brown tints. The Cherry Birch (Betula lenta) of the Northern and North-eastern United States makes a fine object when covered with clear, golden yellow foliage, which is especially attractive in sunlight. The Black or Sour Gum, or Pepperidge—for under

all three names is Nyssa multiflora known in its native haunts, the Eastern United States—has fine, bold, glossy leaves, assuming in early autumn a brilliant orange-scarlet colour; an accidental combination of this with a specimen of Ptelea trifoliata, with its lemon-yellow, pionate foliage, produces a very happy effect.

The Silver-leaf Maple (Acer dasycarpum), which, on account of its rapid growth and beautiful foliage, is much planted as a shade tree in the United States, is one of the finest of deciduous trees; in early spring it is covered with myriads of reddish flowers; then its handsome leaves, green above, silvery-white below, turn in autumn to a golden yellow. The Red Maple (Acer rubrum), more compact in form and less rapid in growth than the preceding, is also very ornamental in autumn, and in spring its deep red blossoms render it conspicuous and beautiful. The Sugar Maple (Acer saccharinum) is one of the noblest of American trees, and is much valued both for its wood and for the beauty of its form and foliage. In summer its leaves are light green, but in autumn they are clear yellow. The Tulip tree (Liriodendron Tulipifera) is one of the largest and most beautiful of North American trees. As an ornamental tree it is at any time hardly surpassed, but in October, when its foliage is suffused with a rich golden glow, it is especially striking, a fine specimen making quite a feature in the landscape. The brilliant autumnal colours of the Sweet Gum (Liquidambar styraciflua) are too beautiful to be passed over without notice; rich orange-scarlet, crimson, and yellow give place in some individuals to a dull purple, the long-stalked, star-like leaves, when well coloured, being especially handsome. This tree retains its rich leaf-colouring for some weeks. Q.

Flower Garden.

PRIMULA CAPITATA.

P. CAPITATA (Hooker, *Botanical Magazine*, t. 4550).—"I retain this species as distinct from P. denticulata with great hesitation, though it differs much in habit and general appearance." This is the opinion of Sir J. Hooker, given in his "Flora of British India," and, no doubt, there are good botanical reasons for it. But from a gardener's point of view the two species differ very widely and require very different treatment, and though I have cultivated several varieties of each, I have found none in which the peculiarities of the one pass over to the other species. The robustness of the constitution of P. denticulata is such, that not only may it be successfully divided at any time of the year, but I have found that the best treatment of it, in order to promote late flowering, is to cut the crowns into sets at the end of summer, dividing each strong crown into several pieces, shortening the roots to within an inch of the base of the leaves, and so planting them. They then flower in April, instead of trying to flower in January. But the large and thick roots of P. denticulata are so prolific, that if a strong plant is cut off in winter or early spring 2 inches or 3 inches below the surface of the soil, the stump of each root will bud into perhaps twenty or thirty shoots, looking like vigorous seedlings, and every one, if detached, producing a large plant in two or three months. I once counted nearly two hundred plants produced from the roots of one which had been decapitated by some accident. The increase of the famous hydra was nothing compared with this.

On the other hand, the roots of P. capitata are weak and delicate, and very often perish—the decay apparently beginning from below—if they dislike the soil in which they are planted. The crown with leaves attached remains lying loose on the surface. This is the end of most plants of this species before the close of winter if left exposed to the weather in the open ground. In fact, if left out of doors, P. capitata behaves almost as a biennial, never shedding its leaves or gathering its growth into a compact bud in winter, like other Primroses. It lives through winter in a frame, but always as an evergreen. Even when it spreads into several heads it is so difficult to divide, that after several years' experience I never consider it worth while to attempt it. Raising from seed, which it ripens plentifully, is the easiest way of increasing it. Such are the differences in habit between P. denticulata and P. capitata. I observe that my friend, Mr. G. F. Wilson, has been exhibiting at South Kensington a P. capitata major. I think it a pity to give this surname, especially in the case of a comparatively new plant which is known to be very variable, because if we are to advance a degree of comparison every time we get a variety a little larger than before, we must soon reach maximissimus, or even beyond it. Besides, we do not know that the increase in size will be persistent; the plant may degenerate when grown from home seed, as I have found some other Himalayan Primroses do. The variety, no doubt, which was sent to England as seed by Dr. King last winter is very fine, and it grew up into flower more quickly than I had ever known P. capitata do before, many plants flowering in September from seed sown in February. If a distinctive name had been wanted for it, var. plana would have been, I think, safer and more descriptive than major, for its most remarkable character is the arrangement of its broad, flat leaves, all being turned quite horizontally close to the ground. The other plants which came up from the same packet of seed are distinguished by their leaves being narrower than typical capitata, as well as more upright. This latter variety follows the normal habit of the species in being less quickly developed, not one of them as yet having shown a bud, though they appeared above ground the same day as the others and have had precisely the same treatment. Another variety I raised from seed, collected and distributed four years ago by Mr. Elwes, is remarkable for shortness of leaf, dwarfness of growth, and pale lavender-coloured flowers. The leaves are very farinose, and in general appearance the plant much resembles P. farinosa. It has preserved all these peculiarities through three or four generations from seed. Perhaps the most remarkable variety of all is one which I saw at Kew this autumn, of which through the kindness of the authorities there I received a plant. It has the rachis and veins of all the leaves of a deep purple colour, and appears to be of more robust and firm texture than any other P. capitata I have seen. C. WOLLEY DOD.

Edge Hall.

White Trumpet Daffodils.—Having seen that the suggestion made at a meeting of the Narcissus Committee in last April, that all growers of white Daffodils should send bulbs of what they believe to be distinct varieties to be grown in the trial grounds at Chiswick, has been repeated, I should be glad to know whether the objection then made to it is a valid one or not; it was that the soil at Chiswick is quite unsuited to the growing of white Daffodils. If this statement was incorrect, the matter ends; but if not, does it not seem rather a mistake that we should send our bulbs to Chiswick? To say that it is as fair for one grower as for another is beside the question; there is no competition in the matter, which is purely one of scientific investigation, and is it not desirable for such a purpose that the specimens should be as perfect and as good as possible, for in badly grown ones the most distinguishing characteristics might be wanting? The puny, miserable appearance which white Daffodils are capable of presenting when not happy, we all unfortunately know too well. I most heartily agree with the writers who wish to have this question of the nomenclature of white Daffodils settled, and I shall with pleasure send bulbs of mine to any place which may be decided on as best suited for testing them. But I consider it a highly important matter that the place selected should be suited to them, which indeed is such a fundamental axiom in the growing of all plants, that I see no sufficient reason in the present instance for departing from it.—H. M. WHITE, *Charleville, Roscrea.*

OUTDOOR CHRYSANTHEMUMS.

How finely Chrysanthemums are blooming in the open air this year! The small-flowered kinds are in quality quite up to those under protection; indeed, in many instances they are better, owing to the greater luxuriance induced by a more extensive root-run. I saw the other day a bunch gathered in a cottage garden which, as regards size and colour, was equal to that produced by an exhibition plant. This is not to be wondered at, seeing that the weather during the past month has been generally of an exceptionally genial character. Copious rains have fostered luxuriance, whilst spring-like days have thrown colour and form into the blooms. Up to the present we have had scarcely any frost, so that the buds have developed without a check of any kind. Such seasons as this, which enable Chrysanthemums to develop so finely, do not come often, but it is nevertheless rare that a fair measure of success does not attend the outdoor culture of this fine flower. Every garden should possess some of the late-blooming Pompon kinds, for they come in when the summer flower garden is past; they give plenty of flowers for cutting, and they help to render the interval between autumn and winter less dreary. Up to the middle of October there is still much brightness in the garden, but after that time Chrysanthemums are about all that can be relied on. I do not see much use in those varieties that bloom in summer; neither do I think that they will ever become popular; but there is a great future for the early autumn-blooming ones. All that we want in them is greater size and more decided colours. When we get a race of Chrysanthemums which in quality shall equal the best show kinds, whilst they bloom six weeks earlier, an addition of inestimable value will have been made to outdoor garden flowers. Considerable advances have been made in this direction during the last few years, and, seeing what has been done, there is every reason to believe that in time we shall get a number of large-flowered early autumn-blooming Chrysanthemums.

Although Chrysanthemums are often grown in the open air the varieties commonly seen are not very varied, probably because the more tender ones die out. Many of the Pompons are not sufficiently hardy to stand hard winters, especially in moisture-holding soils. In their case some form of annual propagation should be adopted. There is no need to take cuttings in the usual way if, when the flowers fade, a root of each kind is taken up and divided; selecting the strongest offshoots and dibbling them in a cold frame, where they can be protected against climatal vicissitudes, they will make good specimens for another year, and the grower will be insured against loss. Young plants, too, will be found to yield larger flowers than old stools allowed to stand from year to year. In the case of kinds of approved hardiness it is best to divide them in March, and their growth will be much improved if a spadeful or two of good manure is buried a few inches under the roots. At the same time there is something to be said in favour of allowing the plants to remain undisturbed for several years, for where they do well they make such a fine show of colour. I have often stopped to admire large bushes of the old pink and yellow kinds in a cottager's garden, each plant bearing two or three hundred blooms. Cottagers are rather fond of planting their Chrysanthemums close up to their dwellings along with Wallflowers, and this is one reason why one often sees them so good there. The plants get warmth and good drainage in winter, and the roots probably ramble down deep among the

foundations. This brings me to mention the usefulness of Chrysanthemums on walls at this time of year. A few plants set out at the foot of a wall and trained to it as they advance in growth, with slight protection will expand their flowers, and, being naturally rather later than those indoors, they will give a succession and be most useful to cut from. Any exposure but a north one will do.

Twenty years ago, when Chrysanthemums were not so popular as now, there was a grower at Hampton, in Surrey, who grew all the best large-flowered kinds in this way. I remember going to see them one fine November afternoon, and was much impressed with the fine show they made. Anyone having a piece of wall unoccupied cannot do better than use it in this way. The ground should be rich, watering must be well attended to, and in hot, dry weather the syringe should be frequently and liberally used, for in such a position it is not uncommon for red spider to make a lodgment. I once had a lot of plants quite ruined by this pest through not seeing it in time. In syringing, the water should be applied with some force to the undersides of the leaves, two good washings weekly being better than an every-day sprinkling. A good mulch and an occasional soaking of liquid manure will work wonders. J. C. B.

GLADIOLUS BULBS AND SEEDLINGS.

"Delta" states facts when he says he has had many years' experience in the culture of the Gladiolus. I have exhibited against him many times, and can bear witness to the excellent quality of his exhibits. His experience as regards the disease coincides with my own. The malady is very mysterious indeed to the ordinary cultivator, and being, as I believe, climatic, there is, I do not think, any cure for it. If we had the climate of the Cape of Good Hope, and would be content to use less manure than we do in the soil, perhaps we would not have any disease amongst our bulbs. A good deal may be done by the proper preparation of the ground; this I have proved many times When I used to grow 2000 or 3000 bulbs for exhibition, it was sometimes convenient to trench and manure it in August or September, allowing it to remain undisturbed until planting time, except so far as to lightly fork over the surface when it was dry. This thorough exposure to atmospheric heat as well as cold caused it to be better adapted to the requirements of the plants than it otherwise would have been; but if only trenched in winter it is not in such good condition for planting in March. Probably the plan which was adopted by M. Souchet years ago at Fontainebleau, viz., that of allowing the ground to become fallow for a season, would be even more beneficial. I have tried different systems of planting, and do not know of any better than that of simply drawing drills as if for Peas. The bulbs were placed in the rows about a foot apart, a little clean sand was placed under and over each bulb, and we used to fill up the drills with some dry maiden loam. The ground was rich in manure, but none of it could come into contact with the roots, as some of it was 6 inches under the surface, and another portion of it 18 inches, as the bulbs require plentiful supplies of water after hot weather sets in about the end of May or early in June, and as this has to be continued until the flowering period is over, which is just before the autumn rains set in; consequently the ground instead of being comparatively dry when the bulbs are ripening is usually immoderately wet. I have stirred the surface with a fork sometimes, or with a Dutch hoe, with a view of helping to dry it.

Harvesting the bulbs in good condition is certainly a very important part of Gladiolus culture. I tried lifting and storing them with the soil, but found that that was not a good plan. We had a long border in a lean-to Peach house, and in this border they were planted in decayed and damp Cocoa-fibre, but the corms shrank more in that way than if they had been dug out of the ground and their tops at once cut off. The best plan is to take some clean pots and a hand-barrow to the quarter in which the Gladioli are, dig them carefully up, cut the stalk off close to the bulb, and place each variety with the small bulblets attached to it in separate pots. We always had an early vinery, from which the Grapes had been cut, in which we placed the pots. Thus situated, they soon dried, and the first opportunity was taken to clean them and store them in paper bags for the winter. "Delta's" plan of hanging them up in a dry shed would answer, but I do not see any advantage in leaving 18 inches of stem, except as a convenient means of tying each variety up by itself.

As regards degeneration, it will certainly not do to put that quite out of the question. I believe many good cultivators will bear me out when I say that Gladioli do rapidly degenerate in some gardens under good cultivation. I have year after year purchased a collection of new and old varieties direct from France, and the result has been that the plants from the French bulbs were much stronger and the foliage of a deeper green than that of English bulbs. Anyone could point the French bulbs out without even looking at the labels. Next season the produce from these same bulbs would be much deteriorated, and so they would go on degenerating until they were scarcely worth growing. This was not the usual disease, of which the bulbs bore no trace; they were as sound as the original imported corms, and generally larger. The same thing happened in the case of our seedlings. I raised at one time from 1500 to 2000 seedlings annually, and was successful in taking many first-class certificates, but I could not get up a stock of healthy corms from these seedlings owing to degeneration—not disease. Like "Delta," I have had diseased bulbs, but they were to be found indiscriminately throughout the collection.

I advocate the raising of seedlings, as being the best way by which a grand display can be obtained at the smallest possible cost. Probably I have described our system of seedling raising before, but recent experience confirms all I have to say in regard to it. The seeds should be saved from pods that have been produced from artificially hybridised flowers. The very best varieties should be selected to save seeds from. The anthers can easily be removed with the fingers before the pollen is scattered. Two or three days afterwards the pollen from another good variety may be applied to the stigma of the seed-bearer. The anthers have to be removed from the seed-bearer before the flowers open. The seed-pods are gathered when it is seen that they are bursting from the top downwards. Sow the seeds thinly in 6-inch or 7-inch pots in a hotbed early in April. The plants will be up like a Grass plot in two weeks, and if well cared for, each pot will produce its quota of nice corms, from the size of a parched Pea to that of a Filbert. Planted out in March of the following year, most of them will produce strong spikes the same season. Some of them will be as good as the parents; a few will be better, and none will be alike. The pleasure of cultivating any class of flowers is greatly increased by anticipating the flowering of the seedlings, and an immense quantity of beautiful flowers can thus be obtained at a small cost.—J. Douglas.

—— "Delta" (p. 430), who somewhat incorrectly quotes me, has not yet seemingly arrived at fixed conclusions on several important, if not vital, points affecting this peerless queen of outdoor autumn flowers. In order not unduly to trespass on your space, or repeat what I have before stated in your columns, I propose to notice first—

The best place to grow Gladioli.—"I had rather grow them in Cambridge than Tipperary, or, notwithstanding so many things in its favour, than in Somersetshire." "Delta" gives no reason for this opinion, and with your permission I would ask him why? I was hitherto under the impression that the soil and climate at Langport were specially suited by Nature for the Gladiolus. And why, may I ask, has he arrived at the conclusion that Cambridge approximates more closely to Fontainebleau than any other part of England he knows? As to temperature, which is a main item in estimating climate, I was, too, of the opinion that our average temperature in the south of Ireland is above that of Cambridge by several degrees. At the same time I am aware that splendid Gladioli are grown at Gourock, in Scotland, and as good at Newtownards, in the north of Ireland.

The time of lifting.—"The end of October or beginning of November is about the best time." I think this is a month too early for the majority of the varieties, and "Delta" seems to agree with me further on, for, after stating he cut a spike October the 25th, he adds, "I have before me two spikes, Duchess of Edinburgh and Marquis of Lothian, cut on November 10," and he very properly says, "it would be absurd to lift these corms the same time as those that bloomed five weeks before." He might have said "fifteen weeks before," as I had some in bloom the end of July.

Lifting and storing.—He says, "I think it was 'W. J. M.' who advocated lifting them with the soil and storing them in that manner," and then comments on the assumption. I take it your correspondent writes from memory, and misunderstood me. My method for many years past has been to lift them gently with a fork or spade, so as to disturb the "spawn" as little as possible; stand them upright against the wall of a dry room, and then cover the corms about 3 inches high with moist river sand. Here they slowly mature and dry out. When quite withered I remove the stems. Now to this maturing process of the late varieties, for that I regard it, I attribute much of whatever success I have had with Gladioli hybrids. I should have remarked when grown with a handful of sand above and below the corms, at lifting no soil ever adheres to them.

Labelling.—Formerly I tied the labels to the stems when lifting, but the corms readily and naturally fall therefrom, and the name among large numbers gets lost. I gave this up and tied the wooden labels to the corms, but this also is inconvenient. "Delta's" method has, to my mind, the fatal objection that they dry too rapidly, and that a portion of the sap in the green stems that would perfect the corm is dissipated and lost to it. Kelway, Dickson, Campbell, and most of the nursery growers store them in triangular paper bags.

Reproduction from spawn.—Every grower should depend to a considerable extent for increasing his stock both on seedlings and spawn—both only from superior varieties. Corms from either method possess greater vitality and produce finer spikes, if fairly treated and well grown, than the old ones.

Lastly. "Delta" does not admit "degeneration," but calls it "disease"—a Rose by any other name will smell as sweet. If a variety, say any of the white kinds, as being most tender, does well this year, worse the next, and dies the third, what name would he give it? I am not sure if I would not be justified following his own illustration of the Potato, in recommending growers to try those varieties native-raised, as those coming from a warmer climate are—like American varieties of Potatoes—certain to degenerate.—W. J. Murphy, *Clonmel*.

Giant Daisies.—I am a little nonplussed with regard to one of these perennial Daisies, and shall be glad to have some assistance under the difficulty. I have a plant which corresponds to Mr. Wolley Dod's description of Chrysanthemum maximum. It is about 2 feet in height, bushy in habit, produces very large flowers, and increases by throwing out suckers at the base. It is, however, in bloom now, and has been for the past few weeks, and yet I read that its proper season of blooming is June and July. Perhaps this unseasonable blooming is due to the plant having been grown on from a small piece planted last spring. Chrysanthemum latifolium, which blooms later, seems to be so tall, that it cannot possibly

be that kind. I can but hope that it is the real maximum out of season. It is interesting to find how the Chrysanthemum family gives us representatives in bloom all the year round. Of course we are indebted to house culture for the winter blooming of the Chinese and Japanese kinds, as also for the abundant blooming of frutescens; but out doors we get none the less a very long season, in which none play a more important part than the wild Ox-eye Daisy. Annual Chrysanthemums of the coronaria and Dunnetti forms are wonderfully floriferous, and give a long season, and the common yellow segetum is now a highly favoured garden flower. None seem, however, to excel in profusion of bloom some apparently distinct hybrids from coronarium crossed with segetum, for these never tire of blooming, and can, indeed, be had in flower under glass all the winter. The Chrysanthemum is thus rendered most useful. —A. D.

ASTER IBERICUS.

Readers of The Garden will wish to know something of Aster ibericus, which so good a judge of flowers as M. Max Leichtlin considers one of the three best Michaelmas Daisies (see p. 451). It is Aster Amellus var. ibericus (De Candolle, "Prodromus," vol. v., p. 231). This is all the description De Candolle gives: "Leaves quite entire and acute; inner involucral scales almost colourless. A. ibericus of Steven or Bieberstein." Boissier, in his "Flora Orientalis," vol. iii., p. 157, also mentions the variety, referring to De Candolle, and giving precisely the same description.

Three years ago M. Max Leichtlin kindly sent me a piece of his Aster ibericus. I afterwards sent a plant of it to Kew for verification; so I may conclude it to be rightly named It grows here about 2½ feet high; has very few stems—with me seldom more than one—which is very thick and strong for the size of the plant, and at flowering time leafless for two-thirds of its height. At this point it divides into many spreading leafy branches, forming a broad and flat umbel, all flowering at once. It flowers at the same time as A. Amellus, and the flowers are of the same colour, but of a lighter and brighter shade. Each flower is not half the size of a flower of A. Amellus, and the leaves are much smaller and broader at the base, quite sessile, if not amplexicaul. Speaking as a gardener, and not as a botanist, I cannot see any resemblance in the plant to A. Amellus, either in habit or in general appearance, distinct and good as it is; but if I had any doubt about having received this very plant as A. ibericus from M. Max Leichtlin, I should think he was writing of a different species. The geographical specific name, intended, no doubt, to be descriptive of the habitat, is unfortunately ambiguous. Iberia and ibericus, to those who know Latin classics, are as applicable to the north-east of Spain, the basin of the Iberus or Ebro, as to the country between the Black and the Caspian Seas, both regions having been peopled by Iberi, so we have to be told that the plant is Caucasian. M. Max Leichtlin's description, judged by itself, and his incidental mention of the Pyrenees, would rather have suggested another species, A. pyrenæus of De Candolle, A. sibiricus of Lamarck, the latter name being still retained for it in some collections. This species flowers early, grows from 1 foot to 2 feet high, and has large light blue flowers larger than those of A. Amellus. It is found only in one or two spots in the Pyrenees, the famous Val d'Esquierry, near Luchon, being the only habitat specified by De Candolle, who adds, rather ambiguously, "nec certissime in Siberia." Nyman, in his "Conspectus Floræ Europæa," though he seldom condescends to any descriptive words, says of it, "planta rarior spectabilis." Still, somehow or other, whether because the disc wants brightness or the foliage is rather shabby, it is not here quite a first-class flower.

Of the other two Asters mentioned in the "three best," A. grandiflorus never attempts to flower here till nearly Christmas, and fails, though I believe it is good in Devonshire. As for Mdme. Soymier, I once saw the name in a foreign catalogue and ordered it. The Aster sent was what is sold in England as longifolius formosus, which evidently is not the flower indicated by M. Max Leichtlin. C. Wolley Dod.

Edge Hall, Malpas.

Christmas Roses failing.—The failure complained of (p. 429) is undoubtedly due to recent removal in combination with a hot, dry summer. If the plants were disturbed in February it is probable that many of the best roots rotted before the soil became sufficiently warmed to induce root action. April is quite soon enough to transplant Christmas Roses, and they should be well looked to in the way of watering in dry weather. We received some roots early in spring which behaved exactly as described (p. 429), they have made few leaves, and will not bloom worth speaking of. We shall give them a good mulch of manure in spring and an occasional soaking in dry weather, and, as a number of small crowns have formed on them, we have no doubt as to their making themselves useful again next season.—J. C. B.

Dahlia roots in winter.—Dahlias are easily and inexpensively kept during winter. In some cases, even, they are mulched over and allowed to remain in the ground during that season; but of this practice I do not approve, as if severe frost does not reach them, the damp condition of the soil in winter is not in their favour. The best way of treating them is to cut the stems over about 6 inches above the ground, tie the label on to them, dig the roots up, allow them to stand in an airy place under cover until dry, and then store them in some dry corner in which there is a temperature varying from 40° to 55°. They keep well on the floor of an Apple room or on any dry loft. The point is to keep them dry and away from frost. I know of some enthusiastic cottagers who store their dry Dahlia roots under their beds in November, where they keep them until March, and they never lose a root.—Cambrian.

Drummond's Everlasting Pea.—I may state that I raise a few seeds of this annually with but little trouble. I keep the seeds until the May following, when I soak them for twelve hours in cold water. They are then kept for twelve hours and sown in a light sandy soil in a well-drained flower-pot, and stood in a cold frame. They germinate in three weeks or a month, and I scarcely have a single failure. Let those who complain that they cannot raise plants of this Pea try to raise them in a cold frame instead of in heat, and I think they will have better success. Have any of your readers succeeded in striking this plant from cuttings? I have experimented with cuttings taken at various stages of development, but so far without success. It is a beautiful Everlasting Pea, and I wonder it is not more grown than it is. I have one large specimen planted out in the open ground, and I think I have taken at least 200 seeds from it. The decaying foliage is cut away in autumn, and a good mulching of short manure given for the winter.—R. D.

Centaurea ragusina in winter.—In many parts this is considered to be only half hardy; it is lifted in autumn and treated as a greenhouse plant during winter. Years ago we, too, followed this practice, and we had often a hard matter to find a place for our Centaureas. Four years ago we decided to allow them to remain outside altogether and take their chance. The first winter they were out they were injured considerably, but recovered in spring, and in the following summer they were as good as ever they had been. Since then we have always left them out and they have become hardier; last winter, although very frosty, did them little or no harm, and we now regard them as hardy plants. Have any of your readers, who have been in the habit of taking them in during winter, ever tried the experiment of allowing a few of them to remain outside on trial? if not, may I ask them to do so this winter.—Cambrian.

Garden Flora.

PLATE 571.

AUTUMNAL CROCUSES.*

The species of Crocus have within the last few years been very considerably increased, chiefly through the untiring exertions of Mr. Maw. Instead of about thirty, as hitherto, we have now something like seventy known species, perhaps fifty or more of which are at present in cultivation, though not yet generally distributed. In the accompanying coloured plate have been placed two spring Crocuses (2 and 4), in order to show the similarity that exists between the spring and autumn sections, and, indeed, throughout the whole genus. In the way of autumn-flowering sorts we have found C. nudiflorus, medius, speciosus, and others do well, and amongst spring kinds, vernus (and its varieties), aureus, susianus, &c., all do exceedingly well. Others, however, of a more tender constitution have to be placed in sheltered situations in which they can be protected, some flowering late in autumn and winter, and others in spring; besides, many require protection from wet during the resting season when the leaves have died down; these should be in isolated patches, as in that way they are easier attended to than when scattered. Some species increase rapidly from small cormlets formed at the base of the old corms; these in two years or so are ready to flower, while those from seed take twice that time to produce good flowers. Many of the late autumn kinds might, we think, with advantage be introduced into the greenhouse in pots.

The following autumn-flowering kinds are all well worth attention, viz.:—

C. asturicus.—This appears to be very variable as regards colour and stature, both in a wild state and also under cultivation. It much resembles some of the forms of C. vernus in its range of colouring, but has deeper basal markings in all the purple forms. It is also nearly allied to C. serotinus, differing from it principally in its bearded throat and broader leaves. It flowers from October to November, and in open seasons has a wonderfully pretty effect out of doors in turf or in the wild garden; it is not so useful, however, as some of the others. Its leaves, which are cotemporary with the flowers, lengthen in spring to 9 inches or 10 inches, and the flowers, which vary from purple to white, are very effective, the darker basal markings setting them off to advantage; the anthers are bright yellow and the filaments white, with a deep orange stigmata. It is found plentifully in the meadows of the Asturias, at 4000 feet elevation, reaching as far south as Sierra Guadarrama.

C. Cambessedesi.—This is a charming little plant when isolated, but it is much more curious than useful; under ordinary cultivation it drags out a very long flowering season, varying from September to April, one or two flowers coming at a time. In a wild state it is said to flower in October and November. In consequence of this variableness it is hardly suitable for the open border, unless specially protected. Its small, but pretty markings render it a fit subject for the conservatory, where planted in a border we think it would do well. Its leaves are few—never more than two or three—1 inch or 2 inches long at flowering time, very narrow and glandular. The outer three segments of the flowers are pale buff, prettily marked externally, with purple featherings, the inner three white, or tinged with lilac. It is a native of Minorca and Majorca.

C. cancellatus.—This is, without doubt, one of the best of the autumnal Crocuses. It is robust in habit, carrying its flowers well above the ground, and rarely failing when the corms are planted in a proper medium. It varies

* Drawn in the Royal Gardens, Kew, last year.

GROUP OF AUTUMN CROCUSES.

1 C. MEDIUS 2 C. ETRUSCUS 3 C. OCHROLEUCUS 4 C. WELDENI 5 C. SPECIOSUS

both in a wild state and also under cultivation. The western forms are generally white, while those from eastern latitudes are invariably blue with varied markings, and Mr. Maw describes a variety from the Bithynian Olympus as being exactly like C. aerius, recently introduced to gardens. C. cancellatus will doubtless take kindly to naturalisation in our wild gardens, in spots where the Grass is thin and never allowed to become long, especially when the ripening season arrives. It flowers with us from October to December. The leaves, which just show their tips at flowering time, grow in the following spring to about 1 foot long. The flowers are white, purple, or marked with purple, and generally have a yellow base; style deep orange, finely divided. It comes from Northern Palestine, Syria, &c.

C. Boryi.—The flowers of this are outwardly much the same as those of the above, and it may, therefore, be placed here for convenience sake. They are white, with a bright orange throat; the leaves, which appear before the flowers, overtop them at flowering time. It is a pretty little species for dry sheltered spots, flowering from October to December. It is a native of the Cyclades, &c.

Crocus Boryi.

C. Clusii.—This is a charming little free-flowering species from the neighbourhood of Oporto, and also from the Pine forests south of the Tagus, where it flowers in October and November, but much earlier under cultivation. It is the Clusianus of Herbert, and, judging from the corm tunic, it is not far removed from the reticulatus group. The tunic is, in general, obviously reticulated, although sometimes obscure. It does well in little groups on the rockery, and is very effective all through the autumn months. The leaves in this species appear before the flowers, and reach their level at flowering time. The flowers are purple, and generally deepest in colour towards the throat; style dark orange, much divided.

C. hadriaticus.—This pretty little species is nearly allied to C. sativus, but has none of the variableness of that species about it. Its flowers, which are pure white, vary only in the forms saundersianus, which has a purplish throat, and chrysobelonicus, which has a yellow throat and reddish lines. The leaves appear along with the flowers, and lengthen to a foot or 18 inches in spring. The figure in the accompanying plate, above and to the right of C. speciosus, gives a fair representation of C. hadriaticus. It is a native of the Ionian Islands, Albania, &c., and flowers from September to November.

C. iridiflorus.—This is one of the most distinct plants in the genus; indeed, so much is it unlike our typical Crocus, that some botanists have suggested its separation and introduction under the name crociris, which would also be descriptive, as it appears to be between the two genera. Parkinson's name of byzantinus, by which it is well known in the trade, has been superseded in the latest monograph of the genus by that given above. Parkinson's name implied an error in its geographical distribution. It is a very charming tall-growing plant, which flowers with us from the beginning of September to the end of October, and thrives well in rich light soil. The leaves, which are broader than in any of the other species, are shiny, and do not appear until after the flowers have been and gone; the outer segments are clear rich purple; the inner ones, which are much smaller, pale lilac. It is a native of Transylvania, &c.

C. medius.—This is a tall-growing, very floriferous species, with large, rich purple flowers, and with a constitution capable of securing for it a place in the wild garden. It is represented by a figure in the plate, and the contrast between the large brush-like scarlet stigmata and the segments leaves nothing more to be desired. It flowers early, generally in September and October, and has therefore every chance of being fully appreciated before severe weather sets in. It increases rapidly, and therefore there is little chance of its running itself out. The leaves, which do not appear until after the flowers have come and gone, lengthen to a foot or more in spring. They are narrow, and there are generally two or three to a corm. The flowers are bright purple, pale towards the throat, and have a few darker lines on their inner side. The style is scarlet, much divided, and little, if at all, exceeding the anthers. It is a native of the Riviera, Mentone, &c.

C. Salzmanni.—This is another variously-coloured Crocus, and a good subject for naturalisation. It is nearly allied to C. serotinus and C. asturicus, but has a more robust habit and larger flowers, more freely produced, than in those species. It is found abundantly near Tangiers and also farther south-west than any other known species. The leaves, which appear along with the flowers, lengthen to about 2 feet in spring. Its flowers are purple and lilac of various shades, with darker featherings and orange stigmas.

C. Scharojani.—This is the earliest of all the autumnal-flowering species, and the only one blooming at that time that has orange flowers. C. Scharojani must be taken in hand by hybridisers, and were it possible to make it as plentiful and as easily cultivated as the spring-flowering kinds, it would undoubtedly be a very desirable addition to our gardens in autumn. This species is perfectly hardy, and, so far as we have been able to judge, likely to do well in most places. Its leaves do not show themselves until after the flowering season is over, and generally remain until the following July. The flowers are deep, unstriped orange, medium in size, and open well. They are produced from the end of July until the middle or end of August. This species is a native of the Caucasus and mountains south of Trebizond at an elevation of 7000 feet.

C. nudiflorus.—Of all the autumn Crocuses this is perhaps the easiest with which to deal. It may be naturalised in the wild garden without much trouble; indeed, in many localities in the midland counties it grows with all the robustness of a native plant; and Withering gives the sandy meadows that lie between Nottingham Castle and the Trent as its British locality. We have had it planted four years amongst lanky Grass, and it has lost none of its usual vigour. It has not, however, increased much, but it holds its own, and appears likely to do so under present conditions. Its leaves, which are not produced until spring, then grow from 6 inches to 12 inches in length. Its flowers are bluish purple, from 6 inches to 8 inches high, and are produced from September to the end of October. The style, which is divided, is rich orange, exceeding the anthers. It is indigenous in the Asturias, Pyrenees, &c. (Syn., pyrenæus of Parkinson.)

Crocus nudiflorus.

C. speciosus (5 in the accompanying plate) is amongst the largest-flowered and the best of the autumn-blooming section. It commences to bloom about the middle of September, and continues to produce blossoms until about the beginning of November, and in favourable seasons even later than that; the markings of this species are very beautiful, forming as they do quite a network of purple. It flourishes in the wild garden equally well in the border, and makes a handsome pot plant for the greenhouse. The leaves are not developed at flowering time, but lengthen to a foot or more in spring. The flowers are large, quite 3 inches in diameter, when open bright lilac and variously feathered with purple lines; stigmata bright orange, much exceeding the anthers. It is a native of the Caucasus, N. Persia, &c. It may be increased with wonderful rapidity by means of the small cormlets formed at the base of the old corms.

Crocus sativus.

C. sativus is so well known in gardens, that it hardly needs more than a passing mention; some of the varieties, however, not so well known in gardens might with advantage be added to existing collections. Cartwrightianus, a handsome kind, is a native of Greece and the Cyclades, and cashmerianus, Elwesi, &c., are well worth cultivating. K.

Books.

THE GENUS CROCUS.*

Mr. Maw's long-wished-for monograph of the genus Crocus is now in our hands. The tantalising tastes he has given us of it in the course of its preparation have made us more eager for the whole work, and though our expectation has been great, it is fully satisfied by the result; for seldom has a monograph been given to the public more likely to please at once all lovers of flowers by its popular qualities, and botanists by the completeness of its scientific details.

The preparation of this book, we are told in the preface, has occupied all the leisure time of the author for the last eight years, during which

* "The Genus Crocus." By George Maw. Dulau & Co., London.

Mr. Maw has not only visited the native home of many of the rarer species, but has also brought back and cultivated successfully in his garden at Broseley about three-fourths of all the known kinds, so that his illustrations are mostly taken from living specimens. We can, therefore, have no better authority concerning the cultivation of Crocuses—a subject to which Mr. Maw devotes a chapter, the fifth of his work, but the first in its importance to gardeners. We may here quote a very comforting assurance, extracted from the author's account of the geographical distribution of the Crocus (p. 29):—

The genus is remarkable for the wide ranging in altitude of the majority of species, those that are essentially alpine or lowland being comparatively few in number, and I believe there is no single species of the genus that is not perfectly hardy and capable of enduring any of the extremes of frost and heat in our climate.

We must not suppose, however, that there is no limit to the degree of frost which all Crocus bulbs can endure. In the case of the common yellow Crocus (C. aureus) that limit is probably reached at about zero of Fahrenheit. In February, 1854, all the Crocus bulbs in a box outside our window were frozen to pulp in one night; the thermometer on that night marked about 2° Fahrenheit; these bulbs were, of course, exposed to frost on all sides. We have never known Crocuses killed in the ground, even when the cold of the air has been considerably greater than this.

But to return to cultivation. Mr. Maw divides Crocuses into autumnal and vernal. The flowering season of the genus extends from early in August to the middle of April. Crocus Imperati, we are told, is the earliest vernal species, flowering in February. In the warmer parts of England, however, it generally flowers much earlier. A friend who lives in Devonshire has sent us the dates of the flowering of this beautiful species for ten years. The earliest is Nov. 29, the latest Jan. 31, this date being eleven days later than any other during the ten years. We have always found it desirable to protect not only this, but all Crocuses which flower between October and March, with a light or bell-glass. A still better plan is to grow them, as recommended by Mr. Maw, in a frame, for which full directions are given (p. 50). It is a great mistake in a climate like England to plant any Crocus in shade. A full southern exposure is best.

A remarkable point in the geographical distribution of species of Crocus is the continuity of the area of each. We find in hardly any case that a species occurs at wide intervals over a great extent. The limits of each are, for the most part, well defined, and are clearly shown in the monograph by diagrams. The Greek Archipelago and Asia Minor must be considered as it were the metropolis of the genus. It would be interesting to find that the species radiate from the celebrated Corycian Cave in Cilicia as a centre. This cave has from the earliest times been renowned in connection with the Crocus, and we might almost be disposed to endorse the opinion, mentioned in Mr. Lacaita's appendix, that Corycus and Crocus are the same word, except for the fact, of which the writer reminds us, that four other places are mentioned in classical authors as bearing the same name. Mr. Lacaita should have said five, for he omits from his enumeration the Corycian Cave on Mount Parnassus, mentioned in Æschylus as the "abode of nymphs and resort of deities." We may add that the Corycian Cave in Cilicia is remarkable in recent times for the discovery of a new Crocus, C. Boissieri, of which only one imperfect dried specimen is known to exist. We remark that Mr. Maw does not allow any Crocus to be included in the indigenous flora of Great Britain. This may seem hard to some of us who recollect Nottingham meadows more than half a century ago in their integrity, before the railway station had begun to draw down the town to the flat ground near the Trent. We shall never forget the view on a clear March day, as one looked down from the Derby road across the park; the meadows looked just as if the sky had descended to carpet them, many acres being completely covered with flowers of blue C. vernus. Again, in September, large masses of C. nudiflorus ornamented a different, but less extensive, part of the same meadows. But England is quite out of the well-defined native area of these and all other Crocuses.

Two curious points remain to be noticed with regard to geographical range. The first is, that species which have a wide longitudinal area, and of which the normal colour in the west is white, have a tendency to deepen in colour as they extend more eastwards, especially C. cancellatus and C. biflorus. The second point is so remarkable, that we prefer to relate it in Mr. Maw's own words (p. 30):—

In Dalmatia there is a general absence of the striping and feathering of species which occur elsewhere with feathered flowers. There are even more marked cases than this of mimetic colouring, and of different species associated in the same habitat putting on some identical special form of colouring. Especially remarkable is the exact identity of the colour and markings of the Santa Maura varieties of C. cancellatus and C. hadriaticus, species which are not nearly allied, and the type colourings of which differ from those of the Santa Maura forms. Another remarkable case is that of the form of C. cancellatus found on the Bithynian Olympus in association with C. aerius, putting on the exact colouring of its companion; moreover, there is a large series of variations in the markings of C. cancellatus which are exactly mimetic of the variations in the markings of C. aerius with which it is associated. I do not think that these are the result of hybridisation, for as far as my observations go I have been unable to detect a wild hybrid Crocus; nor do I know of any authenticated case of the production of garden hybrids.

We must next touch on the important question of classification. In discussing this, Mr. Maw does full justice to the labours of all former authors, more particularly of Dean Herbert, who wrote half a century ago, and of Mr. Baker, who more recently proposed to classify Crocuses by the characters of the stigmata. Mr. Maw gives reasons for preferring the older arrangement, and for following Dean Herbert in dividing Crocuses into two great classes—1, Involucrati (those which have a basal spathe); and, 2, Nudiflori (those from which a basal spathe is absent). This basal spathe, which grows out from the point where the scape leaves the corm, must be distinguished from the spathes proper, which grow out from the base of the fruit, and in many species are two in number. These two primary divisions are subdivided according to the well-defined characters of the corm-tunic, and again into vernal and autumnal.

Arranging them by these characters, Mr. Maw catalogues in order all the known species, from one to sixty-seven, preserving to each its own number throughout the work, a plan of the greatest convenience to collectors. Of course, we must not suppose that the list of Crocuses is as yet closed; on the other hand, the author tells us that the geographical range has recently been found to extend much further to the north-east and south-east than it was before known to do. Information received last year from the Afghan Frontier Commission leads us to hope for new discoveries in that direction, and even in Europe the Crocus-bearing regions are perhaps not exhausted. Asia Minor and Cyprus are as yet very insufficiently explored. Mr. Maw appeals (p. 52) to all travellers to help this branch of botanical science, and points out on the same page how easily it may be done. We have mentioned sixty-seven as the number of species of Crocus already recorded, but we may add incidentally that nearly all those beautiful garden varieties so popular and in such large demand, known as Dutch Crocuses, belong to only two species, C. vernus and C. aureus. Though sold as Dutch Crocuses, they are really grown in a part of Lincolnshire known as South Holland, which extends from Spalding to the shores of the Wash. These bulbs fetch for the raiser about 2½d. a pound, a price at which new Potatoes are thought cheap, and which suggests the thought whether the Crocus might not be utilised as food, the analysis of the corm showing that it is both wholesome and nutritious. Well worth perusal is Mr. Maw's history of the cultivation and uses of saffron, the product of the stigmata of a variety of Crocus sativus, of which the wild origin is unknown. To sum it up briefly: saffron has been in high estimation and value from the days of Solomon to the present time (1) as a perfume, (2) as a dye, (3) as a medicine, (4) as a flavouring for food. The first use is mentioned in the Song of Solomon; the second frequently in the Greek classics; the fourth is at least as old as the Augustan era, as Corycian saffron in mentioned by Horace as an ingredient in a recipe for "double sauce." The cultivation of saffron in England, especially at Saffron Walden, is an interesting episode in its history.

Space will not allow us to follow Mr. Maw in his ample description of the sixty-seven species, every one of which is fully illustrated, not only by a coloured figure of the plant in flower, but by a complete analysis of all the parts, the stigmata, the anthers, the leaf section, the corm tunic, the pollen grain. Some of these parts are so well defined in their character, that a stigma, or even a portion of the corm tunic, is often sufficient to determine the species. Besides these, we have as chapter-headings, well executed engravings of many of the native homes of the Crocus, taken from original photographs. These, as well as the descriptions, show that Crocus hunting has to be carried on amongst some of the most beautiful scenery in the world, and we conclude our notice of Mr. Maw's book by expressing a hearty wish that he may enjoy many another pleasant excursion after Crocuses, and live to add a long supplement of new species to some future edition of his delightful monograph. C. W. D.

WORK DONE IN WEEK ENDING NOV. 16.

NOVEMBER 10 TO 16.

RAINY weather is still to the fore. We have, out of the six working days of this week, had four days and nights of it almost without intermission, besides showers on the other two days; consequently outside work has been quite at a standstill, a little leaf-raking and carting them away excepted. We have, however, always plenty of inside jobs on hand for such weather, and have been fully employed in looking over Potato and root stores, Carrots, Beet, and Onions; also planting out on floor of cellar Cannas and Fuchsias in cocoa fibre refuse, and boxing up tuberous Begonias and herbaceous Lobelias. Fruit rooms have also again been overhauled, and every decayed fruit thrown away. Label-making, mat-tying, pointing sticks for tying plants, repairing netting, Birch-broom making, limewashing sheds, and sundry other little jobs that are essential to perfect order and cleanliness, but which probably would never get done were it not for an occasional spell of bad weather. Of work in the houses there has been no lack. Grape-preservation must have,

and has our first attention; all are well ripened, and now give us but little trouble in the way of cutting out bad berries. Their good keeping is, I believe, due—first, to their having been well ripened; next, to removal of all useless foliage which engenders damp and mildew; and next to the maintenance of a dry atmosphere and of an equable temperature, ranging from 55° to 60°, by keeping slight heat in the pipes constantly. As space in the Grape room can be had, the fruit is cut and placed there. All our Hamburghs are now in bottles, and keep far better than they did on the Vines. Completed pruning of Peaches in second house, and after cleaning it out and limewashing the walls, it was filled with Chrysanthemums that are intended for late flowering. It is only the inconvenience of housing these plants in fruit-growing establishments at this season that hinders their being grown by the hundred instead of the score, for they virtually give no trouble all the summer, except the labour of watering; and to a willing mind in an active body this counts as nothing, for one is more than repaid by a grand floral sight right through the dullest weeks of the whole year. The wet weather has caused us some anxiety as to the well-being of the flowers, as many have damped off prematurely; and in fruit-houses at rest—having the welfare of the trees at heart—one has been afraid to apply much fire-heat to expel damp. This we have done, however, but have taken the precaution to keep the ventilators fully open the while, so that the heat has never been excessive. Pruned an intermediate and mixed house of Vines; washed glass and woodwork and filled it with kinds of bedding plants that a few degrees of frost will not injure, as artificial heat cannot be turned on. Picked over and re-arranged flowering Pelargoniums, Carnations, Cyclamens, and Primulas, with which our Strawberry house is now filled; by intermixing a few Maiden-hair and Lomaria gibba Ferns with the flowers, the effect has been greatly enhanced. The temperature we keep about 60°, and the atmosphere as dry as is possible under the present wet-weather conditions. We have a late lot of Melons, the fruit of which is about half grown, but of late they have made no progress, and I scarcely think they will mature; but we mean to continue the experiment, and have now increased the fire-heat and withdrawn all atmospheric moisture, as there were signs of mildew. Cucumbers, too, are so unsatisfactory, that we shall be compelled to destroy them; the fact is, they have been neglected in the interest of flowering plants. The demand for the latter has ousted the former. A penurious policy is seldom a wise one, and it has not been in this case. HANTS.

HARDY FRUITS.

The Orchard.

As a rule, all root-pruning and planting should be finished by the end of the present month. This year, owing to the mildness of the season, this work in many places has been delayed, as many of the trees were not only in full leaf, but actually growing up to the evening of the 7th, when 10° of frost produced a most desirable check upon vegetation. Just now the burning question amongst pomologists is the best and cheapest mode of growing fine Apples and Pears that will enable them to compete profitably with our enterprising colonists. Another question of equal importance is the best mode of disposing of them after they are grown. Apples, we learn from all quarters, are not plentiful in England, but they are fine, and a consensus of opinion goes in favour of their quality being superior to that of the bulk imported from abroad. This being so, or assuming that they are equal, how does it happen that the producer living a great distance from London barely receives a penny a pound for fine samples, whilst the consumer pays from threepence to fourpence? If the quantity imported keeps the wholesale prices down, one might suppose that the consumer would get good fruit proportionately cheap, and no one would have ground for complaint, but this does not seem to be the present state of affairs; consequently, next to growing good fruit, a question of equal importance is the establishment of more markets and the breaking up of a huge monopoly. In my last paper I dwelt upon the cordon system as being applicable to small gardens and limited plots of ground; but when planting extends to acres, present prices in a comparatively scarce season will hardly induce owners or occupiers to incur the outlay of placing one or two thousand trees on twice that number of square yards of ground. For quality, I believe the cordon system stands unrivalled, but for bulk of fine marketable fruit, trees worked on the English Paradise and trained as bushes will possibly give the greatest return, and that at less cost at the outset. The preparation of the ground for bushes should be precisely the same as for cordons. It should be well drained and trenched, or double dug, and if it is unsuitable, heavy loams may be made porous by the addition of old lime rubble, road-scrapings, clay or stiff soil burnt to ashes with wood; anything, in fact, that will improve their character and favour the free passage of water to the drainage. Light or sandy soils, on the other hand, may be rendered more binding by the free admixture of dry pulverised marl, clay, or chalk, as well as by the use of cool, heavy manures for mulching. Firm treading or even ramming after trenching, always when the soil is dry, also does good service, as it produces a resisting medium, which all fruit trees like, and compresses a greater quantity of food into a given space.

Preparation of the trees.—Bushes, two to four years old and well furnished with flower-buds, can be obtained in any quantity, and, provided a quick return is of paramount importance, properly prepared trees, three years from the bud or graft, should be selected. If economy takes precedence of time and yearly extension of the orchard be the object, then the spaces between the rows of the first batch planted may be utilised by the introduction of maidens, or even stocks, if the occupier is an adept at budding and grafting; otherwise home manufacture should be left alone, as there is a certain mode of procedure which experience alone can impart. When maiden trees are planted in autumn with the view to their making really dwarf, perhaps goblet-shaped, bushes, it is necessary to cut them back in the spring and train the side shoots in a horizontal position; but head room being abundant, the removal of the leading point from well-feathered, untrained pyramids is the most natural as well as the quickest mode of getting healthy fruit-bearing trees. Some varieties are horizontal growers; others assume a pendent habit, and actually require supporting when carrying heavy crops of fruit. A third section will be found decidedly fastigiate, and may require drawing out to induce them to cover the space allotted to them. These, as a rule, attain the greatest height in a given time, and for this reason should be planted where they will be least likely to cast shade upon the dwarf growers.

Distance apart.—Having decided upon the direction in which the lines are to run—from north to south answers best—permanent trees should have sufficient room to admit of their full development and the free passage of sunlight and air, without which colour and flavour will be found wanting. A Kentish grower of great experience says bush trees and pyramids should be placed 12 feet apart, or 300 to the acre, but after looking at some of my own of about twenty years' growth, I should be inclined to give them 18 feet, as I am a great believer in extension and allowing them to grow into fertility. This arrangement would leave a great deal of unoccupied space at the outset, but this, as I have previously remarked, might be planted with younger stock for future transplanting, as more ground is worked into condition. Bush trees, including Gooseberries and Currants, or Strawberries might also be introduced and destroyed as their space is wanted. In the arrangement of the trees great care should be devoted to their selection—in other words, whole rows of one kind or of kindred habit should be kept together, not only for producing a tasty and pleasing plantation, but also for the convenience of gathering and manipulating. When trees on the English Paradise stock are intended to attain their greatest size in the shortest time, all the shortening the shoots require should be directed to the maintenance of the proper balance of the heads, but they will need annual thinning to prevent the centres from becoming crowded. The roots, unlike those of miniature cordons, will not give much trouble, but bearing in mind that these stocks cast out one or two strong anchor roots in a downward direction, whilst surface fibres are the main feeders of the fruit, each tree should be carefully root-lifted when it has been two years planted. By root-lifting it must be understood that all the vertical roots must be raised to a horizontal position, the strongest only shortened and relaid in good fresh loam near the surface. Some may require lifting a second time, but the majority under good mulching will go on for years, as roots once laid in the way they should go seldom depart from it; whilst shoots that are allowed to extend become crowded with flower-buds. If one-tenth of these set, the fruit requires thinning; if they miss, then it may be necessary to maintain the balance by again working round the roots in the autumn.

The Fruit Room.

A season of extremes, although fruit is very fine and clear, does not seem conducive to the keeping of dessert Pears. Apples, on the contrary, are unusually sound, and many varieties look like extending beyond the limits of their allotted period. Pears, especially from walls where there was just a suspicion of dryness at the roots, came quickly up to the gathering point, and that condition may have been the cause of early maturity and an inclination to become sleepy before their time. Marie Louise and Pitmaston Duchess, although allowed to hang a fortnight later than last year, are quite a fortnight earlier in ripening. They do not shrivel, neither do they rot, but when touched nearly all the finest fruits are found to be soft and mealy, and, as a matter of course, unfit for use. Fruit growers in this country like to leave their best Pears on the trees until they part with the slightest touch, or, perhaps, a few begin to drop, but I am afraid I have overshot the mark, as samples from pyramids and standards are maturing gradually, and although smaller in size, their quality is superior to that of kindred or the same varieties from trees trained against walls. People do not often chronicle failures, if fine Pears becoming prematurely mealy can be called a failure, but this is one of those peculiar facts, perhaps the natural outcome of a peculiar season, which others living in drier and warmer parts of the country may be able to explain. To me the phenomenon is new, as this is the first time I have had occasion to complain of too much fierce sun-heat in Herefordshire. Apples, as I have just remarked, are keeping sound and good, and the sweating stage having been got over, the store room may now be kept moderately close, particularly during the continuance of this incessant fall of rain. The crop in many parts of the country being light, some growers will not require reminding that the store should be carefully examined at short intervals, and double or treble rows laid out in single file as the consumption of early varieties sets the shelves at liberty. In this part of the country, although the crop was partial, many varieties, notably Blenheim Orange, have filled the store rooms to overflowing; thousands of pots have been sent away, and still there are quantities requiring more room. These, it is hardly necessary to say, should be taken out of the hampers, as one decaying fruit soon affects the mass, and if better accommodation cannot be provided, a good layer of sweet Fern laid on a dry, cool floor will form an excellent resting-place for the present. Others, again, may be placed in dry barrels or large earthenware pots, in which selected samples free from spot or bruise will keep much longer than on dry airy shelves, especially where the fruit room is easily affected by external changes. Extra fine varieties and choice Pears, if behaving themselves

properly, may be rolled up in white tissue paper and put away in drawers from which the air can be excluded. If sound and free from spot, as every specimen so treated should be, there will now be slight danger of decay, but for all this they should be carefully examined occasionally, as the finest and, I regret the impeachment, the most perfect-looking Pears may be found sleepy.

Strawberries under Glass.

Where very early forcing is contemplated, the first batch of plants should now be placed under cover, and after they have thrown off some of the moisture with which everything in the open air is saturated, the tops of the balls may be rammed and surfaced with rich top-dressing. If a Strawberry house proper is at command, the most promising plants in the smallest pots, after being washed and examined to see that the crocks are satisfactory, may be placed upon the shelves to come on slowly at first, under the faintest taste of artificial heat. Hot water is, of course, the prime agent, but a very important factor will be found in fermenting material, than which nothing can be more suitable than well-fermented Oak leaves, as they not only throw off soft, genial warmth in which plants of all kinds luxuriate, but the moisture constantly exhaled reduces the necessity for continuous syringing. Where suitable houses are not provided, a sharp pitched summer Cucumber or Melon pit, fitted with temporary shelves some 16 inches from the glass and previously filled with a good body of fermenting leaves, will answer fairly well for carrying the plants through the early stages of their growth, but unless it is span-roofed and perfectly ventilated, another structure should be ready for their reception when they come into flower. Lacking these, very early forcing dead against Nature is best left alone, at least for the present. Many people not from choice, but through force of circumstances, plunge into a sea of trouble and worry by filling all available space in their Peach houses and vineries as soon as they are closed for forcing. The temperature at the outset is satisfactory, but the attempt to grow two kinds of fruit so subject to red spider frequently ends in disappointment, as many fine and promising plants often become blind and leave a legacy of destructive insects behind them. By many employers who expect their gardeners to perform miracles these difficulties are ignored, but they exist nevertheless, and it is only right they should know the man who succeeds is worthy of very much credit. If, then, Strawberries must have a place with Peaches and Vines, they should occupy shelves near to the glass and ventilators, and fermenting leaves should be placed beneath them. If not already stored away, the main batch of plants may now be plunged up to the rims of the pots in coal ashes or other materials where these are considered objectionable. Some (myself included) do not approve of covering the tops of the balls with ashes; but this difficulty can be got over by the application of a light covering of leaf-mould.

Vines.

The month of November is always considered the most trying period in the whole year, but when incessant rain darkens and saturates the atmosphere; when one cannot move without carrying mud and moisture into the houses, the difficulty that attends the keeping of half-ripened Grapes is greatly intensified. Grapes, on the other hand, that were black, as all well-managed Grapes should be, in September will now be thoroughly ripe, and capable of holding their own until the time comes for bottling. If all the leaves have not fallen from the Vines they should be gathered up every day, and the atmosphere kept dry and temperate to prevent the spread of mould or condensation of moisture. Cleanliness and the removal of all decaying vegetable matter is, of course, imperative, and ventilation with gentle warmth on fine days, when they come, must not be neglected. Although Grapes and wood may be ripe, a condition which fits them to withstand a low temperature, a sharp circulation of air when the weather does change should be carefully avoided. The Grapes at the time will not show the effect of a chill, but when the fresh healthy stalks of such kinds as Gros Colmar rather suddenly turn black, although too late, it may be well to inquire how they have been ventilated. If not already done, inside borders may now be covered with some dry non-conducting material for the protection of the surface roots and keeping down moisture. Where at hand, fresh dry Fern answers well, and gives the floor of the house a neat appearance. Outside borders, having received so much rain, may also be covered with the same material; or, lacking this, a good layer of fresh dry stable litter. When glazed lights, sheets of corrugated iron, or shutters are used for throwing off rain and snow, they should be elevated to admit a circulation of air, which will prevent an accumulation of stagnant moisture ready to rush into the house when the front lights are opened. If thin-skinned Grapes are still hanging on the Vines, they must be kept very dry and cool, as shrivelling is better than damping. But, in order to avoid either, they will not only keep better in the dry even temperature of the Grape-room, but the Vines will derive great benefit from a free circulation of air before they are let down for pruning.

The Grape Room.

This is now a thoroughly established section of every good Grape-growing garden, and few who have tasted the comfort which attends the removal of the last bunch from the Vines would like to go back to nights and days of anxiety. Much has been said and written about Grape as well as fruit rooms, but the secret of success in their management rests in a nutshell. An atmosphere too damp or too dry, or which fluctuates with every external change, is the bane to long keeping. A dry, well-ventilated cellar is better than an airy room in the upper storey, and expensive fittings are a superfluity. Given a well-ventilated room or cellar, with thick dry walls; fit it up with racks for carrying bottles or other vessels filled with water; limewash every year, and use it not for perspiring Pears when the Grapes are in it. Avoid the use of fire-heat if the atmosphere can be kept dry and the temperature at about 50° without it. Cut the Grapes on a dry day, and be careful to remove every imperfect berry before the bunches are taken into their winter quarters. Each piece of wood carrying a bunch should be severed with a sharp knife—not with secateurs—close to the pruning bud, but not the slightest tip or lateral should be taken off beyond it. If a new Grape room must be built, sound hard brick is preferable to stone, and on the old lines laid down years ago. The walls may be hollow, the ceiling double, but well ventilated, and the windows not too many, fitted with shutters. Hit-and-miss brick ventilators let in near the floor, and a flow and return pipe from a slow combustion boiler placed outside for expelling damp or keeping out actual frost, need not be a very costly affair. The cost of the fuel will be next to nothing, as fires in some seasons may not be needed at all, but this provision should be made for meeting cases of emergency.

W. Coleman.

Eastnor Castle, Ledbury.

SHORT NOTES.—VARIOUS.

Lamarck's herbarium.—The celebrated collection of plants that belonged to Lamarck, and subsequently passed into the possession of the late Professor Roper, of Rostock, has been purchased by the French Government, and will be shortly placed in the Jardin des Plantes.

Boussingaultia baselloides.—Mrs. Axtell, of West Lodge, Dorchester, sends us some delightfully flowered sprays of this plant. It is very fragrant and extremely graceful, and she is fortunate in being able to grow it so successfully. As a rule, it is an unsatisfactory plant, because it is not quite hardy enough to survive out-of-doors about London, and does not seem to flower well under glass.

Sundials.—I have a sundial in my garden consisting of a thick slab of slate 21 inches square, fixed perpendicularly, and placed in its position on June 17. We arranged the shadow from the gnomon at the hour of 12 noon. At this time of the year when the sun makes a lower transit across the sky the dial is not accurate. Would "Veronica," who writes on sundials, or some other correspondent oblige us with information as to any rules that may exist for the correct reading of the instrument at the various seasons of the year? T. H. Delves.

Kitchen Garden.

Messrs. Sutton's Potato Experiments.

Most of our readers are aware that Messrs. Sutton, of Reading, have for two or three years been carrying on a series of experiments with Potatoes, with the view of producing a race that will be disease-proof. They obtained from Kew tubers of what they thought was Solanum Maglia, but by some mistake tubers of the wild Potato (Solanum tuberosum) were substituted. These were fertilised with pollen taken from some of Messrs. Sutton's best Potatoes and were grown on, and on Monday last we went to Reading to see their produce, when the following results set forth in the annexed tables were realised:—

No.	Produce 1885.	Produce 1886.		No.	Produce 1885.		Produce 1886.

No 34, 9¼ ozs.

The motives which led to the commencement of these experiments were to produce, as we have just said, a race of Potatoes which shall have all the good properties of a first-class Potato, be a large cropper, and possess such a hardy constitution as to withstand disease—in fact, be a disease-resister. In order to obtain the constitution it was deemed necessary to go back to the wild state of the plant, but as Solanum tuberosum (the plant from which our Potatoes of the present day are supposed to have descended) is a native of somewhat dry regions in the Andes of Chili, some other kind was sought for; and Solanum Maglia, discovered by Darwin in wet, swampy places in the Chonos Archipelago, a group of islands off the west coast of Patagonia, was thought likely to withstand the vicissitudes of our climate better than its near ally, S. tuberosum, from a dryer atmosphere. Accordingly, tubers of S. Maglia were, as was supposed, obtained from the Royal Gardens, Kew, where wild species of the Potato have existed for some years. No pollen was, however, produced by these wild plants, but their flowers were fertilised with pollen taken from one of the

best (if not the best) Potato yet known, called Antagonist, with the result herewith shown. The female parent of this new race, as will be seen from what has been stated, is not S. Maglia, as Messrs. Sutton would have liked it to have been, but S. tuberosum, raised from imported tubers. By this little mistake, however, we consider that the Messrs. Sutton have been gainers instead of losers, inasmuch as trials recently made with the true S. Maglia have proved it to be of such a rambling habit as to be useless for cultivation. Other varieties crossed with the wild S. tuberosum were Paterson's Victoria, Walker's Regent, and Reading Russet; the results from the latter are heavy, good-looking tubers of great promise, but the most curious fact of all is that cuttings taken from a red-stemmed Potato, which had become white towards the ends of the stems, when struck produced white tubers of excellent appearance, whilst the tubers at the base of the stems from which these cuttings were taken were found to be of the normal purplish red hue, thus showing that, though the original colour of a Potato may be red, it may at any time break into an albino under cultivation. One result Messrs. Sutton's experiments certainly serve to show, and that is that our Potatoes of the present day have been obtained from Solanum tuberosum, as tradition records.

IMPROVED CELERY.

It speaks volumes for the remarkably staying powers of that fine white Celery, Incomparable Dwarf White, that hundreds of strong plants from seed sown ever since April last year still remain unbolted. I have never had such an experience before, but all the same have always found this dwarf kind to be very late in starting off to flower. I think it is a great recommendation to any Celery that it is not only hardy, but in no hurry to bolt. We have need of Celery over a long season, indeed, till the end of May, at least, if it can be preserved. I am not aware that blanching facilitates running off to bloom. I have not found that to be the case, but invariably that much is contingent upon kinds. For that reason I find the Incomparable Dwarf to be so good either for early work, bearing early sowing and planting so well, or for the latest planting, standing so late into the following year before running to bloom. Apart from this recommendation, it is at once one of the most solid and hardy of Celeries, bearing comparison with the red kinds, whilst its short stems conduce to an even head of foliage, which standing just above the earthed-up ridge of soil much more fully protects the stems from frost and snow than do the stalks of those larger-growing and, of course, much looser-leaved sorts. These a few frosts, or a moderate snowfall, utterly demoralise, break, and almost destroy, and once that result happens the younger and tenderer leafage is left exposed to the rigour of the winter. Broken stems soon lead to decay, and that decay soon affects the blanched stalks injuriously. Then the vacancies left around the plants by the decayed leaf-stalks enable moisture and slugs to find free entrance, and hence we see so much stained and half-rotten Celery later in the winter. It is from no lack of quality or endurance that the Incomparable Dwarf kind has been so much put aside.

There has been too much anxiety to get big-stemmed kinds that look well upon the exhibition table. Were Celery served up to the dinner table in massive sticks just as lifted, dressed and cleaned, there might be some reason in this anxiety to get large-stalked kinds. However, that notion is too absurd; hence we see these big sticks of Celery only on the show table. But if the Dwarf White were grown under precisely similar conditions to those of Giant White, Grove White, Prizetaker White, or under whatever designation any large white form may be known, it would be found in the end after the sticks were duly prepared for table, that the dwarf gave quite as much good, edible, blanched matter as did the biggest sort, and much more economically. As evidence of the favour which clusters still round the dwarf, compact Celeries, it is noteworthy that the chief novelties in Celery of late have been dwarf. I think I am justified in saying that the Incomparable Dwarf has had to do duty several times as a novelty, but when so introduced, if true, it is at least a good thing. Some years since, when Celeries were tested at Chiswick, four or five strains of the Dwarf White and Sandringham (the same thing) were grown, it was found that only one lot was true. That at once shows that care in keeping stocks pure is not always found. With respect to some other very dwarf Celeries said not to require earthing, we may take it for granted that no Celery is fit for consumption that is not in some way or another artificially blanched, and it seems moreover that no blanching element produces sweeter or crisper Celery than does the soil, especially when earthing is done with care and the soil is fairly fine and dry.

We have done very little in the way of improving sorts of Celery of late years, as is evidenced by the fact that old kinds still hold their own. We see this fact in the red section prominently, for Major Clarke's is now quite an old kind, and it is without exception the best of all the reds yet. Although not quite so dwarf as is the Incomparable White, yet it is dwarfer and much more compact than are most of the other red sorts. So even and compact are the tops of this red (also known as Leicester Red), that it can be detected at a glance; whilst others are much less easy to distinguish, and several have very irregular, long, loose stalks, which now flop down under the influence of heavy rain or snow. Of course, every seedsman likes to praise and push some special Celery, but unless they produce sorts which excel these old kinds that are everybody's property, it is hardly fair to lay claim to the possession of superior specialties. There is some merit in preserving good strains, and the better or purer the strains, the more credit is due to the house offering them. Considerable discussion took place recently with reference to the best system, or rather time in the plant's growth for earthing up. Without doubt that gardener's system is the best which in the end gives him the best results, but there is very much diversity of opinion in spite of that, and the majority hold to the old notion that gradual and careful earthing is best. I think there can be little doubt that the most effective blanching is produced in that way, and that the Celery, because less exposed to the light, is far more tender and sweet than is the case when blanched after the plants are fully grown. The defect of such a plan is that it may, should the autumn prove wet, have to be done when soil and plants are wet. In such case it would have been far wiser to have begun the earthing during the summer. A. D.

Sweet Brier.

SWEET BRIER.

(ROSA RUBIGINOSA.)

Sweet Brier is ever welcome and ever beautiful, whether in garden, hedge, or woodland. The sweet scent of its foliage greets us in the earliest days of April when the leaf-buds are unfolding; it bears a profusion of flower in June, and a mass of fruit that is highly ornamental in late autumn. Planted near or among the lower branches of some evergreen tree, such as a Holly, a good effect may be gained by encouraging it to throw up its strong shoots through the dark foliage: the showers of bright flowers and brilliant berries are more than usually beautiful when seen in such companionship.

INDOOR GARDEN.

WINTER-FLOWERING PLANTS.

Christmas Roses are, or ought to be, everybody's flowers. No class of plants which we cultivate give such good returns for so little trouble. One strong undisturbed clump is capable of producing hundreds of blooms in one season; we have gathered as many as sixty at one time, and an unlimited supply of such lasting and nearly pure white flowers in mid-winter would be welcomed by any lover of flowers, and more especially by makers of memorial wreaths. It is a mistake often perpetrated, I believe, to attempt to force Christmas Roses; this ends in the production of weakly blooms and the weakening of the plant's constitution. If early blooms are wanted, a few strong clumps may be lifted with plenty of soil about their roots, and either potted or planted in a light house or frame. They will perfect as many flowers as those left in the ground, will be earlier, and most probably much whiter. The stems, too, are thinner—an improvement, I think. Potted-up plants will, if well attended to, flower strongly the second year, after which they should be divided, planted out, and not interfered with for the next two seasons. Our stock of plants is arranged in beds to suit the size of long, narrow, span-roofed frames, and four of these yield us ample supplies of bloom, with no further trouble than protecting them from severe frosts. It is well to cover the plants with glass if possible any time before the blooms expand, handlights and bell-glasses being best for the purpose; without this protection the colour of the blooms will be nearer green than white. Christmas Roses are coarse-rooting plants, and do not succeed well in either poor or light soils. Ours are improved by occasional lifting, this being done in spring, just as active growth commences, and unless lifted, it is almost impossible to maintain the proper degree of fertility in the soil. They like a moderate supply of manure within reach of their roots, plenty of moisture at all times, and are benefited by liberal mulchings of manure. We depend wholly upon one variety, Helleborus niger maximus, and the form being a good one—that grown extensively in the neighbourhood of Bath—it is doubtful if we shall improve on it.

Gardenias are not, as a rule, plants of easy culture. In some few gardens we meet with them in the best of health, but more often they look miserable, being either smothered with mealy

bug or of a sickly yellow hue. The best course with such plants is to burn them and start with clean, healthy stock, such as any nurseryman would be glad to sell at a comparatively cheap rate. Or, if clean, quickly produced cuttings can be procured in spring, these will strike readily in a brisk bottom heat, and may be grown to a good size, *i.e.*, large enough to perfect a dozen or more blooms before Christmas. We find either a heavy loamy soil or over-potting to be both liable to end fatally. If good, fibrous loam, devoid of clay, is available, this may be mixed with an equal quantity of good peat, and after a liberal addition of sand and charcoal, if at hand, has been made this compost ought to grow Gardenias well. Our loam is clayey, and we use only one part of this and an equal portion of good leaf soil with the peat. Large pots are to be avoided. Some of the finest plants I have seen were in 11-inch pots; but a 9-inch pot is quite large enough for a plant 2 feet high and proportionately bushy. Pots well filled with roots are what are required, these admitting of plenty of water being given and frequent supplies of soot water, than which there is nothing better for Gardenias. We find it advisable to mix the soot in the form of paste, a state in which it can be kept in a flower-pot conveniently near, and a small lump of it readily mixes with the water. Very little suffices, the water being little more than coloured with it, and this soon communicates a dark hue to the foliage. A healthy plant is bound to be floriferous; sickly plants also attempt to flower freely, but many of the buds drop off, and the flowers that do open are small. Low temperatures or cold currents are injurious to Gardenias, and dry heat is also unfavourable, often causing many of the buds to drop off prematurely and otherwise injuring the plants. A Pine stove just suits them; they may be said to revel in a high temperature and a moist atmosphere. This may easily be proved by placing a plant or plants over a hot or warm-water tank in a plant stove or forcing house. Some good cultivators never give them any air, not even in the hottest of weather, but they are usually afforded a little shade and are frequently syringed overhead. Syringing overhead whenever the house is very dry not only benefits the plants, but also materially hastens the unfolding of the blooms, and this hint should not be lost on those who may want an extra number of blooms at a given time. We have set strong plants on the hot-water trough and kept them constantly moistened overhead as well as attended to carefully in the way of watering, and this brings blooms forward very rapidly. Mealy bug is their worst enemy, but scale is also troublesome at times. It is not safe to use petroleum, or, indeed, any other strong insecticide during hot, sunny weather, or all the fully-grown leaves as well as the insects may be destroyed. In autumn and winter, petroleum, at the rate of 2 ozs. or one wine-glassful to a gallon of hot water, may safely be syringed on to them, and this proves fatal to both bug and scale. The water should be soft and heated to about 120°, and the petroleum should be kept stirred with the syringe, and thus forcibly mixed with the water it may be effectively used. Subsequently those that escape ought to be killed with a pointed stick. Young practitioners are fond of using stiff brushes for clearing off bug, but these do nearly as much injury as they do good. Gardenia radicans major is sometimes classed as a greenhouse plant, and during summer it will succeed in such a house, but it must be a very warm greenhouse that would agree with it in cold weather. We have it in a moderately warm stove, the temperature of which ranges from 50° to 60° by night and rather higher in the daytime, and, on the whole, we consider it to be the most profitable sort we have yet tried. It is a continuous flowerer, and I should advise all who have not succeeded with Gardenias to their own satisfaction to give this variety a trial. Fortune's variety of G. florida is a useful kind, the blooms of which are larger than those of the type. Many err in cutting wood with the blooms; this plan effectually checks continuous blooming, and autumn and spring crops are the most that are secured. With every bloom are cut away one or two side shoots, some perhaps having buds already formed on them. The blooms with their stout foot-stalks only should be cut or snapped off. It is true, the foliage sets off the blooms to the best advantage, and when cut with a flower a button-hole is ready formed. However, it is a very simple matter to pass a fairly stout wire through the fleshy tube, bringing the ends neatly together, and they may then be mounted on neat shoots of the green and glossy-leaved Escallonia macrantha; or, failing this, a few back Gardenia leaves may be safely removed from strong plants, and may be wired and attached to the blooms. Thus mounted, they are stronger than those cut with leaves attached and not wired, and the blooms last quite as long.

W. I. M.

WINTERING SOFT-WOODED PLANTS.

Calling, a few days ago, upon a neighbour who is an enthusiastic, though not an experienced, gardener, I found him busy preparing a pit in which to winter some plants he had lifted from his flower beds and placed in pots. But he had very crude notions as to carrying out his purpose. He had actually built up a wall of manure in the shape of a frame, with the back against a wall, and with nothing but the ordinary garden soil at the bottom, and in this he expected to successfully winter his favourites. He had no thought of damp and the loss of his plants from that cause; he thought only of excluding frost, and he fancied his wall of manure would retain sufficient warmth to keep away frost all the winter, and bring his plants triumphantly safe through that season of the year. Now, there are a great many amateur gardeners in a small way who take a great pride in wintering a few plants successfully, though they have no greenhouse in which to house them. One can bring safely through the winter a great deal in a cold house, with due precautions, if they will be careful in the matter of watering. Keep the floor of their house dry, and in times of sharp frost cover up their tenderest plants with newspapers and any such material. They can also bring into requisition one of the petroleum stoves now so common and so cheap, and I have never found the fumes from the oil do the plants any harm. But the great secret is keeping the plants dry at the roots and avoiding by all possible means wetting the floor of the house more than is unavoidable.

But it is possible to construct a cold frame in a homely fashion in which many things of a tender character can be wintered in safety. I know a cottager who is an exhibitor of plants during the summer months, and a successful one, too, growing and showing capital Verbenas, Petunias, Fuchsias, Pelargoniums, &c., and as the show at which he competes is held in July, he has to get his plants as forward as possible, and the young plants he grows into specimens are struck from cuttings in July and August. He has constructed a most serviceable frame, which serves him in good stead of a greenhouse. It is a homely-constructed pit rather than a frame: the sides are made of strong rough planks, and set up nearly level with the ground, the lower sides of the planks not quite touching it. The surface slopes from the back to the front, so as to afford natural drainage, if necessary.

Now, in order to have an appropriate base to the bed, the soil was dug out to the depth of a foot or so. Then was laid into it a foundation of 9 inches' depth of stones, brick rubbish, &c., and on this were placed 2 inches of coarse cinder ashes, and then some 6 inches of finely-sifted ones. It is almost impossible that such a bottom could be a damp one, but that the chances of damp should be reduced as much as possible, an outlet was made for water to run away, should any gather. During autumn, a wall of dry tan is built up round the outside of the frame nearly to the top, and outside this a wall of turf. This is removed in spring and utilised for garden purposes. The lining of tan is found to be a better non-conductor of cold than the soil, which is built up level with the tan. The frame is covered with two glazed lights that fit close to the framework. Here the plants are placed, and as opportunity offers they are gone over, any dead or decaying leaves removed, and the surface soil stirred, &c. On all fine mild days in winter the lights are tilted up, if not altogether removed, so that the air may circulate among the plants. At night, when the air is frosty, a covering of mats is put on; indeed, anything in the way of covering is called into requisition. In this way Camellias, Indian Azaleas, Richardias, and things of a similar character, in addition to those named above, are kept through the winter in perfect health. Water is given very sparingly during the dull, dead season, and when a thaw follows a season of frost any plants that have become very dry are lifted out of the frame, the pots immersed in a pail of water, and then allowed to drain thoroughly before they are returned to the pit.

I need scarcely state that such a frame is very serviceable in summer in many ways, and the fine specimens shown by this cottager are grown entirely in this frame and in the open air. Surely this is an example that can be followed with advantage by many amateur and cottage gardeners.

R. D.

COLD FRAMES IN WINTER.

Cold frames are useful in many ways during winter. They afford protection from wind—an important point—and they ward off a great deal of frost and snow. The greatest enemy to the occupants of cold frames is damp, and the great majority of deaths which occur amongst cold-frame plants in winter may be attributed to this cause. If damp can be excluded or timely expelled, it is remarkable how well even half tender plants can be preserved in cold frames in winter, but great care and attention are needed in air-giving, an operation, however apt to be neglected, doubtless not intentionally, but under the impression that damp is best excluded by keeping the frame shut as much as possible. The sun may come out for an hour or two at mid-day, but it may be thought that it is not worth while opening the lights for such a short time. It is, however, often little air-givings of this kind which preserve the plants, as by opening the lights on every favourable opportunity, no matter how short the time, if the outer air is inclined to be dry, good results will follow. Wind, too, when not too cutting, soon dries up the interior of a cold frame, and if the lights are opened in such a manner that the currents do not come directly in contact with the plants, the latter will be greatly benefited thereby. There are many days, too, during the winter when the lights may be drawn off altogether for a few hours, and this helps wonderfully to keep the plants robust. Plants treated in this way are vastly different from close-grown ones. The surface of the soil in which the plants or cuttings are growing should never be wetted more than can be helped, and the soil should always be kept on the side of dryness. A few dry ashes or sand sprinkled thinly now between the plants are one of the best damp antidotes which can be used. Covering up from frost should never be done until absolutely necessary to do so, as many make the occupants of their cold frames tender by covering up when frost is only expected, that they are unable to bear the confinement when it does come.

Cambrian.

Tacsonia exoniensis. I am inclined to put this before T. Van Volxemi as a decorative plant in a conservatory. I was particularly struck the other day with its beauty in the conservatory at Willersby Castle, where there were two large specimens in pots. Their roots had penetrated to the border beneath, and the plants had not only made marvellously free growth, but they also bloomed with a freedom which is truly astonishing, far beyond what I have ever seen in the case of T. Van Volxemi. The rosy magenta flowers hung down in the most profuse manner. The plants are

pruned in pretty freely in the early part of the winter, and break into growth early the following year.—R. D.

SOME EARLY-FLOWERING BULBS.

Many doubtless would like to have a good display of bulbs in flower in December, and especially about Christmas-time. Flowers then are generally scarce, and the addition of a few attractive bulbs is much valued. There are many in almost all classes of bulbs which it would be quite impossible to have in flower on this side of the new year, as they absolutely refuse to be forced early, but there are others more pliable, and these, although not very numerous, are both choice and showy. First and foremost amongst early-flowering bulbs I would place the Roman Hyacinth; it is a free and early grower, and a sure flowerer. No flower could be more delicate in colour or fragrance, and its slender flower-spikes are very graceful; indeed, there is no better flower for choice decorations than this, and it is so easily grown and so remunerative, that in gardens of all classes, even down to the very smallest, it should be grown by the dozen, hundred, or thousand, as the case may be. Other Hyacinths which flower closely after the Roman kind, and which may be had in full bloom at Christmas, are Homer, fine red; L'Ami du Cœur, very bright; Grande Vedette, pure white; Princess Beatrice, pure white; Rowland Hill, bright yellow; and Victory, deep yellow. These are all single varieties. La Tour d'Auvergne is a good double white. Early double-flowering varieties are not so numerous as the single ones, and it is not often that any attempt is made to force double ones, so as to be in flower before the turn of the year. It may be well to remark that the varieties just named are best suited for greenhouse and conservatory embellishment, and are not so useful for cutting as the delicious Roman kind.

Of Tulips for flowering early or in December there are several both showy and good. The Duc van Thols are undoubtedly the best and easiest to deal with. The colours are red, crimson, gold, scarlet, rose, white, and yellow; one and all may be had fully in flower by the middle of December, and it would almost be impossible to imagine anything more showy at that time than masses of these. They are beautiful for front rows in conservatories, and very suitable for cutting and putting in small glasses for the table or rooms. In a dark December day the free use of scarlet and bright Tulips in a room gives it a brilliancy which no other flower is capable of doing. Those who have a good stock of Duc van Thols need not desire many more varieties for early flowering, but there are others only a little later, and almost as easily forced, which are worth attention. Amongst these we would mention Belle Alliance, Bride of Haarlem, crimson and white; Canary Bird, rich yellow; Cottage Maid, rose-pink; Fabiola, purple and white; Joost van Vondel, rosy crimson pencilled with white; Le Matelas, white flushed with crimson; Pottebakker in two colours, white and yellow; Proserpine, dark rose, very fine; Queen of the Violets, light violet; Roi Pepin, white flaked with crimson; and Vermillion Brilliant, which is very effective. The advantage of dealing with these Tulips is that they do not require much space, as from six to eight bulbs may be put into a 6-inch pot, and they will not fail to make an excellent show.

The Polyanthus Narcissi are very sweet-scented, and some may be had in blossom by Christmas. Of these we would name the Early Double Roman and the Early Paper White, which are two of the easiest to cultivate and most satisfactory. Good bulbs of both can be bought in at little more than 1d. each, and a few dozens or hundreds would make an acceptable addition to early winter flowers in either a large or small garden. With these ends our list of bulbs which can be forced extra early and with the utmost freedom. Many could be added, and different classes could be introduced; but they could not be recommended either for special or general culture as early flowering bulbs. We have tried to have Crocuses and Snowdrops in bloom previous to January, but have never succeeded to any extent worth speaking about. Lily of the Valley at Christmas would certainly be useful; but it cannot be profitably or freely forced by then, and unless in the hands of those who have forcing facilities beyond common, attempting its growth early in the season would only end in disappointment. Those who are able to secure a good show of the Hyacinths, Tulips, and Narcissi named above in December, can well afford to wait until February or later for other classes of bulbs to flower.

Bulbs for flowering after Christmas should be potted now. Our soil for one and all is mixed up in one heap; they are potted on the same day, plunged in the same place, and introduced to heat together, and they generally flower together. We do not therefore recommend one kind of soil for Hyacinths, another for Tulips, and a third for Narcissi, and as all succeed under the same treatment, they can be most conveniently treated together. Some of the Hyacinths may be potted singly in 3-inch pots; others of the small Roman class may be put into larger pots in groups, and the named varieties may be treated in this way too. Tulips are always prettiest in clusters, and so are the Narcissi, but the latter require larger pots than any of the preceding, and from three to five bulbs may be planted in a 7-inch or 8-inch pot. The pots should be well drained, and the soil used should consist of two parts of fibrous loam, one of decayed cow manure, and the other of leaf soil and sand. In potting keep the rough material to the bottom, and in planting the bulbs only allow the crowns to be seen above the soil. Finish off firmly, and then shake a sprinkling of sand over the top of the bulb and on the surface of the soil. As soon as potting has been finished they should all be plunged in a shed or frame, where excessive moisture can be kept off them. An empty frame is a good place in which to plunge them, or they may be put under the potting-shed bench or along the bottom of a wall, in a cellar, or in an open shed. The whole should be placed together as closely as they will stand, and then the covering should be put over them. This may consist of ashes, sand, soil, or sawdust, and should be from 3 inches to 5 inches deep. Under this the bulbs will soon begin to emit roots and the crowns push forth, and it is when their tops are up from 2 inches to 3 inches that they should be taken from the covering. If left until the growths are 6 inches or more in height they never assume such a natural habit as when taken out early, and by being left too long the flower-spikes often get injured. It is well to examine them now and again after the first fortnight, moving each kind out as the growths are up sufficiently. At first they should be placed in a cool frame or house away from frost and cold winds until the foliage hardens and becomes used to the light, then introduce them to heat. One and all may be forced in December in a temperature of 60° or 65°, and the best way of keeping up a succession is to move a few dozen from the cool place into warmth every ten days or so. They will all grow freely in a moist atmosphere, but the flowers will not keep long fresh in such a place, and as soon as the first blooms open they should be moved into a dry, airy atmosphere, such as that of a sitting-room or conservatory. J. M.

LIFTING CHRYSANTHEMUMS.

The planting out of Chrysanthemums in summer is likely to be extensively practised where large bushes and heavy crops of flowers are required. The experience of past seasons has shown that with care exercised in the lifting, and liberal treatment afterwards, a capital show of Chrysanthemums can be made, and a great saving of labour effected, through planting out during the summer months. As soon as all danger from frost is over, *i.e.*, not later than the beginning of June, we threw out shallow trenches, as if for Peas, 30 inches apart, and work in a good lot of manure. We then put in the plants the same distance from each other, and if the season is dry surface-mulch. For three months they receive no further attention, except a pinch when they have well started, an occasional inspection for maggot or fly, and a single stake to keep them upright. They receive two cuts round with a spade at intervals of a fortnight, commencing at the end of August, and by the end of September they are strong bushes ready for lifting. The pots used are 12-inch and 16-inch ones, with a few a trifle larger for extra-sized plants. These are taken to the plot where the Chrysanthemums are growing; the plants are carefully lifted and receive two or three sprinklings of native guano about the roots; while the potting is in progress no new soil is used. As the season is well advanced when they are lifted, they are removed at once to the Peach houses, and are thoroughly well soaked with water. With this care exercised in lifting, the foliage is preserved intact down to the rim of the pot, and we do not find any shading or syringing necessary except perhaps a slight dewing overhead if the weather proves very hot and airy; plenty of air is kept on night and day, and this not only keeps the foliage stiff and strong, but is a thorough preventive of mildew. The native guano keeps them right until the buds are on the point of bursting and they are ready for removal to the show house. As soon as they get to their new quarters, we start watering them with liquid cow manure. This kind of treatment will be found to be specially suitable for amateurs, as by it are produced not only good plants, but plenty of very fair blossoms. E. B.

BEST INCURVED CHRYSANTHEMUMS.

It may be assumed that we saw quite a representative collection of Chrysanthemums at the recent exhibition of the National Chrysanthemum Society at the Royal Aquarium. All the sections were not only numerously, but finely produced, and ample opportunity was afforded for making a fine selection. I went carefully through the flowers, and what I took to be the best I will now set down. But before doing so I may remark that there is ample room for more dark-coloured flowers, especially of purple, maroon, and crimson hues. The deepest coloured flower shown was Refulgence, which may best be described as a shining maroon-purple, and when finely grown it is very handsome indeed. Prince of Wales and Lord Derby are both lilac-purple varieties, coming next in point of colour of those shown to Refulgence. Of lilac or lilac-pink flowers there are Empress Eugénie, Princess of Wales, Lady Hardinge, Princess of Teck, Princess Beatrice, Beauty, and Hero of Stoke Newington. The bronze-coloured flowers, with which are included those having more of orange and less of bronze, are Nil Desperandum, Barbara, Golden Eagle, John Salter, Lord Wolseley, Mr. Brunlees, Baron Beust, Angelina, and Mr. W. Shipman. All these are very striking, and tell in a stand of exhibition varieties. The best golden or orange-coloured flowers are Mr. Bunn, Jardin des Plantes, and Yellow Perfection; the best yellows, Mr. Dison, Golden Empress, and Mabel Ward; the best sulphur coloured varieties are Golden Queen, George Glenny, Emily Dale, and Lord Alcester; the leading white varieties are Empress of India, Queen of England, Mrs. Heal, Jeanne d'Arc, and Mrs. George Rundle. Here we get something like thirty flowers, all of the best show quality.

A further good useful dozen will be found in Alfred Salter, deep rosy pink; Abbé Passaglia, bronzy amber, rather small; Beverley, creamy white; Cherub, golden amber; Golden Beverley, golden yellow; Isabella Bott, pearly white; Lady Carey, silvery rose; Mr. Cobay, ruby-red, very fine when caught in good character; Novelty, blush; Princess Teck, blush-white; Princess Beatrice, lively rosy pink; and Venus, lilac-pink.

The reflexed flowers are a very pleasing class when shown in good condition, and when disbudded they grow into large size. At the head of the list must be put Cullingfordi, which has been shown this season in fine condition, its rich bright crimson hue being especially striking. The others are Cloth of Gold, golden yellow; Chevalier Domage, bright gold, very fine; Christine, peach; Dr. Sharpe, magenta-crimson; Felicity, pure white; Golden Christine, golden buff; Julie Lagravère, velvety crimson, when it can be got large enough to show; King of Crimsons, rich crimson; Mdlle. Madeleine Tezier, white, tinted with blush; Mrs. Forsyth, creamy white; and Phidias, rosy blush. I may mention that Chevalier Domage, Christine and its varieties, Dr. Sharpe, King of Crimsons, and Mrs. Forsyth make good

exhibition specimens, being very free. To the foregoing reflexed varieties may be added Triomphe du Nord, a Japanese variety, but one of the finest reflexed flowers grown, the flowers large, full, and very handsome, and of a bronzy chestnut-rose colour.

A selection of the finest Japanese varieties will be found in the following list: Belle Paule, Boule d'Or, Baron de Prailly, Balmoreau, Bouquet Fait, Comtesse de Beauregard, Comte de Germiny, Criterion, Ceres No. 2, Duchess of Albany, Dormillon, Dr. Macary, Elaine, Fernand Féral, Fair Maid of Guernsey, Fée Rageuse, Flamme du Punch, Fanny Bouchariat, Grandiflorum, Galathée, Japonais, Jeanne Délaux, L'Adorable, L'Incomparable, Lady Selborne, Meg Merrilies, Mdlle. Moulise, Mdme. C. Audiguier, M. Délaux, M. Burnet, M. Tarin, M. Moussillac, M. J. H. Laing, M. Astorg, Margot, Mdme. de Sevin, Mdlle. Lacroix, Mons. Ardène, Peter the Great, Roseum Pictum, Sarnia, Soleil Levant, Simon Délaux, Thunberg, Triomphe de la Rue du Châtelet, Triomphe du Nord, Val d'Andorre, and Ville de Toulouse.

I have confined my selections to the three sections named. If anyone might be disposed to form a collection for blooming next season, I would recommend that they obtain cuttings as early in the current year as possible, when they may be expected to have them strong and healthy. Good cuttings may be struck singly in pots; they root all the more quickly if placed on a gentle bottom-heat, and then they can be grown on in a cold greenhouse or frame, and as they gain in size they should be shifted on into larger pots, be grown on into size in a cold frame, but they must be excluded from frost. If it is intended to grow for specimen plants, they must have the extreme points taken out when the shoots are about 9 inches high, so as to encourage the production of side shoots and form a good bushy plant. The plants can be stood out of doors in May as soon as the weather is fine enough and be shifted until they are in their blooming pots. R. D.

STEAMING V. FUMIGATING.

I wish to direct the attention of plant growers, and Orchid growers particularly, to the advantages of the practice of boiling tobacco juice in houses for the destruction of insects over the old practice of fumigating. One great advantage is that the steam does not scald nor discolour the most tender foliage nor the most delicate flower; that it can be done without previous preparation, *i.e.*, drying the foliage, &c., and that the operator can walk about in the house if necessary during the operation. I saw the practice recommended by M. Godefroy-Lebeuf in THE GARDEN two or three years ago, and have exclusively used the plan since with the best results. We have been in the habit of using an old saucepan without a lid, but this does not produce a sufficient volume of steam. I have lately converted an old copper warming-pan into a retort by screwing down the lid, and having a piece of copper pipe fastened in the middle of the lid, upright for 9 inches, and then an arm of an equal length bent at right angles: a screw valve is also fitted for filling the pan. The heat is derived from a clear charcoal fire, made in a zinc pail, which may be introduced into any house without risk of damage, as it does not either flame or smoke. This kind of apparatus, though rough, is useful for small houses, and amateurs who do not care to incur the expense of a more elaborate apparatus. A new apparatus for larger houses has been devised by a French manufacturer, which is a very simple and effective affair. No doubt it will before long be brought prominently before the horticultural public. The copper warming-pan suggested itself to me as the cheapest form of a good lasting utensil; a good one may be bought second-hand for from 3s. to 5s., and the fitting up costs about 3s.

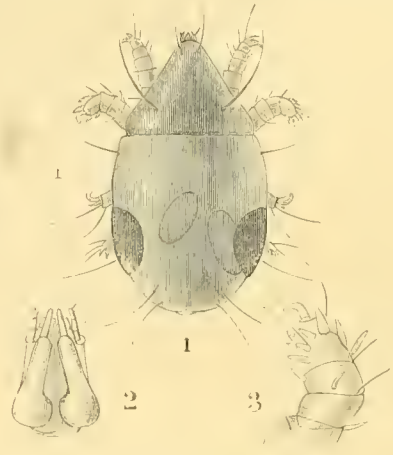
J. C. D.

Leafy Violets.—So far as soil is concerned, the Violet is very accommodating, but it likes plenty of light and air, in spite of its meekness in a wild state. True, in our market gardens hundreds of acres of plants are grown beneath trees, but not where the shading is too dense, and, of course, during the winter and spring the trees are leafless. Then Violets make better blooming crowns and less of coarse leafage where the soil is rather dry and warm. If "Inquirer" has his plants in a cool, shady position, he should divide them and replant in the sunshine. Nothing is said as to kind, but I take it for granted that the Russian or other single kind is referred to.—A. D.

GARDEN DESTROYERS.

MITES ON VINE ROOTS.

THE well-known Eucharis mite (Rhizoglyphus echinopus) now appears to be a not infrequent pest at the roots of Vines grown under glass. I have several times had Vine roots sent me for examination by persons who fancied they had been attacked by Phylloxera. These roots puzzled me; in all cases they were much decayed, but I could find no traces of Phylloxera, and I was unable to detect any cause, either from the attacks of insects or fungi, for the decay, which I then presumed must be due to something wrong in the cultivation of the Vines; but I am now convinced that they had been attacked by these mites, which had left the portions submitted to me for less decayed parts. Another batch of



Root mite. Fig. 1, mite; fig. 2, mouth of do.; fig. 3, foot of do. All magnified.

roots was received by me the other day exactly resembling those previously sent. I was more successful, however, this time, for on examining one of the roots with a pocket lens I detected a small mite, and immediately searched carefully for more on another of the roots. I found them in considerable numbers. These mites are somewhat difficult to recognise, as they are so much like grains of sand both in size and colour. They are, however, rounder, smoother, and more glistening. When once detected they may be readily distinguished from the grains of sand which adhere to the roots. Mr. Andrew Murray, writing on these mites, or rather on a closely allied species (Rhizoglyphus Phylloxeræ), in his work on Acari, &c. ("Economic Entomology Aptera"), says: "M. Planchon, in his work on the American Vine, and Mr. Riley (*loc. cit.*) record the presence of this allied species in North America. They found it in association with the Phylloxera of the Vine, feeding in its young state on the juices of the roots injured by Phylloxera, and when older preying extensively on the root-inhabiting type of that insect. Mr. Riley mentions that when this fact was published it was hoped that the introduction of the Rhizoglyphus into Europe might be of service in reducing the numbers of Phylloxera, and he received orders from Vine growers in France for a supply of the cannibal. Mr. Riley, however, though he endeavoured to comply with the request, did not anticipate much good, in which we agree with him, chiefly because they have already in France associated with the Phylloxera a Rhizoglyphus, which we believe to be the preceding species (R. echinopus), and the one should be as good an exterminator as the other, if that class of mites did really feed upon other insects; but the statement of Messrs. Planchon and Riley to that effect has been viewed with doubt by some French entomologists. Mr. Riley is well known to be a careful and accurate observer, and any statement of his is entitled to great weight, but, like all of us, he is liable to error, and may have been deceived (as sometimes happens) by abnormal conduct under abnormal circumstances.

"There are many instances of insects that are vegetable feeders having eaten their neighbours when shipwrecked into an entomologist's box or breeding cage. Dr. Fumose, who has studied the habits of the Tyroglyphi more than any other living naturalist, objects to the idea, as being opposed to the habits of all Tyroglyphi, which never attacks living animals, and, further, because, although not rare in France on Vine roots attacked by Phylloxera, there never has been any appearance of their number being diminished by them. It is, moreover, opposed to the habits, so far as hitherto known, of the section of Tyroglyphi to which it belongs, for that section feeds exclusively on vegetable food." From this extract it appears that these mites are often found with Phylloxera, but I quite agree with Mr. Murray that it is improbable that they are habitually carnivorous. The mites are evidently feeding on the roots I have just examined, which, as far as I can see, show no trace of Phylloxera or any other insect on which they might have fed; from the manner in which they are buried in the decaying roots there cannot be, I think, any doubt but that they live at the expense of the Vine. Whether they are the immediate cause of the unhealthiness of the roots, or whether they only infest roots which are in that condition, is a more open question; but from the way in which they attack otherwise apparently healthy bulbs, I must say I am of opinion that they are the direct cause of the decay of the roots.

Vine-growers will, I have no doubt, say this is all very fine, but we want to know how to destroy this pest. Well, I am sorry to confess I cannot help them. These mites are very hard to kill, and it is hopeless to try and destroy them by watering the Vine borders with any insecticide I am acquainted with. Even if the Vines were lifted and the roots cleaned and soaked in some insecticide which would kill the mites, it is very doubtful if their eggs would be affected. If the injury to the Vine is very great, the Vine had better be destroyed, and great care must be taken to ensure the removal of all the soil that can possibly contain any of the mites. Water at a temperature of 115° Fahr. will kill them; would it injure the roots? A figure and description of this mite was given in THE GARDEN of the 28th March, 1885. G. S. S.

Spicer's Lady's Slipper.—I send for inspection a two-flowered spike of Cypripedium Spicerianum, cut from a plant that has produced similar spikes for three years in succession. This year it has three two-flowered stems and one solitary flowered one. Our plant was a very small one, in a 2½-inch pot when it first came from the nursery, about four years ago.—C. R. BICK, *Harborne Hall, near Birmingham.*

On the spike sent were two fine flowers, the footstalks of which were sufficiently long to display the beauties of both without crowding. C. Spicerianum seldom produces two flowers on a spike, and if yours does so regularly, it will be valuable.—ED.

ORCHIDS.

Phalænopsis Sanderiana.—A spike of this lovely Moth Orchid, received from Mr. Partington, amply confirms all that has been previously said in its favour; the flowers are upwards of 3 inches across, round in outline, and of a beautiful soft rosy mauve colour, the base of the lip being stained with orange.

Phalænopsis grandiflora.—We have received from Mr. C. J. Partington, Heaton House, Cheshunt, a very fine spike of this Phalænopsis, cut from a plant bearing thirteen large leaves. The spike in question is some 2 feet long, with three lateral branchlets bearing in all forty of its pure white flowers, slightly stained at the base of the lip with yellow; each bloom measures upwards of 3 inches in diameter.

Cattleya Dowiana aurea.—A very fine variety of this gorgeous Cattleya is at the present time one of the chief attractions in the Orchid houses of Mr. Southgate, Selborne, Streatham. The sepals and petals are deep primrose-yellow, the large frilled lip being rich purplish crimson in front, whilst the basal part is primrose-yellow streaked with lines of gold. This plant requires more heat than the majority of Cattleyas, and the variety here named is a more profuse bloomer than the normal C. Dowiana. It lasts a very long time in full beauty.

Cœlogyne barbata.—This species is apparently bearing out the description of Lindley, although some of the earlier introduced plants produced flowers small in size and poor in appearance. We have, however, recently seen a plant in Mr. Southgate's collection at Streatham bearing erect racemes of large flowers, the individual blooms measuring some 3 inches in diameter; the flower is pure white, saving the apex of the bearded lip, which is greyish brown. It is a native of Northern India, and thrives best under cool treatment.

Cypripedium Mooreanum.—This provisional name was given to a new hybrid Lady's Slipper, now in bloom in the Victoria Nursery, Holloway. It is a showy variety, and a valuable addition to winter-flowering Orchids. The foliage of this plant is very long, strap-shaped, and of a uniform green tint. The peduncles, which are upwards of a foot high, are single-flowered. The dorsal sepal is erect, long and broad, snowy-white and plain on the margin, the central part being ornamented with numerous large round spots of reddish brown. The lower sepal is also large, white, and streaked with lines of reddish brown dots; whilst the petals and small pouch-like lip are light brown.

Orchid prices.—The following are a few of the highest prices realised at Messrs. Protheroe & Morris' sale in their City auction rooms on November 5. Calanthe Sanderiana, £1 14s. 6d.; Cattleya labiata, the true autumn-flowering variety, £35 14s.; another plant of the same variety, £7 7s.; Angræcum Chailluanum, fine imported mass, £10 10s.; Lælia elegans, £8 8s.; another plant of the same variety, £5 5s.; Cypripedium œnanthum, £6 5s. 6d.; Cypripedium Arthurianum, £15 15s.; Aerides Ballantineanum, £9 19s. 6d.; Cypripedium œnanthum superbum, £12 12s.; Aerides Wilsoni, a new pure white-flowered variety, £11 11s.; Cœlogyne Massangeana, £6 16s. 6d.; Aerides Lawrenciæ, £12 1s. 6d.

Forms of Cypripedium Spicerianum.—If any good could come of naming chance forms of species, especially Orchids, one might find material to work upon in this Lady's Slipper, which has been introduced in such large quantities. In a large collection of plants one might single out at least a dozen forms more or less distinct. For instance, in Messrs. Veitch's nursery, Chelsea, there is a house nearly filled with this Orchid, and most of the plants are in flower. Three of these we consider very distinct, and as their distinguishing characters appear to be permanent, they might well receive varietal names. There is one plant which persists in producing pendulous flower-stems, which hang on all sides of the plant, and as it flowers like this every season, the plant, a large specimen, has been placed in a suspended pan so that the flowers may be seen. Another large plant always produces twin-flowered stems. There are about half a dozen stems on it at the present time, all bearing two flowers. A third form is very marked in respect of colour, the dorsal sepal being heavily stained with purple on the reverse side, and the flower is altogether larger and brighter than the rest. Several others less distinct may be found in this large collection.

Lælia porphyrites.—From the gardens of Mr. Day, at Tottenham, comes a flower of this elegant species. It belongs to the L. Dayana and L. præstans section. The pseudo-bulbs, however, are said to be much longer than those belonging to either of these plants, and the leaves are larger and broader. The flowers about equal those of L. præstans in size; the lip is, however, very different in shape, and the throat is more open, the front being rich purplish crimson, whilst the sepals and petals are lilac-mauve.

Cypripedium Lindleyanum.—This remarkable species appears to belong to that section of Lady's Slippers of which C. Roezli may be taken as the type. The plant in question has broad, long, deep green leaves, narrowly bordered with yellow. The peduncle is about 2 feet high, furnished with several large boat-shaped green bracts. The flowers are densely clothed with woolly hairs; in colour they are pale nankeen-yellow, tinged with green, regularly streaked with Indian red, the mouth of the pouch being densely spotted with the same colour. We saw it recently in the Victoria Nursery at Holloway.

The hybrid Phalænopsis.—The beautiful hybrid Phalænopsis which has proved to be identical with the P. intermedia Portei is again in flower in Messrs. Veitch's nursery at Chelsea, where it was raised by Mr. Seden. It is the result of intercrossing P. amabilis and P. rosea, both of which may be also seen in bloom. The hybrid is precisely intermediate, the flowers being white with a beautiful vinous-purple lip, while in size they are intermediate between the parents. This is without doubt one of the most interesting and valuable hybrid Orchids yet produced, and it proves conclusively that hybrid Orchids are introduced and regarded in the light of true species.

Orchids at Croydon Lodge.—Mr. Stephenson-Clarke's collection is now gay with bloom, the principal kinds being Dendrobium Dearei, its beautiful white flowers being much in demand for buttonhole flowers; Dendrobium formosum giganteum, the ivory-white blooms of which are very conspicuous; whilst the lovely D. bigibbum appears to be a perpetual bloomer. Amongst Oncidiums, O. Rogersi, with its large yellow lip, is very brilliant; so also is O. varicosum, O. cri-pum, and O. ornithorhynchum. Of this latter plant there are two varieties here, one producing a much shorter and less branching spike, with flowers double the size of the ordinary form. The butterfly-like flowers of O. Krameri are very pleasing, and contrast admirably with such plants as Vanda cærulea and V. suavis, Cattleya Loddigesi, Cymbidium Mastersi, and Cypripedium Sedeni. Amongst old and seldom-seen Orchids we noticed numerous plants of a good variety of Burlingtonia decora, Brassavola nodosa, and the curious Scuticaria Steeli; but the great feature of the place is the brilliant display of Indian Crocuses (Pleiones). They are grown in small pots, in large pots, and in pans, producing hundreds of flowers.

Orchids at Holloway.—Amongst Orchids in bloom at Mr. Williams' we specially noted the following the other day, viz., the charming Odontoglossum Rossi majus, a fine specimen bearing some thirty flowers, and several examples of the beautiful Cattleya Dowiana aurea; it is to be hoped that some method will be discovered by which this species may be made to produce its flowers in greater abundance than it has hitherto done. Another shy-blooming Cattleya, C. gigas, is also displaying its beauties, and contrasting beautifully with the pure white Lycaste Skinneri alba and the blue Vanda cærulea. A highly coloured form of Lælia elegans, called prasinata, is valuable as a winter decorative plant; so also is the rare hybrid Cypripedium called Sallieri, a cross between C. villosum and C. insigne. Amongst seedlings from Cypripedium Harrisianum there are some remarkable variations in colour, one in particular being very noticeable for the intense deep colour of its polished flowers, whilst the lovely C. Sedeni and its variety candidulum and C. cardinale appear to be ever-blooming. The free-flowering Oncidium tigrinum is also very showy, and its flowers fill the air with a delightful fragrance. The shy-blooming Odontoglossum Londesboroughianum is also now in flower. Here, too, are many varieties of that beautiful Dendrobium from New Guinea, D. superbiens, which, although resembling D. bigibbum in habit and being usually found growing in company with it, is nevertheless abundantly distinct when in bloom. Cœlogyne Massangeanum is a beautiful plant for hanging baskets; a specimen here bears five spikes upwards of 2 feet long, each spike bearing some twenty-six flowers of a creamy white colour, the lip being blotched and fringed with cinnamon-brown. Other Orchids here contributing to the November display are the grand old Cymbidium giganteum, a fine form of Oncidium incurvum, called albo-purpureum, Angræcum Leonis, Maxillaria grandiflora, Sophronitis grandiflora, Cattleya maxima, and C. Dormanniana, Lælia Perrini, and the lovely little Trichocentrum orthoplectron, which differs from its near ally, T. albo-sanguineum, in its lip being quite flat and wholly rich purple, with just a tinge of yellowish white in the centre.

BORDER CARNATIONS.

WHAT are border Carnations? may be a fair question to ask. Are not all Carnations adapted for cultivation out of doors? Yes, if circumstances are favourable. But what are understood to be border Carnations are selfs and fancy varieties. They are much more hardy than bizarres and flakes. Take that fine old scarlet bizarre, Admiral Curzon, as an illustration. If, say, six plants of it are grown either in pots or planted out, and two of them retain their original form, displaying the two colours, maroon and scarlet on a white ground, two of them may lose the white and show on their petals the maroon and scarlet only, while two more may produce wholly self-coloured flowers. This is no fancy sketch, as this variety produces all the above in one season, and the plants that have self-coloured flowers will grow the strongest, and their foliage will be the darkest. The variety with two colours from which the white has been discharged will also grow stronger than the original form, and this holds good all through the various classes. Take, for instance, the old-fashioned crimson Clove; it is as hardy as any plant grown in the garden. I have known it for more than thirty years, and cannot see that its constitution has been impaired during that time in the least. It requires no special treatment, producing its bold handsome foliage in ordinary herbaceous borders, and fighting for a place with the strongest of its associates. Many admire this and other self-coloured Carnations in large beds or masses. I greatly admire them when the beds are well placed and in harmony with their surroundings. When employed in a very old garden north of the Frith of Forth, at least thirty years ago, part of my duty was the charge of two beds of Cloves, containing hundreds of plants. The low old mouldering garden walls were Moss-grown, and covered in places with the Wall-rue Spleenwort and the Ivy-leaved Toad-flax. Masses of dark-foliaged Rhododendrons and old Ivy, quantities of the true East Lothian Stock and other sweetly perfumed flowers, and Lavender and Rosemary were all established in the borders—a sort of Corisande's garden, in fact. Here we obtained the best blooms of our Cloves the second year. The first season the bed was formed of good, strong, well-rooted layers, planted 18 inches apart. These produced good flowers, but in no great quantity. In August they were layered. Each plant would produce from six to twelve layers. A slight mound of sandy soil was placed round the base of each plant; into this the layers were pegged. This mound would be about 2 inches higher than the surface of the bed. Late in autumn the entire surface of the bed would be raised as high as the mounds by means of a mixture of equal parts loam and decayed manure. This rich dressing had a most beneficial effect upon the plants. The layers were not in any way disturbed; they were allowed to flower where they were, and the quantity of flowers produced was truly astonishing. The beds were destroyed after the second year. Masses in borders may be treated in the same way. An interesting and instructive way of growing border Carnations is to raise seedlings.

Seeds produced from the best show varieties can be purchased from the principal seedsmen, but seedlings cannot be depended on. I save my own seeds, and we are very careful as regards the crosses; indeed, one would scarcely believe that such results could be obtained as we are able to note year after year. For instance, I wanted to raise some improved light purple-edged Picotees, and the method adopted was to take the two best varieties we had, Nymph and Her Majesty. Both are pure white, with the exception of a very narrow edge, like thin wire, of a purple colour, on the outer petals. The flowers were fertilised both ways—the pollen of Nymph on to the stigmatic portion of Her Majesty, and *vice versâ*. Now for the result. Amongst the seedlings there are a few light-edged purple Picotees, but a large proportion of them are of the most vigorous character, producing large, well-formed purple self Carnations. A peculiar buff ground Picotee produced rose self coloured Carnations. Florence, buff-coloured border Carnation, produced two flowers of the same colour, but many rose and white selfs. We cannot—or at least do not—try to shut out the bees from enjoying the sweets of the Carnation bloom, and to their agency may be attributed the changes to which I have just alluded. All our Carnation and Picotee seeds have been saved from artificially fertilised flowers. We continue the work of fertilisation all through the flowering period, and the seeds are mostly all gathered by the second week in October. The pods are carefully dried, and are stored in a dry place until the seeds are wanted to be sown in April. Sow in pans or pots in frames over a gentle hotbed. The seeds would probably vegetate in the open ground, but a larger proportion would germinate under glass; when it is a question of raising a few hundreds of plants only, it is easy enough to take extra pains with them. In ten days the plants will be up, and in ten days more ready to be pricked out into boxes about 2 inches from each other. They should be kept in a frame until they are well established, when the boxes may be placed out of doors in an open situation. The plants should be placed where they are to flower about the first week in June. They should be planted in rich deep soil at a distance of 18 inches plant from plant. Each plant will produce a large head of bloom the following season, some of them as many as 200 blooms. All of them will be different from each other, and only about one in ten will produce single blooms. Some varieties will produce flowers with ten and others with a hundred petals. Between these there will be all sorts and sizes, but twenty petals is a sufficient number to constitute a perfect flower. Small strap shaped petals in the centre are a disfigurement. A florist's bed of striped Carnations and edged Picotees is his delight. Those who prefer the rich colours and delightful fragrance of the old Clove, and the wonderful variety of colour and fragrance in border Carnations, may enjoy to the full their beauty and fragrance. I recommend their culture in masses or beds, each colour by itself, so placed as to harmonise with its immediate surroundings, but in such a position that the plants may receive plenty of light and air, with, if possible, some kind of shelter to break the force of east and north winds. Where our Carnation layers were exposed to the full force of these winds last year they were nearly all killed in February, while those sheltered from the north-east by a thick hedge were safe.

As to varieties of border Carnations, the Bride, Bridesmaid, Virgo, and W. P. Milner are white varieties of the best description. The Governor blush white, Edith and Lady Cathcart are good yellows, and Florence is a good buff. Rose and pink varieties are best represented by Annie Williams, Gertrude Teigner, Mary Morris, Mrs. Teigner, and Mrs. Whitmore. Field Marshal is an excellent crimson-rose, Fire-eater a pure rosy scarlet, Coroner bright scarlet, Albert and Purple Gem valuable purples. Fancy varieties succeed well out-of-doors, and are, as a rule, merely sports from the usual bizarres or flakes. Titania is a lovely variety, flaked with very delicate pale rose, Grand Master crimson and maroon; Lord Stamford and Lady Stamford are also pretty border flowers. The flowers of the fancy type, usually seen at exhibitions, are merely sports which the exhibitors find amongst their ordinary stock. Any quantity of new varieties can be obtained in this way, but many growers do not care to propagate them. D.

AMERICAN NOTES.

Canadian and American Apples.—Mr. P. Barry writes to us from Rochester, U.S., as follows: "I suppose you saw the great show of Canadian Apples. I see the *Journal of Horticulture* states 'that as regards freshness and general good appearance, the English fruit, as a whole, was markedly superior to the Canadian Apples shown at South Kensington.' I am not surprised at this, because the majority of Canadian cultivators, like our own, are poor and bad. These Canadian specimens were picked up at the various shows by Prof. Saundey, and he had to take them as he found them, and, besides, they had been very much more handled than the English specimens. I have just examined a small collection of Apples grown in Arkansaw or Arkansas In size and beauty they are marvellous. Among them are Ben Davis, Shockley, Willow Twig, Lawver, Shannon, Rome Beauty, M'Afee, well-known western and southern sorts, besides many I had not seen before, local sorts."

A new method of glazing.—It is well known that all glass now (both in portable sashes and in fixed greenhouses) is simply imbedded in putty, and kept in its place by glaziers' points, no putty being now used on the top, as was formerly done. It has been found that when the glass lies on the sash-bar thus imbedded, the putty soon rots or wears out, and water gets in and not only loosens the glass, but rots the bar as well. A simple plan to obviate this is to pour along the junction of the bar with the glass a thin line of white lead in oil, over which is shaken dry white sand. This hardens and makes a cement that effectually checks all leakage. It is quickly done. I have seen glass so cemented that has stood for ten years still in perfect order, and it looked as if it would stand for ten years more without further repair. This plan, which is but little known as yet, is of the greatest importance; had I known of it thirty years ago I would have saved many thousands of dollars in repairing, besides having the plants under this water-tight glazing in better condition.—Peter Henderson, in *American Agriculturist*.

American Blackberries are certainly as easily grown as Raspberries, and come in as a table fruit when there is need for something to take the place of the earlier fruits. As a conserve and cordial they are excellent and much in demand as a pleasant astringent. A dry soil does best for them; it does not require to be rich, but as the plants require more room than Raspberries, the rows should be at least 6 feet apart. In pruning, which should be done after the fruit is gathered, strong leather mittens and a pair of shears with long handles are a great help. The best plants are raised by root-cuttings, and a very large number of plants can be made from the roots of one good stool. If a variety is scarce, it can be cared for in a propagating house by cutting the root into pieces less than an inch long, mixing with sand, and keeping in moderate heat. When a callus is formed, place some fine earth composed of leaf mould and sand in a temperature of about 80°. They can be potted singly when 6 inches long. The old Lawton has been replaced by Kittatinny and Wilson's Early; the latter, as its name implies, is an early variety, as is also the Snyder, which is very productive and hardy, but the fruit is small, though sweet. Wachusett Thornless we have discarded, after a fair trial, as unworthy of cultivation, but Taylor's Prolific, a late, medium-sized berry, is worth a trial, as is also a new fine variety called Early Harvest, of which, however, I cannot speak as yet with certainty until it has stood the test of another winter. I have also received a plant for trial of Minnewaska that made great canes last season, but it has not yet fruited. For profit, the Blackberry does not stand so high as the Raspberry, but often the yield per acre makes the returns average higher. Pickers do not, as a rule, agree so readily to gather Blackberries as other fruit, on account of the fierce scratches that they sometimes give, and the rents that are made in their clothes. There is a running Blackberry (R. canadensis), popularly known as Dewberry, to which horticulturists object, on account of its straggling propensities. Its fruit is, however, large, ripens early, lasts long, and is excellent in quality. My own experience goes to prove that it is the Concord among the Blackberries, and not to be despised, and I think the time is coming when this fruit, in its finest varieties, will be better known and find more favour in our markets than it has hitherto done.—A. L. Jack, in "Report of Montreal Horticultural Society."

The American Mist tree.—According to Mr. Falconer, in the *Country Gentleman*, this grows much faster than the European Rhus Cotinus. It is one of the rarest of American plants, for though long ago discovered and described by Nuttall as Rhus cotinoides, it has only just found its way into cultivation. Our largest plant is 6 feet high, of pyramidal form, very branchy, and 6 feet in spread of branches. We have several plants, now two years planted, and they seem to be hardy enough; in some cases the tips of the young wood get winter-killed.

The Spitzenburgh Apples.—Having often wondered what could be the parentage of our renowned Spitzenburgh family of Apples, which includes the Red Canada, Jonathan, Northern Spy, Esopus, and Newtown Spitzenburghs, I am now of opinion that the Herefordshire Pearmain is the prepotent parent. The Herefordshire Pearmain is an old English variety, and if the Apple I know by that name is the true English sort, it is to me the finest in quality of all imported Apples I know. Permit me to trace some of the points of similarity of tree and fruit between the Herefordshire Pearmain and those of our Spitzenburgh family. In tree the Herefordshire Pearmain is an upright, rather slender, moderate grower, with smallish, rather whitish or downy leaves. The Herefordshire Pearmain tree is rather tender in cold climates, is very productive, does not succeed in many locations, and drops its fruit early. In fruit, the colour of the skin and flesh, the fineness and firmness of grain, the delicious flavour, the keeping quality, and the liability to scab of the Herefordshire Pearmain are all more or less manifest in the Spitzenburgh family. In the great awakening in favour of hybridisation and the production of more hardy choice winter Apples, especially from seed, the Herefordshire Pearmain should not be neglected.—F. K. P., in *Country Gentleman*.

J. O.—"Vines and Vine Culture," by A. F. Barron, Royal Horticultural Society's Gardens, Chiswick.

Names of plants.—*W. Spencer.*—1, Pernettya mucronata; 2, Retinospora plumosa aurea; 3, Cupressus Lawsoniana; 4, Ruscus racemosus.——*T. B. Field.*—1, Chlorophytum orchidastrum; 2, Iris fœtidissima; 3, Saxifraga ligulata.——*H. D.*—Orchid is Calanthe vestita luteo-oculata; other is one of the many varieties of Tydæa ——*T. C. D.*—1, Cotoneaster frigida; 2, Euonymus europæus, and white-fruited variety.——*S. T.*—1, Asplenium viride; 2, A. Trichomanes; 3, not recognised.

Naming fruit—*Readers who desire our help in naming fruit will kindly bear in mind that several specimens of different stages of colour and size of the same kind greatly assist in its determination. Local varieties should be named by local growers, and are often only known to them. We can only undertake to name four varieties at a time, and these only when the above condition is observed. Unpaid parcels not received.*

Names of fruits.—*S. H. B.*—Pitmaston Duchess.——*Rex*—1, Seckle; 2, Marie Louise; 3, cannot name; 4, Cox's Orange Pippin.——*M. T.*—Beurré Bosc.——*Devon*—None in a fit condition for naming: please observe our rules for naming fruit.——*A. B. C.*—1, Doyenné du Comice (fine fruit); 2, Beurré Superfin.——*T.*—Only one fruit of each sent; see rule.—*W. J. Clarke.*—There is no fee for naming fruit, but you must follow our instructions given above. 2 and 4 look like Beurré Diel and Marie Louise respectively; but we cannot name with certainty when only single unripe specimens are sent.——*E. S. Elham*—1, Glou Morceau; 2, Beurré d'Aremberg; 3 and 4, not recognised.——*J. S. C.*—1, Lord Derby; 2, Gascoigne's Scarlet Seedling; 4, Cellini.——*C. H. S.*—6, Queen Caroline; 8, Bridgwater Pippin; 9, Orange Pippin; 15, Flower of Kent.—*A. G.*—Conseiller de la Cour; 2, Beurré Bosc; 3, Glou Morceau; 4, Mannington's Pearmain.——*C. M. R.*—Royal Russet; Welford Nonsuch.——*J. Chawner.*—Beauty of Kent.——Others next week.

WOODS & FORESTS.

NOTES.

TIMBER-MEASURING INSTRUMENTS.—One could hardly suppose that the writer of the paper on measuring standing timber (p. 399) intended to convey the impression that the instruments of which he speaks are, or are ever likely to be, employed to any extent in actual valuations. They, of course, display on the part of the inventor an intelligent application of geometrical principles, and may occasionally be useful in determining the height of a single given tree or other object of which it was desirable to know the altitude; but to assume that in the practical business of ascertaining the contents of standing timber, when, as often is the case, the dimensions of hundreds of trees have to be taken in a single day, such apparatus will be anything but a hindrance and cumbersome to carry about will be contrary to the experience of most of such as have had the work to do. This, at least, would be the conclusion of foresters in the part of the country from which I write. It must be conceded, however, that the character of the timber which has to be operated upon will have something to do with its admissibility. When the bulk of the timber which has to be valued grows in or around fields or in open forest, it is pretty certain that very few contiguous trees will be of the same, or even of approximately the same, height. To use either of the meters under such conditions would occupy more time than would suffice to finish the whole valuation in the ordinary way. In the case of plantations, where the uniformity of height would be likely to be greater, the same would be true if the trees were capable of being measured by the aid of a light ladder and rod. The only conditions, therefore, under which I look upon these instruments as being of practical use are when plantations of very tall and fairly uniform trees have to be estimated. In such instances perhaps a tree here and there along the margins could be selected and the instrument used to ascertain its height, as a check upon the rod and the eye. The great thing, however, in all classes of timber measuring is simplicity, and the simpler the methods the greater is the chance of accuracy.

MEASURING-RODS. — These have to be of two kinds according to whether the timber has to be measured standing, or after it is felled. In the case of standing timber it has of course to be much longer than is necessary for felled trees. The form which it takes is very much a matter of taste; the principal thing to guard against is too much elaboration. When a rod has to be transported from place to place, *i.e.*, over greater distances than it is convenient to walk, it is perhaps better to have it in parts, but when a valuer is not too particular as to this portion of his outfit, it is generally easy to cut a rod on the spot where the work has to be done, which will answer the purpose nearly as well as one which has been purchased, or especially prepared for the purpose. There is one drawback about rods cut for use just for the time being; they are generally too heavy, as to get them of sufficient length they are too thick in diameter. A jointed Bamboo is extremely portable. A plan which I have seen adopted when the operator scarcely liked to trust to his eye alone for the girth of a tree, and yet felt it unnecessary to despatch men up the tree, like able-bodied seamen up a mast, is to fix a short rod of known length and marked distinctly in a few places transversely to the top of the rod used for measuring the height. With a little practice this may become a very fair guide as to quarter girth, and can be adapted to the class of trees about to be measured. A word about the rod for measuring when trees have been already felled. Some use tapes for taking lengths, and when the ground is fairly clear and there are plenty of hands available, it is perhaps the quickest way. When, however, I am measuring single-handed, I infinitely prefer a 5-feet rod. This is especially so in wet weather. The past week has been a very fair sample of measuring under difficulties in this respect, and I think those who recommend complicated apparatus would do well to devote a little of their time to the woods under such circumstances. I have had occasion to be at the work myself during the last few days, and I think that anything beyond the simple rod I generally use would have put the finishing touch to the not very pleasant business.

ROUGH BOOKS.—The book, of which an illustration is given in the further remarks on measuring (p. 443) would be an admirable thing in its way, if time when in the wood or field were no object. As it generally is, with the book as with other things in measuring, simplicity is the thing to aim at. In taking rough notes of measurements when outdoors, the briefer they are, so long as understood, the better and more accurate they are likely to be. When a book in which the first notes of measurements are taken is made too complicated, errors are likely to arise, as the mind, when engaged in accurately gauging the contents of a tree, cannot well at the same time be occupied with a maze of columns in a book. Taste will be sure to vary as to the actual size and form of the rough note-book which goes to the wood. One weighing a couple of ounces, and ruled plain without columns, is what I mostly use, and, considering that other things have to be carried in the hand, and that the book is sure to become soiled with use outdoors and the pages blurred by rain, it seems to me much more reasonable that the permanent record of the work should be made in a book of suitable character which is never taken outdoors.

TAPE *v.* STRING.—It appears that this cause, in which on the conclusion of arguments by counsel the verdict was given for the defendant, has to be re-heard. At least this is what I gather from diametrically opposite views having been expressed upon it by "Yorkshireman" and "Young Forester" (pp. 465-6). The readers of these pages, it is to be hoped, are not very fond of litigation, but as this cause is one which has a practical bearing upon foresters' work, it cannot be without interest. As I have personally no animus either against plaintiff or defendant, but claim to be a speaking acquaintance of both, I hope to be permitted to say a few words upon it. The term "tape" seems redolent of Chancery Lane and the Stock Exchange, whilst its humble opponent can claim no such distinction. It will at once disclose how far we are behind the times if I confess that the string is still in use here. Joking, however, apart, I think "Yorkshireman" is too sweeping in his remarks upon the string. If I read him aright, the common woodman's tape is that with which we have been familiar from childhood, usually a chain in length, marked on the front in feet and inches and on the back in links and perches. I have mentioned elsewhere that these tapes may be properly employed in taking lengths when there are spare hands to manipulate them, but I cannot say that I am so well satisfied as to their suitability in taking girths. When "Yorkshireman" speaks of the common woodman's tape as a ready reckoner, I presume he refers to the reading off of circumferences in inches without having recourse to rules. So far, so good, but is there one tape in half a dozen which is accurate enough for reading off girths without testing by means of a rule. My experience is that there are very few which do not vary in tension, and are therefore more or less incorrect. In taking lengths a few inches amount to but little, but in taking girths it is a serious matter. Then, as "Young Forester" says, there is often a difficulty in getting tapes round trees where the string would readily enough go, and if it can be got under at the expense of considerable trouble it is impossible to saw it through obstructions in the way in which it can be done with string. If I were running through a lot of timber which had, for instance, to be submitted to auction, but of the value of which it was necessary to form a rough estimate, I would as readily use a tape or strap as anything else, but if I aimed at accurate measurement, I should certainly use a string. Perhaps "Yorkshireman" would be surprised to hear that the railway company's measurers in this part of the country use string, so that, like Sam Weller's, though his knowledge may be extensive and peculiar, he is occasionally wrong in his conclusions. Speaking of the strap; with standing timber it is very useful, as using string to encircle objects horizontally is practically impossible, and a tape, unless of steel or some comparatively unyielding material, is but little better; therefore, I take it that for reliable results the forester should confine himself as much as possible to the strap for standing and the string for felled timber.

D. J. YEO.

HINTS FOR WILLOW PLANTERS.

NEVER transplant a Willow, says Mr. Scaling, if a cutting can be used, for all Willows succeed better from cuttings than they do from rooted plants. After planting, keep them clean; never allow weeds to choke or overpower them. No Willows do well in water-logged land, nor in peat bog, nor in dry, sandy soil. The best soil for an Osier plantation is a strong loam, and the most favourable position where they can be flooded at will and yet the land be well drained. In England, Willows may be planted at any time from the middle of November to the end of March. If practicable, break up the ground by a steam cultivator, which is cheaper than ordinary trenching and quite as good. This should be done early, to ensure the ground being in good condition for planting, for if cuttings be stuck into unbroken clods, failure may be expected. In planting basket Willows secure, at whatever cost, the best sorts, and free from mixture, taking care the species is suited to the soil and adapted to the market; it is false economy to plant whatever comes convenient (a mixed crop is always of small value), and a Willow plantation in suitable soil will last from fifteen to thirty years. When cuttings are planted with the view to grow into timber trees, cut to the ground, at the end of the first season, all crooked and defective shoots, for the first year's shoots seldom grow straight enough to be allowed to stand for timber trees. Protect all young plantations from ground game, for even the buds of the Bitter Willow are not proof against the attacks of rabbits or hares.

Never pollard a Willow; pollarded Willows decay, and, in that state, harbour destructive insects; better and straighter poles are obtained by cutting to the ground. Willows make good wind screens or nurse trees; and the long-leaved Sallow or Salix acuminata stand well on the seacoast or other exposed situations. Some of the varieties of this species make good poles for fencing or general farm purposes, but they are not otherwise commercially valuable. After cuttings are put into the ground let the latter be firmly trodden down around them; many cuttings die from this being only partially done. Do not plant little corners with basket Willows and expect such scraps to pay; it would be just as reasonable to plant a rood of ground with Wheat and expect to make a profit out of it. If such bits are to be planted, plant to obtain poles or timber. In this form they will pay well, but they can never pay to cultivate for basket Willows. Willows will grow on land occasionally overflowed by salt water, provided it is suitable in other respects. In collecting Willows for scientific observation or classification, avoid decision until you have grown them in a trial ground and compared them with others similarly situated, Willows being so much altered by soil, situation, and climate as to be unrecognisable even by those who have studied them for years. If this plan be adopted, much of the confusion that now exists will be avoided, and many of the so-called species will be found to be only varieties.

Banks of rivers planted with Willows are of great value in preserving the soil from being washed away, by reason of the grasp and tenacity of their fibrous roots. At the present price of cuttings and labour, the outlay for planting basket Willows, including everything, may be stated at 25s. per 1000 cuttings, which at 20,000 cuttings per acre—the ordinary quantity—would be £25, and, under very exceptional circumstances, this may be taken as the ordinary

cost of forming an Osier plantation. The importance of planting quick-growing timber trees in a country so limited in area as ours is admitted; and the Willow is not only one of the best trees for this purpose, but no wood sells more readily, nor is so difficult to obtain, nor will yield a greater return. All cuttings should be pushed from 8 inches to 10 inches into the soil, and in a slanting direction. The number of cuttings required for an imperial acre is as follows: 18 inches each way, 19,360; 24 inches, 10,890; 36 inches, 4848; 48 inches, 2722.

How timber is valued.—While there are wood agents who never undersell the trade when they do deal with consumers, and who do endeavour to get the best market price going for their timber, there are others who simply value their timber by what they think their neighbours are getting for it, and then underbid them. Example: All over this district, South Yorkshire, sellers have been quoting Larch at from 1s. 1d. to 1s. 3d. per foot, delivered to the purchaser, for some time back, and they have been systematically underbidden by wood agents about forty of fifty miles away. What these agents get for their timber will be reckoned when I state that it costs them at least ½d. per foot to fell it, from 1½d. to 3d. per foot to deliver it at the nearest station, and from 5d. to 6d. per foot to deliver it by rail in this neighbourhood to timber merchants, who get at least 1d. per foot out of it; total average cost about 8½d. to 9d. per foot, leaving the grower about 3d. per foot or less—about the price of Spruce—with discount for cash. Larch has dropped here lately, and I quoted 1s. 1d. per foot for it delivered the other day, and was underbidden the following morning by a timber merchant, who gets, he says, as much as he wants from North Yorkshire, in the Helmsley neighbourhood, for almost any price he likes to offer. I presume the Larch under such circumstances is not valued at all, but simply sold for what is offered. The consequence is that we have determined to keep our Larch, and let those *give it away* who choose to do so.—Y.

Cutting Arris rails.—According to dictionary definition, an "arris" is "the line or edge at which two bodies forming an exterior angle meet each other." I am afraid, however, that if an ordinary sawyer who had never seen an arris rail was instructed to prepare some on this basis, he would not be very clear as to how he was to set about it. Without the help of a simple diagram it is not so easy to explain the way in which these rails are cut, but as they are largely used in park and similar fencing, a word or two will not be out of place. The manner of cutting will depend a little upon the size and form of the timber from which they are to be prepared, and also whether sawn by hand or steam power. When sawn by hand power, the easiest and most expeditious way is to select small round trees of the required length and of suitable diameter, say 8 inches or 9 inches; hew them up to an eight-sided figure, and then cut the log first into halves, again into quarters, and finally each of the quarters again through the middle. This gives eight rails from a single round piece and cuts it up without waste. When required for use, the ends are simply reduced by a small axe to the size of a mortice in the post, with the broad side of the rail to receive the palings, the longest and most acute angle of the rail being of course fitted upwards, so that the wet may at once run off. When the rails have to be cut from larger timber or from planks, their form is slightly different, unless an extra cut is run. In either case the material must be sawn to a square. The simplest form of rail will then be by taking a single diagonal cut and dividing the square into two triangular rails. If the regulation arris is wanted, the only difference will be that, previously to taking the diagonal cut, one of the corners of the square must be sawn off, and then the diagonal carried from this to the opposite angle. This will give just the same form as when eight rails are cut from a single piece.—J.

Measuring timber.—"Young Forester" seems puzzled by "A. P.'s" statement that a piece of timber 12 feet long by 19 inches quarter-girth really contains 38½ cubic ft. He will know that the portion of a tree usually measured is a frustrum of a cone, and to determine the solidity of such a figure it is generally sufficient to obtain the mean area of the two parallel ends and multiply this by the perpendicular distance between them. Now the tree in question is 19 inches quarter-girth, or 76 inches full girth, which gives a diameter of 24·18 square inches; multiply the square of 24·18 by ·7854, and we will have 459·4 square inches, or 3·19 square feet as the mean area of the two parallel ends; and this in turn multiplied by the perpendicular distance (12 feet) gives 38·28 feet as the true cubical contents of the tree. By the ordinary way of measuring, the solidity of a tree is computed as if it were at a square pyramidal frustrum instead of a conical one. To refer to the previous example, a tree 12 feet long by 19 inches quarter-girth; 19 inches is taken as a side of a square mean base, and the contents obtained accordingly. Thus 19 × 19 = 361 inches, or 2·506 square feet, which is the mean area of the two parallel ends, and this multiplied by the length (12 feet) gives 30·07 feet as the cubical contents of the tree—a difference of 8 feet, or 27 per cent. This at first sight looks rather startling, but when we remember that timber is both bought and sold by the ordinary measurement, we can see that no injustice is done to anyone. If the system of measuring was altered, there would be of course a corresponding fall of prices per foot, and we should be no better off than before.—W. B. H.

SEASONABLE WORK.

Plantations may now be thinned, and where Birch, Beech, Chestnut, Alder, &c., are laid up for some time to become partly seasoned in the logs, they may at once be stripped of their bark. Where it is intended to grow timber of great length, care should be taken not to destroy the leaf-canopy. Where clean-grown timber is also required, the branches should always be cleared from the trunks of the standards within two years after the thinning; these rob the crown and produce stag-headedness. The Ash is never in better condition for working up than when felled about this season of the year. Monteath, who is no mean authority on matters of this kind, says: "The Ash should always be felled from after November 15 till the last week in January, and never before nor after that time to have good timber and to do it justice."

Coppice-cutting.—Coppice-felling will now be in full swing, but if the stools are to be left in a fitting condition to produce a good crop for the future, no cutting from the stool should take place during the prevalence of severe frosts. Wherever such is done, the bark is apt to separate from the wood as the winter advances, and thus the water is admitted and the formation of adventitious buds is checked in the spring. By continuous cutting during open weather, and laying the wood in "drifts," advantage may be taken of the frost to cut up and remove from the falls. The future crop depends so much upon the time and mode of cutting from the stool, that this is a point deserving especial attention. If cut too early the bark is apt to separate from the wood and admit water during the winter, thus checking the development of adventitious buds. Experiments have shown that the best crop of young shoots invariably follows a cutting made between the middle of February and the latter part of March. Much, however, depends upon the season and the age of the stools. The younger plantations should always be cut first. Felling is generally continued from early in November until the end of March, and by the first week in April it should cease.

Upon all moderately dry soils, which alone are fitted for the growth of the best kinds of underwood, the stools should be cut almost close to the ground. This ensures a good crop of shoots from the dormant buds, and as these spring from near the surface of the soil, they are generally erect in their growth, and at the same time they help to extend the stool. All the smaller produce should be cut with a light and keen handbill; poles up to 5 inches or 6 inches diameter with a sharp axe; and all beyond that size with the cross-cut saw. Small stools upon light soils require especial care, as the blows of a heavy, blunt axe sever the fibres of the roots, loosen the entire stool, and destroy the continuity of the dormant buds, which proceed from the medullary rays. All finished stools should be rounded off, that no water can lodge upon them; this may be done with the axe, but it is much better finished with the adze. The bark should adhere all round the edge of the surface. Hop poles should be shaved as soon as convenient after cutting, and the larger ones—here called "use poles"—should be striped or notched and covered up before spring. Allotments of coppicing and underwood for sale by public auction should now be made. We have invariably found that small lots, by inviting more competition, command relatively higher prices than larger ones. Without placing any unnecessary restrictions upon the purchaser, the vendor should protect himself by clauses sufficiently stringent to ensure good workmanship—early cutting from the stool, and removal from the wood within a reasonable time. To ensure early removal, mark out good clearance roads. In Kent they "brush" or bottom these with small fagots tightly bound up at the rate of about forty to the rod, laid transversely to the line of road. Such roads will carry heavy loads of poles and fagots during the winter, as well as the timber in the spring.

Nursery.—The cones of Larch and Scotch Fir may still be collected. The rotting seed heaps will now require to be examined, and an additional covering of earth may be placed upon them. Where small seedlings are liable to be forced out of the ground by severe frosts, a good sprinkling of the sawdust from hard woods will be found beneficial. That obtained from Fir timber contains too much turpentine to enable it to be used with safety. Either tanners' bark or sawdust may be used for such purposes. Collect leaves for the nursery; also Ash keys, Alder seeds, the berries of the Mountain Ash, and such other seeds as ripen during the month; also continue drainage and clear out all watercourses. The seeds of many of our native trees may be sown as they ripen, but the same rule does not apply to exotics.

Most deciduous trees are now fit for removal and no time should be lost before getting them into their new quarters. The gradual hardening or acclimatising of early-removed trees is highly conducive to their future progress; and this applies more especially to those which have been taken from warm nurseries. Should frosts set in, transplanting must be suspended, as all young trees receive a severe check if removed during frosts. Draining, trenching, fencing, and holing for spring planting may still proceed as weather permits, and road materials may be carted during frosts. Young plantations of Birch, Ash, &c., may now be dug with advantage to the trees, and two years' transplants, which are not making satisfactory progress, may be cut off near the ground. In dry weather hedgerows may be dug and cleaned, and gaps filled up by plashing from the old plants or putting in new ones. Where the soil is too light for the Hawthorn to grow into a strong fence, an admixture of Beech may be made with advantage. Upon poor or exhausted soils the Cherry Plum (Prunus Myrobalana) will soon form a good hedge, and its formidable spines render it a good fence against cattle. It is also useful for shelter, as its leaves come out very early in the spring and remain long after the Hawthorn is bare.

General work.—The abundance of leaves which are everywhere to be met with in plantations, rides, and in hollows where they have already drifted, will afford good opportunities for collecting and rotting to obtain leaf-mould. Too little value is generally attached to this manure by those who do not consider the large quantities of saline and mineral matters which are drawn from the subsoil by the roots of trees, and afterwards scattered upon the surface of the land by the leaves.

No. 784. SATURDAY, Nov. 27, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

BERRY-BEARING SHRUBS.

Of all the berry-bearing trees and shrubs met with in English gardens, no family taken at all points can possibly surpass the Cotoneasters. Although nearly all the species are natives of warm climes, in this country they are found to be as hardy as the common Oak. Most of them are evergreen, their neat glossy foliage setting off the bright crimson fruits, which birds do not ravenously devour, to great advantage. Moreover, they are readily increased by means of seeds, cuttings, layers, grafting or budding on the Quince or Hawthorn, and will stand against north walls or in the most exposed situations throughout our sharpest winters. One of the finest groups of the well-known C. microphylla I ever saw was in the park at Birkenhead some years ago, and doubtless there are now in many parts of England groups equally fine, if not finer, whose start originated in the pleasing impression which that bright coral-studded mass made upon thousands of admirers. Loudon enumerates eleven species, mostly evergreen or sub-evergreen and worthy of general cultivation, as residents in the coldest and poorest parts of the country can grow the best, if not all, of them to perfection where the majority of berry-bearing shrubs fail. The planter may divide them into three groups: prostrate trailers or climbers, of which C. microphylla is the type; tall or upright sub-evergreens, like C. Simonsi, affinis, and frigida; or rampant ramblers like C. Wheeleri. Those most frequently met with are C. microphylla, one of the finest and fastest evergreen wall climbers we have; C. m. thymifolia, a neat compact variety of the above, also admirably adapted for training, for covering rockwork, or, where it is equally at home, for rambling over large patches of ground in half-dressed places and shrubberies. This charming shrub has always been one of my special favourites, and I now have close-growing masses of it 20 feet or more in diameter. It roots as it travels over cold, calcareous loam little better than clay, forms a rich glossy setting for golden Holly and other shrubs, is a sheet of pure white flowers in the spring, and glistens with bright coral berries throughout the autumn and winter. This, however, is not the only way in which I have used it, for it forms the finest stone wall covering we have, and some years ago, when everybody was planting Clematis Jackmanni, I threw up a few loads of loam, placed a silver-edged Holly in the centre, then planted a dozen of the Clematis, and edged them with the Thyme-leaved Cotoneaster. The Clematises, cut down in the spring just when the new growths are starting, are allowed to ramble at their own sweet will over the Holly, now some 12 feet in height; not so over the Cotoneaster, a most beautiful boundary hedge sweeping the lawn now nearly a yard high, perhaps brightest and best where it faces the north. The proper mode of growing these small-leaved trailing gems on the lawn may be explained in half a dozen words, "plant well and leave them alone." Unlike the wild rambling C. Simonsi and C. Wheeleri, they will stand pruning or spurring to an extent that will keep them in order, although, as a matter of course, much of the flower and fruit is cut away. I have said C. Simonsi will not stand spurring, neither should it be planted where it is necessary to resort to this mode of treatment, as it is semi-deciduous in the mildest seasons, and for this reason alone is unfit for training against walls which must be kept extra neat and dressy through the winter. This, nevertheless, of which I have raised thousands from seeds, is very useful, and just now extremely ornamental in the shrubberies and home game coverts where, as preservers know, pheasants do not care for dense dripping masses of evergreen foliage throughout the winter. Once planted and thoroughly established, seedlings spring up under every favourite roosting tree, and nowhere seem more at home than close to the stem of a Scotch or Austrian Fir. When planted out in groups in the pinetum or half-dressed grounds, it is equally accommodating, as it fruits profusely for years, can be cut down like a white Thorn, and springs up with renewed vigour, or the stems may be pegged down to flower and fruit until such time as the young growths from the stools are old enough for drawing down to a horizontal position.

With C. Wheeleri I have not done so much, its rampant growth rendering it simply unmanageable, even in the game covers, where it not only rambles up the fastest-growing Conifers, but fairly sets the toughest velveteen at defiance. A plant of some twelve years' growth, also on cold clay, has overrun Yews and other shrubs, and although frequently cut back to prevent an attack on a fine Douglas Fir on one side, and the blocking a road on the other, is now 30 feet across and half that number in height. But I digress. I must return to the dress grounds, for I have two or three charming friends to introduce to lovers of good things.

The first is closely related to, if not a variety of, C. microphylla, and is grown here under the name of C. buxifolia. The leaves are ovate, woolly beneath, a little larger than those of C. microphylla, and much darker. It is evergreen, well adapted for forming groups on lawns, for growing on root or rockwork, and carries its fruit throughout the winter. The flowers are pure white, very numerous, and have a wonderful charm for wasps and flies in the spring. The first especially have a great liking for it, a large mass close to my house having lured many scores on their first appearance to their end every spring.

The second, a sub-evergreen, is C. frigida, a low-growing tree from the northern regions of Nepaul. It is perfectly hardy, as one may suppose, in any situation, grows very fast when young, has rather large, glabrous leaves, woolly beneath, and commences flowering freely when about four years old. A group of trees planted at Eastnor some eighteen years ago is now about 16 feet in height, and the branches at the present time are literally weighed down with their load of bright scarlet fruit. The pure white flowers are produced very freely in May, always set well, and the fruits as well as the leaves, unless the winter is very severe, remain on the trees until the spring. Sometimes during severe snowstorms the birds, pressed by hunger, devour the pulpy part of the fruit, but leave most of the seeds to drop, where they germinate and soon grow into nice little plants.

Some years ago I saw a fair tree for smoky London growing in Kensington Gardens, not far from the Albert Memorial. It was labelled C. frigida affinis, but smoke, incessant digging, and other indignities did not suit it. Still a tree, no matter how distantly related to C. frigida, I thought worthy of better treatment, and planted a dozen. The affinity, I should think, is very close, for, with the exception of a slight difference in the leaves when young, all my trees resemble the first in every particular. When planted alone they do not grow into handsome single-stemmed specimens, but evidently on their own roots throw up a number of strong growths, which, in course of time, owing to their great load of fruit, assume a one-sided, pendulous habit. Still, as single trees or shrubs they are very beautiful, but are seen in their greatest splendour when planted in groups and left to take care of themselves.

Eastnor Castle, Ledbury. W. COLEMAN.

Flowers and trees. — This month is, on the whole, rather mild, and the few bright days we have enjoyed lately seem to have brought up what we call in this part of France l'Eté de la Saint Martin. Tropæolums, Antirrhinums, Tagetes, Petunias, and all plants generally destroyed by the slightest frost are still in flower. Leaves began to fall many weeks ago, but many of them are still on the trees, and will keep falling gently until the first frosty night sweeps them off. When that occurs all will be gone, and even the flowers will have vanished. Flowers and trees are associated here in a charming way. They are on the sloping side of a small hill, and seen from a distance over a beautiful piece of lawn they are most effective. The eye catches first the sight of a mass of tall bedding plants, circular in form, and about 130 feet in length. Fringing the lawn are Centaurea candidissima and the blue Ageratum; then we have a line of Achyranthes Commessi, which is of a bright rosy tint, much used here. These are associated with the old white Pelargonium Mdme. Vaucher; then come two rows of Anthemis nobilis of different heights in front of a nice margin of Cephalotaxus Fortunei and a line of Negundo fraxinifolium variegatum. The top of the hill is occupied by some good purple Beeches. Each year this flower bed is changed in form and colour, but, of course, the trees remain the same, and form a noble background. These tints, where red and white prevail, being beautifully blended, are, late in summer, one of the sights of this place.—J. SALLIER, *St. Germain-en-Laye.*

INDOOR GARDEN.

GREENHOUSE RHODODENDRONS.

The tube-flowered section of Rhododendrons that are generally spoken of as greenhouse varieties really do far better in an intermediate temperature at this season than in a colder structure, for the additional warmth assists the blooms, and under such conditions many of the plants are just now laden with blossoms. If asked to select three of the most useful varieties, my choice would be, Princess Royal, pink; Princess Alexandra, blush-white; and Duchess of Edinburgh, brilliant crimson; though all are well worthy of cultivation. Of these, the first two are free-growing kinds; indeed, Princess Alexandra is quite vigorous, but Duchess of Edinburgh is of a more delicate constitution, owing to which it does better grafted on one of the others than on its own roots. Owing to its vigorous style of growth one of the best stocks on which to work the weaker varieties is Princess Alexandra. We have in bloom, besides the above, Taylori, pink, with white tube; Duchess of Connaught, bright crimson, but it does not bloom so continuously as Duchess of Edinburgh; Emblem, deep pink; Duchess of Teck, yellowish buff, and Prince Leopold, salmon-red. To these must be added the typical javanicum, whose yellow blossoms entitle it to a place in any collection, however choice. As we strike most of the varieties from cuttings, a batch was propagated in this manner last summer, and they are now little plants in pots 3 inches or 4 inches in diameter. A striking feature about them is that in many cases they are bearing heads of blooms, which must have been present in the terminal buds before they were separated from the parent plant, and as soon as growth commenced after rooting the heads of bloom were then developed. In most cases I see there are two or three buds below the blossoms already commencing to push, so that nothing is lost by allowing them to flower thus early. The culture of these Rhododendrons is very simple, the principal thing to observe being thorough drainage, for without that they will not long remain in health. The best soil for them is good fibrous peat, with an admixture of silver sand and charcoal; this compost will remain in good condition for a long time, and these Rhododendrons are very impatient of having their roots often disturbed. We have a small bush of the variety Duchess of Edinburgh in an 8-inch pot, which has scarcely ever been without blooms since the commencement of the year. In grafting any of the weaker kinds the stock chosen should be young and vigorous, while for the scion a shoot

that has not quite attained its full woody texture should be selected. Side grafting, leaving the head of the stock entire, or, at all events, only slightly shortened in, is the method generally employed, and when a union is complete the top of the stock can be removed by degrees. After grafting they will require to be kept in a close frame till a union takes place, which will be seen by the terminal bud of the scion commencing to push, and if no grafting wax is used (and it is quite unnecessary), the gradual healing over of the wound may be observed. The principal insect pests to guard against in the case of these Rhododendrons are thrips, but they rarely make their appearance unless the atmosphere is very dry, when a liberal use of the syringe will dislodge them. ALPHA.

COVERING GLASS HOUSES.

THE approach of another winter makes us begin to look to the means which we possess whereby we can set at defiance that arch enemy, frost. Last winter was both long and severe, and although we may not get so protracted a visitation for some time, we ought to be fully prepared for any emergency when it does come. Last winter taught us the value of external coverings for glass houses. They obviate the necessity for employing much fire-heat, and thus their cost is saved in one season. The best plan is to have good stout roller-blinds that will answer for both summer and winter, the main point being to keep the cold from robbing the interior atmosphere of its warmth. Nothing is more wasteful than driving the boiler fires at full speed, and having the pipes so hot, that one can hardly bear one's hand on them. This can to a great extent be overcome by external coverings—a fact which I have proved over and over again. While, however, we guard against excess of fire-heat, as being not only wasteful, but injurious to plants, we must not fall into the opposite extreme and employ too little. During mild wet seasons more plants are lost from damp than from actual frost; and I would specially impress on owners of glass houses the absolute necessity of having the heating apparatus employed more by day than by night, when air can be given to let moisture pass freely off. Our plan is to open the ventilators early and close early, and to be very careful as to keeping the interior of the houses as dry as possible during weather such as we have lately experienced. It is often after excessive downpours that the most severe frosts occur, and that is just the time when the external covering should be in readiness. Failing regularly fixed roller-blinds, very much may be done with mats, bags, and, in fact, with any kind of covering. Old gardeners had to rely a good deal on such coverings to keep their plants in safety before boilers were in existence. I have myself been struck with the way in which some of the old school of gardeners have carried their bedding plants safely through severe winters in cold frames, while some of the more advanced section were losing their stock even with the aid of new and improved appliances. Straw or litter makes a useful covering for frames, but can hardly be utilised for houses unless made into such mats as the French employ, or fastened on to hurdles. It then makes both a cheap and efficient covering for either frames or houses.

Gosport. J. GROOM.

SHORT NOTES.—INDOOR.

Seedling Carnation (*C. Green, Cromer*).—A very fine sort, flower large and full, and the colour extremely bright, and not at all a common tint; it may be described as a carmine-crimson. Such fine Carnations out-of-doors at this season are indeed unusual.—ED.

Best Chrysanthemums.—"R. D." (p. 483) not only mentions all the best incurved varieties, but also the best reflexed and Japanese sorts, and it would doubtless be difficult to make better selections. But one thing is misleading, and that is, he makes Golden Queen and Emily Dale two kinds; whereas, in the National Society's catalogue they are classed as synonyms. In rule 5 (p. 11) of the National Society's rules, it is stated that anyone exhibiting such synonyms shall be disqualified. To those who are unacquainted with Chrysanthemums and their synonyms I would say, purchase one of the society's catalogues. It may on some future occasion obviate disqualification.—JOHN DOUGHTY, *Angley Park, Cranbrook, Kent.*

SAND PAINT.

I OBSERVE that Mr. Peter Henderson recommends whitelead and sand as a substitute for ordinary paint. I have never used this mixture, but at one time we used a considerable quantity of what we termed sand paint. This was made with whitening and whitelead in equal parts, with about a fourth of the whole of silver sand. Sufficient oil was added to render it workable, and this was laid on as thickly as possible. When it dried, it felt hard and gritty—almost like stone; and my experience is that it is the most durable and impervious to weather of any paint I have ever employed. About fifteen years ago we painted the end of a building with it, and I noticed the other day that, although no paint of any kind has been applied since, there is still a fair coat on the walls. Two or three coats of this sand paint would render boards quite impervious to weather influences for years. Whitelead is apt to peel off after a time, but this paint does not do so. It forms a solid body that nothing but the weather-wear of many years can affect. Another way that we have employed is to lay on the paint first, and then, before it commences to dry, sprinkle sand thickly ever it. This gives it a rather rough, stone-like appearance, which in certain situations is desirable.

The anti-corrosion paint is something in this way, oyster-shells, I am told, being ground up fine and mixed with the other ingredients—whatever they may be. Painters assure me that whitelead does not form one of the latter; if so, anti-corrosion paint has not the worth commonly attributed to it. I would prefer to lay on a thinner coat of whitelead. Painting is expensive work and consumes a lot of time, but I believe that the cheapest way is to paint annually. When a house goes two or three years without paint, there is often more to do in taking off old rotten putty, replacing the same, and cleaning, than in the actual operation of painting. Supposing two good coats of paint to be put on, when you come to the work the following year there is nothing to do but to paint; there is but little cleaning to do and no worn putty to replace. In this way one may soon run over a lot of work, especially if it is taken in hand when the weather is fairly warm and dry. A workman with cold fingers cannot get along very fast. I have been told that the best way is to use Pitch Pine, and not paint at all. I do not know if anyone has tried this experiment, but I am not sanguine of success. I rather fancy that without paint the wood would split in the hot sun.

Last winter I had Pitch Pine sills put to a frame. I did not trouble to paint them, and I found that in the course of the summer large cracks came in them. This material is, however, coming into use among market growers, for of course it is more durable. I would warn your readers, however, not to use it for frames, except for the bearers and sills; sashes made of it would be very heavy.

J. C. B.

Hardy Primroses in pots.—When potted up now and placed in a little warmth, Primrose flowers open beautifully, the colours being bright and clear. We have them in many shades of colour besides the old Golden Primrose from the woods, and all of them bear forcing well. Last year, about Christmas, requiring a large quantity of flowers, we lifted a large number of Primrose roots and filled a bed in a forcing house with them, and in a few days they were a mass of flowers. But, raised under such circumstances, the flowers are fragile, and, of course, such treatment breaks the root. Strong roots, potted now in 3-inch or 5-inch pots, will during winter be very serviceable in many forms of room decoration, and the flowers when gathered are very sweet and interesting, especially to invalids. I am thinking now only, of course, of the varieties of the common English Primrose.—E. H.

Worms in pots.—Worms are often troublesome, especially in the case of plants which have been standing out in the open air without due care having been taken to prevent worms entering through the outlet at the bottom. No plant can be kept in health long with a worm in the pot, for it speedily blocks up the drainage and the plant turns sickly, and if not relieved dies. Worms are very sensitive to concussion. Very often a sharp rap on the side of the pot will cause them to come to the top, but if they cannot be induced to come out by any other means, if the plant is turned out of the pot and a long, thin piece of wire (a knitting needle will do) is thrust through the ball in two or more directions, the worms generally come out and surrender. Where many plants are infested with worms a more expeditious remedy should be adopted, and there is nothing better than limewater, which may be made as follows: Place 6 lbs. of fresh lime in a barrel of water (36 gallons); allow it to settle and clarify; then give the plants a good soaking, and gather up the worms as they crawl out. If used in a clear state water will only carry a certain amount of lime, so there is no danger of using it too strong.—E. H.

Steaming *versus* fumigating.—In THE GARDEN (p. 484) there is an interesting communication from "J. C. D." on this subject. It would confer an obligation on myself, and probably others, if "J. C. D." would enlighten us as to the name and address of the French manufacturer who is bringing out a suitable apparatus for steaming purposes. I have evaporated tobacco juice in both tin and earthenware vessels by means of a spirit lamp, but found the process tedious, although certainly successful. My gardener tells me that while I was away in India this year he evaporated the juice very successfully in the troughs over the hot-water pipes by shutting off the steam from all but the one house operated upon. Undoubtedly my Orchid houses have been much more free from insect pests ever since this plan has been tried, and the plants have in no way suffered.—REGINALD YOUNG, *3, Linnet Lane, Wet Road, Liverpool.*

—— Like "J. C. D." (p. 484), I also have exclusively adopted the practice of "steaming" since it was recommended in THE GARDEN by M. Godefroy-Lebeuf two or three years ago, and I simply cannot understand anyone who has given it a fair trial ever reverting to "fumigation." After many experiments, my present arrangement is pretty much like that which "J. C. D." describes, and this is, no doubt, good enough for enthusiastic amateurs; but what is wanted to bring "steaming" more into vogue is the "new apparatus devised by a French manufacturer, which is a very simple and effective affair." Personally, I would feel much oblized to "J. C. D." if he would state where this apparatus can be obtained.—A. K.

Sparmannia africana.—This old inhabitant of our greenhouses is capable of rendering very useful service, either in the way of aiding the cut-flower supply, or as a pot plant for decorative purposes. It is surprising the quantity of blooms which one large plant will yield, and if picked singly and used for button-hole bouquets, or other purpose where they can be mounted on wires, few more valuable plants can be grown, the colour of the flowers being quite distinct from that of any other plant with which I am acquainted. We have some large bushes of this Sparmannia now covered with flower-heads that keep on expanding all through the winter in a warm greenhouse, where there is just enough heat to expel damp. During summer we set these plants out of doors, so that their young growth may get well ripened. Last spring we put in a quantity of cuttings, and grew them on under glass until June. They were then set out on a coal-ash bed in a sunny position, where they made fine bushy plants. They are now covered with flower-heads that promise to be very effective when fully expanded, and they may be advanced or retarded at pleasure. Those who have conservatories to keep gay throughout the winter would find that a good batch of young Sparmannias would be most welcome.—J. G. H.

Bricks of cork.—The waste cuttings of cork are now being employed for making bricks, which can be used for walls, impervious alike to heat or damp. The cork cuttings are reduced to powder in a mortar, and mixed with lime or clay; and from this composition the bricks are made in the usual way.

TREES AND SHRUBS.

THE WISTARIA.

(W. SINENSIS.)

How much a simple building may be beautified by a good climber is shown by our engraving of an old Wistaria on a modest cottage, the office of Mr. Virgo's nursery. The tree was planted by Mr. Virgo nearly fifty years ago, and, judging from its vigour—for the engraving shows only half its extent—it seems to promise endurance for perhaps another half-century. The crop of blossom was this year not a very full one, as was the case with most of the Wistarias in the district; in a year of good bloom the little house looks almost smothered with the pretty lilac bunches.

Balsam Poplar.—Seeing how distinct this is from trees generally, the wonder is that it should not be more extensively planted. Unlike the common Poplar, it does not run up to any great height, and may therefore be employed where tall growing trees are inadmissible. Another point in its favour is the strong, but very agreeable perfume which the young leaves exhale. A moderate sized specimen will load the air with perfume for many yards round. A striking instance of its value in this respect is afforded by a tree which grows on the highway in the immediate neighbourhood of a farmyard, from which pungent and very unsavoury odours assail passers-by at certain times of the year. I have remarked that the Balsam Poplar in the season of its odoriferousness quite masters the evil smells from the above mentioned place. At that time one may pass without quickening one's pace, which only those abnormally impervious to nasty smells could do at any other time. This, then, should be a disinfecting tree, and one which, unlike the much-vaunted Blue Gum, is perfectly hardy. There are, unfortunately, places where evil odours have to be borne by those who do not create them, and where such is the case I recommend the use of the Balsam Poplar.—BYFLEET.

MENZIES' SPRUCE.

(ABIES MENZIESI.)

THIS Fir was introduced from Northern California, and from the first plants having been brought home in 1831 by Douglas, its discoverer, specimens may now be found of the Abies Menziesi throughout the country of sufficient size and bulk of timber to enable us to state with some degree of precision, not only as to the hardihood and rapidity of growth of the tree in Britain, but also to form some approximate idea of its probable value as a timber tree worth growing for profit in our woodlands and plantations in different situations, soils, and altitudes.

Immediately after its introduction by Douglas in 1831, Menzies' Spruce became, probably from its association with the name of its discoverer, widely sought after, and was generally planted in pleasure-grounds throughout the country; and from its improved foliage and appearance upon those features of the Norway and American Spruce—which in many other points, however, the new acquisition closely resembled—it at once acquired an amount of popularity which shortly led to its being more generally and extensively planted, not only as an ornamental specimen in the pinetum, but in quantity in ornamental plantations and groves.

In a paper read before the Highland Society by Mr. R. Hutchison, an interesting account of this tree was given. He says that, generally speaking, it appears that Abies Menziesi is one of the hardiest of the newer Coniferæ in soil which is not too dry; in moist, damp, alluvial land, and especially if near water-courses or river-sides, or ponds, it is of a very rapid and free habit of growth, attaining greater dimensions within a given number of years in such sites than the common Spruce. In open situations, its stately, thick-branched, pyramidal head forms a handsome and striking object, which is greatly enhanced in value by the beautifully glaucous colour of the under-sides of the leaves being displayed when its branches are swayed by the wind. In Britain, Abies Menziesi blossoms in early summer (about May or June), and the cones, which are produced in numbers, and crowded together, become mature in the following winter. As compared with the common Spruce, with which, as has already been remarked, Abies Menziesi has many points of resemblance in common, it is uniformly conical, with foliage—which in the case of A. Menziesi is much denser—always luxuriantly umbrageous in the lower tiers of branches, and which in well developed specimens sweep down in green tresses to the very ground. The branches towards the upper part of the tree are rather more obliquely upright in habit in the Abies Menziesi, and longer and bolder than in the case of the common Spruce (Abies excelsa), whose tiers of branches about this part of the tree are invariably horizontal, and in length give a more gentle tapering form to the general contour or outline of the tree than the more numerous and projecting points of the lateral limbs of the Menziesi can attain. In this respect it resembles more Abies Douglasi; and indeed it may be said that in general style and appearance the Abies Menziesi is to the common Spruce what the Abies Douglasi is to the common Silver Fir (A. pectinata). In some instances it has been observed that this Fir bears a considerable resemblance in general outline and appearance to the A. Douglasi, but it is not nearly so fine a tree, nor is it so rapid in growth, nor even so hardy as the Abies Douglasi.

One peculiarity of the Abies Menziesi is its proneness to drop its leaves before the new ones are expanded, and this habit gives it a semi-deciduous appearance. This feature, when first observed, leads to an erroneous idea being formed as to its hardihood in our country, some planters supposing

Wistaria on Mr. Virgo's house, Wonersh, Surrey. Engraved for THE GARDEN from a photograph.

that it arose from unsuitability to the climate, but it has been ascertained that this is a habit quite natural and common to the Menziesi, even in its native habitats; and although the almost naked branches detract from the beauty of the tree for a short time in spring, it is no indication of tenderness of constitution or disease. In shaded situations, with a northern aspect, this peculiarity is not so striking, and probably the sudden changes from heat of the sun to the cold of spring nights foster and intensify the habit. When placed singly on a lawn, or in a rather moist soil, this deciduous tendency is greatly checked, and it is always most apparent when the tree is planted in dry sandy soil. One of the handsomest, if indeed it is not the finest specimen of Abies Menziesi is growing at Castle Menzies, near Aberfeldy, in Perthshire, and is luxuriating in a damp soil, quite adjacent to a pond, where the atmosphere around it is charged with moisture, and where its growth has been exceedingly rapid.

ORNAMENTAL TREES IN CANADA.*

I HERE wish to direct attention to certain trees, not natives of our province and but little known, but which would add greatly to the beauty of our parks and gardens.

The winter of 1884-85 was unusually severe. "The most tingling winter that we have had at Abbotsford for ten years," were the words that greeted me on my return from the south in the spring. We had, during the previous ten years, lower means for December and January, and in one case for each month a lower minimum, but that February and March of 1885 showed a much lower mean, and March a lower reading than any of the previous ten winters, and the mean of these four months was no less than 6·18° colder than the mean of the previous ten years. The average temperatures for the three months recorded in the city of Quebec is 4·2° colder than that recorded by the more sheltered observatory in Montreal. It would be, therefore, quite safe to say that the cold of the winter of 1884-85 in Montreal was greater than it is on an average in the city of Quebec.

I have, growing on my exposed hill-side at Abbotsford, about 145 varieties of trees, which are not natives of this province. Some were exposed to the cold of last winter, and were uninjured; others were injured. These test winters furnish facts of great value.

DECIDUOUS TREES.

MAPLE (Acer).—Of the Silver Maples, Weir's Cut-leaved is a curiosity, an eccentric, wayward grower, as great a contrast to the compact growth and dark, massive foliage of the Norway Maple as a German Cut-leaved Birch is to a Grape-leaved Linden. The foliage of the young growth is so slender and so deeply cut as to be scarcely recognised as a Maple. I have several trees of it, four or five of which must be 20 feet high, and I recommend it as a tree thoroughly suited to our climate. Of other varieties of this Maple, heterophyllum laciniatum—a seedling raised by Ellwanger and Barry, of Rochester—is a strong upright grower, with long, deeply-lobed leaves, but, strange to say, it is not quite hardy. When growing rapidly, it is almost sure to lose several inches of its terminal shoots. The variety Ricii has quite small leaves, and, though it has not succeeded with me like Weir's, is fairly hardy and worthy of trial.

THE NEGUNDOS suffered severely last winter. The last year's growth was mostly killed. They did not leaf out until nearly three weeks after their usual time, but then grew rampantly, and their bright, green foliage throughout the summer was very ornamental. On the other hand, the Winnipeg form of this tree, the same as the Ash-leaved Maple of Iowa and Minnesota, is noted for its perfect hardiness and rapid growth in unsuitable soils. This tree is therefore becoming a favourite, but I would offer this caution, that it is a tree which attracts flies, and therefore should not be planted too near houses.

THE NORWAY MAPLE I find to be a satisfactory tree. It is darker in foliage, more spreading, and more rapid in growth than our Sugar Maple. There is a fine young specimen in Victoria Square, and in the autumn, when the Sugar Maples surrounding it were scarlet, this was still green, and after they had lost their foliage, its was still yellow. This European Maple has also sported in an odd way. The Cut-leaved (dissectum) has foliage so regularly and deeply cut as almost to divide the leaf into three parts. It is a very slow and crooked grower, and suited to small places. I have only seen one large tree of it, one in Vienna, and that had seen the growth of generations. This tree never received the slightest winter injury with me until the winter of 1884-85, and then only in transplanted trees. Lobeli, I believe another variety of the Acer platanoides, is just as slow, though a straighter grower, and some of its leaves have so far strayed from their original type as to be scarcely recognisable by a botanist. If one were to gum half-a-dozen pieces of leaves at different angles upon the end of a stalk, it would be an approach to what some of its leaves are; most of the foliage is like that of the Cut-leaved. I have but one tree of this. It lost 4 inches of its leading shoots last winter, but as this is the only winter injury it has ever received, we may consider it hardy.

SCHWEDLER'S MAPLE has its seasons of great attractiveness. The leaves as they unfold in the spring are a brilliant crimson, and continue a brilliant crimson until full grown and a few days after. They then become a dull red and gradually change to a dark sombre green, darker than the ordinary Norway Maple. In midsummer the new growth starts with the same brilliant colours as in spring, like a lot of red Roses peeping out of the dark contrasted green. Imagine an avenue of this Maple on some prominent place leading to our mountain park, in its brilliant spring plumage; the whole city would see it, and for a few days in spring hundreds would flock to it, just as, in London, thousands go to see the Horse Chestnuts in bloom at Hampton Court. Reitenbach's is another German variety of the A. platanoides. It lacks the brilliancy of colour of Schwedler's; at times the upper side of the leaf is a sombre purple, while underneath it is pure green. My trees are small, but stood last winter without injury. Another curious variety is the Curl-leaved, or cucullatum. The leaves curl into strange forms; and in the structure of the leaf, the way in which the veins radiate is remarkable, so that it is a botanic as well as a horticultural curiosity. My Tartarian Maple (A. tataricum) was killed back an inch or two at times, but otherwise is hardy; but for some reason it has not those large clusters of blossom and seed which make this shrub Maple such a favourite in the Russian gardens.

ALDER (Alnus).—The Imperial Cut-leaved Alder is a tree which I cannot compare with any other. Its light feathery foliage and dark, dull colour give it an expression peculiar to itself. It seems quite hardy with me, now that I have it planted on moist soil. I specially recommend this as a small tree for sheltered city gardens. Snow off roofs would break it all to pieces, so give it such care as its frail, delicate constitution requires. The Cut-leaved (laciniata) is more vigorous and becomes a larger tree, not like an Alder, and well worthy of being planted.

JUNEBERRY (Amelanchier).—I have fruited four varieties of this tree. Last summer the little bushes, from 9 inches to 2 feet in height, bore an abundant crop of berries, the size of the largest Saguenay Blueberries, and richer in flavour. I think Grinnell was the finest in flavour, Green County and Gardener being also good fruits. The alpine Juneberry of Mexico, though quite hardy, does not bear as large or as fine a flavoured berry.

BIRCH (Betula).—The European Birches excel our native species in beauty, and of these I know of no finer tree than the European Cut-leaved Birch, which Scott speaks of as "the acknowledged queen of all the airy graces." I know of no tree I should prefer to plant, especially where dense shade would be an objection. The variety atropurpurea, owing to the dark purplish red of its leaves during spring and early summer, is well worth planting. The Fastigiate Birch is as upright as a Lombardy Poplar or a Funereal Cypress, and as we have no medium-sized tree of this form except it, it may be used to good advantage in ornamental planting. The variety tristis is the most slender and delicate of the Birch family that I know; the ends of its branches are nearly as slender as a piece of thread. This tree I should consider hardy enough for a sheltered city garden. Young's Weeping is a tree that might well take the place of the Kilmarnock Willow for planting in our cemeteries. Top grafted, it is just as pendulous, and more graceful, and will prove a longer-lived tree. The European Birch, when grown from seed, is obtainable at cheap rates from nurserymen. A good deal of the seed which comes to this continent is from Russia. These trees differ a good deal in habit of growth, whether grown from Scotch or Russian seed. I have planted out about eighty trees which I believe to be from Scotch seed, for, towards the middle of November, when the Canoe Birch on Yamaska Mountain, and the white Birch of the flat lands below have but a few remaining yellow leaves, these Birches of mine are still green. I therefore believe them to be Scotch, although among them I find some trees with a triangular leaf, like the B. alba verrucosa of the Russian forests, and like the native white Birch of our low lands; and others, with the round-sided leaves, like the pubescens of Ehrhart, and like our native Canoe Birch.

CATALPA.—I cannot say that I find this tree hardy, and yet I have some fine trees fully 15 feet in height. I have also ten trees planted around a two-storey summer house, from which I have counted the spires of sixteen villages, and from which I can see mountains which are 180, if not 190, miles apart. In this bleak exposure they are doing well, much better than some thirty trees which I have in a forest plantation and which are more sheltered. One specimen on my roadside bloomed beautifully last summer, though for some cause the blossom was not succeeded by those long slender pods which give the tree such a curious appearance during autumn. The young trees on the college ground at Ames seem thoroughly adapted to that climate, and I feel that by getting the Catalpa speciosa from its farthest limits northward, we may yet get a surer and a hardier tree.

YELLOW-WOOD (Cladrastis).—I have two specimens which have proved quite hardy. It is in one of the finest of the American flowering trees, and its hardiness with me should cause it to be tried in Montreal.

BEECH (Fagus).—After failing with about a dozen specimens of the Copper Beech, I find a young specimen at Verdun which has stood the cold of some six or seven winters and is doing well.

ASH (Fraxinus).—The common Ash of Northern Europe (F. excelsior) I find quite hardy, but the more curious and interesting of the Ashes are quite tender. The Gold-barked varieties were long ago condemned. The Single-leaved Ash (monophylla) and laciniata are strange-looking trees, quite unlike Ashes, but they usually lose a few inches of growth each year, and without a yearly cutting off of this dead wood, would cease to be ornamental. The variety concavæfolia variegata is remarkable for the silvery bright tint of its young growth; very curious, but not at all hardy. It can only be grown as a shrub, and needs slight protection. The kind known as scolopendrifolia is a delicate little shrub, with leaves as slender as a blade of Grass. It needs protection. The aucubæfolia is a variety of our native Ash, and of course quite hardy. Its leaves are often as richly spotted with gold as some of the finer Crotons. Like all variegated trees it loses its freshness during our hot summers, yet it is the finest variegated-leaved tree I know of for our climate.

HONEY LOCUST (Gleditschia).—I find the variety known as caspica a good grower, and just as hardy as the American ones I have. The Chinese I found quite tender, and I do not know of our having as yet a hardy variety from that country.

KENTUCKY COFFEE TREE (Gymnocladus).—My trees have killed back a few inches each year, and therefore make slow progress, and there is a tree in Montreal which stands as a record of the number of inches of injury it has received for many years back. I have another tree which seems quite hardy. There are good specimens in Mount Royal Cemetery and elsewhere, so let us grow this from hardy stock.

* Extracts from a paper read by Mr. C. Gibb before the Montreal Horticultural Society.

Tulip tree (Liriodendron).—I have a fine young specimen about 12 feet in height in a very exposed place. Last spring it did not leaf out till two weeks after its proper time, but then seemed none the worse. Smaller specimens which I had were affected in the same way. On account of the peculiar foliage and beautiful bloom of this tree, it should be tried in our sheltered city gardens.

Mulberry (Morus).—The Russian Mulberry, brought by Mennonites from near Azov, has been grown from seed, and differs much in the size of its fruit. I have seen it three-quarters of an inch long, and some trees have produced fruit still larger. The best will be sorted out and propagated from cuttings. It is not a timber tree, but only a scrub bush. The Mennonites use it largely in the west as a hedge plant, and when planted closely, as in hedge form, it produces a large amount of fruit "for pies, for sauce, and for the birds," and for a "preferred fruit" for the birds and a protection to the Cherries. A few plants I bought five years ago cost me but 1s. each, and now plants may be had for even less.

Poplars (Populus).—There is a straight-trunked variety of the Silver Poplar (Populus alba) which I had noted as growing in the Botanic Garden at Kazan, in Russia. I regret to say that I do not know of its having been imported. In the grounds of the Iowa Agricultural College there is a large collection of the Poplars of Eastern Europe. There are Populus alba, and its varieties, nivea, acerifolia, &c., from different sources. Some of these are very large and Maple-like in leaf, and decidedly snowy, but the trunks have a tendency to wabble; they are not straight as the mast of a vessel, like those I saw in Kazan. [This erect-growing Abele is probably P. alba Bolleana, now being planted largely in England.—Ed.]

White Beam tree (Pyrus Aria).—We saw large collections of this tree at Riga. They seemed to thrive there. They are, however, not doing as well as was expected at Ames, Iowa. The summer heat seems too great, but greater than it is here, so we must give them a fair trial.

Oaks (Quercus).—I find the Chestnut Oak (Q. castanea) and the Scarlet Oak (Q. coccinea) both hardy so far, that is they have passed through about five winters without injury. The latter holds its leaves into winter, and they continue brilliant in colour, when other trees have lost all their foliage. The Burr Oak of the West (Q. macrocarpa) I find just as fast a grower as our native Red Oak. I have them planted side by side in a timber plantation. The Pin Oak (Q. palustris), a straight trunked species valuable for avenue planting, also seems quite hardy.

Gingko (Salisburia).—I have one solitary tree. It grows, but is sometimes killed back a little. It is a great curiosity, and is hardy enough to warrant its being planted in the sheltered gardens of Montreal, where it has done much better than with me.

Elms (Ulmus).—I have two fine young trees of the purple-leaved English Elm. Its name, purple-leaved, is quite misleading; but for some reason it has done well, while other English and Scotch Elms have proved failures. The Camperdown Weeping Scotch Elm has been twice severely injured. The Elms of North-eastern Europe I have not tried. Neither the Manchurian nor Japanese varieties of Phellodendron are hardy with me. They might do in Montreal. The Oriental Plane is proving much hardier than I had expected.

Evergreen Trees.

Spruce and Fir (Abies and Picea).—For general planting there is no Evergreen like the Norway Spruce. It is cheap, transplants easily, grows quickly, and forms a large and beautiful tree. For wind-breaks and shelter-belts it is our best Evergreen; for hedges I prefer the native Arbor-vitæ, which makes a good hedge in less time. Engelmann's Spruce is a beautiful Evergreen, perfectly at home in our climate. A specimen I have is remarkably glaucous. In spring it is the colour of frosted silver, not green at all. Nordmann's Fir is a beauty of a different type. Its long, dark, shining, rich foliage is very striking, but it is not hardy above the snow line. I have a variety of our White Spruce (A. alba cærulea) nearly as silvery as Englemann's, but bluish. It is a dwarf and has borne its second crop of seed, though the trees are not more than 3 feet high. The Siberian Fir (P. Pichta) is remarkable for its refreshing green colour, and I may add that such specimens as I saw in Russia showed no signs of early decay, as is the case with our native Balsam. Morinda, of course, died. The Tiger's-tail Spruce of Japan (A. polita) is, I think, hardy or nearly so. It has stood the test of about five winters, but is small and often covered with snow. Its leaves are as sharp as pins. There is a dwarf form of our beautiful Hemlock (Abies canadensis macrophylla), a foreign looking, compact shrub, just the thing to adorn a well-kept lawn with.

Pine (Pinus).—Of the foreign Pines, the Scotch and Austrian are most commonly planted. They are grown from seed and may be bought cheap. They are as hardy as our native Spruce, but I find them more difficult to transplant than the Spruces. This has always been my experience on my soil. The Scotch is the faster grower, but not as rapid in growth as our White Pine. The Black Pine of Austria is a slow grower; I know their relative growth, for I have them all growing side by side in a trial timber plantation of about 1000 trees and twenty-five species. The Swiss Stone Pine (P. Cembra helvetica) is a five-leaved Pine, not rough and bristly like the Scotch and Austrian, but soft and silky, far more so than our own White Pine. It is a slower grower than any I have yet mentioned. The Manchurian Stone Pine (P. Cembra manchurica) has unusually broad leaves for a five-leaved Pine. It is a lovely grass-green in colour and seems quite hardy, a beautiful tree well worthy of trial. The Himalayan Pine (P. excelsa) I had two specimens of, which seemed hardy, but they were killed by a borer which has done no injury to any other kind I have. The Cluster Pine (P. Pinaster), though not satisfactory in the Eastern States, seems hardy so far with me. The Mugho Pine is a dwarf mountain form. It will never make a saw log, but is a dense compact little shrub, a curiosity in its way. Mine are not more than 1 foot high and have been planted five years. The silvery form of the White Pine (P. Strobus nivea) is interesting on account of its bright colour—a colour, however, not as striking as my Engelmann or cærulea Spruces. P. ponderosa I now have grown from seed from the Kootanie Valley, in British Columbia, and, coming from that region, I hope it will prove hardy.

Of other Evergreens, allow me to direct attention to a very ornamental tree or shrub, almost unknown, and yet a native of some parts of our own province. I mean the Red Cedar (Juniperus virginiana). When grown from northern seed, it is of course quite hardy, and some of its glaucous forms highly ornamental, and quite unlike anything else we grow. Peabody's Golden Arbor-vitæ, a variety of our own so-called White Cedar, is very bright in colour. The beautiful Retinospora plumosa aurea I find hardy, that is, hardy enough to be highly ornamental. It may look blue in winter, especially when not covered with snow, but in spring it forgets its past troubles. It is of dense habit of growth, feathery, and its outer branches tipped with lively yellow, which colour it maintains throughout the season. In spring it has a sparkling brightness. What great contrasts in colour we find among Evergreens!

In conclusion, let me impress upon your attention the peculiar beauties of some of these hardy European trees—trees in many ways quite unlike our own. The beauty and variety of our native forest trees have caused us to plant them too exclusively; and far more varied and beautiful would be our parks and streets and gardens to-day, had we planted, in greater quantity, some of the more beautiful and suitable trees of the Old World.

Propagating Maples.—I am anxious to know how to propagate some of the varieties of Japanese Maples, of which I possess good plants.—J. Ardew.

*** These shrubs, to a great extent, are increased both by grafting and budding. Most of the vigorous growing kinds are budded, and those of more slender habit, such as the beautiful Japanese varieties, are grafted on allied species. Budding is done towards the end of the summer in the same way as Roses are, and, like them, if the bark does not run freely, a good shower or a soaking of water at the roots will frequently remedy this. If young vigorous plants are budded, they may with advantage be somewhat shortened back when it is done. As before stated, they may be layered, but it is not always possible to do this, though it is generally employed for the increase of Acer palmatum, which in its turn is used as a stock on which to graft its many varieties that are now becoming so popular. For grafting these small Japanese Maples the stocks should be established in pots, and the plants kept close under glass till a union takes place. Side-grafting is the method generally employed, and it may be done at almost any time, provided stock and scion are in good condition, though perhaps the most suitable season is when the young growth is about three parts ripened. If one possesses plants of any of the varieties large enough to layer without injury, they can then of course be increased in this way.—Ed.

Pernettyas in flower and fruit.—Among a collection of the newer varieties of Pernettya here there are a few plants heavily laden with berries, and at the same time flowering most profusely. The contrast between the pure white blossoms and the dark green foliage is still further heightened when laden with fruit, for the darkest-berried forms are those that are thus flowering. Possibly by means of selection an autumn-flowering race might be established, which would assist in the embellishment of our gardens during the dullest season of the year.—H. P.

Elæagnus longipes.—On account of the ornamental appearance of this, both when in flower and fruit, it has deservedly become one of the most popular species of the genus. It is, moreover, perfectly hardy, in this country at any rate. Where allowed sufficient light and space, the plant soon forms a good-sized bush, and produces an abundance of long-stalked oval red-speckled fruits, which might be turned to account for preserving. Mr. Gibbs, in a paper in the report for 1883 of the Montreal Horticultural and Fruit Growers' Association of the Province of Quebec, entitled "Hasty Notes on Trees and Shrubs of Northern Europe and Asia," thus speaks of it: "E. longipes, from Japan, we saw at Kew. It is a shrub 6 feet high, bearing large quantities of spotted red berries, like oblong Cranberries. At Verrières, in the garden of M. Henri Vilmorin, we again saw this plant bearing heavily; fruit red, a nice acid fully equal to that of Cranberries, and as free from seed. It seems a very abundant bearer, and well worthy of introduction as a fruit-bearing plant—a plant likely to yield quite as much of a fruit, as good and as saleable, as the Cranberry."—G.

Abies Pattoniana and Hookeriana.—These two Conifers are often confused in nurseries and gardens, but although somewhat alike in habit, they are totally distinct when examined together. The leaves of the former are green on the upper side and whitish beneath, while A. Hookeriana has a uniform glaucous colour all over. The leaves also have no proper upper surface, being rounded and densely set on the branches. Both species are exceedingly hardy, and, like the Abies Albertiana, luxuriate in soil naturally composed of loam and peat. As these Conifers have a great tendency to branch on the surface of the ground, instead of cutting them off I would recommend them to be treated as layers. By doing so a great advantage will be gained by inducing in them an upright growth. The way I find the layering of these plants to succeed best is to bare all the lower branches of their leaves and small side-shoots, leaving 8 inches or 10 inches at the point undone; then twist a very fine copper wire tightly round the lower portion cleared, and peg the branch down in a mixture of loam and peat, previously prepared and placed round the plant, covering the surface afterwards with a coating of Sphagnum Moss, and placing stones on the surface to prevent the Moss from being blown about, as well as to assist to retain the moisture round the layers. If the layering practice is carried on for a few years, the plants will soon begin to assume an upright habit. I have never succeeded in striking either of these species of Abies by cuttings.—J. M.

Holly berries.—In answer to "Veronica's" note about Hollies, I may say that the green-leaved Hollies here rarely fruit, but a large silver-variegated tree is covered with berries every year. I have observed the same fact in another garden near here.—Northumbria.

FLOWER GARDEN.

CHRYSANTHEMUMS AND THEIR CULTURE.*

Of Chrysanthemums we have two British species, viz., C. segetum, the Corn Marigold, and C. Leucanthemum, the great Ox-eye Daisy, both of which bear very pretty flowers. C. Leucanthemum grows abundantly and luxuriantly on the hedgerows and railway slopes in Cheshire, and flowers from June to August. C. segetum is not so plentiful in this district as the preceding. It formerly was very abundant about Bowdon, but an improved system of farming has, so far as I have been able to ascertain, completely eradicated it. I am informed that in Cornwall C. segetum is the greatest pest with which the farmer has to deal. Some ten or twelve years since there were several exhibitions of British flowers held every year in Whitefield. At these exhibitions, even in the depth of winter, there were always flowers of C. segetum to be seen and admired. Mr. James Percival, president of the Manchester Botanists' Association, informs me that the Whitefield growers, by persistent selection and good cultivation, had brought the flowers of these Chrysanthemums to such a high state of perfection, that they beat all other exhibits, Cypripedium Calceolus included, though by most persons the latter is considered to be our rarest and choicest British plant. When a variety is raised which produces really good flowers, it is perpetuated by means of cuttings.

Annuals.—Amongst annual Chrysanthemums the best is C. carinatum, a native of North Africa; it is a useful plant, either in a cut state or for making a display in the flower garden. C. Burridgeanum, a compact-growing variety, bears large yellow flowers. The white and yellow forms of C. Dunnetti are very showy. C. inodorum fl.-pl. is useful in a cut state. Of this there are generally many forms to be obtained from a packet of seed, and if perchance there should be a really good double form, it should be preserved by means of cuttings. C. coronarium, or Crown Daisy, is a fine annual plant, which grows about 3 feet high. The cultivation of these Chrysanthemums is of a very simple description. The seed should be sown in April in rich, well prepared soil, and in the situation in which the plants are to flower. When they have attained a height of 2 inches or 3 inches, if they have come up too thickly, they should be thinned to 12 inches or 18 inches apart.

Amongst herbaceous Chrysanthemums C. lacustre, the Marsh Ox-eye Daisy, is a strong robust grower, which increases rapidly under favourable conditions. It grows about 2 feet high, and bears flowers that much resemble those of the Ox-eye Daisy of our pastures, but they are in every way considerably larger. It flowers profusely for a lengthened period, and is, in my opinion, the handsomest of the herbaceous varieties. C. maximum is a useful, tall-growing variety that flowers later in the season than the preceding, but its flowers are not nearly so large. Chrysanthemum, or rather Pyrethrum, uliginosum is a tall-growing and profuse-flowering plant which in some situations attains a height of 7 feet or 8 feet. It flowers abundantly from the latter part of September for six or seven weeks, unless cut down by severe frost. This variety is very effective in autumn when mixed with Rhododendrons or similar plants. C. frutescens, commonly called Paris Daisy, or Marguerite, is extensively cultivated on the Continent for bedding purposes; here it is chiefly grown in pots for decorating conservatories, and its pretty white flowers, which are freely produced, are very acceptable in a cut state.

The Chinese Chrysanthemum was originally introduced into this country about the year 1764, but it was soon afterwards lost, and was re-introduced in 1795. In the *Botanical Magazine* for 1796 there is a coloured figure of C. sinense or indicum. The Chrysanthemum is the favourite flower of the Chinese, and is carried with them wherever they emigrate. Our Japanese forms of it were introduced by Fortune about the year 1860, and three years after this date it was figured in the *Botanical Magazine*. Both forms are very popular in this country, and deservedly so; their flowers are varied in size, form, and fragrance, and are of every conceivable shade of colour, except blue; they are produced, too, naturally at a season of the year when other out-door flowers are scarce. They are easily propagated by means of cuttings, layers, division of the old plants, and also from seed, which may be obtained in our seed shops. The latter method of propagation is chiefly adopted with the view of obtaining new varieties, and these superior to existing kinds are difficult to obtain. The late Mr. John Salter, of Hammersmith, estimated that there was only one seedling Chrysanthemum out of every 2000 raised that was worth naming. There are probably 1500 or 1600 varieties in cultivation, and many of these have two or three synonyms, so that there is close upon 2000 names to select from. Several of the principal nurserymen have adopted the plan, and an excellent one it is, of giving the synonyms after the correct name. The following selection, which is fairly representative of the different forms of flowers, is found generally to give satisfaction, viz.: *Incurved*—Alfred Salter, Beauty, Blonde Beauty, Barbara, Baron Beust, Beverley, Empress of India, Fingal, Golden Queen of England, Lord Alcester, Guernsey Nugget, Hero of Stoke Newington, John Salter, Mr. Cobay, Jardin des Plantes, Mr. Bunn, Mrs. Heal, Novelty, Princess Teck, Prince Alfred, Queen of England, Refulgence, Venus, and Jeanne d'Arc. *Japanese*—Brize du Matin, Baron de Prailly, Criterion, Comtesse de Beauregard, Ethel, Elaine, Fair Maid of Guernsey, James Salter, La Incomparable, Lord Beaconsfield, Lady Selborne, Mdlle. Moulise, Mdme. C. Audiguier, M. Astorg, M. Henri Jacotot, Margot, Mdme. de Sevin, Mdlle. Lacroix, Bend Or, Soleil Levant, The Sultan, Fabias de Maderanaz, Meg Merrilies, and Triomphe du Nord. *Reflexed*—Ariadne, Cullingfordi, Chevalier Domage, Christine, Dr. Sharpe, Progne, Golden Christine, Julie Lagravère, King of Crimsons, Gazelle, Felicity, and Orange Annie Salter. *Pompons*—Adonis, Fanny, Crimson Perfection, President, Mdlle. Marthé, Golden Mdlle. Marthé, St. Michael, White Trevenna, Sœur Melanie, and the yellow, lilac, and white varieties of Cedo Nulli. The two beautiful large Anemone-centred varieties, Lady Margaret and Fleur de Marie, are deserving of a place in the most select collection.

Of late-flowering kinds we have Ethel, Fair Maid of Guernsey, Thunberg, Hero of Stoke Newington, Fulton, Meg Merrilies, Princess Teck, Nuit d'Automne, Mdlle. Lacroix, and Comte de Germiny. This year, however, we had one plant of Mdlle. Lacroix in flower in the middle of October, while others of the same variety and treated in the same way have not yet expanded their flowers. There has been a very marked improvement in the cultivation of Chrysanthemums during the last few years, one of the most notable features of which is the reduction of their height; most cultivators now manage their plants so as to keep them much dwarfer than formerly, and it has been proved beyond doubt that equally good flowers can be produced by such plants. It is a matter of surprise to many that the early flowering varieties are not more extensively grown than they are for the decoration of the outdoor garden in autumn. An orange-yellow variety named Précocité begins to flower early in August and continues for three months to be one of the brightest ornaments of the garden, and is invaluable for cutting. Illustration, light pink, changing to white; Nanum, creamy blush; Bob, maroon-red; Anastasia, purple; Early Blush, Virginia, white; Frederick Pélé, crimson—these all succeed fairly well under herbaceous border culture. The different varieties of Cedo Nulli and Madame C. Desgrange do very well if planted in a sunny situation against a wall or building.

As to the best time for propagating the Chrysanthemum for pot culture, a considerable difference of opinion exists. We have put in cuttings from the first week in December until the second week in June. The earliest rooted plants invariably produced the largest flowers. They also grew stronger and higher, and were more liable to become unsightly through the loss of the lower leaves than those rooted at a later period. February I consider to be the best month in which to propagate for ordinary decorative purposes. Plants propagated then usually grow from 18 inches to between 3 feet to 4 feet high, according to the variety, treatment received, and strength of the cuttings employed. Suckers that spring from the base of the old plant should be used for cuttings, preference being given to such as have travelled some distance from the old stem. They should be 3 inches or 4 inches long, and the leaves and buds should be removed from the portion inserted in the soil. Place each cutting in a small pot of sandy loam and leaf-mould in a cold pit or frame as near as possible to the glass, in order to keep them short-jointed and sturdy. Frost must be excluded from them, but they should not on any account be subjected to a close, high temperature; otherwise they become drawn up weakly, and from such growth good flowers cannot be expected. They should be kept close until rooted, just giving sufficient ventilation to prevent damping off. When rooted they may be exposed on every favourable opportunity to the full influence of the atmosphere. As soon as the pots are well filled with roots, care must be taken never to allow them to become pot-bound; they should be transferred to pots 5 inches or 6 inches in diameter, and from these into their flowering-pots, which should not exceed 8 inches or 10 inches in diameter. Place the strongest growers in the larger-sized pots. In order to cause the plants to become bushy we pinch out their growing points twice in the course of the season. The last pinching should be performed between the first and the last week in June, so as to have a succession of flowers. The alternative plan is to allow the plants to grow without check from the cutting state until the first week in June, and then cut them down to within 6 inches or 8 inches of the top of the pot. The objections to this method are that the plants receive a severe check; some of them do not push sufficient shoots to form a good plant, and the wood having become hard, the buds are a considerable time in "breaking." If the season happens to be cold and sunless the wood does not ripen, and the result is a scarcity of good flowers. Plants grown by the former method usually produce more shoots than are required. When this is the case they should be reduced to seven or eight, selecting those that are of about equal strength. When requisite a neat stake should be placed to each shoot, to which it must be secured. Cuttings made of the last pinchings and grown in 6-inch pots make useful little plants for vase or room decoration. Dwarf plants are serviceable for forming the front rows of groups, as they screen the pots and stems of taller plants. To obtain these, plant out a sufficient number of old plants in a sunny situation as soon as all danger from frost is over. When the flower-buds appear plunge as many small pots filled with suitable compost as may be required round each plant; with a sharp knife make an incision—similar to that which is made in layering Carnations—a few inches below the bud, then press the cut parts into the soil and secure them there with a hooked peg. In about a month the layers will be rooted, when they may be removed from the parent plants and placed in the shade for a few days to recover from the check sustained by removal. The compost should consist of a rich fibrous loam of a light rather than a heavy description, cut from a pasture field that has been laid down and well manured for a number of years. September is the best month for obtaining and stacking such loam, which should not exceed 3 inches in thickness. To every eight barrowloads of loam add one of lime rubbish broken small, also 16 lbs. of bone meal, and about the same weight of soot

* Read by Mr. Neild, Wythenshawe, Northenden, before the Manchester Horticultural Improvement Society, November 17, 1886.

will enrich the soil and make it unpalatable to worms. In potting the soil must be well rammed into the pot before the plant is placed in position, which should be sufficiently low to allow of a mulching being applied in August. Firm potting is an important item in the successful culture of this plant; it prevents over-luxuriance. The wood and leaves produced by this system of potting are not so gross and sappy as that which is grown in less firm soil, but it is much firmer and shorter jointed, and being less pithy will ripen under less favourable conditions. Well-ripened comparatively weak wood produces much better flowers than that which is unripened, however strong it may be. It is not a good plan to pot all the plants indiscriminately at once; it is better to examine them every week and repot only those that require it. The compost should be in a comparatively dry condition when used, otherwise it shrinks and cracks if permitted to become dry after being rammed into the pots in a wet state. As soon as all danger of spring frost is over the pots should be partially plunged in a bed of coal ashes in an open, sunny situation, out of the shade of trees or buildings, and sheltered from strong winds. If large flowers are desired—and we consider one large, well formed bloom preferable to a number of inferior ones—all side shoots and buds, except the centre or crown bud, must be removed as soon as they appear. If there be any doubt as to whether or not the crown bud is blind, it will be advisable to leave a shoot immediately below it, so as to have a chance of obtaining a flower from a later bud.

Pompons and any of the large-flowered varieties required for cut-flower purposes should be treated in a similar way to those grown to produce large specimen flowers, except that the first bud should be removed, and three of the side shoots nearest the bud retained. On these all the buds may be allowed to remain. The plants should be taken under glass the latter part of September or early in October, according to the state of the weather. If left out later they are liable to be injured by frost and mildew; to the latter they are very subject if left out after the dates mentioned. They may be put in Peach houses or vineries from which the fruit has been gathered, or in any other house that may be vacant, if provided with the means of excluding severe frost. Chrysanthemums are voracious feeders; therefore they should frequently be supplied with weak stimulants from the time when they become established in their flowering-pots until the flowers have attained full size; its use may then be discontinued. As regards the best kinds of manure to give them, I find those that contain the largest percentage of ammonia are most beneficial. Sulphate of ammonia is perhaps the best for the purpose. It is a strong fertiliser and requires to be used with discretion, as an overdose might ruin all to which it is applied. One hundredweight per statute acre is considered a liberal allowance for land under farm cultivation. That would amount to only about 1·25th of an ounce per square foot, so that plants in pots from 8 inches to 10 inches in diameter will each require only a very small quantity. Chrysanthemums will bear stronger applications without apparent injury, but I consider that it is better to apply it at the strength mentioned, and repeat it once a week if necessary. It should be used in a liquid state, as it is more likely to permeate the whole body of soil in that condition than if applied in crystals.

Greenfly is their most common enemy. A sharp look-out should be kept for the first appearance of this insect, and as soon as discovered means should be taken for its destruction. One or two applications of tobacco-powder or a solution of tobacco-juice will destroy it, and these can most readily be applied to the plants when in their summer quarters; whereas, if attacked after removal indoors fumigation with tobacco-paper will be the most effectual method of dealing with it. When plants are attacked by aphides in large numbers, they cause great injury by extracting the juices that should have been devoted to the development of the flowers.

The Marguerite Daisy fly (Phytomyza affinis) is a destructive pest, which appears to be rapidly increasing. The presence of this insect may be readily discovered by the leaves becoming discoloured where attacked. The fly usually appears in spring, and lays its eggs on the undersides of the leaves beneath the skin. When hatched the grubs begin to feed on the sap and interior cells of the leaf. Various insecticides have been tried for the destruction of this insect, but none of them are of any value; if applied sufficiently strong to destroy the grub they are almost certain to injure the plant. The most effectual way of destroying the grubs is to carefully examine the plants and pick off any leaves seriously damaged. The insect, in those that have been but slightly injured, may be dispatched by pressing it between the thumb and the finger. The affected leaves and stems of plants, after being cut down, should be burnt instead of being thrown to the rubbish-heap. Any grubs that have attained full size will undergo their transformations under such conditions, and will doubtless prove a source of trouble and annoyance in the future. Chrysanthemums are also sometimes attacked by the larvæ of Mania typica, which cause great damage by eating through the flower-stem immediately below the bud, thus rendering it abortive. This species only eats half the thickness of the leaves they are consuming. The most effectual method of exterminating it is by careful hand-picking. Earwigs are considered to be very destructive to the Chrysanthemum. From experiments that I have recently made with these insects, I have come to the conclusion that they do not commit so much damage as is generally imputed to them. Their food consists chiefly of decaying vegetable matter, but they are not, strictly speaking, vegetarians. My observations lead me to believe that they cause little or no injury to the buds or flowers, to which they go for the purpose either of feeding upon some other insect that infests the plants or to escape notice. In some parts of the country they are much more numerous than in others. If considered necessary they may be trapped in small flower-pots partially filled with dry Sphagnum Moss, in short lengths of Bean or Sunflower stalks, or in any other hollow object that will provide a retreat for them. Whatever is employed should be examined every morning and the insects destroyed.

Tunica Saxifraga. Engraved for The Garden from a photograph.

Mildew is very injurious to Chrysanthemums, and spreads quickly if not prevented. It may be removed by one or two applications of sulphide of potassium. The best way of preventing an attack is to maintain an abundant circulation of air amongst the plants, which should stand clear of each other, and on a fine evening, about once a week, syringe the undersides of the leaves with a weak solution of sulphide of potassium of about a quarter of an ounce to two gallons of water. After the plants have flowered they should be cut down, and put in a cold pit or frame where they can be protected from severe frost. If there is not sufficient convenience for protecting the old plants a number of cuttings required may be put in at once, and when the time for propagation arrives in spring their tops may be taken off and rooted. In this way the stock may be retained in good condition, and occupy less space than if allowed to remain in the flowering pots.

Sweet-scented Flag.—"Veronica's" list of sweet-smelling-leaved plants given recently in The Garden did not include the sweet-scented Flag, but being an aquatic perhaps he did not think it desirable to mention it. It is not, however, an uninteresting plant, for if its leaves are crushed in the hand they emit a peculiar odour not at all unpleasant. Once planted in a pond or lake in a depth of 2 feet or so of water, it requires no further attention.—J. C. C.

White Everlasting Pea.—Can any reader of The Garden say if the white Everlasting Pea comes true from seed? I ask this question because a friend of mine sowed a quantity of seed which germinated well, but of the progeny only about one-third came white. Near to the white was a plant of the common red kind, and I thought that my friend might by mistake have mixed some of the seeds of this with the white sort. I found, however, that he had carefully cleared the coloured one away before gathering the seed from the white variety. Assuming that no mistake was made, it is evident either that the two varieties were cross-fertilised when in bloom, or that some of the white ones reverted to the typical form, for I suppose that the white is a sport from the pink kind. I think it more likely to be a case of reversion, as all the pink-flowered seedlings were identical in colour. There was not the slightest difference between them and the ordinary pink-flowered kind. Had they intercrossed, one would naturally think that some would have come paler in colour than others. If any of your readers have any experience in raising the white Everlasting Pea from seeds, they would oblige by stating whether the results are the same as in the above-mentioned instance.—J. C. B.

TUNICA SAXIFRAGA.

This little plant is not often seen in gardens, perhaps because its place and use are not so obvious as those of more showy things; but rightly employed it is a pretty and useful plant. It does well in bare, poor ground and is very handy for carpeting over bulbs. Where the Meadow Saffrons are grown in borders (their right place being of course in grass), there can be no better plant to cover the space they leave bare before and after flowering. The bushy, rather wiry nature of the Tunica flower-stems gives just the support needed by the Colchicums, whose heavy flower-cups, lacking the friendly support of their natural ally, fall over before their beauty is over and present a miserable appearance, lying flat upon the ground.

Verbenas and red spider.—Watering with soot water will not destroy red spider on "B.'s" plants. Possibly he misunderstood his instructions, which were probably to sprinkle the Verbenas overhead with soot water, or, better still, dip them in it. This, if it does not kill the spiders, renders the leaves and stems too bitter for the pests, and they decamp. But tobacco water, in the ratio of one of juice to three or six of water, according to the strength of the material delivered,

is a more potent and thorough dip for red spider and other insects, and is equally safe if tested before using it extensively. Concoct your mixture, thoroughly incorporate it with the water, dip a few plants and leave for a couple of days and examine them. Should the insects be dead and the plants safe, dip the whole and the pests will be got rid of; but should the pests not be dead, strengthen the dip by adding more tobacco liquor. Should the test plants be injured in leaf or shootlet, water down the dip to safe proportions. All this may seem excessive care to take about such a small matter; and were tobacco liquors of uniform strength, Verbenas or other plants always endowed with the same power of enduring dips, the matter might be reduced to mathematical certainty. But while both these vital factors to the solution of our problem vary widely, there is no safe way of proceeding but by experiment. Dips are also far safer than fumigation, for thrips and spider—and they are mostly associated on Verbenas—will bear almost any amount of smoke with impunity, the leaves and shoots being apt to be burned up before these pests will succumb. Neither will soot water at the roots free Verbenas from rust, if by that he means a sort of canker apart from the effects of red spider and other pests. During the winter clean water is best, as the object is not to stimulate the plants into fresh growth, but to preserve that already made until warm weather or the season of propagation comes. During the season of free growth slight dressings of soot are a useful manure for Verbenas, but, if overdone, they partially burn their roots and may become a fruitful source of canker, *alias* rust. From 45° to 50° is a safe temperature for Verbenas in a state of rest in winter, though the largest collection ever handled by the writer was wintered in cold pits under mat coverings, and at a temperature of about 40°.—Hortus.

—— Verbenas will keep well through the winter in any light, airy greenhouse from which frost can be excluded. "B." should keep them well up to the glass, give as much air as the outdoor temperature will admit; give only sufficient water at the root to prevent flagging, and an occasional dust of sulphur as a preventive of mildew. With respect to red spider and other enemies, put a wineglassful of paraffin and an ounce or two of soft soap in a pail of warm water, mix all well together, and thoroughly incorporate the paraffin with the water by frequent syringings; dip the Verbenas in the mixture. Some varieties keep much better than others, and it is as well to discard at once any that appear weakly and delicate, reserving only those of dwarf, bushy habit and of vigorous constitution. The Verbena has always been a favourite of mine, and I am pleased to say I have discovered a new bedder that is likely to prove an acquisition. Amongst a batch of seedlings it arrested my attention three seasons ago. It was saved and propagated, and has quite answered our expectations. It is pure white and scented. The truss is good and thrown well up above the foliage. It has been very effective in our flower garden this summer. I would strongly advise all who grow Verbenas to select any seedlings that are out of the common, either in matter of colour, freedom, or vigour, the last-named quality being indispensable. Verbenas succeed best in a fairly holding soil—a sandy loam, and if the weather is hot and dry when they are first put out, a slight mulching and good soaking of water are necessary; they should be pegged down as soon as possible, in order that the surface may be quickly covered with growth, and this little extra attention at starting will be amply repaid. One sometimes hears the remark made that the strike of Verbenas has not been good owing to the scarcity of young, tender growths, but this can always be remedied by the application of a thorough soaking of weak manure-water early in August; we secure in September by this means hundreds of good cuttings from a very small bed.—E. B.

Japanese Anemones and Tritomas.—These associate well together, *i.e.*, the variety Honorine Jobert. Much has been said lately about both these plants, but nothing respecting them when massed together. The Torch Lilies, conspicuous as they are, are rendered more so when intermingled with the Anemones, and, on the other hand, the whiteness of the Anemones is enhanced by being intermixed with such brilliant neighbours. Three years ago we had to divide some large plants of Tritomas, but we have found that they do not like division; this is the first year in which they have flowered again, although they started into growth nicely soon after they had been divided. We possess also the red form of the Anemone in various tints, but we find the white sort is always preferred for decorations and vases indoors.—J. Sallier, *St. Germain-en-Laye.*

Gladiolus Colvillei de Versailles.—Bulbs of this plant came to me last spring, along with some other early-flowering sorts, and I concluded it would flower at the same time as the others; but it did not do so—in fact, it was the middle of October before a blossom opened. However, the flowers are well worth waiting for, they are so very pretty. No doubt this variety is known to some, but for the information of such as do not know it, I may say that it is an enlarged form of The Bride, which is well known to be an early-flowering white variety; the one under notice, however, has a beautiful white-pink stripe running down the centre of the three lower petals. The top petals are pure white, while the throat of the flower is pink—colours which contrast pleasingly with those of the other parts of the flower. It is more vigorous than The Bride, and, if it did but flower at the same time, it would be invaluable; but, as it flowers so late, when winds and rain prevail, a good deal of its beauty is lost.—J. C. C.

Planting out Arums in summer.—Mr. Muir (p. 445) does well to recall this practice, at one time more common than it is now. Towards the end of May or early in June the Arum Lilies used to be divided and planted in rich soil; some of the strongest flowered in the open in the late autumn, and the whole were potted up several at times in full flower towards the middle or end of October. By the way, this fine old plant used also to be very successfully employed for the furnishing of shallow tanks in the conservatory. One of the first and finest plants ever seen by the writer was grown in a vinery tank placed over two flue furnaces; it was grown in a 12-inch pot, but the roots overflowed the pot in all directions, and at times used to almost fill the tank. When they encroached too much on the water, a great proportion of the overflow roots was cleared out; more were speedily forthcoming, and the plant did not seem the worse for these severe root-prunnings. Two features about these Arum Lilies in the warm tank impressed themselves on my mind; the first, that the plant was never without leaves and seldom without bloom, either fully expanded or partially grown.—Hortus.

Aster ibericus.—On sending a better specimen of M. Max Leichtlin's Aster ibericus to Kew, I received a letter giving an opinion that it could not be A. Amellus var. ibericus of De Candolle and Boissier. It may perhaps be a variety of hybrid origin, accidentally raised in cultivation. I am sending a plant to be grown at Kew, and regret that I have not more to distribute at present, but it is very slow of increase, seldom making more than one stalk from a plant one or two years old. Hybrid Asters from accidental seed are often found in gardens, and are worth notice because I am convinced that many of the best Asters in cultivation have originated in this way.—C. Wolley Dod, *Edge Hall.*

Primula capitata major.—I quite agree with my friend Mr. Wolley Dod that caution should be used in adding to the names of plants, and in the case of Primula capitata major, to which he alluded (p. 474) some time back, I brought to the notice of the floral committee some flowers of this Primrose, and without leaving the chair said it was only a fine form of Primula capitata, but as the plants developed themselves they seemed to be, horticulturally speaking, new, and as leaves, heads, and flowers were all so much larger than the type, I proposed the addition of major; the strong stem of one measured was 20 inches high, and I doubt this being the tallest. From some experience with Himalayan Primroses, among them P. capitata (see report of the Primula Conference), I do not fear the plant degenerating in this country. Several experienced hardy plant growers who saw the flowers exhibited were of my opinion as to its being a new and valuable plant.—George F. Wilson, *Heatherbank, Weybridge Heath.*

Iris susiana in full growth in November.—Mr. West's note of the unprecedentedly early blooming of Iris stylosa in Surrey induces me to record the early growth of susiana. I am also anxious to learn how to treat it for the best. The whole of our dozen or so of plants are throwing up young leaves and stems, and I fear that the unseasonable growth will tend to the destruction of this magnificent, but never over-hardy, variety by frost. Would a wisp of Bracken wrapped round them insure their safety? or would it be better to box or pot them up and winter under glass? After a good deal of trouble we have obtained a pretty good stock of this fine sort, and should not like to lose it. Last summer we had some fine blooms, and next season we expected many but for this unseasonable growth.—D. T. F.

Moss-covered stones.—When pieces of stone, especially sandstone, are used about a garden for the shelter or general good of plants, they will be found in some situations to be completely coated with bright green Moss. Having, at Oakwood, a long mound in full view of the cottage windows, on which mound it was desirable to put some stone to prevent the soil washing away from the plants, I collected Moss-covered pieces of stone and sunk them about half their depth in the soil. The Moss, though dried up in summer, has become again bright green, so that in place of bare stones we have quite a pretty object to look upon at a time when flowers are almost over. It is possible that this hint may be useful to some of your readers. —George F. Wilson, *Heatherbank, Weybridge Heath.*

NOTES.

Winter colour in the garden.—There is a story told in the studios now and then of a French artist who never studied from Nature, because, as he remarked, she was "too green and too badly lighted." Now, the time of winter, when Nature is all greys and browns, ought to have satisfied at least one of the above conditions, but there is, after all, no hope for the last. If Nature is not always beautiful to us, she will never try to please us at all; she, at any rate, can well afford to await the coming of admirers like a queen. The colours in the garden on these fine sunny November days are very rich and precious—not glaring, like those of the rosy summer-time, it is true, but as is the russet Apple or the red-brown Pear to the rosy cloud, or the snowy whiteness of their blossoming, so now are the winter tints most lovely in the garden. Even the stones, so dry and harsh in summer, are now moist and embroidered with velvety Moss or soft grey Lichen, and Saxifrage or Sempervivum, unnoticed in flowery summer, are now a study in themselves of rich, warm olive-greens and reds and browns. Here and there are brighter glints and gleams of Chrysanthemums, yellow, red, crimson, and brown. There is Veitch's Creeper, with its many-footed wreaths of bronzy red leaflets still slowly creeping up the old grey walls. If you do not know how this plant really walks up a bit of sunny wall, step over to the first bit you see, and you will think its curious method of progression but little short of a miracle. Tufts of flowering Ivy of a golden green are covered with flies, as if the summer time had not yet left us, and there are Violets and Primroses enough in blossom to remind one of spring. But somehow one always feels a tinge of melancholy on these soft, warm November

days, for there is ever present the conviction that they are too good to last—an unseasonable luxury for which we shall have to pay too dearly.

Colchicum Bivonæ.—So far as I know at present, this seems to be the very latest of all the autumnal species of Colchicum. I say autumnal, because I hold that what we call Bulbocodium vernum now is only the Colchicum vernum of Besler's "Hortus Eystettensis," a Colchicum which flowers in early spring instead of in late autumn. I saw a good group of the above C. Bivonæ (Guss.) flowering freely in a friend's garden on November 19, and, as he informs me, he obtained roots under the name of C. lusitanicum of Brotero, this last being, as I suppose, a synonym, but, as I apprehend, it is by no means common in gardens generally. Perhaps Mr. Ewbank or some other lover of hardy bulbs will tell us more of this robust and hardy plant. Its flowers are borne well above the soil, and are of a soft lilac-purple or rose colour faintly tessellated, as is so generally the case with these flowers. It would appear naturally to affect dry localities in the warmer parts of Portugal, Italy, near Naples, Sicily, Greece, and in the island of Crete. As a plant for a high, dry, and sheltered position on rockwork in full sunshine, this late blossoming bulb seems worthy of more attention than it has hitherto received.

Corbularia minor.—The first Narcissus to flower with us opened its eyes to the sunshine of November 21, but Canon Ellacombe tells me that one of the varieties of N. Tazetta, called the Scilly White, has blossomed with him in the open air at Bitton. It opened its first flowers on November 1, and, accidental though it may be, the very fact that it is possible for Narcissi to flower thus early suggests many potentialities in the management of our bulbs. I think it was Loudon who recommended the keeping of bulbs dormant or at rest for one season, in order to make them more precocious the next, but I am not sure if any well directed experiments in this way have ever been tried. The little Hooped Petticoat Daffodil now flowering with us is in a greenhouse wherein it has been grown ever since the late Rev. H. Harpur Crewe made his journey to Spain along with Mr. George Maw. He was the most generous of collectors, and sent me something like a tithe of his lucky finds in Leon and the Escurial. It would not be so very difficult to get such early Daffodils as is N. pallidus præcox to bloom in November, or at the latest by Christmas Day, by growing them, ripening them off, and resting them by keeping them dry in the pots in a greenhouse climate. So treated, it would be easy to have them a little earlier every season, and if well and judiciously nourished when in full vigour of growth and flowering, the bulbs would increase in size and strength instead of deteriorating, as they do when starved and neglected. There is a good opening for anyone who will treat some of the earlier blooming Daffodils from Portugal, Italy, and other warmer lands than ours with the care we give ungrudgingly to Amaryllises or Nerines. As it is, we do not obtain a tithe of the beauty and grace of which Narcissi in pots are capable of giving.

Cultural variability of white Daffodils.—I believe those who originated the idea that white Daffodils will not grow healthily and well in the Chiswick garden of the Royal Horticultural Society have not as yet proved their case. The fact is, they used to grow well there in the days of Salisbury, Haworth, and Herbert, a fact, however, which does not absolutely prove that they will do so now. My own impression is that they will do so, and certainly we may "go further and fare worse" in the selection of neutral territory on which to hold a tournament. I have more faith in a common-sense plan of deep digging and early planting in August than in any scientific investigation whatever. Nutrition nowadays seems to be at the bottom of everything really important in plant culture, and if Mr. Barron does not tell us that the atmosphere at Chiswick is too impure for white Daffodil culture, I would venture to go bail that all other details of soil and culture are or will be well provided. Miss White grows white Daffodils so well, and is such a great authority upon them, that I feel a little taken aback when she mentions growers in the matter. As she wisely observes, there is no competition in the matter so far as growers are concerned, but, as I imagine, no one can deny that any one soil and climate is equally fair and equal in its effects upon any one Daffodil from any number of growers. This is the point, of course, and I hold that Chiswick is the best place for a trial of Daffodils of any and all kinds, if you take all the facts of the case into fair and impartial consideration. Mr. Barron is a past master in trials of this kind, and that he is not Daffodil-mad is, as I take it, a good many points in his favour as an arbitrator in such a delicate matter as this appears to be. I am glad to see that Miss White (p. 474) admits that soils different and places apart do really alter or obliterate the characteristics of white Daffodils. I have upheld this view of the question for some time. I, of course, grant freely that Chiswick may not be the very best place for white Daffodils *per se*, but, considering all things, I believe Chiswick to be the best place obtainable near London.

Bulb growth.—There is a little mystery about bulb growth since, but few of us seem to have any clear and practical knowledge of how the little seedling bulbs get down into the earth, although most of us know that the natural tendency of Crocus, Lilies, and many other full-grown bulbs is not to go down, but to come up to the surface as soon as ever they can. When the seeds of Crocus and most other Irids fall on the surface of the ground, those which fall accidentally into cracks or depressions of the surface have so far the advantage, and these seeds germinate first, the germinal bud or embryo being, moreover, actually pushed lower down into the earth by its normal growth force. There are, however, other agencies at work. I forget the exact details, but in Darwin's work on earthworms he shows how the surface of a field actually becomes raised above a dressing of limestones, and possibly the earthworm also helps to cover up bulbs in the garden by throwing up the soil. In vol. viii. of the "Journal of the Horticultural Society of London," pp. 117, 118, there are a figure and description of Crocus bulb development by Thilo Irmisch, but he, like Mr. Maw, does not allude to the down-thrusting power of the seed on the young germinating point which ultimately becomes the bulb. The main point seems to be this, young seedling bulbs work downwards into the soil on which the seeds naturally fall, and the question I would put to all practical observers of the fact is, how is this done? Only the other day I had to throw a thick top-dressing of earth on to our lines of old Crocus, as the tops of their bulbs were showing above the surface of the soil, and these bulbs were planted 5 inches deep only three years ago. The way the bulbs of white Lilies come to the surface is well known. Veronica.

Imperishable labels.—I send you one of the labels manufactured at Stratford-on-Avon, and which has been exposed to all weathers on a wall facing the west for sixteen years. As you will see, it is in as good condition now as when it first left the mould in which it was cast, and for that matter, if left in the same position, it would evidently last an indefinite time, and as it only cost a penny, no one can say it was dear. On a previous occasion I suggested that nurserymen should send out with their trees this or some other imperishable label, the purchaser, of course, paying for them, and for fruit trees and Roses I see no difficulty why such an arrangement should not be carried out. If a label that only cost a penny will last out the life of a tree, surely it is worth an effort to secure it. For dwarf Roses we have such labels attached to an iron support rising about 9 inches out of the ground, and although they are not legible at any great distance from them, their imperishable nature renders them very suitable for outdoor subjects. For pyramid and cordon fruit trees we use the same kind of iron support, to which the label is attached by a crook at the end, and I am perfectly satisfied with them, as I get a label, iron support and all for the sum of 2½d., and it ensures the identity of the tree for an indefinite time.—J. C. C.

*** The label to which these remarks apply is a little oval one with raised letters, perfectly legible, and apparently indestructible. A hole at the top enables it to be fastened to the wall.—Ed.

Rose Garden.

ROSE STOCKS.

It is refreshing in these times of general compromise to read such a slashing article as that by "T. W. G." (pp. 437, 438). Whatever opposition or enthusiasm it may evoke, no one can fail to admire its thoroughness. It is virtually a peremptory notice to the Manetti to quit, begone, bag and baggage, out of field and garden. It is as easy to do this as to call up spirits from the vasty deep. Will the latter come, or the Manetti begone? That is the all-important question for rosarians to settle, the hard nut for them to crack this winter. As is generally the case, something like a calm has succeeded or followed "T. W. G.'s" sledge-hammer blows on the Manetti. True, "J. C. C." mildly remonstrates on page 453, but he finds less fault with the Manetti than with its removal. Work it where it is to grow, and it will prove anything but worthless. Not a few other stocks would be much improved and sooner converted into charming Rose bushes could this rule be generally applied. Unfortunately, it is impracticable unless every rosarian grew his own stocks and had patience to wait until these could be grown, worked, and developed into Rose trees where first planted. But while the trade is expected to rush up plants and provide them at the cheapest possible rate for the public, Roses must be transplanted, and also transported almost so soon as worked, and the stock that will not bear either or both with comparative impunity must give place to a better one. But is the Manetti really so bad, and the Brier so very good as "T. W. G." affirms? These are questions that can hardly be answered by any one man, however gifted or well qualified to hold and forcibly express an opinion.

While admiring outspoken thoroughness either of praise or blame as much as most rosarians, such sweeping condemnation of one stock and unqualified praise of another is not the likeliest method to beget implicit confidence. People also have a lingering affection for any bridge that has carried them safely over, and there can be little doubt that the Manetti has given a wonderful impulse to Rose culture, and possibly carried Roses into hundreds and thousands of gardens where they could hardly have entered without it. It is also still such a potent factor in Rose culture that it must not be dismissed in disgrace so soon as one loud blast of denunciation has been uttered against it. The use of the Manetti Rose as a stock, its rapid rise to fame and fortune, are matters almost of yesterday, and it will be passing strange should its fall be as rapid as its rise. It almost annihilates time in the raising of Roses, and promised rosarians deliverance from most of their troubles, if not a sort of processional series of triumphs and unbroken prosperity. Rooting

like a weed, growing vigorously as a Willow by the watercourse, taking on all sorts of foreign buds, as to the manner born of the most generous foster-mother that had yet been found, the Manetti became the stock of the period and promised to remain the most popular stock for posterity.

It is hardly an exaggeration to write that Manettis were propagated and planted by the million. How are your Manettis (Briers)? is becoming the question among rosarians as common as, how are your Mangolds or bullocks? among farmers. No inspection of great trade grounds was considered complete until the eyes, fatigued by running along lines or through breaks of glowing beauty of any length or depth, cooled themselves in the broad breaks or wide fields of Manettis. This was as refreshing as a series of headers to a robust swimmer on a sultry day.

The Manetti was written up as the stock for all sorts, classes, and forms of dwarf Roses. Roses in pots, or in the open, Teas or Perpetuals, all must be manetticised before perfection could be reached. This popular stock revealed the mystic art of making weak Roses strong, and strong ones still more vigorous and beautiful.

No stock could foster growth so rapidly; yards were thrown off from this rootstock faster than feet, or even inches, from some other; such, for example, as some Brier own-root Roses, and in such speed there was great profit. There was not only popularity, but more money in Manettis than any other stock, and hence, doubtless, to a great extent its legitimate extension and great commercial success. Not that it was ever quite all gold that glittered in regard to this stock; for early in its history its evanescent character was whispered abroad; but longevity is not everything, retorted its devotees, and, further, they were ready with a plan that rendered the length of life of the stock of small moment. Here is any reasonable amount of vigour. Let us take advantage of it as it flies. By working Manettis low on the root-stock and, in fact, burying the point of union, the Rose is liberally fed by the foreign stock, while it is also, as it were, making a double lot of hay while the sun shines—that is, while its foreign supplies of food last by rooting itself in the ground; and then before the stock perished, or rather, in many cases, the Rose tired of its foster mother's supplies, the bud or graft had developed into an own-rooted independent Rose. This simple means of counteracting the high death rate of Roses worked on the Manetti was promulgated and practised very soon after its general introduction, and I cannot see that thus worked Manetti stocks have proved "the root of all evil," nor the conspicuous failures that "T. W. G." has indicated.

I am, however, fain to admit that they have not seldom been found wanting in permanency, and almost as much may be said of Briers and other stocks. So unsatisfactory are transplanted Roses from certain trade grounds, that not a few rosarians prefer buds in the summer to huge plants in the autumn, and I am not sure that some would not refuse a thousand Roses on fat-rooted Briers as a gift rather than go to the trouble and expense of planting them, as "T. W. G." assures us he would their number of Manettis.

"T. W. G." while praising the Brier seems anxious to have as infinitessimal an amount of it as possible. Hence he advocates working his Roses on the roots of the Brier with the view doubtless of allowing them to root for themselves, as well as feast at the Brier's table so long as the latter lasts. It may be admitted that the latter will provide roots for the Roses longer than the Manetti stocks without counselling the wholesale dismissal of the latter. For after all a very important question seems lost sight of by "T. W. G." in his able and semi-exhaustive article. It may be stated thus: practically the durability of the stock itself, or of the union between the stock or scion, may in the case of the Manetti be of far less moment than it seems at first sight; say, for instance, the stock perishes, or the connection between it and the scion at the end of two or three years.

This may mean the destruction of the Rose, or its resuscitation into a higher, because more independent, life; for surely "T. W. G." cannot mean that Roses that have been assisted to root for themselves on Manetti stocks are shorter lived than those that have been similarly assisted by Brier, Polyantha, or any other rootstock, or that have been struck from cuttings. No; once a Rose or other plant has formed roots for itself its longevity can hardly be affected by such accidental circumstances, as whether the roots were formed from the crown of a stock or in sand or other compost in the usual way. And if not, there is then still a mission for Manetti stocks in the future as in the past in sustaining and augmenting the vigour of Rose or graft, while these are forwarding their intention to become own-root Roses. If, as seems probable, the most important function of dwarf Rose stocks in the future is simply to shorten the period and add to the vigour of their own rooting, then for such a purpose commend me to free-growing, easily-worked Manetti to the difficult-to-work-down-among-the-roots-and-the-mud Brier stocks. But this may be a matter of taste. But as experience shows that the longevity of our Roses is hardly affected by their mode of rooting, and as they root outside the stock as rapidly, if not more so, on the Manetti as on any other stock, and as the latter can be grown into workable form sooner than any other, there surely then is still a brilliant future before the Manetti as the foster mother of own-root Roses. As to the latter, I agree with "J. C. C." that these should be the Roses of the future, and hence I welcome and wish to retain every means at our command, including Manetti stocks, of increasing their numbers with the utmost possible rapidity.

D. T. F.

Roses in November.—It is not often that a collection of open-air Roses is exhibited at a Chrysanthemum show, but at Bath, on November 11, Messrs. Cooling had a really good show of blooms. Of these, the best—*i.e.*, the largest and freshest—were A. K. Williams, Captain Christy, Madame G. Schwartz, Gloire de Dijon, Countess of Oxford, Baroness Rothschild, Bartholemy Jobert, Hippolyte Jamain, Clothilde, Duke of Wellington, Fisher Holmes, Mabel Morrison, and Madame Gabriel Luizet. The last-named was at one time considered to be of no value for affording successional or autumnal blooms, but for the past two seasons it has agreeably surprised those who cultivate it.—W. I.

Rose Cramoisie Superieure.—We have two long borders of this Rose; the first was planted fifteen years ago and partially renewed; the second is only ten years old. We consider Cramoisie Supérieure to be one of our best Roses, these borders furnishing us with flowers all the year round. They were planted in some mixed soil, in which loam formed the greatest part, and they have had yearly a good dressing of cow manure mixed with Parisian street-sweepings. This town product is very much used about here; when well rotted there is no better manure for Vines and Asparagus. In autumn high frames are put up round the Roses, and later on they receive a large shelving bed for protection. All the winter through some thick straw mats (*paillassons*) cover the lights at night, according to the French custom. During the daytime they get as much air as the temperature will allow. As they flower so freely and quickly after pruning, we manage to prune one part while the other flowers in such a way that last year our blooming season began in January and since that time we never have been without blooms. Cuttings of this Rose made in August last strike freely in a sandy soil, protected with hand-lights at first, shading, and after a while giving air according to the state of the weather.—J. Sallier, *St. Germain-en-Laye.*

SHORT NOTE—ROSES.

Cheshunt Hybrid Rose.—This is a robust and persistent blooming Rose, which for cutting has but few equals. If it has a fault it lies in its colour, which I cannot praise quite so highly as Mr. Muir. But even in colour it is an advance on most of its predecessors.—D. T. F.

Miniature Roses.—These are much more effective when planted out in good soil in the open than I supposed them to be. For several years I grew them in pots, and, although interesting when so grown, they did not give so many flowers as I expected. I therefore planted them out two years ago, and from their behaviour this season I am very glad I did so; thus treated, they have proved such perpetual flowerers, that in that respect they have surpassed all other Roses in the garden. In the middle of October, the variety named Mignonette was heavily laden with large clusters of rosy pink flowers. The white variety, Paquerette, has been equally well covered with blooms of the purest white, and, owing to their being in such large clusters, they are certainly very pretty. Since the plants have been out of doors, I find that mildew does not attack them. These Roses evidently like a light rich soil; their roots are not so large as those of other Roses; consequently they cannot grapple with a coarse heavy medium. I may add that I have never pruned these varieties further than to take off just the tops of the shoots which have flowered and to cut out dead wood.—J. C. C.

GARDEN FLORA.

PLATE 572.

ADENOCARPUS DECORTICANS.*

This beautiful free-flowering and perfectly hardy shrub is a native of the mountains of Granada, in Spain, where it was discovered by the French botanist, Boissier, growing as an undergrowth in woods of Pinus Pinsapo. It was first brought into cultivation by Messrs. Thibaut and Keteleer, of Sceaux, near Paris, from whom I received my plant of it in 1883, shortly after a coloured plate of it appeared in the *Revue Horticole*, which first introduced it to my notice, but did but scant justice to its abundant blooming qualities, having been evidently drawn from a small or imperfectly developed specimen of this handsome shrub. It is most easily propagated by seed, which, however, in this country sets but shyly, my specimen bush having this year only perfected half-a-dozen pods, each of which contained only a single seed. It thrives best in comparatively poor peaty sandy soil, and as it does not bear transplanting well, it should be grown in a pot till planted out where it is intended to remain permanently. The general aspect of the plant when in flower much resembles that of the common Gorse, but it is entirely destitute of thorns. It stood the exceedingly severe winter of 1879-80 in the neighbourhood of Paris quite uninjured, so may be considered to be quite hardy.

W. E. Gumbleton.

Comparative hardiness of Platycerium grande.—At the late Colonial and Indian Exhibition were some very good specimens in pots and on wood of Platycerium alcicorne and a superb example on cork of P. grande, the most magnificent of its section, kindly lent for the occasion by Sir George Macleay, of Pendell Court. P. alcicorne is generally grown in a cool, or intermediate house, where in most cases it succeeds admirably; therefore no fear was entertained on its account. But the same could not be said of its companion, P. grande, which, although given in most of our leading Fern publications as indigenous to Australia, is from a much higher temperature than that in which it has recently been placed. In both cases, however, the results have been practically the same; by the side of P. alcicorne P. grande has produced a handsome shield-like sterile frond, and also developed two magnificent fertile fronds, which for size, colour, and texture can bear comparison with the best plants of the same kind grown in heat. What the

* Drawn from a plant in Mr. W. E. Gumbleton's garden, Belgrove, Queenstown, Cork, May 20, 1886.

ADENOCARPUS DECORTICANS

lowest temperature in which it would stand unin jured is, it would be interesting to know; all we can at present say is that it has stood the frequent changes to which it has been exposed well, and this success may be the means of inducing some of us to try the effect of cool treatment on this grand Fern.—S.

WORK DONE IN WEEK ENDING NOV. 23.

NOVEMBER 17 TO 23.

THE weather having greatly improved—only one showery day—we have had a busy time of it, cleaning up after the rain and wind storms, rolling roads and walks, and our soil being of a light, sandy nature, we have been able to continue trenching and clearing off all exhausted crops in the kitchen garden, together with Pea sticks and Bean rods. We are now getting to look a bit tidy in this department, and our next want is frost, to enable us to wheel manure on to the various vacant plots, as also to mulch Asparagus and Strawberry plots. Roses we are already lifting, trenching and manuring the ground, and replanting, after cutting back the long, thong-like roots and any Brier suckers that may be on them. Every alternate year this lifting is done, and the labour is well spent by a long season and a rich profusion of flowers. Before we adopted this practice, mulch and feed as liberally as we knew how, the Roses never did satisfactorily. The first drought or spell of hot weather caused them to become a prey to spider and mildew; now we are seldom troubled with either, and if we do not get show flowers, we certainly do get good flowers in plenty from May to December. Souvenir de la Malmaison we have at the present date in abundance, and in a wonderful state of perfection. Root-pruning—on one side of the tree only—a few strong-growing Pears; only those grafted on the Pear stock require this operation in our light soil, and at very rare intervals indeed. Frequently the pruning of roots on the one side of the tree has the desired effect of inducing fruitfulness; consequently the other side is not done. But should wood-growth be excessive next summer, then, of course, the other side of the tree will be pruned next autumn. Apples we serve exactly the same. Apricots and Peaches on walls are annually root-pruned, if such it may be termed, though it hardly amounts to that. Our borders are wide and are cropped with vegetables, and are annually heavily manured and trenched each year to within 5 feet of the wall to which the trees are trained; this 5 feet is never dug, but is sacred to the roots of the fruit trees, being well top-dressed twice a year, but all roots that during the summer make their way and feed on the new material in the trenched part of the border are cut clean off at the annual trenching. The plan answers admirably, as we never fail in having good crops of fine fruit. The new-made roots in the newly broken ground are, I think, the main supporters at fruit-swelling time, and the cutting back of them keeps the trees in full fruitfulness by a check in growth, and, as it were, enforces a great amount of root formation in the permanent borders, which, being hard, rooting goes on slowly—indeed, I may say under difficulties; but the resistance they meet with causes lateral extension of them till they become perfect frills of roots, and these are far more to be desired than strong, sappy roots, the bulk of which perish during the winter. Began to prune arched cordon Pears and Apples. It is but little they need, as summer pinching prevents the necessity of that; still it is necessary to go over the trees to cut close back any small shoots that may have been left, as well as to shorten any old spurs that may be getting too long or gnarled. An excellent plan to prevent the trees ever getting into this condition is to cut back to within a couple of buds of the main stem a few of the longest spurs on each tree annually. With all fruit trees that bear best on the spur system this is our invariable rule. The foregoing, together with leaf-carting and preparing stable litter for hotbeds, forms the sum total of our outside work for the week. Indoors, there has been a considerable amount of labour spent on Chrysanthemums and other flowering plants, shifting them from one house to another in order to prepare for forcing early Vines, early Peaches, and Figs, as these houses having to be closed up, damp would soon make short work of the flowers. A dry, airy atmosphere free from frost is the best suited for Chrysanthemums, Carnations, and Pelargoniums now in flower; hence we have given them quarters in second Peach house and an intermediate vinery. Bouvardias, Primulas, and shrubby Begonias enjoy warmth, and for the present our Strawberry house is given over to these, and will be for some weeks to come, as we prefer to start our first two or three batches of Strawberry plants in pits that are filled with Oak leaves. Our first fifty plants have now been put in; neither our stove house nor variety of stove plants are of very formidable proportions, but what we have we strive to make the best use of. At present, Calanthes and Poinsettias are the predominant plants, and we have intermixed, or rather made a setting for them with Ferns, principally of Adiantum cuneatum, pubescens, formosum, and farleyense. The present night temperature averages 65°, and from 5° to 10° higher by day; no syringing is done other than to walls and floors early in the afternoon. Violets and Calceolarias in cold frames have all been surface-stirred to prevent the formation of Moss, which is the precursor of damping off, or of mildew on the plants. Air is freely given whenever the atmosphere is at all drying, and when rainy and mild, a little is always kept on by tilting up the lights at back. Put the first lot of Roman Hyacinths in warmth. Potted up roots of Solomon's Seal for forcing, also potted roots of Tarragon and Mint, and put a frame over Parsley on a south border, which will be kept closed up in sharp frost or snowy weather. Began closely packing together with leaves the general stock of Strawberry plants in pots; all we can make room for in cold pits we do, and those thus stored are the plants intended for earliest forcing.

HANTS.

FRUITS UNDER GLASS.

THE ORCHARD HOUSE.

JUST now houses that are made to yield the greatest amount of pleasure and profit will most likely be gay with Chrysanthemums, and the legitimate occupants will be resting in the open air. If well plunged to the rims in coal ashes, tan, or that excellent, but to us expensive, material, Cocoa-nut fibre, and a good covering of horse litter or Fern is cast amongst them, they will not require further attention until the time comes for taking them under glass for another year's forcing. A few start the early batch in December, but the majority leave them out of doors until the end of the year, and although they may be a month later at the outset, with a judicious selection of sorts of Peaches and Nectarines, they pull up time, and have ripe fruit as early as it is worth eating. Where in large gardens pot trees are forced to give the earliest fruit, and at the same time spare good old-established varieties like Royal George and a score of others equally good, the best extra early sorts, well established in their pots, should now be in their places. If properly thinned immediately after the past season's crop was gathered, they will only require careful washing with warm soft soapy water, and placing on inverted pots to favour the introduction of fermenting material and its frequent renovation without disturbing them. Light and fresh air being such important factors, overcrowding is the first thing to be guarded against, for, no matter how well all forcing details may be attended to, neither colour nor quality can be secured where this class of trees are forced dead against Nature, when the sun, seldom seen for days or weeks together, never rises more than a few degrees above the horizon. The next question is the distance from the glass. If strong shoots are shortened before the trees are taken in, 12 inches to 18 inches should be allowed for summer growth; if, on the other hand, this operation is deferred until the flower-buds are safe and swelling freely, allowance must be made for cutting back. Each pot should be well scrubbed, and the apertures for it should have several examined to see that worms have not been at work amongst the crocks. A neat sod of free calcareous turf, placed Grass side on the inverted pots or pedestals for intercepting liquid and keeping the roots at home, will complete the housing. Meantime, well-worked fermenting Oak leaves should be in readiness for introducing loosely amongst the pots when the time arrives for starting. Precocious trees that have been forced for several years, and whose roots have never felt the want of water, will commence swelling their buds without the aid of fire-heat; others, taken in for the first time, may require a little coaxing; but on no account should fire-heat be applied when the minimum can be maintained at 50° without it. The best time to apply fire-heat, when needful, is early morning with plenty of air, and moisture from the syringe should also be applied when the temperature is rising. Direct syringing is not, however, often necessary when the atmosphere is kept moist by the proper use of fermenting material.

Later houses.—These during the time the trees are out of doors should be thoroughly cleansed and painted, but the trees themselves will be best left unwashed until they are wanted. Then, although they may look and be free from the larvæ of insects, it is always a good plan to cleanse with soapy water. A half-worn paint-brush, drawn outwards over the shoots lying on the left hand, is a suitable instrument for dislodging filth and scale; and where the latter has been troublesome a second washing will be found preferable to the use of paint or strong insecticides. When Peach trees have been some years in pots, they make a quantity of short, spur-like shoots thickly clothed with flower-buds, the terminal and perhaps one at the base being the only wood-buds. These the practical gardener may find it necessary to thin out to make room for the succeeding year's growth, but he never shortens them. Strong shoots he keeps in check by summer pinching, and prunes back to triple buds when the trees are dormant. The amateur may follow in his wake, but unless he is thoroughly up, all shortening may be deferred without detriment to his trees until the buds break, when mistakes by which whole shoots are often destroyed will be avoided.

Potting and top-dressing.—If the potting of fruit-bearing trees has been overlooked or neglected, they may still be reduced and repotted in fresh compost, but they will not be safe subjects for forcing. They will, however, if reduced and even washed, commence making new roots immediately and carry good crops in the ordinary orchard house next season. Upon the principle that an empty house is better than a bad tenant, I have dashed the balls of declining trees in a tub of water until not a particle of soil remained on them, trimmed the roots previous to repotting in rather dry compost, and they have not only recovered, but borne good fruit the following year. This driving to extremes is not recommended, but is introduced to show how accommodating the Peach is, and how grateful for a new pasture. Newly purchased trees are often potted from November up to April. The first and last are better than mid-winter, but there is nothing like going to the nursery one's-self, choosing, and potting up at leaf-fall. The compost for potting purposes need not be extra rich, but it should be prepared a few weeks before it is wanted, and used in a semi-dry state. It will then stand any amount of ramming; small rootlets will ramify in every direction, and there will be no possibility of its holding too much water in suspension. For top-dressing it may be a mixture of highly concentrated stimulants, including rich calcareous loam, manure from well-fed animals, bone dust, charcoal, or wood ashes. If these are well mixed and kept covered with fresh stable litter, the mass will improve in quality and keep for a considerable time.

VINERIES.

Pot Vines.—Where the earliest new Grapes are still obtained from Vines in pots, the latter will

now be in position, if already they have not been started. Like Peaches, and all other fruits which enjoy moist bottom-heat from fermenting materials, the first step after cleansing the house should be their arrangement on solid pedestals, which will hold them steady throughout the season. Inverted pots, glazed drain pipes, or dry bricks built up to the required height answer well, the latter perhaps as well as anything, as warmth rises and water descends freely through the chinks. On the tops of these sods of turf should be placed for the Vines to stand upon, but before they are placed the crock roots may be set at liberty by a considerable enlargement of the aperture with a hammer. This will not only remove a barrier to good living, but it will favour copious watering when the fruit is swelling. Beyond this breaking of the bottoms of the pots and rich top-dressing the roots must not be disturbed, as such a course, in my experience, leads to certain failure. Over-anxious forcers have before this day turned their fruiting canes out into troughs filled with rich compost, but the latter has become sour, the balls dry, and the roots have perished. The proper course, then, is to leave the Vines in their pots, be they large or small, and the tighter the roots are coiled the more freely will they show, set, and swell their fruit. When forcing is commenced a good body of Oak leaves cast loosely into the pit, and perhaps a little above the tops of the pedestals, will keep up a continuous ascent of gentle warmth and vapour under which the buds will swell and break kindly; firing in mild weather will be reduced to a minimum, and incessant syringing, which often does more harm than good, to a great extent will be dispensed with. The walls, paths, and other surfaces must, of course, be damped with tepid water, and the fermenting materials frequently turned and renovated, but these operations can be performed without jeopardising the half dormant roots by getting them too wet before the buds break. Once in full leaf, this danger will have passed away. Up to this stage root watering should be conducted with great care, as the best of Vines are often ruined by the constant trickling of water from the can and the syringe, when the blame is cast upon the nurseryman who grew them.

The early vinery.—The modern system of manufacturing and fruiting planted canes within two years fortunately has rendered pot culture almost obsolete. Whether this sharp running of yearlings and two-year-olds will result in the formation of old timber, men now have not time to pause to inquire. Grapes they must have quickly and in quantity to make up for low prices, and if the Vines cannot live to grow into veterans they must fruit and go out as biennials. This system high-feeding growers for market now make one of their specialities. A few private growers are following in their wake, but, like all other produce, there are Grapes and Grapes, and the question arises, are Grapes that are fed and forced up with rich animal manure as good as others from older Vines grown in sound sweet borders? I venture to think they are not, but with the million, size and bulk now take precedence of colour and flavour. When strong young canes are forced for the first time they should not be raised above a horizontal position until all the buds are well on the move. Old ones may be tied to the wires as soon as they are pruned, and, although very little warmth be applied, the buds about their usual time will commence swelling. If confined to internal borders, they should be well watered with water at a temperature of 90° and top-dressed before the house is closed. Then, although here the syringe is less dangerous than amongst pot Vines, a good ridge of fermenting material will be found a powerful aid and save a great deal of trouble. The roots of Vines having the run of external borders will require protection from the elements as soon as the house is closed. The materials used may consist of long stable litter, dry Fern, or a good layer of Oak leaves, with shutters or tarpaulin to secure them from wind and bad weather. Fermentation, it must be understood, is not to take place in these materials—at least for the present—but when the Vines have started, mild warmth from a good layer of fresh, dry Oak or Chestnut leaves is a great help, not only in the production of fresh surface roots, but also in drawing them up through the top-dressing. Many people are averse to external surface warmth because the roots they say perish, and the soil becomes wet and sour. If rank, raw stable manure is used and allowed to get very hot, then very cold cases of poisoning may be frequent, but no one in his senses would think of applying such crude matter to the delicate roots of a tree whose home is on the warm volcanic slopes of sub-tropical countries, remove it suddenly, and then condemn a system which he has done his best to abuse. Manure is a fine thing in its place, but it is out of place on a Vine border, except as a mulch when protection from drought and feeding in summer becomes necessary. Well-harvested leaves, on the other hand, are dry, light, and warm. They draw superfluous moisture as well as roots upwards, and feed the latter when the strain of the crop is upon the Vines. Leave them alone until the crop is ripe, then remove them piecemeal, but on no account expose the roots to sudden chills until the last layer gives way to the autumnal top-dressing of fresh compost.

Figs.

Good forced Figs are not only an acquisition to the dessert, but in many places where a few years ago they were unknown they are now as regularly looked for as Peaches or Grapes. The majority of growers obtain their earliest fruit from trees well established in pots or tubs, but suitable varieties planted out in internal borders of limited area answer equally well; whilst the trees are less liable to sudden checks, which so often prove fatal. In order to have ripe fruit in April, pot trees should be in their places by the first week in December. Like Peaches and Vines, a firm, steady base should be provided for each pot to stand upon, otherwise they will be constantly sinking away from the light, and frequent renovation of the bed will soon become impracticable. When small trees are forced in low span-roofed pits, it may be necessary to place them within the influence of the bottom-heat pipes, when a sod of rich light turf will form a suitable base, but trees from which quantity as well as quality is expected should be something more than toys, and old enough to bristle with short fruitful pieces of spur-wood. The best trees I ever saw were grown by that excellent gardener, the late Daniel Judd, at Hawkstone. They were perfect pyramids, about 8 feet in height, and carried two good crops annually. Each tree stood on a pedestal 2 feet in height, hot-water pipes ran round the house, but bottom-heat was obtained entirely from a bountiful supply of Oak leaves. The manufacture of trees of this size is a work of years, and when once formed, they are worthy of all the attention that can be devoted to them. It is not necessary, neither is it wise, to pot them every year, but all the old mulching and top-dressing, together with the roots which have escaped over the rims, should be removed when the second crop is over at the wane of summer. Fresh compost placed about them at once, and proper attention with water, ensures a wig of fresh roots ready for their work in November or December. Where trees of this class exist, if not already done, they should now be well, but very carefully washed with soapy water, and, although the balls have never been dust-dry, moderate supplies of tepid water must be repeatedly given until they are brought back to growing order. When placed in position, each tree should have plenty of room to develop the coming year's growth, as well as to admit of getting in amongst them. Well-worked leaves in a mild fermenting state, thrown in rather loosely at first and in sufficient quantity to hide the bottoms of the pots, will soon produce gentle excitement of the roots, and, although invisible, the continuous supply of moisture will tell upon the embryo Figs also. Although this warm vapour will greatly reduce the necessity for continuous winter syringing, the Fig being so terribly subject to insects, tepid water may be applied to the trees and walls when the day temperature begins to rise, and again when the maximum is reached between twelve and one in fair winter weather. As days increase in length after the turn of the year and the trees get into full leaf, the second syringing may be a little later, but always in time for the foliage to get dry before nightfall. Notwithstanding the fact that the Fig will stand any amount of tropical heat when the fruit is swelling, it is not well to hurry it through the early stages; therefore, let forcing be commenced at a minimum of 50°, and 5° to 10° more by day when the weather is mild for the season. The sun being so weak and seldom seen in December, its influence cannot be depended upon; but when it does touch a sharp-angled roof a few more degrees at mid-day will give strength and favour the outlet of vitiated air.

Succession houses containing trees growing in internal borders may now be taken in hand as opportunity serves. A month or more may elapse before they are started, but every day will bring its work, and where labour must be sharply organised to make both ends meet, pruning should be kept well in advance when cleansing and tying can be performed on wet days. Where trees are trained upon modern principles, *i.e.*, the main branches in a horizontal position and the intermediate or fruit-bearing shoots, always from the top side, slightly on the rise, all the alternate shoots from which the second crop was gathered may require cutting back to a single eye. Those left and well furnished with embryo Figs will give the first crop; whilst the summer shoots which start from the back buds so left will produce the second on green wood. Old-fashioned trees whose name is legion have a gnarled and twisted appearance, and in order to secure a good point wherever it is wanted not unfrequently contain a great deal more distorted wood than is absolutely necessary. These it is hardly possible to reduce to modern lines, but considerable progress might be made by root-pruning to check growth and cutting a great number of long, straggling pieces back to dormant buds. The quantity from the first gathering may be reduced, but the quality will be improved by the inlet of sunlight and air, and the summer shoots will more than balance the account by producing a heavy crop after midsummer. In days gone by the roots of Figs were allowed too much freedom, and fagots of gross wood were allowed to grow into a tangled mass to carry off the superfluous sap. A few Figs near the exposed points ripened, but the greater part of the crop never reached maturity and dropped off after the leaves fell. All this is now changed by annual root-pruning, and the Fig at one time unmanageable is now as tractable and reliable as any other fruit tree.

Young stock.—If propagation is contemplated, short-jointed and well-ripened pieces of wood with good points should be selected from the early prunings. If taken off with a heel and divested of all their lower buds, to prevent the growth of suckers, they may be potted at once and set aside safe from frost until the 1st of January, when they must be plunged in bottom heat and treated precisely the same as Vine eyes. Young trees struck last year and intended to make another growth before they fruit may be set aside in a dry, cold house also safe from frost until the turn of the year, or they may be shaken out and potted at once. Clean, well-crocked pots 8 inches across will be quite large enough, and, provided they are well watered or soaked before the old balls are broken, they will not require more water until they are taken in for starting. Pot Figs enjoy good living and make good trees in small pots in a short time under high pressure. The compost which suits them best is light, rich, turfy loam, or heavier loam corrected with charred wood and refuse from the rubbish-yard fires, old lime rubble, and a small quantity of old cow manure. These should be thoroughly incorporated some time before the compost is required for use, and after trimming back the straggling roots the trees must

be firmly rammed with the potting-stick Bottom heat is an important aid to quick growth, but where this cannot be given, the young trees will make fair progress on the kerbs of early vineries. If pyramids are wanted, each tree must be staked as soon as it is potted and the most promising shoot tied up to form a straight leader. These leaders will require pinching from time to time as growth proceeds to induce the formation of side shoots. Bushes can be formed by judicious summer-pinching and frequent pressing downwards of the young growths to give them a horizontal position. The varieties of Figs are now numerous, but until they are thoroughly proved satisfactory results will be obtained from Brown Turkey, White Marseilles, Osborn's Prolific, and Negro Largo. W. Coleman.

Eastnor Castle, Ledbury.

Kitchen Garden.

FORCING ASPARAGUS AND SEAKALE.

Asparagus started now in a bed of from 75° to 80° should be fit to cut by the beginning of the new year. To obtain a steady temperature a mixture of tree leaves and stable manure is better than all manure, as less turning and mixing will be necessary to sweeten the fermenting material before the bed is made up. If forced in a frame—an excellent plan—the bed should be from 9 inches to 12 inches wider on all sides than the frame, and the inclination from back to front should be from 9 inches to 12 inches, according to the width of the bed. If about equal portions of leaves and manure are used, the Asparagus roots may be placed on the bed as soon as the heat rises, as there is no danger of overheating. At this season the bed should be about 4 feet high at back, and about from 9 inches to 12 inches lower than that in front. The Asparagus roots must be lifted carefully without injuring the crowns or lacerating the roots, and should, of course, be of sufficient strength to produce good-sized heads. Young plants, four years old, will force well, and start away quickly on the application of heat, the tops coming well together, and as the roots suffer from exposure, the bed should be ready to receive them as they are taken up. Where it is necessary to keep a regular supply of forced Asparagus in winter, the rows of plants must be covered now with litter to keep out frost. Make the surface of the forcing bed level and firm by treading, then put in 2 inches of light rich soil, and on this place the roots as near together as can be done; the closer the crowns are placed together the more the frame will produce.

After the frame is filled with roots cover with light rich soil 2 inches in depth and water with tepid water to settle all down. The frame should be covered with mats till the young Asparagus heads are peeping through the soil, when air and light will be necessary to give flavour and colour. Those who prefer white or blanched Asparagus must place a greater depth of soil on the crowns. It is a disputed point, and one I am not called upon to discuss here as to which is the best, the blanched or the green. I suspect it is a matter of taste. There are other ways of forcing Asparagus; indeed, from this time onward to the spring it is one of the most manageable plants to force. It is chiefly a question of procuring plenty of strong roots. Given a steady, regular, genial temperature, Asparagus can be forced anywhere. It may be forced in pots, boxes, or baskets, in a Pine stove, or Cucumber house, or a vinery at work. The roots may be started first in a Mushroom house in the dark, and be moved to the light, when the young succulent heads push through the soil to give the finishing touches as regards flavour and colour. Beds of Asparagus are sometimes forced as they stand in the open ground, and in this way they may, after a season's rest, be utilised again. Simply covering the beds over with frames without any artificial heat will bring on the produce much earlier in spring. Keeping the summer's warmth in the ground, and attracting the sunshine in the spring, will make three weeks' or a month's difference, especially if the spring be a backward one.

Seakale-forcing may go on briskly now. There are many ways of doing this. The old-fashioned plan was to cover with pots and a mixture of leaves and manure. This plan is not much followed now, as it takes much less labour to transfer the roots to the heating apparatus than to bring the heating medium to the roots. In many gardens the Mushroom house offers every facility for forcing Seakale, Rhubarb, Chicory, and many other things—in fact, the Mushroom house is a very valuable structure when made the most of, and might with advantage be made much larger than it is in most gardens. When forced in a bed in the Mushroom house or in a pot, the Seakale roots should be planted about 2 inches or 3 inches apart, according to the size of the crowns, but it is rare for all the crowns to start up together. The temperature should not be much below 55°, nor yet much above 60°, and light must be altogether excluded. When the roots are lifted, all the small side shoots should be cut off and the tap root shortened; the thongs or cuttings to be preserved in sand till March, and then planted to raise plants to force next year. Seakale roots may be forced in pots or boxes. Plant five strong roots in a 10-inch pot and cover with another pot of similar size, and envelop in an old sack or a mat. Any number of pots may be filled at the same time and brought on under the stage in a forcing house; they must be deeply covered, or the roots may be planted in a deep box with a close lid to shut down. The boxes can be moved anywhere. E. Hobday.

White Elephant Potato.—In the spring of 1884 I planted two tubers of this Potato, the produce of which was lifted at the end of summer, and stored for planting the following spring, none being made use of. They were planted in March 1885, and lifted at the end of August. A bushel was made use of, and the remainder stored for planting again, which was done in March this year. The crop was taken up in the third week in August, and amounted to no less than 112 bushels, or about three tons of very fine Potatoes and of excellent quality. I may add that no special preparation was made for them; they were planted with the general crop. From the time of planting the two tubers and digging the three tons was about two and a half years.—D. Uphill, *Moreton, Dorchester.*

GRAVEL AS A SEED BED.

Mr. G. F. Wilson, of Heatherbank, to whom all readers of The Garden are largely indebted, calls attention to gravel as a seed bed and as a protection from frost. As to the first, those responsible for the good keeping of many yards or miles of walks or roads are only too familiar; whether it be the hardness, the colour, the mechanical texture, the very sterility of gravel, or the porosity of gravel that foster the germination of seeds, or some hitherto hidden chemical properties, seems uncertain; but the fact of a gravel bed fostering germination to the uttermost is only too patent to all who have to battle with crops of weeds on gravel. Most cultivators have also had many proofs of the abnormally active and perfect germination and rapid growth of garden plants on gravel surfaces, such as those that Mr. George Wilson refers to. But the powers of gravel as a frost-resister have, so far as I am aware, been now mooted for the first time by Mr. Wilson; that these are very considerable seems also established by the fact that sifted gravel holds a great deal of air in its numerous interstices, and also by Mr. Wilson's experiments. Having admitted so much, it may seem almost an ungracious act of temerity to call a halt before going into gravel or fine-sifted stones largely as a protector against frost. We are all familiar with the use of sand for this purpose. Doubtless Mr. Wilson would say that his inch stones would be more effective almost in the ratio of their excess of size over sand grains, and doubtless, area against area, a heap of small stones would contain more air than a heap of sand.

But then we have other materials besides sand, coal ashes, charcoal dust, pounded coke, cocoa fibre refuse, sawdust, spent Hops, &c. Several of these may be scarce or costly, and so impracticable on any large scale. But several of them are cheap and plentiful, even more so than gravel. Neither do I understand Mr. Wilson as being so sure that gravel is best, as to counsel the discarding of any other proved protector in its favour. Quite otherwise; he suggests the trying of gravel of different degrees of coarseness by way of experiment, and such experiments cannot fail to prove useful. Still, on the good old principle of speaking well of the bridge that carries one over, I wish to testify to the great efficiency of coal ashes as a protection for bulbs and other plants against frost. From 4 inches to 6 inches of coal ashes are invulnerable to frost in our climate. It is more efficient when the fine residuum in the form of dust is sifted out. Coal ash is plentiful, cheap, light, everywhere present or procurable. Its lightness constitutes a double or treble merit; thus it is easily applied and removed, and also lifted up or pushed aside by leaf or stem should the bulbs or plants commence growth under their frost-protectors, as they not seldom do; it holds as much or more air, and will exclude as much or more cold as gravel or small stones. Coal ashes, as well as spent tan, Hops, coke, and sawdust, also prove antagonistic, if not perfect antidotes, to slugs, snails, grubs, and other pests, while stones or gravel, especially in a damp state, may be defined as neutral. Only those conversant with the ravages of slugs among Lilies and other bulbs will be able thoroughly to appreciate the superlative practical importance of combining powerful protection with discomfort or death to the slugs. There is one more thing to be urged in favour of coal ashes: they combine a maximum power of resistance to cold with a minimum measure of compression or injury to the surface covered. Cover a surface with sawdust, tan, or spent Hops, the chances are we get substances into the soil that may injure our roots; cover it with gravel or stones, they may sodden or sour the soil; but use ashes, and the surface under them will be found almost as mellow and sweet as before.

Hence, I would confidently advise all young cultivators to stick to coal ashes, as if not the best, the next to the best protector within easy reach of cultivators. D. T. Fish.

Garden Destroyers.

THE EUCHARIS MITE.

It has been frequently stated of late in The Garden and elsewhere that there is no cure for this destructive little pest, but the result of an experiment made by me this season proves this to be a mistake. As is well known, the mite does not confine its ravages to the Eucharis alone; there are other plants which it favours with its attention, notably the Vallota, and it was with a bulb of this that the experiment in question was made. This bulb, which is the eximia variety, came from a private garden, and seeing after a time that it was not doing well, I turned it out of the pot and found that all the roots were destroyed. Examination revealed the presence of the mite in considerable numbers. I carefully cut away all diseased parts, washed the bulb and placed, it in gentle bottom-heat to encourage the production of new roots. For a time this seemed to have the desired effect; new leaves formed, but then they turned yellow, and I found that the mites were as numerous as before. It then occurred to me that the new remedy for mildew, *i.e.*, sulphide of potassium, might kill them, and having just previously dissolved 3 oz. in half a pint of water, I dipped the bulb in it and then laid it in the soil again. Several days afterwards I found on examination no traces of the mite, but thinking that some might appear later on I looked again in the course of a fortnight and found one or two. I again dipped the bulb in the same solution, and since then it has grown away with considerable vigour, looking as healthy as any bulb in the place.

As will be remarked, the solution used is very much stronger than any insecticide hitherto recommended, and it is, of course, the extra strength that has effected the cure. Whether this strength, which is equal to 3 lbs. of sulphide to the gallon, would be injurious to Eucharis bulbs I cannot say, but I know that it has no effect on Vallotas, and it is worth knowing how to get rid of the mite on them. This is the only instance with me of the mite having appeared on Vallotas, and not a bulb of my own raising has suffered, which shows how careful those who have a clean stock should be when adding to their collection. Had I not been fortunate in discovering the pest and taken prompt measures in separating the infested plants from the healthy ones, I should have had much labour and vexation later on, for I believe the mite increases with great rapidity. I did not intend to make this experiment public just yet, thinking that I might have the opportunity of again testing the efficacy of the remedy, but as I saw it stated quite recently in THE GARDEN that the only thing to do with infested Eucharis is to throw them away, I give the result of my experience at once, as it may be the means of saving some collections from the rubbish heap. One thing is certain, *i.e.*, that sulphide of potassium at a certain strength will annihilate the mite; the next thing to find out is whether it will injure Eucharis bulbs, which are, of course, more tender than those of the Vallota.

I would advise those having infected bulbs to use the sulphide at varying strengths on a few bulbs, as that is the only way of ascertaioing what they will bear without injury. In any case, it will not do to rely on one dipping. There are sure to be some left, and, however few these may be, they will multiply sufficiently in the course of a year or two to hinder growth. When the bulbs are cleansed, they ought not to be potted, but be laid in in light soil right away from the house in which they are growing, and if the pots have been plunged in tan or cocoa fibre, I should be inclined to clear it out, or at least the topmost portion where some of the insects are likely to be. J. C. B.

CLOUDS OF APHIDES.

THE immediate cause of the sudden appearance of clouds of insects in certain localities is not very apparent, but it may be surmised that the predominance or scarceness of their natural foes has much control over the phenomenon; added to which must be taken into account the effects of weather and temperature. On October 5, Mansfield, on the borders of Sherwood Forest, was visited by a cloud of aphides, which swarmed in the town and over the country round, across an area of many miles. The town was visited "literally by millions—everyone, as they walked along, waving their handkerchiefs or newspapers before their faces to avoid inhaling the insects. . . . Wet paint was covered by a mass of these black aphides." This swarm continued with decreasing numbers throughout five days, and heavy rain during part of this time did not seem much to affect them. On the road to Nottingham these insects were noticed as engaged in singular gyrations and undulatory dances above the tops of the Spruce Firs, there forming dense pyramidal columns. A similar cloud, but less remarkable as to numbers, was observed about the same time at Birmingham; which, however, as it must have been at least 40 miles distant, can be scarcely considered as a part of this same swarm. Possibly similar causes operated to produce the like phenomenon in both places. These insects proved on examination to be Aphis persicæ of Morren, A. rapæ of Curtis, and A. vastator of Smee. It is a veritable pest in some years, doing considerable damage to Turnip, Mangold, and other crops, and in our gardens injuring our Peach trees. This present notice of its swarming is, however, by no means unprecedented. In September and October, 1834, Morren noted an immense swarm all over Belgium, and states his belief that it came across from England. He says they obscured the light of day, and covered the walls of the houses so as partially to conceal them. Gilbert White notes that in August, 1785, the people of Selborne were surprised by a swarm of "smother flies." Those who were walking in the streets found themselves covered with these insects, which blackened both hedges and vegetables. White thought these might be emigrations from the Hop gardens of Kent and Sussex, and from those near Farnham. If so, the species differs from the insects above noticed.—G. B. BUCKTON, in *Nature*.

Begonia insects (*Miss G.*).—Your Begonia roots are attacked by the grubs of the black Vine weevil, or some very nearly allied species. The only practical way of dislodging them is to unpot the plants and pick the grubs out of the roots. Any insecticide which would kill them so far below the surface would injure the plants. The parent weevils are very destructive to the foliage of many plants, gnawing great holes and notches in the leaves. The best way of destroying this insect is by killing the weevils. This should be done at night, for it is then that they feed. During the day they hide themselves away, so that they are very difficult to find. When the leaves of a plant are attacked, place it on a white sheet, and at night enter the house suddenly with a bright light. This generally startles them, and they fall, feigning death; if they do not, even after a smart shake of the plant, search it well.—G. S. S.

LOBELIA CAVANILLESI.

THIS showy species was introduced from Mexico about fifty years ago, but afterwards lost to our gardens. The only way to grow it with success is to cultivate it in the open air, either in pots or

Lobelia Cavanillesi.

planted out. It may even be treated as an annual. Plants of it sown in February began to develop flowers in abundance at the beginning of August, and have even produced ripe seeds, a circumstance which scarcely ever happens in the case of Lobelia cardinalis or fulgens. Plants of it, if wintered in a greenhouse, will of course begin to bloom earlier, and probably also more abundantly, than seedlings. One of the principal merits belonging to this Lobelia is the beautiful colouring of the flowers, the tube being brilliant scarlet with orange-yellow tips. For re-introducing this species we are indebted to Messrs. Haage and Schmidt, of Erfurt. It will prove to be a welcome addition to Lobelias now cultivated in gardens, and some good hybrids may be expected from it. It is equally desirable when grown as a pot plant for market or for decorative purposes, or when planted out in groups or beds. Its lively green and slender foliage contrasts admirably with its beautiful, bright red and yellow-coloured flowers.

NEW POMPON JACOBÆA.

(SENECIO ELEGANS POMPONIUS.)

THIS new handsome Pompon-flowered variety of dwarf Jacobæa is being distributed by Messrs. Haage and Schmidt, of Erfurt. It is very regular in habit, and the flowers are short-petalled, small, and beautifully imbricated, rivalling even the prettiest of the Pompon Chrysanthemums. This variety is perfectly constant, and produces without any exception very double flowers, while the older varieties bear sometimes double, semi-double, and single flowers on the same plant. It is well adapted for borders, or for the formation of carpet beds; the colour, being bright purple, is very effective.

FRUIT GARDEN.

THE FRUIT GARDEN IN AUTUMN.

THERE are certain general principles that underlie the whole business of gardening, and which more or less influence all we do. In the matter of pruning, for instance, we should firmly grasp the fact that the leaves are the lungs of trees. This every pruner should know, and indeed every man who is employed about a garden, whether for pleasure or profit, for most assuredly such knowledge is valuable. If the leaves were constantly picked off a plant, debility would set in, and death would soon follow. It is plain, therefore, the leaves should have the first consideration. The sun is the chief factor in fruit culture; through its agency, assisted by the atmosphere, the work of separating the true sap from the surplus water which the roots send up is performed. If we have a piece of land to dig and more men are placed upon it than have room, the work will be badly and expensively performed. This is just what takes place when a trained, or for that matter, any fruit tree is allowed to become crowded with wood. It is easy to tell by its growth and foliage when a tree has its roots deep in the earth beyond the influence of solar warmth. Long-jointed, soft, watery wood and soft, spongy leaves which hang on till detached by frost are indications which cannot be mistaken of the evils of deep-rooting.

The pruning of wall trees where the summer pruning has been properly attended to will consist mainly in the removal or shortening back of the snags left from the summer pruning. Occasionally an old spur will require removal, as it is in the nature of things that the old should give place to the new; and by this gradual removal the bearing wood of the tree may be kept in a constant state of usefulness. The most important part of the pruner's work is to so regulate the growth of the tree that the sunshine and air can penetrate every part of it. One good, leathery leaf firmly built up under the conditions I have named is of more value in bringing forth a plump, fertile bud than three or four weakly things that, from their overcrowded condition, cannot produce or render any assistance in the organisation of vigorous blossoms. As a rule Pear trees are so trained, that the spur system of pruning is the only one applicable to them; but stone fruits—the Plum, Apricot, &c.—are often treated on a different principle, and Peaches and Nectarines form a distinct class by themselves so far as regards their pruning and training. The best way of pruning the Plum and Apricot when trained to a wall is to encourage the production of natural spurs, and to this end as much young wood as space can be found for without overcrowding should be laid in every summer. The artificial spurs are created by the knife when the young shoots are shortened back in summer, but the natural spurs spring from the young wood without any aid from the knife, and the only way to obtain these is to lay in plenty of young wood. Wherever there is room to lay in a young branch in summer, and if it is not overshadowed by foliage the sun will ripen it, and probably little spurs will form which will develop blossoms and fruit, and these nestling close to the wall escape spring frosts and come to maturity. With the view of making room for the young wood, an old spur or an exhausted branch may with advantage be cut out, always supposing that the work be done in a temperate and tentative manner. One of the greatest evils in fruit culture on walls, especially where the fan system of training is adopted, is the overcrowding of the branches; there is less danger

with horizontal training, though often in the case of Pear trees more room may be given with advantage. A foot between the branches of Pears on a lofty wall is hardly enough when the trees get old and the spurs spread out. When every bit of wall surface is covered up with wood and foliage the rays of the sun cannot reach the wall behind, and a good deal of its ripening, nourishing influence is lost. This is especially important in the case of Peaches and Apricots, where maturity of the wood is everything.

Winter dressing for insects.—Gishurst compound, dissolved in rain water at the rate of 5 ozs. to the gallon, makes an excellent wash at this season for all fruit trees, whether insects are present or not. If the trees have during the past year been free from insects, it may be syringed over them when the pruning and training are finished. Its benefits are considerable as a preventive, and it cleanses the bark from all impurities; when the trees are infested with scale or any other kind of insect, a brush should be used for all the thick branches, and in bad cases the trees should be unfastened from the wall so that all parts of the tree can be got at. This dressing now, if effectually done, will save much time in the spring and early summer, when, perhaps, there will be many other matters pressing upon us, and it is always better to prevent than to cure. Paraffin oil, at the rate of a wineglassful to a gallon of the mixture, will tend to make it more effectual, but in order to keep the oil well blended the mixture should be frequently shaken or stirred, as the density of the oil being less than that of water it will float on the surface unless frequently agitated. The simplest and best way of doing this is to syringe each alternate syringeful of the mixture back into the pot. E. Hobday.

Grapes at Longleat.—Some time ago I called at Longleat to see the Grapes grown there. One vinery—a span roofed one—is 200 feet long and 30 feet wide, and is divided into three compartments, in which there is plenty of heating power, efficient ventilation, and large tanks. The latter are heated, so that during the growing season a plentiful supply of water is given the roots at a temperature of 80°. One compartment is planted with Black Hamburghs, consisting of four Vines, two on either side, the whole carrying at least 300 bunches, some of which were very fine, each bunch probably averaging 3 lbs. The next division contained Muscats. This, like the previous one, has but four Vines, carrying 360 bunches, each of which would average 3½ lbs. The last division contains two Lady Downes, two Alicantes, and one Mrs. Pince, viz., five permanent Vines. Lady Downes was carrying 150 bunches, each of which would average 1¾ lbs. The Alicantes carried 120 bunches, each averaging 3½ lbs. They were swelled and black as Sloes. Mrs. Pince had not done quite so well as the others, amongst which the Muscats are the best.—A. Evans.

Market Pears.—"R. D." gives (p. 471) a list of good market Pears and the prices which they realised during the present season, but he does not mention the market in which the prices quoted were obtained, and I must say that Pears at the prices named make one anxious to know a little more about them than can be gleaned from the information given. I have no wish to question the accuracy of "R. D.'s" statement, but I feel sure he has been unintentionally led into error by giving second-hand information instead of what is always so valuable, viz., a record of bare facts. For instance, he says Calebasse Pears of inferior quality, but large in size, realise 24s. per bushel, and Williams' Bon Chrétien 20s. per bushel. Well, I can safely say, that fruit worth that money ought not to be sent any distance in bushels at all, but packed in single-layer boxes. Large fruit is very liable to bruise and to lose 20 per cent. of its value by a rough shaking. I only hope that "R. D.'s" informant was correct, for if so, he could hardly have any cause to complain about glutted markets or low prices, and of one thing I am fully convinced, viz., that in the southern counties we could very successfully compete with the foreigner in growing first-class market Pears that would quite equal imported ones. I had myself very fine crops of Pears this year on bush and pyramid trees, but I must own that nothing like the prices given above were obtainable for them. —J. Groom, *Gosport.*

DOES FRUIT-GROWING PAY?

With this year's experience before us it would at first sight appear that the reply to this question must be in the negative, but I am disposed to affirm that fruit-growing does pay, *i.e.*, provided it is carried out in no half-hearted manner. For many years past much less attention has been paid to fruit culture in the provinces than was the case, say, about half a century back, and if this somewhat unfortunate season has the effect of still further impeding progress it will be, to say the least about it, matter for regret. All around large towns, and especially in the home counties within easy distance of London, immense quantities of all kinds of fruit trees have been planted during the past twenty-five years, and if the railway companies could be prevailed upon to carry something like half of what is grown at a much cheaper rate than they now do into some of the worst supplied country districts, we should hear much less about losses having been sustained.

New double Jacobæa (Senecio elegans pomponius). See p. 502.

According to present accounts, the London markets are too well supplied with fruit, and, as a consequence, prices are very low indeed, though, if I am rightly informed, the consumers on the whole do not get the full benefit of this abundance. The more important provincial towns are also fairly well supplied with all kinds of fruit in season, but the case is very different in numerous smaller towns, few of which are overdone with any kind of garden or orchard produce. At the present time Apples are very scarce, and 4s. per bushel and upwards, according to quality, can be had for them, and it is only when they are exceptionally plentiful that they do not realise good prices. Here we are in the midst of a fertile district, and one in which Apples and nearly all other hardy fruits thrive remarkably well, and yet we have to depend upon growers from a distance, notably America, to keep up the supply. Notwithstanding this, there are no signs of our orchards being increased or improved; on the contrary, there is every prospect of a still further decadence both in the quality and quantity of the crops grown.

At one time nearly every farmhouse had an orchard near it, but when these have become worn out, as all orchards will do unless exceptionally well treated, they are either allowed to fall or are grubbed up, and one looks in vain for young trees to take their place. Many farmers do not even grow sufficient Apples for their own table; and it is this want of energy, enterprise, or whatever it may be termed, that has led to so many of them failing. Some seem to think that landlords ought to plant new orchards, and there is much to be said in favour of this view, but, according to my experience, if the trees were planted by the landlords, tenants in many instances would also expect them to protect them from cattle. In some few cases we see an attempt made to renovate an orchard, but such efforts are usually attended with failure. Nor is this to be wondered at, seeing that the trees are frequently planted on land that has been occupied by orchard trees probably for fifty years previously. It is useless to plant a tree in a small hole, even if filled with perfectly fresh compost, as the latter will only sustain vigour for a short time. No; this is not what is needed. A young orchard should be planted on a perfectly fresh site, the soil should be deeply worked and well manured, and it may be cropped till such time as the trees cover most of the ground, then Grass may be allowed to grow. An orchard thus treated would produce Potatoes and other roots without impoverishing the trees or thereby inducing them to strike root down into an unkindly subsoil. One of the best orchards in Kent was also for many years a Hop garden, and I could point to various other instances where the ground was made more profitable than ordinary farm land up to the time the fruit trees required the space. Even after an orchard has been grassed over, the farmer finds it of great service in various ways, especially if it adjoins the homestead, as it ought to do.

Some hesitate to plant fruit trees, thinking that, in their time, they would not prove remunerative, and if this were really an indisputable fact, landlords ought to do the planting. But that is not so, unless indeed they purchase dried-up trees that have been to more than one market, and plant these on old orchard ground. If good trees, not necessarily the dearest that can be obtained, are purchased, and at once planted on good ground, these, if allowed to grow naturally, or with only sufficient pruning to form good heads, will soon arrive at a bearing state. Starvelings will commence to fruit at once, but it is far better for a tree to make vigorous growth before it fruits heavily. Orchard trees are very different from closely-pruned miniature specimens seen in gardens; these require root-pruning, both to check gross ness and to cause them to be fruitful. Although I have confined my remarks to Apples, it by no means follows that these only are suitable for orchards. Pears, Plums, Damsons, Cherries, Filberts, and bush fruits are all well adapted for culture in orchards, and with plenty of variety there is much greater certainty that one or other kind will pay the rent, if no more. I have termed this a somewhat unfortunate season, not because there have been many failures, but quite the reverse, there having been too many Pears, Plums, and bush fruits, notably Gooseberries, to be profitable. It is when crops are light that prices are best, but, as before hinted, the time may come when the facilities for distributing orchard produce in less favoured localities may be more equable, and then fruits will pay well even in times of abundance. It is to be regretted that something could not be done with the many tons of Plums that have been either spoiled, or as good as given away in Plum-growing districts, especially at Pershore, in Worcestershire. Damsons, I believe, are extensively bought up for dyeing purposes, and we all know that surplus supplies of Apples can be made into good wholesome cider. Filberts, whether grown scientically, as in Kent, or roughly, that is to say, without pruning, as in Somersetshire, Dorsetshire, and other western counties, rarely fail to be profitable, and some seasons they are more remunerative than any kind of fruit, yet we never hear of many being planted

hereabouts. Walnuts, again, used to be planted near farmhouses and gentlemen's places, but in very few cases do we see any young trees springing up to take the places of the giants now decaying. Not much planting now-a-days for our heirs in the case of Walnuts, and it is just the same with Mulberries. The latter are now to be seen only in old places, and in many instances these are past their prime and splitting up; yet they never fail to bear well, and their juicy, acid fruits are much liked by some. Instead of being content to sit down and wait for everything to be sent us from a distance, including foreign parts, we ought to be up and doing and learn to be more self-dependent, as in the "good old time" when railways and steamships were not such important factors in all undertakings as they now are.

Somerset. W. I.

STORING APPLES AND PEARS.

Many complain that their Apples and Pears are keeping badly. Well; we have a good deal yet to learn in the matter of storing fruit. I have seen fruit rooms built specially for storage in which the fruit kept so badly that they were given up as failures, and some ordinary shed or outhouse substituted. My impression is that for storing late-keeping fruit the system of open shelves is about the worst that could be devised, as spread out in that way the fruit parts with its moisture too rapidly, and when ripe the fruit is by no means so juicy as it ought to be. Rather than store on shelves I would store in bins or tubs, or even in large heaps on the floor. In Kent many of the fruit growers, who are also Hop growers, utilise the Hop kilns for storing late-keeping Apples in winter, and such sorts as Northern Greening, Wellington, and others that come in after Christmas are put into large heaps on the floor and covered with straw, out of which they come in spring with scarcely any loss of weight, and very few decay. I may also mention another case—that of a cottager who had a much larger quantity of Apples than he had means of storing, and, owing to the low prices offered at the time, he resolved to try and keep them through the winter. He therefore purchased some empty casks, packed them full of Apples, and then set them in a shed. When severe frost set in he covered them over with protecting material, and he was so well repaid in spring by the increased price obtained for them, that he resolved in future to store all his fruit that would keep for any length of time rather than part with it for about half its real value. I am, therefore, sure that many owners of gardens who find a difficulty in storing their fruit will do well to try the barrel plan for late hard Apples and Pears. One of the most important points to bear in mind is not to gather too soon; if left until the main bulk of the crop is ready to come off easily, maggot-eaten and specked fruits will have dropped prematurely, and at gathering-time there will be nothing but sound fruit, which, when gathered and put in a heap for a week or ten days and then stored in barrels, keep well. Late Pears will keep well on the trees if covered with fish nets quite a month after the majority of growers have gathered their stock. We have just gathered our Winter Nelis Pears. They hung on the trees until most of the leaves had dropped; we put them into boxes and stored them in an underground cellar, in which they never fail to keep well into the spring. Premature ripening is brought on by premature gathering, a fact deserving of consideration. J. Groom.

Gosport.

Outdoor Grapes.—Mr. Cornhill's remarks on "Grapes in the Open Air" (p. 469) interested me greatly. I feel convinced, from experience obtained here, that Grapes may be profitably grown out of doors on any well-sheltered wall south of a line drawn, say, from the Bristol Channel to the mouth of the Thames. On my cottage here last year I had excellent bunches on an old Black Hamburgh that has evidently, from the thickness of its stem and style of training, done good service before it was placed in its present position. I send a few bunches for your inspection of this year's produce. The Vine from which they were cut has its roots under a well-worn Grass plot, and they never receive the slightest attention. Not a bunch upon it ripened previous to last year, when I stopped and thinned out the shoots and cut away some of the bunches and thinned the berries. As regards mildew, I only had to sulphur once; therefore, the result is, I think, very encouraging. If outdoor Vines were properly planted and received a tithe of the attention which those under glass get, there is no doubt that good Grapes would be produced. It is only the hardiest varieties of Vine that should be grown out of doors, but I should be inclined to grow Black Hamburgh, as it is superior in flavour and size and appearance to the Black Cluster. Given a wall with a south aspect, and, most important of all, proper treatment, especially in keeping mildew off, and very good Grapes for autumn use could be grown outdoors—at least in the southern parts of this country.—F. Thirlby, *Broadlands, Romsey, Hants.*

*** We thank Mr. Thirlby very heartily. The Grapes are well flavoured, though not rich. The berries are smaller than those of Vines in greenhouses, but not too small for table. The bunches are neat and the colour good.—Ed.

YOUNG *V.* OLD BUSH FRUITS.

One amongst the many errors committed in private gardens is that of allowing fruit bushes to stand year after year after they have become so old and decrepit, as not to pay for the space which they occupy. For several years past I have made a comparison of the produce of young and old bushes, and I find that young ones invariably produce the finest fruit; and, whether for private use or market supply, there can be no doubt that young bushes are those to which we should trust. Many think that it takes years to get up a stock of fruitful bushes, but such is not the case. If good strong bushes that have been headed back once or twice in nursery rows are planted, they will bear some fruit the first season, and a really good crop the second. Much, of course, depends on the mode of pruning adopted, and whether the culture is good or indifferent. Bush fruits are such voracious feeders, that they make growth just in proportion to the food they get. In bygone days, too, people used to cut their bushes so hard back year after year, that it took a long time to get anything like a bush large enough to bear a crop. Now, however, the rule is the less pruning the better; in fact, I know a gardener who gets good crops of Gooseberries, without fail, by planting young bushes every year, and destroying an equal number that have got too large. He never prunes, and yet better shaped or more fruitful bushes than he has it would be difficult to find. I have tried the same plan with Black Currants, and found it to answer admirably. I have had as good crops from three-year-old bushes as are usually got from bushes much older, and in size of berry the young bushes have it all their own way. In the case of Strawberries few would think of keeping beds of them longer than three or four years, and I feel sure that the sooner the custom of annually grubbing up any fruit bushes that show signs of failing, and planting an equal number of young ones on fresh soil, the better it will be for the fruit supply. Young bushes are very easily raised, and are so cheap as to debar no one from having the best sorts in cultivation, and how people can go on year after year propagating and growing second-rate kinds passes comprehension. Now is the time to make new plantations, or add to and improve old ones, and in doing so take care to give a good supply of rotten manure. There need be no fear of making bush fruits over-luxuriant.

Hants. J. G.

SHORT NOTE.—FRUIT.

Root-pruning.—If "Anti-Radix" will read again what I said in reference to this subject, he will find that it was as follows: "With stone fruits, however, considerable caution is needed, as gumming not seldom follows the cut of the knife on their roots; and for Peaches and Nectarines especially careful lifting and replanting are often preferable to root-pruning as generally understood by the phrase—that is more or less cutting in," and to every word of this I adhere.—Radix.

WHAT TO CUT IN VINE-PRUNING.

I have been studying the philosophy of Vine-pruning in another paper, where it is stated, as the result of certain reliable experiments, that in Vine shoots "the production of starch increases gradually from the leaves at the base of a young shoot to the middle, and as gradually diminishes from the middle towards the point, starch being absent from the very young leaves near the apex. These facts supply a reason for pruning, for the young leaves above the bunches not producing starch, but on the contrary consuming it, in so far deprive the berries of their sugar." According to the same authority, the best store leaves are the first that are formed behind the bunch. In these starch is produced. "This starch is subsequently dissolved, converted into sugar and other substances fit for the food of plants, and transmitted to the growing points or to the store places where it is again converted into starch," that is to say, the "starch and other substances" are transmitted to the bunch and the young leaves beyond, but the fewer young leaves or growing points there are beyond the bunch the better for the fruit. Now, how does this theory affect those cultivators who, on an entirely opposite principle, encourage the young points beyond the bunch to extend as much as possible and lose both space and crop in providing room for the same. Their practice must be wholly wrong. It will be remembered by your readers that I have at different times stated in The Garden that the successful finishing of a crop of Grapes depended on the first formed leaves, that it was not even necessary to leave a leaf or a joint before the bunch, provided the leaves behind were taken care of; and although I came to this conclusion from observation of what actually happened under a Vine so treated, and not from any theory regarding the sap and circulation, still what I wrote agrees with the view I have just quoted. The words I used, some years ago now, were as follows: "It is the old or first leaves on the shoot that do the most work (in maturing the bunch), and if they be lost mere extension beyond the bunch will be of little advantage." This view was, of course, disputed at the time by the advocates of unlimited lateral extension, but I still hold that it is the correct one, and I am inclined to believe that the physiologist quoted is also correct in assuming further that the production of young leaves beyond the bunch is an evil. One thing is certain and confirmed by general experience, viz., that young Vines that have been cut back and allowed to make a long leading rod the following season invariably produce small berries on any few bunches that may be left on at the base of the young rod; whereas on Vines that are stopped short the berries fill up much better. Of course what happens on a main Vine rod happens also on the lateral shoots, only in a different degree. The general practical conclusions to be derived from these facts are, first, that it is wrong to permit much young growth beyond the bunch; second, that it is of the utmost importance to keep the first formed leaves behind the bunch in good health; and third, that there is no need to give Vines so much room as some recommend in order to accommodate young lateral growth, thereby losing cropping space. S. W.

New stocks for Apples.—Mr. W. Morgan, Pukekohe, East Auckland, New Zealand, writes: "How is it that nurserymen in Great Britain do not adopt blight-proof varieties of Apples for stocks, and thus effectually prevent Apple trees from being blighted at the roots? In this colony of New Zealand the Winter Majetin and Northern Spy are now generally used as stocks, both for grafting and budding, the latter being the common mode of working Apples. These two varieties are not subject to attacks of the woolly aphis, and both being robust growers, they make excellent stocks, though their manner of growth is very distinct. The Majetin throws out roots which extend a great length from the tree, while the roots of the Spy are one mass of rootlets and small fibres. Of course the Spy is found to be the best for dwarf trees, though some nurserymen prefer it to the Majetin for all kinds of Apple trees, and use it exclusively. Stocks are raised with very little trouble indeed, simply by planting bits of roots in a similar manner to raising White Thorns. When the roots have struck and young plants are about 6 inches high, they are earthed up, the shoots sending out rootlets, and growing vigorously if the land is rich. Some

of these would be fit to bud the following summer; but generally they are planted out when a year old, and then they make excellent stocks either for budding or grafting. In using these stocks the great advantage is that the bottoms and roots of the trees worked upon them remain free from the aphis. And it is not a difficult matter to keep the tops clean so long as the roots are not affected. Years ago, before the introduction of these blight proof varieties, so bad was the woolly aphis in many districts, that Apple growers almost gave up in despair; but now the extent of Apple plantations is very great.—*Gardeners' Chronicle.*

LATE-KEEPING PEARS.

Although large fruits are just now fashionable, there are, nevertheless, some really good medium-sized ones that are indispensable, owing to their great excellence, and from the fact of their coming into use at a time when their larger rivals are not in the field. Of Pears, so many are ripe in October and the early part of November, that it takes something exceptionally good in the way of fruits of medium size to prevent their being quite overshadowed by larger sorts at that time; but fruits that will keep until December, or into the new year, have less to contend with, and are more fairly dealt with. Several of our old favourites are therefore still popular late in the year, and amongst sorts specially deserving of good culture may be mentioned the following: Winter Nellis—This, in my estimation, is one of the very best Pears in cultivation. It is of medium growth, and well deserves a south wall, when it proves to be a regular cropper. We cover our latest Pears with fish nets, and let them hang on the trees as late as possible. If the trees are liberally supplied with water at the root, they continue to swell up as long as the leaves keep fresh and green. It is surprising how much rain it takes to saturate the soil about the base of wall trees, and, as the roots naturally hug the wall, it is a good plan to give copious supplies close to the base, where the wall itself keeps off the rain. Easter Beurré is perhaps without a rival for very late keeping. In south Hampshire it attains very good perfection as a bush or pyramid tree, but of course it well deserves a wall. It is surprising that the monopoly for this variety has so long been held by foreign growers, as in the south of England, on warm, well-drained land near the coast, this kind proves far more profitable and useful than Peaches or Plums that come in while other fruits are plentiful; whereas, in the season when fruits of Easter Beurré are fit for table, there is but little variety in the shape of dessert fruits available; and, moreover, many fail to grow Peaches satisfactorily that could hardly fail with Pears. Josephine de Malines is another late-keeping sort of undoubted merit: and, although only of medium size, its quality is so good as to make it a valuable addition to the fruit store, from the fact of its keeping well into the spring. It succeeds well as a bush or espalier in the open, being very hardy; and, like most of the late kinds of Pears, it should not be gathered before severe frost renders it unsafe to leave it out longer, as it continues to swell up very late if assisted with mulchings and waterings of liquid manure. Passe Crassane, a grand Pear if well grown, is decidedly worthy of a wall. In this locality no artificial drainage is required, the subsoil being gravel; but in cold, wet soils it is of the highest importance to drain well for such kinds as this. Beurré Rance, one of the finest of late-keeping Pears, requires a warm soil and situation. Root-pruning, or root-lifting and mulching, to keep the roots near the surface, are amongst the best means for promoting fertility and overcoming the tendency to crack that this Pear has in cold, wet soils or situations. Bellissime d'Hiver is a baking or stewing Pear of great excellence, and one that is very prolific as a bush, pyramid, or cordon. It is most useful when home-grown fruit is at its lowest ebb.

Gosport. J. Groom.

Assorting Apples.—Apple growers do not give sufficient attention, when storing winter Apples in their fruit rooms for future use through winter and into spring, to making a distinction between those which show near signs of ripeness and those which are evidently long keepers, in the same varieties. Take, for instance, say, a pile of twenty bushels of Rhode Island Greenings. Some of these begin already to show a shade of yellow colour, and they are gradually softening and will be soon fit for use. These should be placed where they will be easily accessible, to be used first. Other specimens will be still quite green, with that peculiar cast of surface indicating that they are the longest keepers. These should be deposited where they will remain for some months to come. If these two kinds of Greenings are placed promiscuously together, a part will begin to decay, and imparting this condition to others, will injure the keeping quality of those which otherwise will remain sound a long time. Some practice will be required to select in advance the earliest ripening from the longest keepers, and this skill will be materially aided by observing for a few years the results of such selections as the specimens become fit for use. The same attention may be given to other sorts. Where the winter Apples are kept on shelves, in shallow drawers, or in flat boxes placed in piles, as we have recommended on former occasions, this selection may be assisted every time an examination is made during winter. By giving this attention to our winter Apples, we find no difficulty in keeping selected portions several weeks longer than by common promiscuous management, and sound specimens of such sorts as the Baldwin have been secured in good condition till the middle of June. *Country Gentleman.*

FIGS AT HOME.

From a paper by Dr. Eisen, on Fig culture in California, we learn that in the best Fig-growing countries there are three crops a year. When the leaves die in the autumn, a Fig comes from the axil, on the last year's wood, next year. Then Figs come out from the axil of the new leaf, and later in the season Figs come from the ends of the growing shoots. These do not always ripen. The intermediate ones are the best, and furnish the chief Fig crop. "When Figs are ripe, or sufficiently ripe to be dried and cured, they in some varieties drop to the ground, but in others hang on to the tree, and must be cut off. When this time arrives in Smyrna, the Figs are picked and put one by one, without touching each other, on matting, or even on the ground covered with cut Grass or straw. The Figs are on this exposed to the sun for ten or twelve days or less, according to the weather. To begin with, they are turned every day, so as to be equally exposed to sun and air, and if dew is expected they are covered over with matting during the night-time. What is needed during the drying season is, not an excessive heat, but steady sunshine and dry winds. When sufficiently dry the skin feels dry, but the inside should yet be perfectly soft and pliable. The ripe and sufficiently-cured Figs are now picked out, and the others left to remain until ready. It will thus be seen that Figs are not dried haphazard on roofs or the ground, and then dumped into boxes and shipped. When Figs in Smyrna are dried sufficiently, they are by the Fig raisers assorted in three different sizes, then placed in sacks made of camel's hair. The merchant who has furnished the Fig-raiser with his year's supply takes the crop out of his hands. The Figs are again assorted, and are then ready to be packed.

"In packing, Smyrna excels both Portugal and Spain. We all admire the way in which the Smyrna Figs are packed. When the dried Figs reach the packing houses, they are assorted by women and then packed by men. While packing, the hands of the packers are constantly kept moist by sea water, which prevents the sugar sticking to them. There are two ways of packing: In the first, the Figs are flattened out in such a way that the eye of the fruit is placed very nearly in the centre, and the stem very nearly opposite the same. The Figs are now packed in layers in boxes in such a way that the front margin of every Fig just sufficiently covers the stalk end of the Fig next in front. The Figs are packed in straight rows the same in the bottom, middle, and on the top. To keep every row separate, and to prevent one row overlapping the other, I am satisfied that they use a small frame of iron, with partitions running longitudinally and vertically. The Figs must first be packed in this frame and slightly pressed. The frame is now withdrawn from the box, and a heavy pressure is applied, which causes the surface to flatten out and become smooth.

"The Fig itself is something more than a seed vessel of a flower. The fleshy part is a thickened, hollow receptacle, closed, except at the very narrow opening called the eye, situated at the top of the Fig. This receptacle on its inner side contains numerous minute flowers, crowded together and covering the whole of the surface of the cavity. These flowers are male and female, or staminate and pistillate. The female flowers occupy by far the largest room and all the lower part of the cavity. The male flowers, again, the more or less narrow zone immediately surrounding the eye of the Fig. In the cultivated or edible Fig the male flowers are generally wanting, or rather replaced by barren scale-like leaflets. In the different crops the proportion between the male and female flowers is quite different. The Figs of the first crop are those which carry the most male flowers. The second crop carry few, and the third or last crop carry none but female flowers. As I said, except in the wild or Capri Fig, the male flowers are seldom developed. In the Figs grown in California, and which I have had opportunity to investigate, the male flowers were always replaced by scales; this has also been previously found to be the case in Italy, and Prof. Arcangeli states that, according to his observations, the two most generally cultivated Figs around Pisa—the Fico verdino and the F. piombinese—never have any perfect seeds developed; while the F. biancolino, which is considered a semi-wild variety, has, among numerous imperfect seeds, some which are easily germinated."—*Gardeners' Monthly.*

Cherry Bigarreau Leona Quesnil.—This Cherry, raised by M. Tyman, seems likely to prove an acquisition. A coloured plate of it in the *Bulletin d'Arboriculture* represents it as being a very high-coloured fruit, described by M. Rodigas to be of excellent quality. It comes to a good size; the ground colour is yellow, strongly marked with bright red on the sunny side. Its habit is vigorous, and it is remarkably productive, naturally assuming a pyramidal form. Its fruit is in season the beginning of July. If any reader of The Garden should happen to belong to the Belgian Cercle d'Arboriculture, he may obtain grafts from the raiser, who has announced his intention of distributing them gratis to members of that society.—J. C. B.

LAWNS IN WINTER.

We all enjoy a velvety sward in summer, and a clean, neat lawn is very desirable throughout the winter months. It is now impossible to have the Grass so close and carpet-like as it was in the months when it was growing close and fast; the fresh verdant hue has left it; but, for all that, lawns may still be made and kept attractive and pleasing. During the time when leaves are falling it is impossible to have lawns clean for any length of time, as if cleaned one day they are just as bad the next, and sweeping at such a time is almost superfluous work. In fact, constant sweeping of the leaves very often spoils the surface of the lawn, thinning the Grass, making it very muddy, and disfiguring it for the whole of the winter; whereas, if the rough of the leaves was only raked off once a-week or so with a wooden rake, and sweeping deferred until the whole of them were down, the surface would be almost as close and firm in December as it was in September. I recommend the leaves to be raked off, because if left all on until the whole has fallen, they may become so thick on the ground as to blanch the Grass, and this must be avoided. Lawns certainly appear to be littery when the leaves are lying on them, but that is only for a short time; and if the walks are kept clean, the leafy condition of the Grass may surely be excused—at least for three weeks or a month—when the leaves are dropping. Thus treated, a fine lawn throughout the whole of the winter and spring will be the result; whereas the constant "brush-harrowing" just now or recently disfigures the Grass to such an extent, that it will fail to appear to advantage until well into the spring. Worms draw a great many leaves partially into the surface of the lawns at this season. If these are swept when wet they simply stick to the ground, but if brushed off when quite dry they may all be cleared off easily. As soon as the leaves are all down a thorough cleaning should be

given. All leaves under bushes, for a considerable distance under the branches, should be raked out, and the ground from end to end should be swept perfectly clean, but this should only be done when the surface is moderately dry, or as dry as it can be at this season. After the whole of the ground has been brushed the roller should be taken over the surface several times, and as soon as rain comes after this the Grass will assume a very pleasing appearance. J. Muir.

Maryam.

ORCHIDS.

PREPARING FOR WINTER.

We have now reached the end of November, a time when no ray of light should be intercepted, whether the recipients of it are in the coolest or the warmest house. Time cannot be better utilised than in cleaning, not only the plants, but also the wood and glass, operations which require to be done much more frequently near London than in the country. I stated some time ago that the successful culture of Orchids depended to a great extent on atmospheric conditions, especially as regards moisture. No greater mistake can be made by young cultivators than that of keeping up an atmosphere during winter saturated with moisture. The temperature of the East India house may now range from 60° to 65° as a minimum. It is at this season that the lovely Moth Orchids, by injudicious treatment, get into an unhealthy state, from which they do not speedily recover. In the garden of Mr. J. Partington, Heaton House, Cheshunt, is a house containing some remarkably well-grown plants of the genus Phalænopsis, none of which seem as if they had lost a leaf for many years. A single stem of P. grandiflora had thirteen leaves, some of them 13 inches long by 3 inches across, and accompanied by a strong flower-stem showing forty-one flowers. P. amabilis had nine leaves, and a flower-spike showing fifty-three flowers. Other species had leaves a foot long and 5 inches and 6 inches across. The atmosphere in which these remarkable plants grow is not at all moist, the temperature being kept at from 60° to 65° at night. This and the next three months may be termed their period of rest, but they also produce flowers which continue longer in beauty in the drier atmosphere than they would in a wet one. Angræcum sesquipedale is also pushing flower-spikes, and the drier atmosphere seems to suit this genus quite as well as it does the Phalænopsis; they are making fresh roots very freely, and must not lack for water at the roots. Aeranthes leonis is now well established; the leaves are glossy green in colour, and the plants seem to do best in the warmest house, and in baskets better than in pots. We pot them in clean Sphagnum without any admixture of peat. Cypripedium Spicerianum is not only the most distinct and pretty species in cultivation, but it grows freely and gives great satisfaction; when grown in baskets the flowers have a tendency to hang over the sides, and are very pretty. One may safely predict that it will be the parent of many fine hybrids. We have C. Dominiana always in flower in this house; it is now as fully furnished with flowers as it was at midsummer; this is a valuable characteristic of this hybrid form. It certainly does best all the year round in this house. All flower-spikes pushing from the axils of the leaves or otherwise must be carefully watched for slugs and other depredators. Slugs and small snails are very active in all the houses at this season of the year.

The Cattleya house temperature should not be allowed to fall below 55°, although the minimum may be as low as 50° when the nights are very cold. We have cleaned and re-arranged all the plants, placing them as near as we can to the glass roof. Most of the Pleiones are out of flower; we pot all of them that require repotting, an operation which may be done once in two years. They succeed in pans or pots placed close to the glass roof. The commonest species and varieties are the prettiest. P. lagenaria, P. Wallichiana, and the loveliest of all, the pure white and crimson P. maculata, we grow in quantity; P. humilis flowers later, and will do in a cooler house; P. birmannica we do not yet possess, but it is distinct and beautiful. I saw plenty of it the other day in Mr. Dorman's garden at Lawrie Park, Sydenham; it flowers with P. maculata; the peduncles are two-flowered, the colour of which is a soft rosy lilac, the lips being very pale lilac with a yellow centre. Except Cymbidium Lowianum, no other of the occupants of this house need be repotted now. Root-action cannot be in a very active state for a long period, and when that is sluggish the plants are better left in the pots in which they were growing. Sobralias do best with a good season of rest; they may now be kept dry at the roots, unless, as is not improbable, some of them are still making young growths; in that case they may be supplied with water about once in ten days, less or more according to the size of the pots in which they are growing. I alluded in The Garden (p. 350) to Cattleya Warneri as requiring water about once in two or three weeks. Some growers complain that this species is very shy as regards producing flower-sheaths, and that is so if it does not have a good season of rest at the right time, *i.e.*, after the flowering period is over in July, August, and September. About the end of October signs of growth appear, when the compost must be kept moderately moist, but not wet; let it dry before watering. The Cattleya house has been very interesting during this dull season. All through November we have had Vanda cærulea in bloom, every plant bearing either one or two spikes. With these, too, we have had Lælia autumnalis and L. elegans in grand condition; while at the other end we had a groundwork of Pleiones arranged amongst small plants of Maiden-hair Ferns, and overhead long-branched spikes of Oncidium tigrinum and O. crispum. The sweet perfume of the flowers of the former add immensely to its value. Moreover, we have now the elegant Cymbidium Mastersi, bearing pure white flowers, which continue a long time in perfection at this season. As soon as the flowers of Oncidium tigrinum are over, the plants are placed in a rather dry, cool house to rest, and they get no water whatsoever. The cool-house minimum now ranges from 45° to 50°, with 10° higher by day, and is a pleasant place in which to spend an hour at this season. We have about 600 Odontoglossums, and out of that number some of them are always in flower, many opening for the first time. We have not potted any of the occupants of this house during the past autumn, nor will we do so until a convenient opportunity occurs after the new year. We have found this plan to answer very well in the past. I ought perhaps to add that, on looking over some of the best collections near London, I found that the Odontoglossums were being re-potted during the months of October and November. All I can say to this is, I have found by recent experience that the early spring months are best for this work, winter being even preferable to the autumn. Of course, it may often happen that we have to do such work when it is most convenient, whether it be in autumn, winter, or spring. Odontoglossum nebulosum is doing remarkably well this year suspended near the glass. It is making strong growths, which do not damp off. The distinct-looking O. Edwardi seems to delight in the coolest part of this house; it likes plenty of water at the roots. The right state of moisture is ascertained by keeping up a carpet of green Moss over the surface of the compost. This is what most Odontoglossums like all the year round. I ought to add, that even in this house excessive moisture is injurious. In dull, cold weather it may not be necessary to damp the paths and stages more than once in a day, or it may even be omitted altogether. Except during severe frost, this house is not altogether shut up, air being admitted at what we call the hit-and-miss ventilators, which are placed in a row in the front wall exactly opposite the hot-water pipes. The air has, therefore, to pass amongst the pipes before it gradually filters up amongst the plants. J. Douglas.

ORCHID CULTURE IN THE MIDLANDS.

A densely packed meeting of the members of the Birmingham and Midland Counties Gardeners' Mutual Improvement Association took place at their rooms in Paradise Street on Wednesday evening last, the chief item on the programme being a paper on the cultivation of the Cattleya, by that well-known local Orchid grower, Mr. E. Cooper, gardener at Highbury. Mr. Cooper, being fortunately in a position to practise what he preaches, having charge of one of the most extensive collections in the midland counties, was listened to with marked attention. He commenced by pointing out the dates on which the various older and well-known varieties were introduced, and, particularising them, he passed on and referred to the excellent work done in the way of hybridising by the veteran Orchid grower, Mr. Dominy, especially in connection with C. exoniensis. Touching the commencement of his own career as a gardener and orchidist, he said the impression made on his mind by a first glimpse of C. crispa superba, twenty-five years ago in the gardens of Lord Laconfield at Petworth, would never be entirely effaced. At Dale Park subsequently his affection for and knowledge of Orchids wonderfully increased, for there the then unusual circumstance of a house entirely devoted to them was discovered, and in it the various occupants were grown exceedingly well. From Dale Park he went to Dangstein, where he was more fortunate still, for in that establishment he fortunately found a house entirely occupied with Cattleya and Lælia, two subjects which were cultivated in first-class style by the then head gardener, Mr. Vair. Alluding to his own cultivation of the Cattleya since entering the service of his present employer, the Right Hon. J. Chamberlain, M.P., he said, twelve years ago, to the best of his belief, there were only three Cattleyas in the plant stove. Mr. Chamberlain, however, soon began to add to this meagre collection, and has continued making additional purchases at such a rate, as to place him, Mr. Cooper, in charge now of one of the most important collections in the midlands. Touching the method of cultivation pursued at Highbury, Mr. Cooper said the majority were grown in pots, pans, or baskets in the orthodox mixture of peat, Sphagnum, and potsherds. Some few, however, were found which it was imperatively necessary to cultivate on blocks. Laying great stress on cleanliness as being absolutely essential to the well-being of the plants, and sounding also a warning note on the necessity of efficient drainage, he gave a few plain and intelligent instructions as to the treatment of newly-imported Orchids, especial stress being laid on their isolation till all doubts as to their cleanliness and freedom from insects were removed. Allusion being here made to the sun and light-loving proclivities belonging to C. citrina, Dowiana, gigas, &c., he described the cultivation of these varieties, and then gave a few seasonable hints on watering, touched upon the irreparable injuries inflicted on Cattleyas in general by the indiscriminate use of the syringe. Ventilation was next alluded to, the benefits found to accrue from the admission of air properly warmed even in the coldest weather being adverted to, closing the houses only for a few hours daily during the growing season. Evaporation in the shape of pans containing weak liquid manure standing about the compartment, but not on the hot-water pipes, seemed, he said, to be very beneficial to the plants. Temperature was next dealt with, his opinions on the matter coinciding with those of the majority of Orchid-growers. A slight shade during June, July, and August was advocated in the hottest part of the day, Mr. Cooper not being able at Highbury to discard it entirely, like Messrs. Backhouse at York. Respecting insect pests, he warned growers particularly against tolerating the ravages of the Cattleya fly, which in the grub state played such havoc with the young growths, advocating the entire cutting away of the part affected, by which means he had entirely rid his collection of the pest. For thrips, greenfly, &c., the usual remedy of fumigation was advised, *i.e.*, three mild smokings at intervals of about twelve hours in preference to one strong dose, as being less likely to injure

the delicate foliage. A few words of advice to those members who by force of circumstances were compelled to grow Orchids in mixed houses concluded his address, and the usual vote of thanks brought one of the most interesting meetings at present held by this society—which now numbers upwards of 230 members—to a close.

Mr. W. B. Latham, curator, Birmingham Botanic Gardens, occupied the chair as president of the society.

J. H. H.

Masdevallia tovarensis.—At Lythe Hill, Haslemere, the residence of Mr. J. Stewart Hodgson, there is a plant of this in a 9-inch pan with no fewer than ninety-nine spikes, a good percentage of which is each carrying four blooms. The foliage, which is perfectly free from spot or blemish, is deep green, thus setting off the delicate white flowers to advantage. During summer it is grown in the cool Odontoglossum house, but it is wintered in the Cattleya house. It is potted in coarse fibrous peat and Sphagnum Moss, with a liberal addition of charcoal, and the plant is elevated a little more than the other varieties with which it is associated.

Lælia amanda.—This is a rare and handsome species; the slender pseudo-bulbs bear a pair of leaves some 6 inches or 9 inches long; the flowers, which measure 5 inches across, are borne in pairs; sepals and petals soft rose colour, lip deep rose beautifully streaked and lined with rich purple. We recently saw it in flower in Mr. Measures' garden at Streatham.

Cymbidium affine.—This is a valuable winter-flowering Orchid. In growth it somewhat resembles C. Mastersi, whilst the raceme bears numerous very fragrant flowers, about the shape and size of those of the last-named species; sepals and petals ivory-white, lip white, profusely dotted and spotted with purple. It is flowering with Mr. Measures at Streatham.

Pilumna nobilis.—This handsome plant, known also under the names of P. fragrans grandiflora and Trichopilia fragrans nobilis, is now flowering abundantly with Mr. Bull; it bears four or five of its fragrant blossoms on a spike; the whole of the flower is snowy white, saving an eye-like spot of yellow at the base. It is one of the most desirable of winter-blooming Orchids, and thrives admirably under cool treatment, such as is accorded to Odontoglossum crispum.

Trichosma suavis.—This Orchid in growth somewhat resembles a Cœlogyne, but its pseudo-bulbs are not thick; it, therefore, must never be kept thoroughly dry, and as its native habitat is the Khasia Hills, it does not require a high temperature at any time; the racemes are terminal, and bear several fragrant flowers, the sepals and petals of which are creamy white, lip three-lobed, the side lobes white, streaked with dull crimson; middle lobe yellow, bordered with crimson. It is usually considered a spring-blooming plant, but we saw it this week flowering profusely in Mr. Bull's nursery at Chelsea.

Choice Masdevallias.—There is a remarkable collection of this genus in Mr. Measures' garden at The Woodlands, Streatham. All are grown very cool and kept well supplied with water. We noted on a recent visit the following kinds blooming profusely: M. Chelsoni, the flowers of which resemble those of M. Veitchi, but are less brilliant in colour and smaller in size; M. Chimæra, of which there are many forms; the rare and curious M. Schlimi, the flowers of which are borne several together upon a long erect scape and are dull purple with yellow tails. Another curious and distinct species now blooming here is M. polysticta, which belongs to the racemose-flowered group. The flowers are white, sometimes pale lilac, freckled, dotted, and spotted with purple, the tails being greenish yellow. M. amabilis, although not one of the largest, is remarkably floriferous, and this and M. ignea and M. Veitchi add materially to the display, and contrast beautifully with the paler Odontoglossums.

Cypripediums in flower.—The Lady's Slipper Orchids contain many species which produce their blooms in winter, and as the species and varieties are now so numerous, beautiful effects are produced when grouped together, as in Mr. Bull's nursery at Chelsea. Amongst the principal kinds now in flower we noted C. Lawrenceanum, with its handsome leaves and large, bold flowers, the dorsal sepal broad and pure white streaked with bands of shining purple, and large lip of purplish brown; the old C. insigne in many forms, and the old, but beautiful C. venustum in several varieties; C. Harrisianum, with its varnished blooms, is a very desirable bloomer for winter; whilst the brilliant flowers of C. Sedeni and C. cardinale are welcome at any season, as also are the exquisite and chaste blooms of C. Spicerianum; whilst C. selligerum is both handsome and interesting, as being the result of a cross between C. barbatum and C. lævigatum. As these Cypripediums are very easily cultivated, and the blooms last many weeks in full perfection, it is no wonder they have become extremely popular with lovers of Orchids.

Cœlogyne Gardneriana.—This old and little-known species is now flowering beautifully with Mr. Measures at The Woodlands, Streatham. It has flask-shaped pseudo-bulbs and broadly lanceolate dark green leaves. The racemes are drooping, and bear numerous flowers, which are arranged in a somewhat two-ranked fashion. The flowers are pure white, saving a faint tinge of lemon-colour in the lip. It is a native of Northern India, and requires a slightly warmer temperature than that of an Odontoglossum house.

NOTES OF THE WEEK.

Pancratium guianense.—There is not a more beautiful species than this in cultivation, whilst its dwarf habit renders it available for those having but limited space for the accommodation of the plants. It produces short and broad leaves, and the scape rises just above them, bearing nine to ten erect flowers, which are pure white; the slender tube is about 9 inches long, and the sepals are about half the length of the tube, pendent, and beautifully undulated; the corona is somewhat small and the stamens are very long. It is in flower in Mr. Bull's nursery, Chelsea.

Tillandsia Lindeni.—This lovely Bromeliad is now flowering in considerable numbers in Mr. Bull's nursery, the large azure-blue flowers and rosy bracts being very conspicuous. This family of plants should become popular, as, independent of their great value as decorative objects in the stove, they are invaluable as ornaments for indoor decoration, inasmuch as they withstand uninjured the variations of temperature, and any dust or dirt which may accumulate upon their foliage is easily removed.

Azalea rosæflora.—This extremely handsome and dwarf-growing Japanese Azalea is now flowering. The blooms in the bud stage resemble in shape the buds of Niphetos Rose, but when open are very double and reflexed; they are rosy red in colour, and are so persistent that they do not fall, but usually die on the plant—a peculiarity which enhances their value when cut. It is sometimes found under the names of A. Rollissoni and A. balsamæflora.

Epiphyllum truncatum violaceum.—This good old-fashioned plant is now flowering plentifully in many gardens, and we cannot understand why plants like this, which produce such striking effects in the dull and foggy winter days, should ever be allowed to drop out of cultivation. Epiphyllums are easily grown, requiring but little attention, and can be brought into bloom at almost any time in winter by a little regulation of temperature either to force or retard them.

Winter-blooming Carnations.—These plants need no recommendation; everyone knows Carnations, and everyone loves them, and the tree or winter-flowering kinds are invaluable for button-holes and bouquets at a season when flowers are always scarce, and always in demand. We recently saw a very fine lot in Mr. Bull's establishment at Chelsea just coming into bloom, amongst which we noted the following kinds as specially good: La Perle, white, flaked and streaked with rose; Mdme. Sainte Hyacinthe, salmon flaked carmine; The Colonel, deep crimson; Bernhard Voigt, yellow flaked with crimson; Jean Magne, carmine self; White Swan, pure white; Mrs. Hawtrey, soft yellow, large and fine; Mdme. Schwaller, pink flaked carmine; Soligne, salmon flaked cerise; Henriette Magne, rose-pink flaked dark rose; Rufus, bright scarlet; Andalusia, primrose yellow, fringed petals; Sir G. Wolseley, buff, flaked puce; King of the Belgians, bright rose; Charles Mercier, purple self. These and many other kinds are just coming into bloom, and the beauty of their flowers is quite indescribable.

The Neilgherry Lily.—The New Plant and Bulb Company, Colchester, send us flowers of Lilium neilgherrense, which they say is now flowering in the open air with them, and they think it much hardier than is generally supposed. The plants have withstood several frosts, and are still in good condition. This Lily much resembles the commoner L. longiflorum both in growth and flower, but the blooms, instead of being white, are of a yellowish white.

Aralia papyrifera in flower.—There are two specimens of Aralia papyrifera now in flower in the conservatory at the Royal Botanic Society's Gardens, Regent's Park, of a size and vigour I think seldom seen; the leaves are over 40 inches in diameter, with petioles 30 inches long. It is a good example of how plants will grow when planted out, instead of cramped in tubs and pots. I have seen the plant growing in the open both in the south of France and Italy, specially in Mr. Hanbury's magnificent garden at Mortola, near San Remo, but never came across such noble specimens as ours.—W. Sowerby.

Gardeners' Royal Benevolent Institution.—We learn that at a meeting of the committee of this institution, held on the 18th inst., Mr. Harry J. Veitch, of Chelsea, was unanimously elected treasurer of this institution, in the room of Mr. Edward Tidswell, who has resigned that office on account of serious ill health. At the same meeting it was also determined to make an addition of ten pensioners to the list in January next, six of whom will be admitted without election, under Rule No. 6, they or their husbands having been subscribers for fifteen clear years. An election will take place for four pensioners out of a body of seventeen selected and approved candidates. The voting papers will be issued on or about the 16th December.

At the Potato Centenary on December 2 and 3, to which we have already referred, the following subjects for conferences have been proposed: First day, Morning: (1) historic consideration of the question, Whence came the Potato to England? (2) the Incas and their cultivation of the Potato; (3) distinct wild species of the Potato as at present recognised; (4) the production of varieties by cultivation. Afternoon: (5) the Potato disease; (*a*) historic sketch, (*b*) our present knowledge of the disease. Second day, Morning: (1) proposed methods of preventing the disease; (2) methods of using partly diseased Potatoes; (3) methods for storing and preserving Potatoes. Afternoon: conference of cultivators on rates for transport of Potatoes.

Pelargonium Col. Holden.—I send you a truss of bloom of this zonal Pelargonium, a variety which neither "W. I. M." nor any of your correspondents have mentioned in their recent notes in The Garden on winter-flowering Pelargoniums. I find it a most profuse bloomer at this season; cuttings struck in July, and now in pots varying from 3 inches to 5 inches in diameter, are carrying from three to seven trusses of blooms each, while the old plants, cut back at the same time and in 5-inch pots, are carrying as many as nine trusses each. The blooms of this variety last a long time, either on the plant or when cut and in water. I need not say how useful Pelargoniums of this class are, blooming as they do at this dull season, and how effective they are for decorating either conservatories or rooms.—Robt. Goodall, *Goldsboro' Hall, Knaresboro'*.

*** A very fine sort, judging by the truss sent. The colour is brilliant, a sort of carmine-crimson.—Ed.

Escallonia pterocladon.—I send you flowers of this Escallonia which seems to be rare. Its small, very dark green foliage and white flowers make it well worth growing, especially as so few shrubs are in blossom at this time of year. The frost has as yet

spared the pretty little flowers of Parochetus communis. They are almost hidden in its pretty Clover like foliage. We find the flowers of Eupatorium odoratissimum very useful at this time of year for cuttings.—C. M. Owen, *Knockmullan, Gorey.*

*** The Escallonia is a pretty shrub and very valuable at this season. It resembles E. rubra, but is smaller and the flowers are white. It is quite hardy about London. The little sky-blue Parochetus is seldom seen, but a prettier plant could not be found in flower in November.—Ed.

Winter-blooming Pelargoniums.—These are just now producing a brilliant display in Mr. Coulthurst's garden at Streatham Lodge, where a house is set apart for them during winter. These plants were struck about midsummer, and grown in pots in cold frames, but not allowed to produce any blooms until about the beginning of October, when they were removed to the flowering house, which is kept at a comfortable temperature. Amongst the numerous good kinds grown here we noted the following as being the most desirable: In the white-flowered section were Queen of the Belgians, Niphetos, and Duchesse de Cars; in purplish-pinks the best were Eurydice, Jean Ill, and Mrs. Stratt; of salmons, Fanny Catlin, Lizard, Gustav Gower, and Queen Ann appeared the best. The finest scarlets were Atala, Metes, Ferdinand Kauffer, West Brighton Gem, Ellen Terry, Henry Irving, and Barry Sullivan; rose-coloured flowers were represented by Queen Matilda, Lucy Bosworth, Edith George, and Queen Elizabeth. Amongst double forms the following were exceptionally fine: F. V. Raspail, large pips, very double and bright scarlet, a decided improvement upon Wonderful for market growing; Charles Darwin, rich purple-magenta; Charles Lalande, deep crimson; Mad. François Desbois, deep pink sulfused with purple; Mr. H. Cannell, fine market kind, surpassing Wonderful in floriferousness; and Madame Leon Dalloy, blush white.

Societies and Exhibitions.

NATIONAL CHYSANTHEMUM SOCIETY.

A meeting of the floral committee of this society met at the Royal Aquarium, Westminster, on Wednesday last, and a large number of new varieties of Chrysanthemums was submitted to them. There was a dense murky fog at the time, so that it was impossible to judge the exact colours of the flowers. However, by the aid of the electric light the committee managed to get through their work. First-class certificates were awarded to the following: To Mr. Winkworth, Childwell Hall, Liverpool, for *R. Brocklebank*, a fine sport from Meg Merrilies; to Mr. Sullivan, Downshire House, Roehampton, for a seedling Japanese sort named *D. B. Chapman*, flowers large, narrow florets of deep lilac; to Mr. W. E. Boyce, Highgate, for *Rubra perfecta*, a small reflexed sort of a deep and rich maroon-crimson; to Mr. Mizen, Mitcham, for Miss Norman Davis, a fine large incurved; to Mr. R. Owen, Floral Nurseries, Maidenhead, for Osiris, a pretty Pompon of a beautiful deep peach-pink colour; to Messrs. Cannell, Swanley, for l'Or du Japon, a large Japanese, of a peculiar buff shade; for Mrs. W. Holmes, an Anemone-flowered sort, large and finely shaped, and of a pale pink; and for *Marigold*, a bold-looking single sort, with a large centre and bright amaranth florets. The new sorts commended included *Syringa*, a large and fine pale pink Japanese sort from Mr. Martin, Dartford; *Charles Hulle*, a reflexed sort of perfect shape, and of a deep pink, shown by Mr. Ware, Tottenham, who also sent *Iona*, another reflexed seedling of a singular shade of reddish yellow. Mr. Owen's Cloth of Gold Marguerite was also commended. It is an improvement on the typical kind.

Among other noteworthy kinds shown was a sport from Golden Queen of England, from Mr. Rogers, Ashford, but was considered not sufficiently distinct. A sport from Striatum was shown by Mr. Smale, Torquay, but also not distinct enough. Messrs. Veitch showed R. Bottomley, which the committee considered too much like Pelican. Messrs. Cannell, of Swanley, showed a large collection, which contained many beautiful sorts, chief among them being several single and semi-double sorts charming in colour, beautiful and informal in shape. These, however, do not seem to be appreciated much by the committee, because perhaps they do not conform to the inflexible points laid down as the criteria of perfect Chrysanthemums, but the time will come when single Chrysanthemums will rival the doubles as surely as single Dahlias have become as popular as the show and fancy kinds. The Swanley singles comprise sorts of all shades of colour, and particularly beautiful were those named Crushed Strawberry, a soft peach colour, and Ethlyn Goldring, of a pleasing chestnut-red shading to yellow, with peculiarly twisted florets. Other kinds shown by Messrs. Cannell included Domination, white Japanese; Mrs. W. A. Harris, a pale blush Japanese; Mrs. Wheeler: H. Cannell, in the way of Thunberg and grandiflorum, but of a pale straw yellow; Lady Cave, a lovely reflexed white; James George, in the way of the beautiful Cullingfordi; and Mrs. Cannell, one of the purest of whites in the Japanese section. Messrs. Laing, of Forest Hill, showed half-a-dozen new sorts, including D. B. Chapman, La Gracieuse, l'Or du Japon, Mrs. Holmes, and Mdme. Murel. Mr. R. Owen showed several new sorts, including Mr. Glover, white reflexed; Lord Palmerston, incurved, of a deep pink colour. A beautiful new golden sport from Ethel, named Mrs. Jones, was shown in an excellent way by Mr. Ware. It is one of the best pale yellow Japanese sorts we have, and will sure to become popular. New sorts were also shown by Mr. Boyce, Mr. Stevens, Putney, and others. At the close of the meeting it was proposed to make a rule: "That certificates be given to the best blooms of such varieties as may be shown at more than one of the society's exhibitions." There will be a mid-winter show held on January 12 and 13.

CHISWICK CHRYSANTHEMUM SHOW.

Among the Chrysanthemum shows in the neighbourhood of London was one held the other day at Chiswick, where in the Vestry Hall there was a very bright and attractive display. A group sent from the gardens of Chiswick House (Marquis of Bute's) was admirable in every respect—a glow of colour—such flowers as the following showing in true form:—

Incurved and reflexed sorts.—Guernsey Nugget, White Venus, Golden Queen of England, Julie Lagravère, Jardin des Plantes, Marquis of Lorne, Pink Christine, Golden Christine, Fingal, George Glenny, Dr. Sharpe, Progne, St. Patrick, Mr. Bunn, Refulgence, Lady Talfourd, &c.

Japanese.—Cossack, Sultan, Peter the Great, River Fleuri, Comtesse de Beauregard, Roseum pictum, Baron de Prailly, Master C. Hubert, Fair Maid of Guernsey, Diamond, Source d'Or, Fulgore, La Nymphe, Bend Or, Red Dragon, Ethel, &c.

Pompon sorts.—Jean Hachette, Dick Turpin, Model of Perfection, President, Margaret du Coi, Pearl, Marabout, Snowdrop, Antonius, Adèle Presette, &c.

There seems to be more diversity of opinion in judging bouquets than anything else at shows. For instance, the second-prize bouquet many would have thought was better than the first. It consisted of the Source d'Or variety as a groundwork, topped, and gracefully, too, with the white button-shaped flowers of Snowdrop, and a frond of Maiden-hair giving elegance and finish to the arrangement. Mr. Watt's gardener also showed excellent table plants, viz., such as Geonoma gracilis, Cocos Weddelliana, Croton Warreni and Aralia Chabrieri.

What was a very simple and graceful arrangement in grouping, but a few plants being employed, consisted of the following, contributed by Messrs. Fromow: An Areca lutescens at back, with Erica gracilis (in flower) and Adiantum cuneatum intermingled at the base, a few Palms and Crotons rising above. It is not very often we see Orchids well grown at such local shows, but a good plant of Cypripedium insigne, bearing eighteen well-developed flowers, was noteworthy. It was exhibited by M. A. Wright. The group from the Gunnersbury Park Gardens, arranged by Mr. Roberts, was much admired, and the first prize competing group from Messrs. Fromow was a credit to the exhibitors. B.

Royal Horticultural Society.—The following are the dates of the meetings of the council, and of the scientific, fruit, and floral committees in 1887:—

Council Meetings—	June 14 and 28
January 11	July 12 and 26
February 8	November 8
March 8 and 22	December 13
April 12 and 26	Fruit and Floral Committee Meetings—
May 10 and 24	January 11
June 14 and 28	February 8
July 12 and 26	March 8 and 22
October 11	April 12 and 26
November 8	May 10 and 24
December 13	June 14 and 28
Scientific Committee Meetings—	July 12 and 26
January 11	August 9 and 23
February 8	September 13 and 27
March 8 and 22	October 11 and 25
April 12 and 26	November 8
May 10 and 24	December 13

all the meeting days being Tuesdays.

Development of Silloth.—The public who are on the outlook for new watering places will be glad to learn that the directors of the North British Railway Company have just taken a step towards the improvement of Silloth. With a view to increase its attractions the directors have called in the advice of Messrs. Little and Ballantyne, of the Carlisle Nurseries, who have executed a plan for providing shelter and ornament, by breaking up the great stretch of green sward between the parade and the sea by ornamental belts, mounds, rockeries, and clumps of flowering and evergreen shrubs. The health giving Pine, so great an attraction at Bournemouth, will be largely employed, and the whole appearance of the town and recreation grounds will be completely altered and largely extended. The streets of the town are also to be planted with avenue trees. They will be planted 30 feet apart, and will consist of Sycamores, Norway Maples, Elms, Chestnuts, Limes, and other trees.

QUESTIONS.

5530.—**Tropæolum albiflorum.**—I have a strong bulb of this which refuses to grow. It has been planted several years, and the soil in the pot has been changed in the hope that some soil or other might induce it to start, but it persists in refusing to do so. We keep it in a temperate house. Have any of your readers had a similar experience, and can they favour me with any suggestions in reference to it.—W. H. Tillett, *Sprowston, Norwich.*

5531.—**Eradicating Gorse.**—Will some of your readers kindly inform me how to get rid of young Gorse plants, which cover one of my fields in Surrey. About six years ago I grubbed a portion of a hillside, on which I built my house. The hill was covered with copse, and here and there were bunches of Gorse and Heather. Young Gorse plants soon came up, both on my lawn and on the hillside, which I wished to convert into pasture. The lawn, being of moderate size, was picked over by hand, and I have not been troubled with Gorse there since—perhaps the mowing keeps it down; but the hillside, though it is cut twice a year to make it look presentable, is becoming a huge Gorse bed. I tried spudding a part of it this spring, but it took days to do a few square yards. The roots came up 18 inches long. Is there any ready way of getting rid of the plant—any mixture that will kill it without destroying other growths. If I grub all the field again—a costly process—I fear I may only have a repetition of the nuisance.—E. W.

Names of plants.—*T. S., Aberdeen.*—1, Cypripedium insigne Maulei; 2, C. insigne, good form; 3, C. insigne, common type.—*W. S., Doncaster.*—1, Selaginella stolonifera; 2, specimen too much shrivelled to identify; 3, Selaginella uncinata; without number, Adiantum concinnum.—*F. P., Ringwood.*—Iochroma tubulosum, ordinary greenhouse treatment.

Naming fruit.—*Readers who desire our help in naming fruit will kindly bear in mind that several specimens of different stages of colour and size of the same kind greatly assist in its determination. Local varieties should be named by local growers, and are often only known to them. We can only undertake to name four varieties at a time, and these only when the above condition is observed. Unpaid parcels not received.*

Names of fruits.—*J. Eade.*—Easter Beurré.—*J. W. S.* 1, Beurré Charmeuse; 2, Beurré Rance; 3, Knight's Monarch.—*S. K. T.*—1, a local sort, not known; 2 small Warner's King; 3, Manks Codlin.—*L. W.*—2, Beurré d'Aremberg; 20, Passe Colmar; 21, Flemish Beauty; large Pear, rotten; small Pear, Beurré de Capiumont; round Pear, Old Crassane—numbers illegible.—*C. Batty.*—Name of Pear not known. The fruit seems to decay in a perfectly natural manner; some Pears always decay early at the core whilst maintaining a firm exterior.—*Sylvanus.*—5, Old Russet; 6, Northern Greening; 8, Brabant Bellefleur; 7, not known.—*S. Hoskin.*—Marie Louise.—*R. Edgar Jacobs.*—1, Chaumontel; 2, Glou Morceau; 3, Josephine de Malines.—*C. Earl.*—1. Uvedale's St. Germain; 3, Chaumontel; 4, Knight's Monarch,

WOODS & FORESTS.

THE BEST PLANTING SEASON FOR FOREST TREES.

I NOTICE one of your forestry correspondents writing on November 20 to the effect that "most deciduous trees are now fit for removal." I believe it is the general practice of foresters to delay planting to a period of the year when gardeners have all their deciduous trees comfortably in the ground before winter sets fairly in—at least they try to do this. I superintend woods as well as gardens, and it may surprise the writer at p. 488 and others to hear that at the time he took up the pen to tell us the planting season had begun, we had got our trees nearly all in. We began in the last week in September with all sorts of the Fir tribe that we use, except Larch, and had by the middle of November about 40,000 safely planted, which now look remarkably well, but the earliest planted will do best. Up till now, November 20, we have also got in about the same quantity of Sycamore, Ash, and other deciduous trees, all planted with foliage, but hard in the wood and with plump, mature buds. The foliage fell off naturally soon after planting, and I have no doubt the trees will make a better growth next year than if they had been planted later. On the other estates near not a tree has been put out yet. The leisurely-system foresters have of losing the very best season for planting, October and November, and planting most of their stock just before or after Christmas right away into March, or even April, cannot be too severely condemned. As soon as the wood is ripe it is time to begin, and by October most kinds of forest trees are quite ready to be transplanted. What applies to shrubs applies to trees. It is not wise to transplant before the young wood is so mature that it will not shrivel: but I have seen shrivelling take place and no harm result the following season. The advantage of early autumn planting of all trees is that the roots get partly established, which is a great gain, as a tree so established will sometimes make a long leader (especially deciduous trees) the following year, while one planted after the new year will stand still, thus practically losing a year. Trees planted late in extensive plantations cannot be watered effectively, and should the season be dry, they die. Vast losses are incurred in this way under careless or ignorant management. We grudge every man or boy who, from any cause, is absent from planting after the end of September, and long before that we are taking out pits and preparing generally to save time when planting begins. Besides, there is the weather to look at. Last year the snow came before Christmas, and did not lift long enough to permit planting operations to be resumed till March, when it was too late. Fortunately, we had most of our last year's planting done before the snow came, but the majority had not begun. Nurserymen tell me, both in England and Scotland, that their trade with foresters last year was practically nil, owing to the snow coming soon after the beginning of the usual planting season. One nurseryman told me it was by far the best plan to put out deciduous and other trees early if the former cost more for labour and carriage on account of their leaves being still upon them, and which, I understand, is one of the objections to planting at that stage.

A FORESTER AND GARDENER.

Improved method of preserving wood.—A French method of preserving wood by the application of lime is found to work well. The plan is to pile the planks in a tank, and to put over all a layer of quicklime, which is gradually slaked with water. Timber for mines requires about a week to be thoroughly impregnated, and other wood more or less time according to its thickness. The material acquires remarkable consistence and hardness, it is stated, on being subjected to this simple process, and the assertion is made that it will never rot. Beech wood, prepared in this way for hammers and other tools for ironwork, is found to acquire the hardness of Oak, without parting with any of its well-known elasticity or roughness, and it also lasts longer.—*North British Agriculturist.*

CUSTOMARY AND TRUE MEASUREMENT.

I AM not so entirely satisfied with the condition of things in general as to believe that whatever is must of necessity be right; still I cannot see that any useful purpose would be served by altering the basis upon which cubic measurement is at present estimated. The question is an old one, but "W. B. H." in his remarks (p. 488) has clearly and concisely stated the way in which the difference arises, and I commend his explanation of the example he has taken to any who may not be well posted upon the subject. I take it that when any change or reform is intended, there must be very cogent evidence that the good resulting is likely to be greater than the evil which must follow the upsetting of one system and the establishment of another. I do not know whether the "true" content measurement has ever been adopted in actual transactions, but in one or two instances I have known of its being attempted by some paper foresters who have happened to be *pro tem.* in charge of a place during a change of wood managers. The result was that the timber was not sold at all during their regency, and the succeeding man had to dispose of it upon the old and recognised lines. If there was any good ground for supposing that the timber-producer would receive a fraction more for his trees by the suggested plan of true measurement, it would be everyone's duty who is acting in the interest of such to promote the change by every means in his power. Matters standing as they do make it practically certain that the only outcome to be expected would be confusion. The merchant, of course, knows how much saleable material he can cut per cubic or customary measure, and will fix his price accordingly. If every forester in the kingdom persisted in selling by true content, every merchant, on the other hand, would be equally persistent in buying at a corresponding reduction in price. Practically, it does not matter if 1000 feet were called 100 feet, or *vice versâ*, so long as everybody knows that the unit of measurement represents a given and unvarying quantity. If, again, there were two recognised ways of calculating for this class of timber, it would be perfectly reasonable that every effort should be made to ensure the survival of the fittest; but when there is one only, and this works well in practice and fairly to both sides, I can only conclude that, however well-intentioned, anyone who advocates the theoretical as against the practical is doing more harm than he is good. On the present lines the seller of unsawn timber would be quite within his rights to have each tree hewn to a square or rectangular figure, but it would cost him more to do so than the wood so hewn would be worth. If the forester does his best to find a good market, it will be much more profitable to him than trying to set up a new system of measurement which is in no way better than the old one.

D. J. Y.

Allowance for bark.—There is no detail in forestry in which there is greater variation of practice than in that of the allowance made for bark in girthing timber. "Young Forester" says he allows 1 inch in trees girthing 12 inches and upwards, and half an inch in trees under that girth. I was not aware that any allowance, for instance, was made for the bark on a smooth-barked Ash or Beech, or, in fact, on any hard wood excepting Oak. His price per foot will compare favourably with mine if he makes that allowance on all hardwoods, for I allow nothing, excepting on Oaks. I may knock off occasionally a quarter of an inch if a tree has very coarse bark, but not otherwise. With the Pine tribe it is different. On all Larch, Scotch, and Spruce I take off a quarter of an inch, which is considered sufficient to make up for any loss of bulk in snigging and removing the timber to the railway station. Take an Ash 40 feet long by 13½ inches quarter girth above the bark; it will contain 50 cubic feet, which at 1s. 6d. per foot is worth £3 15s., but by "Young Forester's" method of measuring it will only have 43 feet, or a difference of 7 feet in measurement and of 2½d. per foot in price. If this large allowance for bark is a general thing in the south of England, it explains at once the large prices per foot they get for their timber. A nobleman told me the other day that a friend of his in Sussex had sold some Ash at 3s. 6d. per foot; whilst here in Yorkshire, 1s. 6d. or 1s. 9d. in the plantation is the highest price for the choicest butts. It would be a great advantage to everyone connected with the timber trade if a uniform system of measuring could be adopted.—W. B. H.

TREES ON LIMESTONE SOILS.

THERE are so many limestones belonging to different formations and of such variety of texture and density, that I will at once state that the kind to which these remarks chiefly apply is that known as coral rag. The elevation is several hundred feet above sea level, and forty or fifty miles inland. Generally in the part of this formation where these notes have been made the soil is sufficient to allow of fairly deep ploughing and thorough cultivation, although the implements occasionally come into rather too abrupt contact with the rough stones of the subsoil which are above the ordinary level. This, as the name of the formation implies, consists of rough stones of a coralline character, more or less compactly packed together, according to the presence or absence of rubble. The soil itself is largely composed of the same class of stones more finely sub-divided, and in a free state over this district, which is moderately wooded, most of the common trees indigenous to this country are found, and, of course, introduced species where they have been planted. Taken on the whole, the tree growth about here may be described as moderate, as there is very little of the appearance of stunted growth, and, on the other hand, little of the luxuriance which is met with on some soils and situations. The Elm is a typical tree. It generally has a healthy look, but does not grow with particular rapidity or produce wood of the clearest grain. Some large trees are here and there found, but the indications are that they have taken centuries to come to maturity. A fine old tree of this species (the common English) stands on a village green within the boundary of this limestone formation, and seems to have been used from time immemorial as a trysting-place. Many of its roots are now bared, and from their conformation point to an era long since passed into history. There is one thing which I have noticed in connection with the progress of young trees upon this subsoil, and I have often heard others comment upon it, and that is the effect that any disturbance of it has in causing a fresh growth. In several places within the area quarries have been opened, the stones removed for various purposes, and the rubble, which was useless for road-making and the like, again filled in and the surface levelled. When planted on such sites the young trees as soon as they become established feel the benefit of a free root action in the subsoil from which the closely-packed stones have been removed. In all such cases, care is of course taken that the soil is removed before the quarrying commences, so that when the opening is filled up the soil may be replaced in its natural position. This, however, only in passing, as it is obvious that quarrying an area for the purpose of making it suitable for tree planting would be about on a par with burning the house to produce roast pig—a very unprofitable business.

There is a proportion of Oak timber growing upon this limestone, but it does not seem nearly so much at home as upon the clay soils a few miles distant. What trees there are mostly turn out to be of good quality, and I have seen some very large Oaks upon it, but it cannot be fairly called anything more than an average Oak soil. In speaking of tree growth on soils contiguous to it, the Oak and the Elm improve in just opposite directions. As has been said, the Oak does better as it approaches the clay. The affinity of the Elm is for the sandy loam which flanks the district under notice on the opposite side. With regard to the Ash, when it is found in woods and plantations on this limestone, it grows pretty freely and produces very often good timber, but isolated it does not make any especial headway. From this it would seem that other influences have

their weight beyond the question of soil, and undoubtedly they have, but to enter upon them here would be a little beyond the scope of these notes.

Of Beech there is not a great quantity, but what there is bears out what I have said of the other trees, and the Sycamore differs but little. Unfortunately, the Horse Chestnut is of little economic value, otherwise it is a tree which seems to thrive as well as many. I have never had an opportunity of testing the actual rate of growth by measurement, but its tendency apparently is to grow quickly when young, and then remain in *statu quo* for a number of years. Poplars grow, as they will on almost any soil, but after a generation or two they lose their vigour. A Lombardy Poplar which has often been pointed out to the writer as being planted by a near relation a little over half a century ago has reached a great height and a considerable size, but others within short distances seem to be fast losing their vitality. With respect to coniferous trees, the Spruces do not seem to do at all. Larch succeeds moderately well, and would be a good tree to plant upon spots which had been quarried, and which consequently may not have the level surface which is desirable for cultivation. Of Scotch Fir there is not much, but what there is seems to grow well enough as regards health, but slowly. Amongst the underwoods the Hazel is the most general, and reaches a usable size in a dozen years or so. There are, of course, many trees which have not been touched upon, but enough will have been said to show that though by no means luxuriant, trees upon the coralline limestone in most cases succeed fairly well. D. J. Yeo.

Gardeners, foresters, and valuers.—The remarks of "Yorkshireman" (p. 465) are uncalled for. My few remarks on the methods and appliances applicable to timber measuring were not intended for the edification of such as "Yorkshireman," but for beginners in such work as he seems to be so thoroughly and extensively acquainted with. Those instruments and appliances that I mentioned are not presented as novelties, for they "are as old as the hills," but they may be useful to beginners, who should make themselves acquainted with such instruments and their applications. When experience has enabled anyone to act without their aid, then he may value his thousands and tens of thousands of trees with as much expedition and correctness as our Yorkshire friend. But hundreds of our foresters have to exercise their abilities upon estates that cannot afford that extensive scope for their display as that upon which "Yorkshireman" seems to luxuriate. I have, during an experience of nearly forty years, measured and sold timber of all kinds over a considerable portion of the middle, south, and west of England, and in Scotland, and have found many cases where small buyers insisted upon string measurement. But I never use it, except to satisfy such buyers' whims.—A. P.

—— It is no use taking up much more of your space discussing this topic with Mr. Yeo and others until they have something more than bald assertions to give us. I admit there are some good foresters, and it would be a pity indeed if the sons or pupils of such men were not qualified for their duties; but what is certain is the fact that the great majority of men who, at least, act as foresters in any capacity are sadly ignorant of the *rationale* of their business. I meet many of them, and I have been simply appalled by their ignorance. I should say that, taking masters and men together, not one in fifty reads anything on the subject, and few have books. The truth should be told. Gardeners are a smarter class of men altogether, and they have, as a rule, far better means of learning anything relating to trees and plants, from "the Hyssop that groweth out of the wall to the Cedar which is on Lebanon." They are just as familiar with the culture of trees as anything else, and everything relating to their growth, and most gardeners have also much nursery experience among forest trees. It is a singular fact that gardeners alone are employed by nurserymen as their agents in travelling and dealing with foresters or their employers in all that relates to planting, &c., and that these men, or at least gardeners, as a rule, do mostly all the contract planting engaged in by nurserymen.—Y.

HOW TIMBER IS VALUED.

In a paragraph in The Garden, headed as above, the writer, "Y.," states that he knows a timber merchant who can "get as much Larch as he wants from North Yorkshire, *in the Helmsley neighbourhood*, for almost any price he likes to offer." In the preceding lines of the same paragraph, "Y." enters into a series of calculations intended to show that the growers of this timber will not get more than 3d. per foot at the wood, less discount for cash. Now, nearly all the Larch timber within a radius of six miles of Helmsley is on the Duncombe Park estate, and if "Y.'s" timber merchant means to include that estate, I beg to give his assertion a most unqualified denial. No Larch on this estate has been sold for anything like the ridiculously low price per foot he names; and as to the timber merchant, or anyone else, getting as much Larch as he wants at his own price, it is an idle tale, and not worthy of repetition by a writer of "Y.'s" calibre.

"Y." also assumes that the said Larch costs ½d. per foot to fell. I give 2s. per 100 feet for ours, or just 52 per cent. less than "Y." supposes. I hope the figures he gives about the cost of removal by rail and road are more reliable, or the readers of The Garden will be apt to conclude that "Y." is not so well acquainted with all the "many details" of forestry as he professes to be.

I may also assure him that thousands of feet of Larch are turned over by timber merchants in these times of close competition for much less than 1d. per foot profit. Such is the opinion of

The Forester on the Duncombe Park Estate.

HOME-GROWN V. FOREIGN TIMBER.

The impression seems to prevail that we are to be beaten at every point by what comes from across the seas. It is, I presume, pretty well known to most who are interested in home-grown timber that of late a good many spokes and other finished and unfinished articles used by wagon-builders, wheelwrights, and carriage manufacturers have been sent in from abroad, manifestly for the time being displacing British woods, which had hitherto been exclusively employed for the work. According, however, to recent tests, it has been proved that the wood of which these articles are manufactured are of much less value, in the sense of not being so strong and durable, than the wood which had been grown at home, and which had hitherto always been used. This does not go to say that there are no purposes for which the foreign wood may be turned to account, as the greater lengths it often grows to, and its straightness, make it very useful where such dimensions cannot be readily found in our home-grown woods. Therefore it will be seen that in supplementing our own supplies we rather get an auxiliary than a rival. It was, no doubt, perfectly natural that if a market was found here for the larger classes of wood, our friends across the water should try to supply some of their smaller produce as well, but from our point of view it is satisfactory to learn that this attempt has not been altogether successful, and that the best makers who have tried the imported wood for vehicle-building are returning to home-grown timber.

The tests to which I specially referred above are some which have been made by a London firm upon specimens of English and American Oak, and it has come out from trials under various conditions that both in bending, stress, and in resisting crushing force the British Oak is superior. It is, perhaps, not well to attach undue importance to experiments of this kind, although they are very instructive and of recognised value, but the statement from trustworthy sources that in practical every-day wear and tear foreign wood is being discarded for what is grown at home, I look upon as being a circumstance which cannot be misinterpreted, and one which is, at least, a drop of comfort in the bucket of discouragement. From an independent source, and with reference to another class of timber and manufacture altogether, I am pleased to learn that there is more of our English wood used than was the case a few years ago, when I had an opportunity of knowing the extent to which such wood was employed. I do not wish to unduly dilate upon these facts which have accidentally been brought under my notice, and without any idea of further reference being made to them, but, as I remarked in opening, there is such a tendency to go with the current of unfavourable appearances, that I take it we are entitled to assess at its fair value any boulder which may be helping to divert the current into another and more favourable channel to ourselves. Whilst upon the subject, though, of course, this is a thing which growers have in their own hands, I cannot help being encouraged by the greater degree to which those who have charge of building and other operations on estates seem to be recognising the fact that our own produce is not so unfitted for the work, as has been so suddenly discovered since wood from abroad has been comeatable at such relatively low figures. At the risk of iteration, and of getting a castigation from the hands of such as assume that the bulk of wood which is wanted on places in the country is practically out of the calculation when reckoning upon the whole consumption of our home supplies, I must repeat that this gradual change of front by those who have it in their hands to use which class of wood they prefer is another rift in the cloud. A question which I have often put, but never seem answered by those who pose upon the infinitessimal quantity of wood wanted for home use, *i.e.*, in the neighbourhood where it is grown, is, if there is such an insignificant amount used, what becomes of the loads upon loads of foreign woods which are constantly finding their way into these same districts? Is this wood used up for firewood, or is it buried underneath the soil, or weighted and sunk into lakes or rivers, or what becomes of it? It must either be disposed of in some such way as this or used for building and similar purposes, as one would reasonably think would be the case. Perhaps some one in the secret can tell!

D. J. Yeo.

Saw-mill management.—"Yorkshireman" is endeavouring in many respects to alter his tone in saw-mill management. The two old men he mentions as managing the saw-mills on the estate must have been men of experience owing to their being old men. The owner of a saw-mill sawing 20,000 feet annually is rather a large one. But I know owners sending 40,000 feet out annually, and I am certain that they do not entrust the management of their mills to handy labourers. I am glad of the hint upon entering an assurance against the Employers' Liability Act. But prevention is better than cure. We avoid handy labourers working the saws. I imagine that "Yorkshireman's" saw-mills are on a small scale, and he has the advantage over large saw-mill owners in towns by being screened behind hedges out in the country from the eyes of the inspector. Let "Yorkshireman" understand clearly that when I mentioned about the men with mutilated limbs, I did not say that such occurred in our mills. But with the experience which my father and myself have had in England, France, Germany and Russia, we have seen many cases of that nature; therefore I think that the Employers' Liability Act has proved a blessing to many a poor man who is now-a-days counselled to accept almost any post, notwithstanding the danger attached thereto. —Omega.

The magnificent Spruces on Lord Wicklow's estate are well worth a day's journey to see. I believe the finest Spruce in England is, or was ten years ago, on the estate of Lord Normanton in Hampshire, near Ringwood, on the edge of the New Forest, growing on a steep slope, fully exposed to the north and east, and not by any means very sheltered from the south-west; soil moist, sandy, in fact, moorish; the tree from memory would be 5 feet in diameter, and, we venture to say, 150 feet high, forked into twin columns at some 10 feet from the ground.—F.

No. 785. SATURDAY, Dec. 4, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

WHITE DAFFODILS.

A GOOD deal has lately been written about the identity or difference of certain white Daffodils. A few years ago we were told confidently by one who had made Daffodils his special study that, search as we pleased, we should find no more and no less than four distinct white Daffodils, because Haworth had recognised and described that number. We are now aware that Haworth had not the opportunities we have, and that had he lived in this generation, he would have described not four, but probably forty varieties of white Daffodil out of the materials we have before us. Linnæus, though not well versed in Daffodils, made one name include all white Daffodils, and this name was Narcissus moschatus. Setting aside garden hybrids, to which florists' fancy names may fairly be given, it is probable that this name, N. moschatus, properly includes all the white Daffodils which have ever been found wild; but these wild white Daffodils are varied enough in form to present differences which can be made a pretext for distinct names. The supply of names, however, must be ample, if we are to name all of them. Out of, perhaps, three hundred which I have in my garden, imported direct from the Pyrenees, it is an exception to find two together exactly alike. We find perianth divisions shorter than, equal to, and longer than the crown; in some straight, in others twisted; in some broad and obtuse, in others narrow and acute, and the crown equally varied.

WOLLEY DOD.

A CHESHIRE GARDEN.

BEFORE I proceed further, allow me to demur to the old statement repeated by "B." in THE GARDEN of September 4, that Gloxinias require tropical heat; on the contrary, they succeed admirably with me under Vines in an ordinary greenhouse temperature, the pots being wintered under the stages near the pipes. The drawing of Verbascum olympicum in the same number reminds me that my plants of this Mullein have, after three years' waiting, flowered this summer in a bleak sandy spot. One plant produced a many-branched, candelabrum-like spike about 8 feet high, and attracted much attention. Flowering seems to kill this plant, and I shall stick to V. pyramidatum, which flowers every year, sows itself, and is equally as ornamental amongst shrubs as in the mixed border. But to my subject. It may interest "Veronica" to hear a few particulars of a Cheshire garden on a north sandy slope twenty miles from the sea. My object is bloom, and plenty of it from spring until autumn. The garden proper contains about half an acre, and is divided into three lawns, broken up by round, oval, and star-shaped beds, and long, straight borders, intersected by sea-gravel walks, and separated by Rhododendrons, Thorns, Viburnums, Hollies, white Roses, and other shrubs in masses, and by hedges of common red Roses and Sweet Peas, not forgetting a few Keswick Codlin Apple trees kept about 8 feet high. Every bit of bare wall is clothed with Ivy, Crassane Pears (the best late Pear in this climate), Morello Cherries, Wistarias, Jessamines, white and yellow Gloire de Dijon Roses, Clematises (Jackmanni and white-flowered), Aristolochia Sipho, Tropæolums, Kerria japonica, Cotoneaster, and other climbers. Some of the round beds, for variety's sake, are raised by a circle of strong cask staves driven into the ground, and are a mass of Ivy round the sides, the bed proper holding Hyacinths in spring, and a tub Palm or Indian Corn in the summer. The permanent occupiers of the borders and of some of the beds are Mezereons, Pæonies, Delphiniums, Everlasting Peas, white and red Daffodils, especially Horsfield's, Rock Cress, Doronicums, Phloxes, early and late Alstrœmerias, orange and white and Tiger Lilies, Southernwood, Lychnis chalcedonica, Hemerocallis, Hypericum calycinum, white Foxgloves, double Achillea, Anemone japonica (pink and white), Sedum acre, Saxifrages, Irises, and others. The rule is not to have a bare spot to lay your hand upon, and the spaces between the perennials are filled with Polyanthuses, Pansies (Tory being here the most lasting of all), Dutch bulbs, including early and late Tulips, alpine Auriculas, Pinks, Carnations, Pentstemons, Petunias, Lobelias, Cupheas (these make a splendid autumnal bed), Daisies, Stocks, Asters, Verbenas (Purple King), Doronicums, Funkias, Campanulas, Hyacinthus candicans, Indian Corn, Dahlias, single and double (the best that can be got each year), Gaillardias, Gladiolus, Gazanias (for edgings), Everlasting Flowers, Hollyhocks, Sunflowers (annual and perennial), Œnotheras, Tropæolums, Marguerites, Abutilons, Mignonette, Meteor Marigolds, various annuals, especially Clarkias, and Cornflowers and Poppies, intermingled with clumps of Fern, and so on. Sir Walter Scott's advice was, "Aye be stickin' in a tree." Our plan is always to have new plants ready, and whenever anything is over it disappears, and something new takes its place. Nothing is so useful for autumn as Tagetes and blue Lobelia, Mignonette and Purple King Verbena, of which there is always a good reserve. So between fruit and flowers, and with Michaelmas Daisies and open-air Chrysanthemums to finish with, we manage to make a perpetual show outside until October is well advanced—this year much later. The choice Roses are grown by themselves, of course, but the Rose beds are edged with Tagetes, Mignonette, and blue Lobelia, and Gladioli are set between the Roses. The tall-growing plants, such as Hollyhocks, annual Sunflowers, and Œnotheras, are scattered amongst the trees and bushes, and Aimée Vibert Rose (which is the only one that will grow year after year as a standard with us) forms quite a tree of itself, and lasts until the late autumn. Cow manure and a little bone meal for the lawns and Roses are my sheet anchor. Give me plenty of cow manure and some road-scrapings and leaf-mould, and my soft sand will grow nearly anything, except Raspberries and Strawberries. These beat me, though a neighbour of mine not 100 yards away, who has a stiffer soil, grows them by gallons; even mixing the soil with marl does no good, for they will not incorporate. Alstrœmerias, the common white Rose, Anemone japonica, Orange Lilies, Lilies of the Valley, double Achillea, white Saxifrage (especially the beautiful S. Wallacei), yellow Sedum, and Verbascum are almost weeds with us. The garden porch is smothered in white Roses and yellow Corchorus, round, over, and about which twine Tropæolums, Aristolochia Sipho, and Clematis Jackmanni. The latter has not been disturbed for years, and carries hundreds of blooms, owing to a winter mulching of cow manure. I do not forget a few bulbs of Hyacinthus candicans and some tall Œnotheras to peep out of the foliage where they can. Lawson's Cypress, Juniper, and Arbor-vitæ are my best Conifers. Portugal Laurels get periodically cut down by frost, and I and my neighbours have discarded them. My Grapes and flowers together have done quite as well as usual. In my houses, all of which are vineries, I have now a full display of flowers. My Bouvardias, Lasiandras, Cytisuses, Callas, and Abutilons—thanks to my system of planting them out (plunging them in their pots all summer)—are quite a show. Schizostylis coccinea, turquoise-blue Browallia elata, Primulas, Cupheas, climbing Tropæolums, Heliotrope, winter Pelargoniums, Gesneras, Coleuses, and cuttings of Pompon Chrysanthemums (taken off with buds showing about two months ago and potted in small pots of rich soil) add to the general effect, and are useful on the table as well. My Cyclamens and Dutch bulbs are getting rapidly on, so that when Christmas comes we shall be as gay as ever. Even with a pit of Ferns under the Vines in one of the houses Black Hamburgh Grapes are still hanging, but, as I have said before, ventilation all day is the grand secret. In my propagating house a few Cypripediums and Eucharises are in bloom, and a Zygopetalum and two or three pots of Calanthes and a couple of pots of Euphorbia jacquiniæflora are showing for flower. Great gardeners will, I daresay, be amused at all this, but when I state that I have only one gardener, that I cannot spare time to assist him, except with advice, and that what little I know is derived from a fondness for botany, from a careful study of THE GARDEN and *Gardening Illustrated*, and, most of all, from experience and many failures, it will, I trust, be an encouragement to others occasionally to hear what can be done by a mere amateur like myself.

NORTH-WEST CHESHIRE.

INDOOR GARDEN.

EVERGREEN AMARYLLISES.

AT this time of year when flowers are scarce, evergreen or perpetual-flowering Amaryllises supply a want which has long been felt. The size and pleasing colour of their flowers make them invaluable for the stove just now. As regards their free-flowering properties, I may say that a bulb of Mrs. William Lee has flowered no fewer than three times in one year, a fact which speaks for itself. There are now nearly a dozen varieties of this type in cultivation, most of which have reticulated leaves, as in the old reticulata, from which they originated. Mrs. Garfield, Mrs. W. Lee, and Comte de Germiny are the result of a cross between the old reticulata and a deciduous one called Defiance. Probably the most popular of any is Mrs. W. Lee, which has long foliage with a white variegation along the midrib similar to that in reticulata. The flowers are rich rosy pink, netted and veined with a deeper tint of the same colour, and shaded towards the base with deep carmine. Mrs. Garfield is somewhat similar, but differs in having the white band in the centre shading nearly halfway across the surface. This variety usually produces from five to seven flowers, the ground colour being nearly white, and the reticulation the same as in Mrs. W. Lee. The flowers of Comte de Germiny are much larger and deeper in colour than those of the preceding; their ground colour is pink, and the veinings deep carmine.

Her Majesty, certificated by the Royal Horticultural Society in May last, is said to be a cross between Crimson King and Mrs. Garfield. Its form is unique and the colour bright maroon, veined with deep crimson, deepening almost to black at the base. Pioneer, exhibited last month, differs from the former in having the ground colour bright cerise with very faint veinings of a deeper hue, deepening towards the base. The sepals differ from the petals in having a band of pink up the centre, the back being shaded with pink and rose. Autumn Beauty, apparently a variety of Mrs. W. Lee, varies in the reticulation of the flowers. Lady Mayoress is a cross between reticulata and Leopoldi, and is somewhat similar to Comte de Germiny. It is a winter-flowering variety, a term which may be applied to Comte de Germiny, that being the latest flowerer of them all. Pirloti and solandræflora reticulata are two continental productions, raised by M. De Graaff, of Leyden. Pirloti is somewhat similar to Mrs. Garfield, but narrower in the petals; the reticulations are carmine, and the band in the centre of the petals pure white; whilst the colour of solandræflora reticulata is pink with very few reticulations. The tube is longer, and the flowers, which are pendent, possess a pleasing scent.

R.

Isolepis gracilis.—This, as is well known, forms a pretty living fringe of verdure for a plant-house stage; it hangs down in the most graceful manner, and enhances the beauty of plants in the

background. It is of the easiest culture, and may be increased to any extent by dividing the plants in spring; any light sandy soil suits it well. The only thing needful to ensure its growing freely and retaining its charming green colour is an abundant supply of water at the roots. If little saucers are set under each pot, and kept filled every few days with water, frequent waterings will be saved, and many plants succeed better supplied in that way than by constant surface waterings.—J. G. H.

Steaming *v.* fumigating.—Two years ago I used a tin steaming apparatus continuously for a whole week, day and night, in the same house, which contained Orchids only. Fresh plants were brought in daily, though some other plants were left amongst the steam the whole time, one of which, a fine Dendrobium Paxtoni, was reported in a contemporary a few weeks after that time to be carrying 1000 flowers, a circumstance which shows that the whole week's steaming did it no injury. I found the process, however, to be too tedious for practical use.—H. G.

Bouvardias after flowering.—Some of the Bouvardias which have been in bloom during the last ten weeks are now going out of flower, and those who have not had much experience with them may be anxious to know the best way in which to treat them. We have managed them in various ways, and have found the best of all to be the system of drying them off like Fuchsias. Water is gradually withheld as the leaves drop, and when divested of foliage they are kept quite dry. Many of our plants have no water from the middle of December until April, and when watered and placed in heat again they burst into growth very freely. When dry and at rest they may be put into any shed from which frost is excluded, and thus stored, no more attention will be required throughout the winter.—J Muir.

Crimson Chrysanthemums. — "G. H. E." writes in The Garden (p. 462) in warm praise of the Japanese kind Tokio. For all ordinary decorative purposes it is indeed a beautiful kind and a free bloomer. Plants grown here in the open ground all the summer for autumn lifting were stout, erect, and about 3 feet in height when in bloom. None could well have a better habit. Lifted into the house and planted in a soil bed, the mass of rich crimson-chestnut colour furnished by the flowers, especially in the sunlight, is indeed striking and beautiful. Very recently a well-known floral decorater mentioned to me that whilst whites, yellows, and buffs were abundant enough in market Chrysanthemums, rich reds and chestnuts were comparatively scarce. I think no kind so admirably supplies that deficiency as Tokio. It is a kind so rich and striking, that were its blooms of the ordinary show size, they would be found in every stand of Japanese sorts. Not being large enough for that purpose, it is none the less a beautiful kind for pot culture, and it always tells well in Chrysanthemum groups, whilst for cut-flower purposes it can hardly be surpassed.—A. D.

Enduring plant-staging.—Amongst the exhibits at the recent show at the Royal Aquarium was in one corner of the Upper Hall a sample of what was called Perry's patent plant-staging. Why thus termed it is hard to say, as the material of which it was composed—galvanised iron—has for some time been employed for plant-staging, and with excellent results. In the present instance not only did the floor of the staging, however, consist of corrugated iron galvanised, but the supports of the floor were of iron galvanised also, and the whole might well have been described as indestructible. I have seen corrugated iron previously in use at Farnham Royal, where Mr. James has staged his new house extensions with it. The same material is largely employed by Mr. Laing in his plant houses at Forest Hill, and at Major Lendy's, Sunbury, for Orchids, and with great success. In the sample shown at the Aquarium the furrows and ridges of the staging ran lengthwise, thus rather holding water than otherwise. Mr. James had fixed his crosswise, having had it made specially in 4-feet lengths to suit the requirements of his houses. The supports in his case are of wood, but because so very efficiently protected from drip by the non-porous character of the staging, wood of good quality will endure for very many years so employed. Then, further, his staging is so fixed that it has the slightest possible run or fall towards the sides of the houses, thus enabling moisture resulting from watering to run off. Of course there is a space left between the edge of the staging and the wall of the house to enable the moisture to drip on to the soil beneath. No doubt it would be better still to fix a shallow zinc gutter to catch this drip, and thus preserve the floor of the house from excess of moisture. By fixing a strip of wood along the back of the staging in such a way as to leave an opening at the end of each furrow, moisture can escape freely, and yet retain the crushed shell or shingle which forms the levelling material on the uneven staging. I should like to add that Mr. James has, in revising the heating power of his houses, added a small pipe just under the glass on either side for top-heating with capital results.—A. D.

LEAFY VIOLETS.

When Violets form a great number of coarse leaves they seldom bloom satisfactorily, and therefore the aim of all who cultivate them should be to induce sturdy growth. On strong soils they are almost certain to grow too rank, and when this happens they produce but few blooms in the autumn, though, if they survive the winter, abundance of fine blooms may be forthcoming in spring. In this neighbourhood several acres of Violets are grown for the purpose of supplying various towns with blooms, and for many weeks past great quantities have been gathered and bunched up. On several occasions I have noticed how little foliage the plants form. Nor is this to be wondered at, seeing they are planted on a shallow loamy soil resting on gravel, the site also being a steep declivity facing the south. Red spider naturally abounds on these plants, but in spite of this they form good crowns, are fairly hardy, and very profitable. We also devote a considerable amount of ground to Russian Violets, but, as a rule, they grew much too strongly, and we gather comparatively few blooms till after the frost or damp cripples the foliage. To counteract rank growth, it is frequently necessary to plant on firm ground and in exposed positions, and as soon as they become crowded a clearance is made. To be plain, we plant a bed and destroy another annually. Just now several amateur Violet-growers hereabouts are concerned about the behaviour of their Marie Louise in frames They are growing strongly, producing quantities of spindly runners and a very limited number of blooms. Much of this is owing to the mildness of the weather and the humidity of the atmosphere; a drier and more frosty air would benefit them. To check this leafy growth, which is produced at the expense of the blooms, I recommend that the lights be thrown off whenever the weather permits, plenty of light and air being necessary to check luxuriance and to render the plants hardy. All runners, with the exception of about three that have stout crowns attached, should be kept closely removed, thus admitting air to the crowns, and also concentrating the sap on the production of good blooms. Reserved runners, if not already rooted, may be pegged down near the parent plants, and these will flower this season, and also be available for planting out in April or May in preference to older crowns. Violets in frames must be protected from severe frosts, a slight injury causing the leaves and crowns to damp off badly. With us Violets are not quite so plentiful as we have had them at this time of year, but they are of good size, and better than usual in colour. W. I. M.

Chrysanthemums going blind.—Complaints are sometimes made of Chrysanthemums failing to form buds, some varieties being more subject to this misfortune than others. Where this does not arise from the attack of insects, or from the soil becoming over-dry, it may be attributed to defective nutrition. I feel sure that some kinds require more food than others, and I believe that the blindness among some of the newer varieties may be conquered by extra liberal culture. This year I grew a quantity of a late white kind. They were planted out in good ground, and were lifted and put under cover several weeks ago. They are a remarkably even lot of plants, with deep green foliage and abundance of good buds. I also grew some in pots, and these, though looked to with water, did not get much liquid manure. These plants look healthy enough, but although they were at one time the strongest, they are much later than those planted out, and some of the shoots went blind. When I saw this, I began to feed them well, and then they threw out laterals which gave buds later on. Thus it will be seen that poverty produced blindness, and good food restored fertility. In the case of kinds that are apt to miss forming crown buds, it is possible that extra food would ensure their doing so.—J. C. B.

Late Chrysanthemums. — These, with us, are more valuable than early, or midseason ones, and any plan by which a good supply of bloom can be kept up until Christmas will be sure to repay the cultivator, as at that time the demand will be great, and the supply of other flowers at about its lowest ebb. This year Chrysanthemums have been very abundant, and I think it may be safely asserted as a fact that the height of the Chrysanthemum craze has been reached; many begin to say that they are surfeited with Chrysanthemums and want a change, and, as in the case of many other things, we shall probably find Chrysanthemum exhibitions diminish in number. Not so, however, their growth for private enjoyment, for by prolonging their season into midwinter, they are most valuable. They tide over what is really nearly a flowerless time in the case of those who have no heated structures. Such growers can spread out their Chrysanthemum supply quite two months beyond the ordinary date of the great feast of bloom early in November. To do this the plants must be kept out of doors; under the shade of a north wall is a good place, as there protection from early frosts can be given, and when placed under glass the coolest and most airy house at disposal must be afforded them; if the bloom is kept dry, a little frost will not hurt them. Ours are now only in bud, and by making note of varieties that naturally flower late, and availing ones-self of retarding influences, a fine display may be secured at Christmas.—J. G. H.

A GARDEN GATEWAY.

So many gardens are spoilt by an excess of needless masonry and architectural detail, encroaching obtrusively into the domain of plant and flower beauty, that it is well now and then to record a good example of garden architecture designed without affectation, and serving a distinct purpose. Eastbury Manor, near Guildford, has lately been enlarged and altered from the designs of Mr. Christian, architect. The kitchen garden is placed very near the house, and is separated from the pleasure grounds by a new brick wall. At the point where access is wanted the wall is pierced by the well-designed gateway in brickwork shown in the annexed engraving.

Lobelia Cavanillesi.—A friend of mine who knows a little of garden botany writes to ask if this is not an old English garden plant. In Sweet's "British Flower Garden," series 2, 389, you will find a plant closely resembling this Lobelia there called by its older name of Siphocampylus bicolor. I would ask is this new re-introduction the same or not? Both I and my friend believe it is so. The plant has also been called Lobelia laxiflora, L. angustifolia, and L. bicolor, and I remember a plant of it in an old greenhouse as long ago as 1860, and see by the dictionaries of gardening that it was originally introduced from Mexico in 1825. There is a good plate in the *Botanical Magazine*, t. 3600, where it is called L. Cavanillesi. This plant has never been lost to English or Irish gardens. Mr. Smith, of Newry, sent us plants some years ago, and at Newry, I believe, it is quite hardy.—F. W. Burbidge.

NOTES FROM FRANCE.

Late Chrysanthemums.—A writer in the *Revue Horticole* describes a method of growing Chrysanthemums whereby he has been enabled to have them in bloom at a period when their natural season of flowering is well over. His system is as follows: In July cuttings are taken, not the soft terminal points, but long shoots about half the length of the current season's growth. These, if carefully looked to, soon make roots, and about the 15th September, just as the buds are beginning to show, they are taken up and potted, at the same time cutting them down to about 8 inches in height. They are allowed to remain in the open air until there is danger of hard frosts; then they are taken indoors and kept in a cool house till December, watering only just enough to keep them healthy. During this time all suckers as well as side shoots are carefully suppressed, this being an important detail to observe. They are placed in succession during December, January, and February, in a temperature ranging from 55° to 60°, when they immediately begin to push forth side shoots, each one of which shows a bud which expands perfectly well. The writer asserts that by this method he has succeeded in obtaining a good show of bloom all through the spring months. I have no doubt that in this way the natural season of the Chrysanthemum may be thrown back to a considerable extent. The Chrysanthemum is like all soft-wooded plants; if you prevent it from blooming at its natural time, it will try to do so later on. That is only what occurs in the case of Geraniums and some other things grown expressly for winter bloom; the buds which form at the natural blooming time becoming suppressed, others are continually thrown up. It was, I believe, in February that some very good Chrysanthemum blooms were sent to The Garden office, the sender stating that his plants were caught in the sharp frost of the previous September, which destroyed all the buds. The blooms sent came from lateral shoots that formed later on. It does not, therefore, seem difficult to secure Chrysanthemum blooms at any time during winter and spring. I do not, however, think that we need them after the middle of March. Up to that time bloom is more or less scarce, but during the early spring months there is much variety to be had, and not many would care for Chrysanthemums more than six months out of the twelve.

Garden gate, Eastbury Manor, Surrey. Engraved for The Garden from a photograph.

Double-flowered Iris.—It is announced in a French gardening paper that quite a series of double English Irises has been obtained in Holland. The duplicature consists in a multiplication of the erect petal termed the standard. The markings are said to be very distinct. Opinions will probably differ as to the value of double Irises, but they are sure to find admirers. It is not stated by whom they were raised, but, I suppose, by some Dutch bulb-growing firm. As some of them have received names, they will probably soon be in the hands of English growers.

Roadside planting.—The Minister of Public Works in France has recently issued a report on the wayside planting done up to June 1, 1885. Nearly 3,000,000 trees have been set, consisting principally of Elms, Ash, Poplars, Sycamores, and Limes. The work is to be carried on until the whole of the suitable waste roadside spaces are similarly occupied. In commenting on the above, the editor of the *Revue Horticole* observes: "In estimating the value of the trees at a low figure, it will be seen that they represent an important source of production in addition to other advantages, among which may be mentioned the shelter and shade they will afford to pedestrians and travellers generally." In a climate so hot and dry such a refuge from the sun's rays is very welcome, but one cannot help feeling surprise that no mention is made of fruit trees. Those who have charge of the planting in France might well take a lesson from what has been done in Wurtemburg and in some other parts of Germany. One sees there fruit trees bordering the roadsides, which annually give a return for the outlay incurred in planting. In a fruit-growing country like France it does seem strange that only forest trees should be chosen for roadside planting.

Mountain Rice.—Under the auspices of the French Acclimatisation Society, a kind of Rice bearing the above title is now being tested with the view of ascertaining whether it can be profitably grown in the warmer districts of France. This Mountain Rice is said to form a staple article of food in some portions of Madagascar, and the same kind is said to be grown in China. Definite information as to the exact climatal conditions required to bring the Rice to perfection seems to be lacking, but it is said that the large amount of moisture demanded by the ordinary kind is not indispensable. Provided it gets heat enough it will perfect its growth. Experiments on a small scale have already been made, and the reports thereon sent in to the Acclimatisation Society have on the whole been favourable. Some of the best authorities are not, however, very sanguine of success.

Acer colchicum tricolor.—M. Carrière speaks very highly of this plant, placing it in equal rank as a decorative shrub with the well-known A. Negundo. Every tint ranging from deep red or crimson to flesh colour is represented in the foliage, forming charming and indescribable colour contrasts. These colours are continually undergoing modifications according to the age of the leaf, and as there are during a great portion of the season leaves in different stages of growth on the same tree, there results therefrom a most varied and harmonious mixture of tints. This Acer came as a sport from A. colchicum rubrum in the nursery of M. Auguste Gouchault, 19, Rue Basse Mouillière, Orleans. Grafted on the type, it shows no signs of variation, with the exception that in its first stage of growth some greenish leaves push, but these soon take on the variegation. This Acer is now being distributed by the raiser.

Ought vegetables to be washed?—M. M. G. Van Hulle writes as follows in the *Bulletin d'Arboriculture:* "Peas, Beans, Haricots, &c., ought not to be washed, and in a dry state they should be passed quickly through the water just as they are to be put into the saucepan. All roots and tubers should remain in the earth until they are needed, and should not be cleansed until they are wanted for cooking. With respect to those vegetables of which the foliage is eaten, they should not be washed if it is possible to avoid doing so They should be examined to see if they are clean, and whether simply brushing with a dry brush will suffice. In any case never wash them till just before cooking." I have heard it stated by competent authorities that a first-class salad can only be made when the ingredients have not been washed; but I never remember to have seen it asserted that vegetables generally deteriorate in quality if washed. M. Van Hulle is, however, regarded as an authority on all that pertains to vegetable culture, and in the present instance it is an easy matter to prove whether such is really correct or not.

Early Peaches.—At the July meeting of the French National Horticultural Society, M. Margottin, of Bourg-la-Reine, exhibited twenty-three varieties of Peaches in the best possible condition. These came from trees grown as pyramids in the open. They were protected up to the end of May by glazed lights, but after that time were without covering until the fruits ripened. It is stated that the fruits thus grown were superior in flavour to those produced by wall trees. J. Cornhill.

Boussingaultia baselloides.—I should have supposed that this beautiful plant would always have grown and flowered freely under glass—at any rate, if planted in a border (see p. 480). Here it is planted in a border in the Cactus house, where it grows rampantly, and would, no doubt, have filled the house if allowed to do so. It requires the most severe restriction. About two years ago the roots got under one of the stone slabs, which

they tilted high up on one side, so that it had to be taken up and re-laid. This plant produces thousands of its graceful racemes, the effect of which is most charming out-of-doors, under a south wall of one of the houses; it lives and grows moderately well, but does not flower.—R. Irwin Lynch, *Cambridge*.

NOTES.

Laurel leaves.—I should like in all reverence to lay a branch of wild Olive on the newly-sodded grave of a man who loved plants and flowers as but few, even amongst gardeners, can ever hope to do. The late Mr. D'Arcy-Hoey, of Newry, who died the other day a comparatively young man, had made a garden of which he and others were very proud, and although perhaps he was more widely known as a sportsman fond of field sports, and as a shrewd and capable business man, yet it is as an amateur gardener that he will best be remembered by all readers of The Garden. His garden at Dromolane, Newry, is most tastefully planted, and contains for its area a large, rare, and remarkable collection of hardy flowers. There seems therein a diversity of surface and a suitable locality for everything, or something of everything, beautiful that grows, and such things in abundance are there. Here a little brook rushes headlong down to the pond in a hollow, both being fringed with American Lady's Slippers, with rare Lilies, with shrubs many and beautiful, or with rare hardy Ferns or Spiræas from South America, New Zealand, or Japan. In the plant and fruit houses, in the kitchen garden even, there was ever something worth seeing. The owner was a large-hearted and a generous man, with sympathy for everything and everybody who entered his gates. The speckled trout that lie among the rare Water Lilies in the ponds there to-day will miss him. They used to come at his call and nibble their breakfast from his fingers; while the Japanese or Chinese pheasants and other of his pet birds would be jealously demanding his attention on all sides at the same time. His garden is a paradise of bulbs and other rare plants from earliest spring to latest autumn, and everyone who cared to see his garden was welcome to enter and wander over the place at their own sweet will. I hear that his garden is likely to be preserved as a memorial, and I sincerely hope this is true.

Gladioli for pot culture.—G. Colvillei albus, otherwise called The Bride, is so free and vigorous when well grown in pots that one may be excused for wishing to obtain variety of colour and form into the greenhouse during early summer by the pot culture of other suitable varieties. Last season we tried G. byzantinus, and had it in flower with The Bride, and this season we are trying some of the best varieties of the G. ramosus section in the same way. No doubt all the species of Gladiolus may be well grown in pots, but some seem to thrive better under pot culture than in any other way. This is true of G. Colvillei albus and G. ramosus in all their forms. G. insignis and G. cardinalis, G. Saundersi and G. blandus also form fine subjects for growing in pots. Three bulbs of G. insignis in a 6-inch pot rival even Disa in colour when in flower, and there are many other Gladioli, some, unfortunately, no longer growing in our gardens, which resemble and rival terrestrial Orchids in singularity of form and in brilliancy of colouring. In the Cambridge garden a year or two ago I saw Tritonia crocata beautifully in flower in pots, and as shown in the old gardening periodicals and alluded to in the earlier numbers of the *Botanical Magazine*, the Ixias, Babianas, and Tritonias were usually well grown in this manner. I saw some allusion in the last number of The Garden (p. 496) to Gladiolus Ville de Versailles. It is a fine plant, and the latest of all to bloom here in the open air, being now at its best. This would be most valuable as a pot plant. Six bulbs in an 8-inch or 10-inch pot would produce growths 4 feet to 6 feet in height, and these flowering at this season amongst Chrysanthemums would be very distinct and effective in their way.

Cœlogyne Gardneriana.—This rare old Orchid is now pretty freely distributed in gardens, and is flowering with us for the first time. It is a snow-white flower with a little stain of citron on the lip, its spikes being densely packed with blossoms and produced from the base of the last year's bulb. It is figured in vol. vi. of Paxton's "Magazine of Botany" (p. 73), and we therein learn that the late Dr. Wallich, of Calcutta, originally discovered this species; but it was introduced by the late Mr. John Gibson, when travelling in Khasia for the Duke of Devonshire, in 1837. It is said to flourish near the summit of the Khasia Hills, on trees and rocks in moist and shady woods. Its favourite position, however, if luxuriance of growth be taken as a proof, is near a waterfall from which it is bedewed with spray. It first flowered at Chatsworth in December, 1838, so that it is of some interest to find that it even yet adheres to the calendar. In its native habitat it is said to bloom at the rainy season, and Mr. Gibson described the appearance of the plant at home as being most beautiful. Its blossoms, hanging as they do from the branches of trees, are said to resemble floating garlands of snow interwreathed with the golden colour of the bracts and the vivid green of the pseudo-bulbs and leaves. The modern re-introduction of this plant seems to have been due to the late Mr. Freeman, who collected Vanda cærulea and many other Orchids in Khasia ten or twelve years ago. As an interesting plant it well merits careful culture, but it cannot be compared to advantage with the great-flowered C. cristata and its white and lemon-lipped forms.

Euonymus europæus.—When the white-leaved form of Negundo variegatum was first introduced it soon took the town by storm, and it so continually met the eye in suburban gardens, that one tired of its "white-rag-on-a-bush" effect, and one of my friends went so far as to say that half a dozen plants of it dotted about were quite sufficient of themselves to spoil the effect of a good garden. A good healthy piece of this Negundo near a golden Laburnum or a flowery mass of Jackmann's Clematis is very good to see in August, and it is possible to otherwise place the plant so as to show its peculiar leafage to advantage, but, of course, it is easy to have too many violent contrasts of this kind. But wherever cultivated taste can appreciate quiet homely tones on the lawn, or in the shrubbery belts or plantations near the house, one might do worse than plant a few healthy young bushes of the above Euonymus, or Spindle tree, for the sake of its soft terra-cotta coloured crop of fruit now beautiful in the winter sunshine. There is a white-fruited form, but the common red one is that most generally useful. Its beauty is not startling, but as seen here and there in sunny nooks, or on the margins of home woods, this plant and Cotoneaster frigida yield quite a rich warm glow of colour to the browns of Beech and Bracken, and the bright firm red tone is intensified delightfully by the ashen-grey trunks behind. If you plant this Euonymus, and the gold and crimson Osier and crimson Dogwood, in good bold groups here and there along the margins of woods or plantations, you may add much warm and precious colour to the masses of browns and greys which betoken the waning year.

Calanthes.—These are deciduous Orchids with annual bulbs or stems, and deserve culture in hothouses everywhere. Their prevailing colours are rosy crimson (C. Veitchi) and white (C. vestita and its varieties), and when well and strongly grown they bloom so profusely and endure fresh and fair so long, that they become invaluable for winter decoration. Last year a friend of mine who grows these plants remarkably well drained his Calanthe pots and pans with dry, half-rotted bones instead of crocks, as is usual. The size of bulb and of flower-spike were enormous, and he thinks the colour of C. Veitchi was much intensified by this addition to its usual food supply. A compost of turfy loam, fibrous peat, chopped Sphagnum, and charcoal suits them on a well-drained bottom, and when the leaves approach their full size, an occasional watering with weak liquid manure helps them along wonderfully. They should be grown near the light, but protected from the full force of the mid-day sun during the summer-time. The finest plants I ever saw had three bulbs in an 8 inch pot; each bulb was 15 inches in height, and they threw three spikes each—that is, nine spikes to a pot. All the spikes were over 2 feet in height, most of them over 3 feet, but the finest spikes bore sixty flowers and buds, and were over 4 feet long. As so seen, Calanthe Veitchi is a very useful plant. I have another little memorandum anent bones for drainage. The finest-grown Dendrochiliums I ever saw were grown in shallow pans drained with dry, half-rotten bones. It is a matter worth the attention of those who fail to grow these fairy Orchids satisfactorily.

Salvia Pitcheri.—This is a tall, free-growing, half-hardy species, well worth growing for blooming at this season in the conservatory along with white or dark bronzy Chrysanthemums. It produces long wand-like shoots, each now wreathed with 1 foot or more near their apices of bright sky-blue flowers; as seen spearing up through the fleecy clouds of blossom, such as are produced by Elaine or White Princess Chrysanthemums, its blue flowers are most effective, being quite unlike any other blue-blossomed thing now in season. It roots readily from cuttings in March, April, or May, and if pinched once or twice, and plunged outside during the summer, and treated like a Chrysanthemum, it is easily grown. We have a batch of things of this kind every season—Justicia speciosa, Goldfussia isophylla, Salvia splendens, Linum trigynum, &c., all of which succeed best from cuttings rooted in May, and grown on in pots plunged outside or in an open frame. A little stimulant of some kind improves these things much when in full growth. None of these are, however, quite so distinct and effective as is the Salvia. For one reason, blue of this lovely soft and fluctuating shade is rare at any time, and especially so at this season of the year, and another point about this plant is its elegant Bamboo-like grace of habit. It is to the greenhouse or conservatory what the scarlet Euphorbia jacquiniæflora is to the hothouse or stove, and should be grown everywhere where blue flowers are in request during the dull months of winter, when blossoms of all colours are welcome.

Epiphyllums.—All Lobster Cacti, as these are called, are beautiful, and by no means ungraceful in habit, whilst their winter-flowering tendencies give to them an added charm. One beautiful way of growing them is to plant out a strong-growing Pereskia as a stock, and to train it, in Grape Vine fashion, up the rafters of a

moderately warm greenhouse. The Epiphyllums can then be engrafted into the soft stem at suitable intervals, and if of different varieties, a very pretty contrast may be made. They may be grown on their own roots in wire baskets suspended near the glass, but, being very impatient of stagnant moisture at the root, the compost should be mixed with charcoal and broken crocks. But it is as dwarf standards on the above stock in pots that these plants are most generally useful, either for decorative uses in the conservatory or as table or bracket plants indoors. Of late years the race after novelties has been so great, that the beautiful succulent plants so popular in the days of Haworth are now rarely seen. The best varieties of Epiphyllum and Phyllocactus are, however, well worthy of careful culture. There is a lovely white Phyllocactus which flowers freely and is as fine as any Orchid in its way; and the purple shot-blossoms of Cereus speciosissimus are most gorgeous when seen at their best. Once upon a time the night-blooming Cereus caused as much sensation as do the finest of new Orchids of to-day; and I believe the coloured plate and description of this flower which I saw in McIntosh's "Practical Gardener" had much to do with my being a gardener to-day. I think it a poor picture now, but it was lovely to me at the time as a boy.

Odontoglossum Alexandræ.—This plant is popular already, being the Orchid *par excellence* in English gardens to-day, but if people generally were less afraid of the word "Orchid," and knew how easily this plant can be grown in a close and moist greenhouse temperature, it would be grown ten times more abundantly than is already the case. A winter minimum of 50° and a summer temperature as much below 70° as is possible suit it perfectly. Just at this season, when choice flowers are apt to be scarce, this plant gives wreaths of long-enduring flowers, and scarcely any two plants out of an imported batch will be precisely alike in habit of growth or in size, form, and colour of the individual flower. There are a good many beautiful Orchids in our gardens, but if a *plébiscite* were taken to-day, I believe this lovely plant from the Andes would receive more votes than any other Orchid whatever. Certainly there is a little knack in getting this plant to grow well, but it is a knack easily to be learned, and the results are better than those which attend the ordinary culture of less beautiful things. Any gardener who can grow really good Cyclamens or Chinese Primulas (to say nothing of Clianthus Dampieri, or Leschenaultia biloba, or Lisianthus Russellianus) ought to manage this Odontoglossum to perfection. I shall never forget seeing Dr. Paterson's little cool Orchid house one chilly day in October of last year. The door stood wide open, and there was but little, if any, fire-heat: I believe none, but the great arching paniculate spikes hung out above the most vigorous of leaves, and the snowy flowers, contrasted with scarlet Nerines, were very lovely, while overhead a happy marriage between the white and the red Lapageria completed the picture.

Aralia Sieboldi.—This glossy-leaved Japan Ivy, or Fatsia japonica, as it ought to be called, is perfectly hardy in most sheltered localities near the sea; and even were it not so, it is so distinct and ornamental, that as a pot plant in a cool house it really has but few rivals. I saw a big bush of it at Mount Merrion yesterday bearing perhaps fifty of its stout, ivory-white flowering stems, which contrast very beautifully as seen amongst dark green shining leaves. As planted out in sheltered positions near Bamboos or clumps of Eulalia japonica it is most effective, and in winter gardens or in cool conservatories it is most useful. If we except Aspidistra lurida, there is no more noble pot plant for a partly shaded window than a well-grown plant of this Aralia in a terra-cotta pot, or in an old copper Venetian bucket. Seedlings make the best plants, and they grow best in pots when plunged in coal ashes in the open air. As the pots become filled with hungry white roots, a little sprinkling of Standen's manure or a weekly dose of manure water strengthens them wonderfully, and an occasional watering with soot water improves the colour of the leaves, as it does those of nearly all other plants whatever. I am often asked to name the six best foliage plants for room culture, and this is my selection: Aspidistra lurida, Aralia Sieboldi, Acacia lophantha, Dracæna rubra (a hardy green-leaved kind of vigorous growth), Corypha australis, or Kentia australis, both of which grow well in rooms; while the India-rubber plant (Ficus elastica) is and ought to be a general favourite for this purpose.

Outdoor flowers in winter.—Roses are still blooming everywhere in sunny, sheltered gardens, and only yesterday I saw a Narcissus Tazetta in full bloom on a dry and sunny border alongside white Snapdragons and tall, scarlet Lobelia ignea. Scarlet Geraniums, Fuchsias, Gaillardias, and Calceolarias are as yet uninjured, and there are clusters of freshly-opened China Roses, Escallonia, and purple-flowered Veronica, and odd blooms of the large-flowered Clematis yet linger on thus far into the time of fallen leaves. Such a season will give a wonderful impetus to the even now popular outdoor culture of Chrysanthemums, for seldom, if ever, have we had such a suitable winter for them. Schizostylis coccinea and Gladiolus Ville de Versailles, and one or two of the G. Lemoinei group are also in flower. Ionopsidium acaule looks very neat and pretty in amongst the autumn Crocuses, and I think the earliest Christmas Roses are this year blushing more deeply than ever at finding so many unexpected floral friends around them. One of the sweetest of all the November flowers, however, was the pure white form of the mule Pink, and Painted Lady Carnation has only just opened its latest buds, and the seedling Primroses, Polyanthuses, and Crown Anemones are everywhere throwing up flowers. Even the Auriculas are yielding a few velvety clusters, and there are many Violas and odd seedling Pansies here and there opening in the sunshine. Gentiana acaulis flowered here more freely in November than it did in May or June. The Arbutus trees are now very fresh and covered with clusters of Lily-of-the-Valley-like flowers and the soft, grey catkins of the Garrya or Tassell Bush dangle gracefully in the breeze.

White Everlasting Pea.—I believe I am right when I say that twenty-five per cent. would be a very good yield of white-flowered plants from the seeds of Lathyrus latifolius albus. The white Ramanas Rose (Rosa rugosa alba) affords us another instance of the strong tendency to progression or reversion, as shown by the seeds of white-flowered varieties. But, on the other hand, we have selected races of white Stocks, white Chinese Primroses, and of white Snapdragons which will invariably produce from fifty to seventy-five per cent. of white-flowered plants. I suspect no one has yet taken the necessary care in growing and selecting the seeds of this lovely white Lathyrus latifolius, but, on the other hand, has not Mr. Eckford succeeded in giving us coloured strains of the common annual Sweet Pea, all of which come fairly true from seeds? On some soils the white Everlasting Pea grows and seeds freely, and the first step necessary in such localities is to grow the white form only so as to ensure self-fertilisation, or the intercrossing of white individuals only; this plan would soon fix the white form sufficiently, and we could then rely more implicitly on the seed than is now possible. If the blush and rose-coloured forms be grown in the same garden, there is always the danger of their pollen infecting the white flowers, just as the pollen of Polyanthus or Cowslip will soon ruin a good strain of true Primroses if they be grown in close proximity to each other. Veronica.

Rose Garden.

NOTES ON ROSES.

Rose stocks.—It speaks well for the value of the seedling Brier as a stock for Roses that so practical an observer as "J. C. C." should be driven to figures for evidence against it (p. 453), and that even so, the best evidence adducible of its unsuitableness is that the distribution of many thousands of Roses worked on seedling Briers has not prevented continued annual mortality among the almost countless myriads of Roses worked on the Manetti simultaneously distributed. For, be it observed, "J. C. C." does not state that plants on seedling Brier die every year; only, that the distribution of many thousands of such plants has not reduced the outcry against annually moribund Rose trees. Nor is this to be wondered at, for figures have only a relative value, and however imposing "many thousands" may sound, the expression is meaningless, except when regarded in proportion to other figures. Now, if the number of plants on seedling Brier that have been of late distributed be regarded in proportion to the millions of plants on Manetti sent out during an equal time, what a drop in the ocean does it appear. Perhaps it would be no exaggeration to say that the proportion of plants on Manetti to those on seedling Brier now in course of distribution is about 100 to 1. The Manetti is still the main stock in most nurseries (of course, there are one or two well-known exceptions), and though a few great growers may not send out more than three or four plants on Manetti to every one on seedling Brier, who shall reckon the innumerable plants distributed every year by the general nurseries all over the country, nurseries in which from 10,000 to 50,000 Roses are worked annually, and in which no other dwarf stock than Manetti is known for Roses? Under these circumstances it will be a long time before the seedling Brier can possibly be on an equal footing with the Manetti, nor will this end be attained until the Rose-buying public are convinced of the superiority of, and insist upon having their plants worked upon, dwarf Brier stocks.

Referring to the liability of seedling Briers in the young state to an attack of mildew, "J. C. C." makes a startling assertion in saying that "plants so affected at the beginning cannot, under any circumstances, prove to be sufficiently vigorous to sustain robust growth." "J. C. C." must know perfectly well that almost all seedling Roses invariably get smothered with mildew; and therefore his statement amounts to the assertion that no variety of Rose yet raised is sufficiently vigorous to sustain robust growth. But if it be said that this surprising remark was only intended to refer to seedling Briers, then this disparaged stock is credited with the achievement of the impossible, for instances may be cited *in infinitum* in which it has proved and continues to prove quite sufficiently vigorous to sustain not only robust, but exceedingly strong and lusty growth. It is certainly a remarkable fact that plants worked on seedling Briers should be so much less liable to mildew than plants worked on Manetti, although the former stock in its young state is such a victim to the pest from which the latter is itself exempt. I cannot but regard it as highly satisfactory that so experienced a grower as "J. C. C." concurs in holding the Manetti, as ordinarily employed as a stock for Roses, to be a failure; while the only objection put forward against seedling Brier is what may be called the

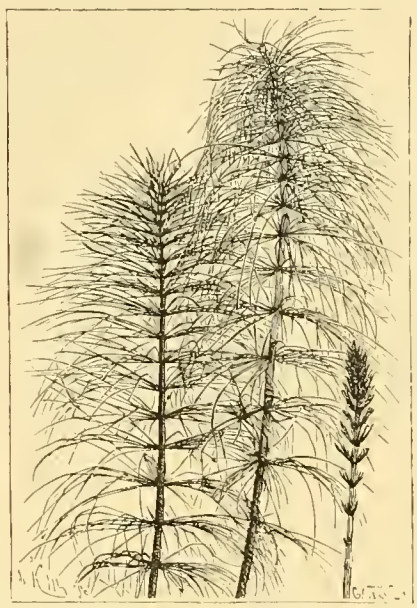
trivial charge of getting mildewed in the young state; but even granting the assertion about the insufficient vigour of seedling Briers (although I am not in the least prepared to relieve "J. C. C. of the *onus probandi*), I may once more point out that I stated that I found very little to choose between established (five and six-year-old) plants on seedling Brier and Brier cutting stocks, and that for those who resented the youthful indiscretions of the former in the matter of over-indulgence in mildew, the Brier cutting was the stock, as with so many of the seedling Brier's good qualities, it has further the merits of the Manetti in being free from mildew and easy to bud. Therefore, with "J. C. C.'s" support in regard to the worthlessness of Manetti, except as a roundabout means of establishing Roses on their own roots, and from the fact that Brier cuttings are not liable to the charge brought against the seedling Brier (which charge I submit to be quite unimportant), I would continue to urge that dwarf Briers are the stocks for Roses, leaving the selection of seedling or cutting as a matter of taste.

Into the question of the relative value of own-root Roses I do not propose to follow "J. C. C.," as I hardly feel qualified to offer an opinion in the matter, having never grown more than two or three hundred plants in this way; but I may mention one or two points in connection with them. My difficulty with own-root Rose trees has been that the suckers coming up from the base of the tree to form the plant the following year make their appearance just as the flowers in July are about to open; consequently, if the suckers are left alone, the flowers seem to stand still and never attain their greatest possible beauty, or, if the suckers are sacrificed to the flowers, the plant is damaged for the next season. In the case of worked plants, these strong growths from the base of the plant do not appear until the flowers are expanded, and hence neither interfere with the others. There is no doubt that Roses on their own roots endure well enough, and I have many plants of well-known varieties which were struck as cuttings not less than twenty years ago, and which are still flourishing; but to say that this shows "plainly that we can do without stocks altogether," will certainly strike most people as rather an over-statement of the case—at any rate, until Rose-growers generally become a more patient race than they are at present. Why, for instance, in the case of a novelty, should we wait wearily and watch laboriously for four or five years to see the plant in character on its own roots, when, by the insertion of a few buds upon dwarf stocks, we may, under ordinary circumstances, obtain sufficiently characteristic plants and blooms to form an estimate of the value of a new variety in a single season?

"J. C. C." gives an instance of one variety that succeeds on its own roots, so I will mention one with which I have failed. For the last five years I have been trying to establish Maréchal Niel on its own roots out of doors. Good, sturdy plants were planted and carefully tended, but only one now survives, and I have never had from them a single flower fit even for a button-hole; while numerous plants on dwarf Brier seedlings and cuttings that were put in at the same time are flourishing all over the walls and fences. If, therefore, "J. C. C.'s" one instance proves that we "gain nothing by using any kind of stock," I suppose this proves the converse.

Rose exhibitions.—In his genial Rose jottings under this heading, "E. H." has a dig at the exhibitors of Roses which can hardly pass unchallenged. "E. H." cannot be really an opponent of exhibiting, or he would not give such excellent advice on the subject as he does in the latter part of his remarks; he does not mention, moreover, which exhibitor's garden he found empty and flowerless. Could one of those great exhibitors have so far forgotten the laws of hospitality as not to have handed "E. H." a large bunch of Roses when leaving, that he implies that exhibitors do not grow Roses for their own beauty, nor have them in their rooms, nor give them to their friends? I have seen the gardens of growers who exhibit in classes of all sizes, from those for six blooms to those for seventy-two, and I do not believe in the possibility of any such grower returning from a show to find his garden empty and flowerless, though I have seen many gardens where Roses were supposed to be a feature, but where, through the growers never having learned from exhibiting the best development and culture of the Rose, there has been hardly a flower to be seen. If, as "E. H." truly says, "in the full flush of the Rose season, the more we cut them the more they flower," then it must be that the exhibitors who cut day after day will have the most continuous display of bloom; and it is certainly my experience that the exhibitors are the very people who most deck their rooms with Roses and keep their friends supplied.

The instancing of Gloire de Dijon also as a reliable show Rose might be misleading to intending exhibitors, for according to Mr. Mawley's record of the Roses most frequently shown during the eight years 1877—1884, Gloire de Dijon failed to obtain a place among even the twenty-four most frequently exhibited varieties of Teas and Noisettes coming after a so difficult and rarely



The great Horse-tail (Equisetum Telmateia) Engraved for The Garden from a photograph.

shown a variety as La Boule d'Or; while from the analysis of the National Rose Society's London show this year, it appears that Gloire de Dijon was not shown in a single winning stand. Of Glory of Waltham, again, I cannot recall or find any record of any instance of its having been successfully exhibited of late years. There are two Roses, however, which may well be recommended for planting where good plants as well as exhibition blooms are wanted, namely, Bouquet d'Or and Emilie Dupuy, both climbers, nearly as hardy and free as Gloire de Dijon, and both giving flowers good enough to show, the former even among twelve Teas.

Cheshunt Hybrid.—Mr. Muir might also mislead unwary exhibitors in classing this Rose as a Tea; whereas it may not be shown in the Tea and Noisette classes, as it is a Hybrid Tea, and therefore classed among Hybrid Perpetuals. Were it really the "*alpha* and *omega* of bright-coloured Roses," I would be inclined to say the Rose alphabet begins at *beta* and ends at *psi*. Has Mr. Muir grown Reine Marie Henriette really pure in colour, and always (even now) in flower? We have not been without blooms of it since May this year from plants out of doors, and since its arrival not a bloom of the dingy Cheshunt Hybrid has come into the house. T. W. G.

The Everlasting Rose.—This old Rose, the crimson Monthly, deserves all the praise that "Veronica" bestows upon it either as a pot plant in the window or elsewhere, or in the open on warm soils and in sheltered sites. Closely related as is this old favourite to the pink China, or Monthly Rose *par excellence*, it is much weaker in growth, and also more tender. Again and again have I worked up sufficient crimson Chinas to edge beds or groups of the pink; and while both colours have been subjected to identical treatment and the same protection, the crimson has sooner or later, and mostly sooner than later, succumbed. The only protection given, however, in most cases has been a handful of Bracken or Spruce boughs over the Fern fronds to keep them in position. But further north these Roses used to have a foot of dried leaves placed over their crowns and among their branches, and these were kept in place with an additional screen of boughs. Thus treated and uncovered and pruned about the end of May, they yielded any quantity of crimson and pink blooms and buds until November. By the way, does "Veronica," who has so admirably cleared up the history of the white Japanese Windflower (see p. 449), know the history of the so-called white variety of the pink Monthly China Rose? This variety is also more tender than the pink, from which it is probably a sport. In certain soils and positions it is almost pure white; in others, it seems to have taken several steps backward towards the pink variety, from which it may have evolved. Or is any proof forthcoming from China or elsewhere that the white China Monthly is the original type of these Roses? One more nut for "Veronica" to crack for us while he is about it: is the crimson Fairy Rose a dwarf sport from the Rosa semperflorens of botanists? and if so, it is rather singular that we do not seem to have a Fairy Rose of the exact shade of colour as the common pink Everlasting or Monthly China Rose. The latter phrase deserves revival, if only "for the days o' auld lang syne." —D. T. F.

Flower Garden.

THE GREAT HORSE-TAIL.

(EQUISETUM TELMATEIA.)

A native plant of great beauty, highly desirable to naturalise in any moist spot where its free-rooting nature would not endanger other plants. Nothing could better adorn a fairly large space of wet ground where its graceful plumes, 4 feet to 5 feet high and of a brilliant green colour, could be seen from a sufficient distance as well as close at hand. It may be called a most important landscape plant.

Carnations in winter.—The following remarks do not refer to flowers, but to plants only, and more especially to those good kinds which bloom in July and August. These are generally increased by layers, an operation performed in September, as a rule. The young plants are mostly rooted by the end of October, and it is the practice of some growers to lift them as soon as rooted and either plant them out in frames under protection, or pot them and put them in frames afterwards. This is no doubt good practice, but many growers of Carnations have so few frames and glass protectors, that it is almost impossible for them to treat their plants in that way. We do not keep any of our Carnations under glass in winter now; in short, they are not disturbed after layering in September until they are replanted in April. Managed in this way, they never suffer in winter to any serious extent, and they are preserved in health and strength mainly through being mulched with leaves at the end of November. These are packed closely between the plants and shelter them wonderfully from both wind and frost. I have often known young Carna-

tions to suffer through the ground being frosted about the roots, but this the mulching of leaves prevents.—J. Muir.

LILIUM NEILGHERRENSE.

I am much surprised at the performance of Lilium neilgherrense at Colchester. If there is one thing more than another of which we think we have a good share in the Isle of Wight, it is sunshine, and if there is any one garden in the island which lies particularly open to the sun, it is my own; but Lilium neilgherrense has never gladdened me with a single blossom, though I have had it in abundance for several years, and I have consulted for its wishes in every possible manner. I grow it in full sun in a loamy, sandy border, where it runs about *ad libitum*, and its whole appearance is that of being completely and happily at home. But, then, this is not all that is required. At this present time many strong stems and fresh green leaves seem to say there is just one thing they want to crown their lot, and that is a longer summer. And so it has been over and over again. Given only an additional month or so of bright weather, and I think I should have Lilium neilgherrense in blossom to my heart's content, but that is just what never comes off. This Lily is with me very late in rising from the ground; it makes a few delusive promises, and then at the first touch of winter it goes to rest without doing anything at all. It wakes up the following year only to repeat the performance, and to wander in a most erratic manner all over the border. It is therefore rather a puzzle to me why it blooms so well at Colchester in the open ground. I should like to know if it has ever done so before, and I shall be curious to see if it ever does it again. I am sure that my bulbs are in good, sound health; they were all kindly sent to me by Mr. Griffiths from India, and they succeed to perfection in this place, if only that be left out of account for which bulbs are generally prized, viz., blossoming. A garden, however, abounds in compensations, and when one thing falls below the mark another is sure to come up to it. Ornithogalum lacteum was in full glory here in the open ground a week or ten days ago, and I think it would have been so still if I had not plucked the blossoms. I more and more believe that a large majority of Cape bulbs only want to be kept dark and dry in the ground during the winter months, and then they will be sure to succeed; at any rate it is so in such a locality as this. A large covering made of Willesden paper meets all their requirements, and many of them start forth into beauty at once when this is taken away on the arrival of spring. Even Buphane ciliaris has got through one trying winter after a fashion of this sort. It is in very strong form now, and will, I hope, blossom with me next year. And there are others to whom the same hope applies. Mr. Bull, of Chelsea, most kindly gave me the other day some valuable bulbs on which to experiment, and as time goes on I shall be glad if I can report favourable results to him. Like "Veronica," I have attentively studied Prof. McEwen's remarks in your contemporary of the 6th inst. With regard to western Cape bulbs, I do not know that they have any great significance here, but with regard to eastern Cape bulbs they will make all the difference between life and death. If you let a bulb be wet when it should be kept quite dry, there will soon be no bulb to keep at all. I think that many of the eastern Gladioli may now have a chance with us. I enclose the first Snowdrop of the season, Galanthus nivalis var. corcyrensis. It has been out nearly a week; also a Crocus from Beyrout, Crocus vitellinus, which might well have had a place in your autumnal gathering of Crocuses (p. 476).

Henry Ewbank.

The first Chrysanthemum.—Referring to the remarks in The Garden on this subject (p. 467), allow me to say that I have Dr. Sharpe in flower, and was able to make the comparison between it and the kind figured in the *Botanical Magazine* in 1795, and the likeness between the drawing and a very poor flower of Dr. Sharpe is, I must say, very striking. There ought to be no difficulty in tracing its parentage, as it was sent out with Mrs. Sharpe as a new variety either in 1866 or 1867. I used to take notes of all the new varieties at that time both at Mr. Salter's and at Mr. Forsyth's, Stoke Newington, both of whom had Dr. Sharpe in 1867, and it was exhibited that year as a new variety. Messrs. Salter and Forsyth were almost the only trade growers who got up exhibitions of Chrysanthemums at that time, and unfortunately there was sometimes a certain mystery about the introduction of new varieties. Mr. John Salter's own seedlings were well known and acknowledged, but I fancy Dr. Sharpe was not one of them, and unless its parentage can be proved we must credit Mr. Burbidge with having made an interesting discovery.—J. Douglas.

MONKSHOOD.

(ACONITUM NAPELLUS.)

This old favourite is one of the good hardy flowers that has lived most prominently through the now happily dead-and-gone period of their

The Monkshood (Aconitum Napellus). Engraved for The Garden from a photograph.

neglect. Its fine spikes of hooded flowers, purple, blue, or blue and white, may be seen in most cottage gardens. Unfortunately, it is a dangerous plant where flowers and vegetables are grown together in a small space. The root is a deadly poison, and lives have been lost through its ignorant use in mistake for Horse Radish, and in even more purely accidental cases.

Tree Pæonies.—These are in many respects like Hydrangeas. They are deciduous, and require an open situation where the soil is deep and rich; they are most effective when large in size. There is, perhaps, no more showy plant in cultivation than one of these large Pæonies in flower, the massive blooms of which weigh down the branches. The foliage is also ample, and distinct from that of ordinary lawn subjects. Before planting Pæonies, a thorough preparation of the soil should be made, then the plants will each season increase in attractiveness. A space 4 feet square and 2 feet deep should be trenched up for the roots, and if the natural staple is at all poor, it should be removed and some good turfy loam substituted. Tree Pæonies start into growth early in spring; therefore, the planting out should be completed by the end of February. There is a good variety of colour amongst this class of plants; one is almost white, and another rosy red, but the most common sort bears pinkish lilac flowers. There is a very old variety belonging to the herbaceous section of Pæonies which bears large rosy crimson flowers, and this, when grown singly on a lawn, is a conspicuous plant; indeed, it would be difficult to find another more striking. Plants of this variety growing in poor soil in mixed borders and crowded by others give but a poor idea of their capacity to make telling specimens when grown in good soil and with plenty of room. This sort is quite hardy, and starts into growth early in spring; it should be planted at once.—J. C. C.

Tropæolum tuberosum.—In the interesting note on this fine old plant by "T. W. G." (p. 447) it is incidentally stated that the plants were still uninjured at the time of writing, though five degrees of frost had expended its force on them on the 3rd of November. Fully a week later, on the morning of the 11th ult., I gathered some nice sprays of the Canary Creeper to mix with Veitch's variety of the Virginian Creeper in draping a dinner-table decoration. These and many similar illustrations convince me that not a few plants endure more frost with impunity in the autumn than in the spring. In the case of many plants, too, the cause of this difference is obvious enough. The wood and leaves are harder and more matured in the autumn, and hence comes their greater power of resisting frost. But this explanation can hardly apply to the late autumnal growths of such plants as these. The Canary Creepers were soft and tender in full fresh growth and bloom; the terminal shoots were brittle almost as glass; and even the flowers were soft and tender as in the early spring and summer. And yet the fact remains that they endured more frost with impunity. Nor is this peculiar and superior hardiness of plants in the autumn confined to Tropæolums. It is equally or more marked in Tomatoes, Dahlias, Vegetable Marrows, ridge Cucumbers, &c. These are frost-bitten or killed in May or June, with degrees of frost that leave them unharmed in the autumn. Before leaving Tropæolum tuberosum, I may add, what I think I have stated before in The Garden, that the finest lot of it ever seen was growing in a Yew hedge. The roots were planted within a few inches of the Yews, and the plants allowed to scramble over them at will. The effect was something quite unique, large portions of the Yews being hidden beneath the rich scarlet and golden drapery of this myriad-flowered Tropæolum.—D. T. F.

Unseasonable flowers.—Here we have still Roses and Carnations of all kinds in bloom; Gladioli, too, are still good. Hollyhocks we have in sufficient abundance for table decoration. Violets are scarcely so good as usual, but to make up we have every variety of single and double Primrose in flower. Christmas Roses are doing well. On the 22nd we picked red Salvia, Stocks, Snapdragon, Pentstemon, purple Honesty, Scabious, large St. John's-wort, Poppies, Marigolds, Lupins, purple Clematis, Mignonette, Sweet Peas, Forget-me-not, Nasturtiums, Marguerites, Auriculas, Candytuft, Œnotheras, Godetia, red Flax, Cyanus minor, Wallflower, a stray Dahlia, and other flowers.—T. Duff, *Kenmure Castle, Galloway.*

White Everlasting Pea.—"J. C. B." (p. 495) may think himself peculiarly lucky in getting one-third of his seedlings white. I have often saved the seed myself to be sure it was true, and have given it to various friends, but in only one instance have I or they got a white seedling. I now propagate the white variety by cuttings of the underground suckers in spring. They strike very certainly, but not very quickly.—W. Wilks, *Shirley Vicarage, Croydon.*

—— I can confidently assert that the white form of this Pea does revert to the red or pink kind. About three years ago I purchased half a

dozen plants of the white and planted them against a wall, as they are most useful for supplying cut flowers late in summer, when there is a dearth of good white blooms; this year only one out of the six produced white flowers; the rest had reverted to the pink, which is, I presume, the original colour. I am decidedly of opinion that the white is only a sport, and therefore liable to go back to the original form.—J. G., *Hants.*

—— I obtained a few seeds of white Sweet Pea some years ago and sowed them in pots, and every one came quite white. In 1883 I saved some seeds some of which were sent to Norfolk, where they flowered last year and every one came red. I also heard of a similar case happening about the same time.—Chas. Jeffries, *Boston House, Brentford.*

Centaurea ragusina in winter.—If anyone who values this plant feels disposed to take "Cambrian's" advice, they had better take it quite literally, and only allow a few to remain out. We used to grow several thousands of this very striking foliage plant, and, like "Cambrian," found great difficulty in finding room for it, so we began to leave it cut. It stood pretty well the first season, and hence we were tempted to leave it out the second, and the frost made a complete sweep of our stock, root and crown, and we have never recovered it. The Cineraria maritima shared the same fate, though that seemed more hardy than the Centaurea. A great deal depends on soil, site, and local climate; but it is unsafe to trust any large proportion of either of these plants in the open for the winter, unless in very mild localities. I noted a very excellent mode of propagating the Centaurea ragusina a few weeks since which may be worth detailing here. Each leaf with its bud in its axil was cut off from the stem with a small segment of the latter about an inch long, and a little thicker than the sheaf of wood for Rose budding attached; this was cut through with a clean cut about half an-inch under the bud on the segment. Pots half filled with drainage and surfaced with leaf-mould were then filled with coarse silver sand, and the leaf-cuttings inserted close to the sides, and compressed as firmly as possible, the leaf segment that formed the side of the cuttings being placed in contact with the edge of the pots. This and the smallness of the cutting being little more than leaves were the chief vital points, and on the rapid callusing of the raw segment of wood in contact with the hard pot, the chief reliance was placed for sure and successful rooting. The cuttings after insertion were placed for six weeks in a cool, close frame. In that time most of them were callused, when each was potted off singly and grown on into bulk in a temperature of 60°. These small plants grow rapidly after rooting, and form useful material for ground-work on dinner-table or for other decorations before being wanted for use in the flower garden in May.—Hortus.

Japan Anemones.—"Veronica" having apparently satisfied himself, and probably most others, that the white and rose-coloured Anemones of the japonica family were hybrids, he proceeds to avow his belief that the white kind is after all the typical species. This is hard to understand, inasmuch as he had just previously shown that it was not a species, but a true hybrid. Whether the flowers of the true A. japonica should be red or white seems of little importance in face of the fact that the plant introduced into Europe by Fortune produced red flowers. In no case does this species seem to have broken sportively into any other form or colour; hence it seems fair to assume that it is not only a species, but a typical one. I know I am treading on dangerous ground, not being a botanist, but I look at the matter from the common-sense aspect peculiar to practical gardeners. Now, the late Mr. Gordon, it is shown, crossed Anemone japonica with the white-flowered vitifolia, and the result is a plant producing rather larger and better-formed flowers than those of the type of a pale red or rosy hue. Still farther, the foliage has the Vine-leaved characteristics of vitifolia more prominently marked than in the Japanese parent. Later from this hybrid comes a break, and what more natural than that it should produce white flowers, because most experience shows that the male or pollen parent in cross-fertilisation leaves the strongest impression on the progeny. Thus there seems no room whatever for doubt, the whole business being of a very matter-of-fact description. The only difficulty remaining is as to the proper designation of these hybrid products, and if the rose one is properly named A. japonica hybrida; it seems certain now that the white one is fully entitled to the designation of Honorine Jobert.—A. D.

Crocus bulbs.—There must be some unexplained reason why "Veronica's" Crocus bulbs, planted 5 inches deep, came to the surface in three years. My own experience is, that they work downwards in some unexplained way. When I first took charge of the gardens at Loxford Hall I planted a long row of Crocus bulbs close to the margin of a path. They were not planted very deep, and no covering was ever placed over them. There they remained for eighteen years, and at the end of that time they were 7 inches or 8 inches deep. How does "Veronica" account for that? I am quite aware that the new Crocus corm is formed over the old one, the natural inference from which would be that the bulbs would in time work out of the ground. But we know that neither Crocus bulbs nor those of Gladioli do so. We had bulbs of Gladioli growing in the same garden without being disturbed for twenty years. I have just been examining some bulbs planted last year, and I find the new corm pushing over the sides of the old ones, and the base of the new ones is already lower than that of the old corms. I believe they go down at the rate of an inch in three years.—J. Douglas.

Trees and Shrubs.

EVERGREEN SHRUBS.

The important part of a garden devoted to trees and shrubs should bear inspection from more points of view than one. Collective effect should be secured by the right disposal of the materials, in the shape of trees and shrubs, deciduous and evergreen, which the planter has at command, without which the work must ever be deficient in a leading feature. But although the collective appearance of the trees and shrubs associated is an indispensable feature in this department of gardening, still it is only one of the needful essentials, and though it may satisfy those who see nothing in the cultivation of plants deserving of consideration, except what, for want of a more appropriate term, may be called artistic effect, yet, those who can see individual beauty in each tree and shrub are not likely to be content with effect taken in its general sense, but require as much variety in the plants they cultivate as is consistent with their ability to thrive and maintain a healthy appearance. The desirability of securing this will be generally accepted, but in practice it is so far from being generally acted on, that it is rather the exception than the rule. What, for instance, do we usually find in the shape of Evergreens in the ordinary run of gardens? The same Laurels, Aucubas, Cotoneasters, Berberis, Box, Euonymus, Hollies, Rhododendrons, Laurustinus, and others of a like character, represented by the commonest varieties. Whereas all that stands in the way of any ordinary garden of moderate size containing ten times the variety with a proportionate increase in the beauty and interest attached, is a non-acquaintance on the part of those who own gardens with the quantities of beautiful plants now within reach, and the little apparent disposition of many who are entrusted with planting to go beyond what was done when the number of species now at the planter's command were yet unseen in the wilds where Nature placed them, and the many fine seedling varieties that have been raised were non-existent. Possibly a few words respecting the most desirable of the less known kinds and the best of the commoner sorts of evergreen shrubs may be of use to some who wish to make their gardens more interesting.

The Laurel (Cerasus) has ever been a favourite. The common kind is still most planted; yet this is a mistake, inasmuch that there are two or three others that have all the good properties of the old one with none of its defects. The character of their leaves is so far like that of the old sort, that the uninitiated would not see the difference, but their general habit is better, and the growth closer and less straggling; whilst their hardy nature is such, that they bear our severest winters without injury in the way that the common kind suffers. Of these, C. Laurocerasus rotundifolia, C. L. caucasica, and C. L. colchica are all fine sorts that only require to be sufficiently known to insure their finding a place in every shrubbery. The first-named of the above, C. L. rotundifolia, may be set down as the best, taking all its properties into account. C. lusitanica (the Portugal Laurel) is one of the best known of Evergreens, and is always a conspicuous object, either massed in the shrubbery or as a single specimen on the lawn, where its dense habit of growth and healthy, vigorous appearance, thriving as it does in almost any locality, will always ensure it a place. C. lusitanica myrtifolia, the small-leaved variety of the last-named plant, is compact in growth and suitable for using where the type is too large.

Arbutus (the Strawberry tree).—The common A. Unedo is met with in most gardens. Independently of its beautiful red fruit, which it produces freely in some places, whilst in others it does not bear, its appearance is such as to make it still deserving of being cultivated generally. A. Andrachne, another fine kind, is not so much grown as A. Unedo, although long in the country. It is a distinct-looking and beautiful plant, a stronger grower, attaining a much larger size than the common species, and one which might with advantage be more used by planters than hitherto.

Andromedas.—The commoner kinds of these shrubs are too well known to require any remarks, but there is one which, though long enough introduced, is not so much planted as it should be—A. floribunda; where a dense, compact-growing, low shrub is required it has few equals, independent of the profusion of pretty white flowers with which it is annually clothed. A. japonica is a desirable kind; its panicles of white flowers are effective, whilst the habit of the plant gives it a distinct appearance. A. formosa is also a desirable sort.

Azara microphylla.—This is one of the most distinct of all Evergreens in cultivation; its slender branches, densely furnished with neat foliage, spread out as flat as the feathery fronds of a Fern. It is one of the best and most suitable of all plants for clothing a wall, the protection of which is an advantage, as its ability to bear a severe winter in the open ground is doubtful.

Aucubas.—The old spotted-leaved female A. japonica maculata is one of the best known and most useful plants ever introduced to British gardens, and its presence is more acceptable now when there is the means of having it annually furnished with beautiful red berries, by simply planting here and there amongst the females a plant of the male variety, of which there are different forms, each of which is handsome. It does not require many, even in a large place, to insure a crop of berries, yet there are many gardens where only the female exists.

The Bay (Laurus nobilis) is one of the best evergreens we possess, and never looks more at home than when located against the wall of a building, the shelter of which preserves it from the effects of the occasionally low temperatures that visit us, and which, even in the south of England, often make sad havoc with this plant when growing under conditions more conducive to vigorous growth than well-ripened wood.

Berberis.—Most people are acquainted with the charming B. Darwini, which is undoubtedly one of the finest evergreen flowering shrubs existent. Although in parts of the kingdom less favoured by climate it suffers from occasional low temperatures, nevertheless everyone should grow it; as also the beautiful hybrid B. stenophylla, which has few equals as regards the elegance of its slender drooping shoots, that when furnished

with their strings of yellow flowers are extremely effective. This plant should be in every garden.

Buddleia globosa.—If only for its appearance, which is so distinct from that of all other plants, this Buddleia is worth having. In many parts it will not stand the winter in the open ground, but wherever room can be found for it on a wall it deserves a place. Its perfectly globular flowers give the plant an appearance like nothing else that I recollect. When grown against a wall it should not be kept pinned in too closely in the way sometimes practised; allow it more liberty, simply keeping the branches from getting too far away to admit of the protective influence of the wall.

Cotoneasters.—The value of C. buxifolia and C. microphylla for covering walls or rockwork is generally known, and of C. Simonsi, the red berries of which brighten up the shrubbery in winter. Another kind, C. Roylei, may with advantage be added to those previously named.

Cistus.—C. ladaniferus (the Gum Cistus), although a very old plant, is not so common in gardens as the distinct character of its charming flowers might lead one to expect. Even in places where it suffers in hard winters it deserves the little labour that is involved in giving it the necessary protection during severe weather.

Garrya elliptica.—Though this plant is devoid of the gay-coloured flowers that many possess, still there is a peculiar elegance in its long, drooping catkins that is attractive and different from everything else I have seen. It does well on a north wall where few things would succeed.

Choisya ternata.—When better known this plant can scarcely fail to become a favourite. In those parts of the kingdom where it will succeed, it well deserves a place amongst the most select wall plants, protection of which kind it most likely will require.

Ceanothus.—Of these there are now a good many varieties besides the better known sorts, such as C. dentatus and C. azureus. C. azureus albidus, C. azureus Gloire de Versailles, C. floribundus and C. Veitchianus are all handsome kinds, but even in the southern parts of England they should have the sunny side of a wall.

Desfontainea spinosa.—If one were to imagine Osmanthus ilicifolius bearing small flowers of Lapageria rosea, it would give a tolerably correct idea of what Desfontainea spinosa is like when in bloom. Unless in the mildest parts of the kingdom, it is not safe without the protection of a wall, which it well deserves. The aspect should be south. Being a slow grower that does not attain a large size, little space will suffice for it.

Daphne Cneorum.—In the whole range of fragrant flowers, it would be difficult to point to any plant that surpasses this little gem. It is just the sort of plant that everyone who has a garden might be supposed to grow, yet it is a question if it could be found in one place out of fifty. The little room it occupies, which is not more than that required by the common perennial Candytuft, puts it within the reach of those who have not much space at command.

Box.—The ability which the common Box has of maintaining a fair appearance when under the shade of trees where few plants can live is sufficiently understood, and as a dense, healthy-looking shrub when it receives better usage it will always keep in favour. There are several varieties that should not be lost sight of. Handsworthiana is a useful sort, and also the gold and the silver varieties of the common kind; japonica aurea is remarkable for its clear yellow colour, and the strong-growing balearica deserves planting in localities where the winters are not too severe.

Escallonias.—Unfortunately, the beautiful Chiloean species, E. macrantha, is not hardy enough to show its true character except in the mildest parts of England, but it makes a good wall plant in most of the southern counties, though even under such conditions it sometimes suffers from exceptional frosts. E. Phillipiana is a comparatively new introduction from the Andes; it is a distinct and pretty species, bearing numbers of white flowers, which are well shown off by the neat foliage.

Eugenia Ugni.—Although this shrub failed to realise the expectations held by some when it first appeared of its turning out a useful edible fruit, still its general appearance, which is enhanced when in berry, is such as to make it a desirable plant.

Euonymus.—The Japanese kinds of Euonymus have turned out valuable shrubs for the various purposes which they can be used for. E. japonicus is one of the best Evergreens for planting in and about towns, and it is an excellent plant for use near the sea. The golden and the silver variegated forms as well as the green kind are amongst the best Evergreens for covering a wall; whilst the little E. radicans variegatus, besides being one of the best edging plants we have, is an excellent subject for a wall, reaching a height which its humble appearance when trailing on the ground would scarcely lead one to expect.

Laurustinus.—This old favourite is too well known and well proved to require anything to be said in its favour. Its ability to thrive almost anywhere, together with its healthy appearance and the profusion of pretty flowers it bears when there is little else to enliven the shrubbery, will always ensure its being largely planted.

Ligustrum.—L. vulgare, the common Privet, is one of the best-known plants for a screen or hedge about gardens or grounds where ability to resist cattle is not required; for the purposes named its neat appearance befits it. But L. ovalifolium, the oval-leaved kind, which is much stronger in habit and one of the quickest-growing shrubs we possess, is supplanting the old variety. It is one of the most useful Evergreens for town planting, its vigorous constitution enabling it to thrive where few things can live. L. coriaceum and L. japonicum are both distinct and desirable plants for shrubberies.

Magnolias.—M. grandiflora is one of the most remarkable Evergreens we have, and one of the best plants for a wall in the south of England where a considerable space has to be covered. Its large glossy foliage is very handsome, and equally so are the massive fragrant white flowers which the plant produces freely when in good condition. It is not well to trust it away from the protection of a wall except in the most favoured localities. In the northern counties it sometimes suffers when on a wall, unless protected in exceptionally severe winters. The Exmouth variety and M. ferruginea are both desirable plants, requiring similar treatment.

Osmanthus.—O. ilicifolius, with its gold and silver-variegated forms, are desirable plants, best adapted for standing in the front of large growing things, as they never get coarse or attain a size such as to encroach on other plants. O. myrtifolius and O. rotundifolius are also handsome.

Phillyreas.—The contrast which these plants present to things with massive foliage, combined with their ability to thrive in most localities, are the chief merits which they possess, and will doubtless still keep them in favour, although planters are not now confined to the limited field they had to choose from when these old-fashioned Evergreens were first introduced.

Rhamnus.—These plants are more interesting than striking in appearance, but are worth having to give variety. R. angustifolius and R. latifolius, with its varieties, are amongst the best deserving of the planter's notice.

Skimmias.—Amongst berry-bearing shrubs S. oblata holds a first place, but it is dioecious and a female; consequently, to secure berries, the male, S. fragrans, requires to be planted with it. The hermaphrodite form usually sold as S. japonica, which is more generally grown, so far as my experience in a good many localities goes, is not near so desirable a plant as S. oblata, but no harm will be done by having all three. These and other small-growing plants are not enough used at the outer edge of clumps and shrubbery borders, large coarse-growing things often being planted instead; the result of this is that they get too big for the positions they occupy either to look well or to be allowed to remain.

Ulex (Gorse) is too common a plant to suit everyone's taste; yet there are few gardens where the double variety might not with advantage be more freely introduced to the front of shrubbery borders than it usually is. When rightly placed, its dense sheet of yellow bloom lights up everything near it.

Ilex.—It may be safely said that there is no Evergreen which plays a more important part in decorative planting than the British Holly with its numerous varieties that have appeared in the form of seedlings and sports, in which latter direction it has a greater tendency than many things. The type will ever be a favourite from its excellent properties and the varied purposes to which it can be turned; but there are several other green-leaved sorts that are especially deserving of notice for their handsome appearance. Of these may be named I. Hodginsi, I. laurifolia, I. Shepherdi, I. ferox (the Hedgehog Holly), I. cheshuntensis, I. donningtoniensis, I. myrtifolia, the yellow-berried, and the Weeping Holly. Of the variegated varieties, Gold and Silver Queen, aurea marginata, argentea, Handsworthensis, aurea picta, and alba picta, the Gold and Silver Milkmaids, the gold and silver forms of I. ferox, Waterer's dwarf golden, and the gold and silver weeping varieties are all good. Other kinds that deserve notice are I. balearica, I. maderiensis, and I. opaca. The above are the cream of the Ilexes, though there are others that anyone desirous of growing a collection might be inclined to add. T. B.

Berry-bearing shrubs.—I have read with much interest Mr. Coleman's remarks on these in The Garden (p. 489). The collection of berry-bearing shrubs and trees at Eastnor is almost unique. In my opinion they are not so much planted as they ought to be. Their useful properties may not be conspicuous in summer, but in winter, and especially in December and at Christmas, berries in the open air are most valuable. As a rule, however, it is only the Holly that is planted to produce them, and the Holly is about the most uncertain berry-bearing subject that could be selected. It is only every other year—frequently not so often—that a crop appears, whereas if a greater variety of berry-bearing bushes was planted, the absence of Holly berries would cause no inconvenience. Last winter Holly berries were plentiful hereabouts, but at present I do not know where to find one. I would therefore advise planters not to overlook Mr. Coleman's remarks on Cotoneasters.—J. Muir, *Margam, South Wales.*

New double Lilacs.—The double-flowered varieties of the common Lilac have of late years had a good deal of attention directed towards them by M. Victor Lemoine, of Nancy, and one of his earlier productions (Lemoinei) has had its merits recognised by a certificate from the Royal Horticultural Society. Since that time, however, M. Lemoine has raised others which he claims to be greatly superior even to Lemoinei, so that these double Lilacs should when better known be very valuable, not only for open-air planting, but also for forcing into bloom early in the season. M. Lemoine now announces in his catalogue the following list of double-flowered varieties: hyacinthiflora plena, Alphonse Lavallée, Lamarck, Le Gaulois, Lemoinei, Mathieu de Dombasle, Michel Buchner, Renoncule, and rubella plena, as well as three novelties for the present season, viz, M. Maxime Cornu, President Grévy, and Pyramidal. Of this number, I have up to the present seen in flower but Lemoinei and Mathieu de Dombasle, and this last was too weak to judge of its merits, but it seems difficult to understand that all the above differ in any marked manner from each other, as the range in colour among Lilacs is not great. No doubt, however, they are the cream of double Lilacs, and I shall watch with interest the flowering of the various

kinds. Besides those previously mentioned, M. Lemoine announces that yet another variety, Comte Horace de Choiseul, for which he has received recognition when exhibited in France, will be distributed at some future time.—H. P.

THE CANADIAN WILD VINES.

The Frost Grape (Vitis cordifolia).—Those deep, embowering masses of foliage; those verdant draperies that fall in such graceful, leafy curtains from branch to branch, roofing the dark shady recesses of our wooded lakes and river banks; those light feathery-clustered blossoms that hover like a misty cloud above the leafy mass, giving out a tender perfume as the breeze passes over them—like sweet Mignonette—those are our native Vines, our wild Grapes.

Yon tall dead tree, that stands above the river's brink, is wreathed with a dense mantle of foliage not its own. The changing hues of the leaves, the deep purplish clusters of fruit, now partially seen, now hidden from the view, have given a life and beauty to that dead unsightly tree.

The ambitious parasite has climbed unchecked to the very topmost branch, and now flings down its luxuriant arms, vainly endeavouring to clasp some distant bough; but no, the distance is beyond its reach, and it must once more bend earthward or, in lieu of better support, entwine its flexile tendrils in a tangled network of twisted sprays, leaf-stalks, and embowering leaves and fruit.

The fruit of the Frost Grape—our northern Grape Vine—is small. The berries, round blue or black with little or no bloom, very acid, but edible when touched by the frost, and can be manufactured into a fine jelly and good wine of a deep colour and high flavour. Whole islands in the Trent and Rice Lake are covered with a growth of this native Grape. There is not a lake in Canada but has its "Grape island," and many persons cultivate the plants about their dwellings over light trellis-work, under which circumstances they will yield an abundance of fruit. It is also very useful to conceal unsightly objects, as out-houses. An old Pine stump can be converted into an ornamental object by nailing Cedar poles—fastened at the top—round it, and planting Grape Vines around it, having first prepared a bed of good earth and large stones to bank the lower part; a few plants of the wild Clematis intermixed with the Grape Vine and a sprinkling of Morning Glories, make a lovely pyramid and convert a defect into a charming object during many months of the year.

The wild Grape seems to flourish best, in its natural state, near the water, but will grow and flourish well in gardens where it is given the support of a trellis or in any suitable position where it can climb. I have even seen a dead tree specially planted for such a purpose.

The Fox Grape (Vitis Labrusca).—This is the original of the cultivated Isabella Grape, which has long been introduced into our gardens and vineries as worthy of the attention of fruit growers. The leaves of this species are very densely woolly, covered, especially when young, with tawny, silky hairs; the fruit is of a dark purple, of a musky flavour, whence its common name, Fox Grape.

This wild Grape is found on the shores of Lake Erie and to the westward. From the improvement made by cultivation in the size and quality of the wild Fox Grape, we may perceive how much might possibly be done with others of our wild fruits, which, when introduced into our gardens, would have the advantage of hardiness in bearing the severity of our climate beyond that of exotics.

It seems reasonable to suppose that plants that are indigenous to a country could, by due care, be brought to a state of higher perfection than when under a foreign sun and soil, and that the culture of wild plants would amply repay the cultivator. Attempts of this kind are rarely made or persevered in, so that the result is not often satisfactory; either the process is thought to be too slow, or we despise as common that which is within our reach, valuing that which is more costly above what is easily obtained; whilst we eagerly spend our money to obtain a foreign species, which may possibly have been originally taken from our native woods and wilds to a foreign country, there cherished and cared for, improved by cultivation, and returned to us increased in value. It would greatly enhance the pleasure of cultivation if we were ourselves able to show native flowers and shrubs and fruits rendered equal to the imported kinds by our own culture.—*Plant Life in Canada.*

White-stemmed Bramble (Rubus biflorus).—Among choice shrubs this Bramble would need to be introduced with caution, for its vigorous character tends to make it an undesirable neighbour for delicate-growing subjects; but when so situated that it can attain the dimensions of a good-sized clump, the peculiarly whitened stems form quite a prominent feature in woodland scenery, especially at this season, when so many shrubs are devoid of foliage. This Bramble is a native of the Himalayas, and is occasionally injured during very severe winters, but from its vigorous nature it quickly recovers. It will form a large mass some 10 feet or 12 feet high, and may be readily increased either by detaching some of the stems with roots, or by layering the tips of the branches. It is frequently met with under the name of R. leucodermis.—H. P.

Gaultheria procumbens.—In a moist, peaty spot this pretty little shrub flourishes. It forms a small compact growing shrub, reaching but a few inches in height, and with dark green shining leaves. The flowers, which are bell-shaped and of a whitish tint, are borne during the summer months, and are then succeeded by red sealing-wax-like berries, which remain on for a long time. I was recently struck with its beauty on a rockery. In a cool, moist situation it had formed a good clump, and the red berries nestling among the dark green leaves had a pretty effect. Though this species was introduced from North America during the last century, it is much less common than its more vigorous relative, Gaultheria Shallon, as this latter will hold its own under anything like favourable conditions. It is a free-growing shrub, reaching a height of a couple of feet or so, and bearing during the summer a great profusion of drooping bell-shaped blossoms of a pinkish tinge. They are succeeded by dark purple coloured berries, which ripen in the autumn, and are much sought after by birds. For this reason it has been highly recommended as a game covert plant, while objection has been taken to it on the ground that it does not grow to a sufficient height for that purpose. Be that as it may, it is very useful for carpeting the ground under trees, especially if the soil is largely composed of vegetable matter, as in this the roots run freely and the plant quickly covers the ground.—Alpha.

Variegated Privet (Ligustrum ovalifolium variegatum).—The variegated variety of the Oval-leaved Privet is now one of the most conspicuous shrubs, from a foliage point of view, that we possess, and for furnishing empty flower-beds or other bare spots at this season it is most useful, as it can be struck without difficulty from cuttings, is quick in growth, and transplants readily—all desirable features in a shrub such as this. It has the ordinary foliage of the Oval-leaved Privet, except that the greater part of the leaf, from the margin inwards, is of a rich golden yellow colour. There are a great many variegated Privets now in cultivation, but this is the finest of all. Cuttings may be put in at almost any season, but the best time is during the autumn months, and if they are then sheltered by a cold frame they will be rooted by the spring. Where needed for bedding and such purposes as small bushy plants are the most useful, the cuttings, when rooted, should have their points pinched out in order to ensure a sturdy growth, for if allowed to run up naked at first, it is impossible to get them to form good bushes afterwards unless cut back severely, and in that case a season's growth is lost.—T.

Snowberries.—Among berried shrubs, the Snowberry (Symphoricarpus racemosus) stands out almost alone among those with white fruits. The berries, too, are larger than those of most other shrubs, and, being borne in considerable numbers, form a prominent feature at this season of the year. It is a native of North America, but has been long known in this country, and, being easily increased and hardy in constitution, it is now among our commonest shrubs. Though the berries are by far its most conspicuous feature, yet the pretty little pink blossoms that are borne freely in the spring and early summer are well worthy of recognition. There is another species of Symphoricarpus (vulgaris) which is also well known, though the berries do not form so conspicuous a feature as those of the last named kind. The regular arrangement of the leaves is noticeable in S. vulgaris, and a variety in which the foliage is variegated with creamy white is a very pretty shrub during the summer months. In this species the fruits are, when full grown, much smaller than those of the Snowberry, being about the size of a small Pea and crimson in colour. One feature about the two shrubs herein mentioned is, that they both will thrive fairly well where shaded by overhanging trees, and, with regard to soil, they are in no ways particular.—H. P.

GARDEN FLORA

PLATE 573.

DOG'S-TOOTH VIOLETS.

(WITH A FIGURE OF ERYTHRONIUM DENS-CANIS.*)

This is a comparatively small genus of plants, not more than seven being admitted as distinct species, but with the addition of garden and other varieties it becomes raised to eighteen or more; four of the species are Californian, two are confined to the Atlantic States, and the well-known Dens-canis has a wide distribution ranging from Southern Europe to Russia, Siberia, and Japan; it has been known and cultivated almost from time immemorial, and has changed but little or none within the last three centuries. The name, it is said, occurs in "Pliny" and "Dioscorides," and certainly the Dog's-tooth Violet was a great favourite with the older botanists. The whole of the species are charming and rank amongst the first to flower in spring amongst hardy bulbs. They are suitable for the rockery, border or wild garden, and are even much appreciated when grown in pots for greenhouse or conservatory decoration. In the case of the American kinds, a light peaty soil is, we find, one of the essentials of success; and although, perhaps, hardy enough, they are all the better for a little protection. One or two of the species make charming edgings to beds or borders. Dog's-tooth Violets should never be planted less than 3 inches deep and more in light soils than in heavy ones. Deep planting keeps them cooler than they otherwise would be and out of harm's way. E. grandiflorum and its varieties might, with fair expectations of success, be planted on sloping, sunny banks, where the Grass is thin; some light sandy soil should be put round the bulbs at planting time, and plenty of room given them. E. Dens-canis has finely mottled and blotched foliage as well as pretty flowers; it is an effective border plant, and also does well in warm nooks in the rockery, and even in the wild garden in sheltered spots we have seen it flower well. It increases rapidly by means of offsets, which are produced at the base of the old bulbs—much the easiest and quickest way of propagating it.

E. albidum (white Dog's-tooth Violet).—An old species resembling in many respects the yellow Adder's-tongue. Its leaves are lanceolate spotted, not dotted as in the latter; flowers large, produced singly on the stem, white or bluish white, and drooping; bulb roundish and emitting subterraneous runners, by which means it is increased. It thrives under much the same conditions as those indicated for americanum, and, like that species, it is all the better for being restricted. It blooms in April. It is found in low thickets from

* Drawn in Captain Nelson's garden, Holme Lodge, Godalming, April, 1886.

VARIETIES OF DOG'S TOOTH VIOLET
(ERYTHRONIUM DENS-CANIS)

Albany, W. Pennsylvania to Wisconsin and southwards.

E. AMERICANUM (Yellow Adder's-tongue).—This is doubtless the plant intended by Collinson in his catalogue under the name of E. Dens-canis, as follows: "After many years' expectation, the 3rd April, 1761, the Dens-canis from Pennsylvania showed its yellow flowers." Later on he says, "It appears, by Rea's 'Flora,' to have been known in our gardens nearly a century before, but was lost until re-introduced in 1754." It appears to be a very common plant in the States, where it begins to flower about the end of April or beginning of May, earlier or later according to circumstances. It is said to have received the name of yellow Snowdrop from the earlier settlers of Pennsylvania, perhaps by way of remembrance of the Snowdrop of their old homes. It has also been named yellow Snake-leaf, &c. The markings on the leaves are said to vary, and in some localities to almost entirely disappear; then it is called Lamb's-tongue. The length of time that elapsed between its introduction and flowering is very characteristic of E. americanum when improperly managed, the general impression being that it is rather a shy bloomer. In a shady, moist situation in rich, peaty soil it flowers freely enough, as it also does when the roots are confined in a box pocket in the rockery. It increases rapidly by means of subterraneous runners, and flowers all the freer when these are restricted, otherwise leaves are developed at the expense of flowers. It might be used with advantage in edging Heath beds where the soil has to be kept moist, and where the roots of large trees are kept at bay. It appears to succeed all the better for the little protection afforded by a bed of Heaths, &c. The leaves are lance-shaped or elliptic-ribbed underneath, green or slightly glaucous above, spotted and dotted with purple, &c.; the flowers, which are yellow, are drooping, bronzed on the upper surface, and produced singly on slender stalks from 6 inches to 9 inches in height, the outer segments being broader and more reflexed than the inner. The variety bracteatum we have never seen alive; it differs from the type chiefly in having a bract developed on the scape, as we sometimes see in robust forms of E. grandiflorum. (Syns., Nuttallianum, lanceolatum, flavum)

American Dog's-tooth Violet (Erythronium americanum); flowers yellow.

E. DENS-CANIS (European Dog's-tooth Violet).—This old historical species is the only one indigenous to Southern Europe. It has, however, geographical varieties extending in the forms sibiricum and japonicum through Asia to Japan, and differing from the type more or less in the size, shape, and markings of the leaves, as well as in the flowers. They are perhaps of little or no importance to the cultivator, as they are inferior to the old form in usefulness. So charming does the old Dog's-tooth Violet look in early spring, that it has become quite indispensable for edgings, &c., out of doors, and so numerous are the forms ranging from purple through rose to white, that quite a gay display can be made with them alone, either mixed or planted in patches of separate colours. It is very easily grown, thriving best perhaps in an open sunny border, backed by a wall or other shelter, from which its tender flowers may have a little protection from cutting east winds. The annexed illustration is a good representation of the old plant. Other varieties which may be had in the trade are album and album majus, purpureum majus roseum, and roseum majus, and others. There is also a distinct variety with long, sparsely-blotched leaves called longifolium, and another called altaicum, but we doubt very much if the latter is distinct enough from sibiricum for practical purposes. It is figured in the first number of the *Botanical Magazine* (tab. 5), where americanum is also mixed up in the text.

E. GRANDIFLORUM and its varieties, of which there are three or four distinct, are, without doubt, the handsomest plants in this genus. They all thrive admirably under ordinary cultivation; clumps of them, either mixed or separate, look well in the spring garden. Producing flowers as they do so freely, they are well adapted for cutting, and last a considerable time in water. On one or two of the varieties single flowers only are produced, but on the type and some other varieties there are often as many as five or six, varying according to the strength of the bulbs, and they generally measure about 2 inches in diameter. In the type the leaves are oblong-lanceolate, not mottled, or, if so, very obscurely. They are acute-pointed, and have broad, short stalks. The flowers are primrose-yellow or cream-coloured, and have a more or less orange base; the segments are recurved and pointed. There are often from two to six flowers on a stem, from a foot to 18 inches in height. E. g. var. Smithi has large flowers tinged with purple or rose, and very handsome. Revolutum, found by Smith in the redwoods of Mendocino. E. g. albiflorum, which includes giganteum, is a noble plant, having large mottled and white flowers with a yellow and orange base. They are often 4 inches in diameter, and invariably have only one flower on each stalk—a good character by which to distinguish it from the type. It is also called speciosum, maximum (Douglas, 1829), and pallidum. E. g. var. minor differs but little from the type, except that its flowers are smaller. Most of the forms of this variable plant would look well in our spring bulb gardens could they be naturalised in quantity; where the necessary shade abounds, their establishment would only be a matter of time, seeing how well they succeed in borders. The type is found in Washington territory, Oregon, Vancouver's Island, and North California, and it flowers with us in April and May.

E. HARTWEGI, is a comparatively new species, which we have not yet seen in cultivation, but it promises, we hear, to be a very desirable plant. Its leaves are oblanceolate and mottled; its flowers are solitary, or two or three in a sessile umbel, and light yellow and orange in colour. It is E. grandiflorum of Bentham, and is a native of the Sierra Nevada, Butte county, &c.

E. PROPULLANS.—This is a comparatively new species, and, as far as we are aware, not yet in cultivation. It has a very ingenious way of increasing itself. In Dens canis, as everyone knows, the new bulbs are produced directly from the sides of the old ones, and grow so closely as to form close clumps. In americanum and albidum, as we have already seen, the increase is by means of offshoots or subterranean runners, produced from the base of the old bulbs. In the present instance, the offshoot springs from about the middle of that portion of the stem which lies between the bulb and the base of the leaves, usually about 5 inches or 6 inches long. This lateral offshoot sometimes grows downwards and lengthens, as in albidum, but sometimes it remains an inch or so long, and its apex dilates into the new bulb. The flowers, which are produced in spring, are much smaller than those of any of the other species; they are bright pink or rose, with a slightly deeper base. It is a native of California.

E. PURPURASCENS.—Although this has comparatively small flowers, it is really a charming plant, and should find a place in every garden; besides E. grandiflorum, it is the only other species having more than one flower on a scape. In the case of the present species they vary from 6 inches to 9 in. or 10 in., and would no doubt, under good cultivation, produce them larger than they are found to be in newly imported plants. The leaves are undulated, oblong, or narrow lance shaped, acute-pointed, and narrowed to a very broad short stalk. The flower-stalk is sometimes divided towards the base, or carries the flowers umbellate fashion. They are smallish, light yellow, more or less tinted with purple and deep orange towards the base; sometimes they are quite purple and very pretty. (Syns., E. grandiflorum var. multiflorum and Fritillaria multiscapidea.) E. p. var. uniflorum, a slender one-flowered plant, is made to include E. revolutum, introduced by M. Max Leichtlin in 1874, and grandiflorum (Torr.) flowers with us in April and May. It is a native of the Sierra Nevada. D. K.

WORK DONE IN WEEK ENDING NOV. 30.

NOVEMBER 24 TO 30.

We have had a week of true November weather—fog and darkness—and our diary notes are few, for it has not been possible to do half a day's work on any one day of the week. Having a light soil to deal with, we have been able to continue the planting of Roses, and have also planted a few bush fruits—Currants and Gooseberries—the ground for which had been trenched at least 3 feet deep, and two layers of well-decayed manure worked in with the soil. The trees are now being securely staked, and afterwards, so far as their roots extend, we shall spread a thick layer of half-decayed stable litter to serve the double purpose of protection from frost and the too rapid evaporation of moisture from the soil surrounding the roots. Roses as planted are served in the same way, except that in the dressed grounds where neatness must be maintained, the mulching is well beaten down and covered either with fine soil or Cocoa fibre. Pruning of Plums, Pears, Currants, and Gooseberries is being done as rapidly as hands at command admit of. We had not much root-pruning to do, and this work is therefore completed; some half-dozen Pears that are worked on the Pear stock, which trees always grow most luxuriantly, were all that needed root-restriction, and now these trees, alike with their congeners on the Quince, will be heavily mulched with good manure. We continue the work of trenching the vacant plots in the kitchen garden as opportunity offers, and between whiles go to the work of leaf-raking, carting, and stacking them for hotbed purposes. All our Pines are grown with the bottom heat obtained from leaves, and for them we reserve the driest Oak and Beech. As our Strawberry house is likely to be required for flowering plants for some time to come, we have filled another three-light pit with leaves for the purpose of starting forcing other relays of Strawberry plants; a second batch of fifty plants has been added to the first-started pit. The warmth and moisture generated by the leaves render either firing or syringing unnecessary, and but little watering is as yet required; about twice a week we look them over with that intent, as we strongly object to their ever getting dry. It is sheer nonsense to suppose, as some do, that dryness at the roots is ever essential; nay, more, it is ruinous, for it is, I feel sure, almost solely the cause of blindness or non-setting. Too high a temperature or great humidity of atmosphere may sometimes conduce to non-setting, but very seldom indeed. We can speak confidently under this head, for ours set well in any temperature between 50° and 75°, humidity or dryness of atmosphere being apparently immaterial, for we have had them do equally well under each condition. Full maturity of crowns, and soil never to be what we understand as dry, are the two elementary, yet principal, lessons that must be learnt if non-setting of fruit is to be prevented. Once these are learnt and acted on, temperature and humidity will come to be regarded as of secondary importance. From the foregoing will be sur-

mised what my opinion is concerning the wintering of Strawberry plants piled together on their sides. No; they must have water; better have twice or thrice too much than get half dry, and, by way of practising what is here preached, all the plants that we could not afford space for in cold pits have just now been placed closely together in a sheltered position, and between the pots to protect both these and the roots from frost has been rammed plenty of dry leaves, and in the event of extraordinary severe weather we shall cover the plants entirely over with Bracken or straw. Tied Peaches to trellises. We cannot get rid of Chrysanthemums from the house, else our first Peach house would be closed up for forcing. A week or two late at this season can easily be made up by slightly increased forcing as soon as the fruit is set, and again after the fruit has stoned; hence this delay in starting is not of much consequence. Pruned Figs; we are apt to train in the summer's growth too thickly. Appearance has something to do with this, as we like to see the trellis well furnished, but it is bad policy; better fruit is produced when the fullest amount of daylight and sunshine can reach it. In the pruning now being done we are striving courageously to thin out the wood as thin as it should be; all shoots that are budless to the greatest length are those that are being cut out, together with others that are shrunken near their points, because not well ripened. Soon as pruning is done, the whole will be painted over with a strong lather of soft soap and sulphur, to which pepper will be added, which we have tested as being an excellent dislodger of the small white scale, which is the only parasite that afflicts our Figs. Our earliest vinery is now fairly started; we have a bed of Oak leaves on the floor, and these prevent the necessity of syringing; present temperature, 55°. On the bed of leaves we have placed Spiræas, Deutzias, Hyacinths, and a few Tea Roses, which is a capital place for them in the earliest stage of forcing. Put more Grapes in bottles; Golden Queen, Alnwick Seedling, and Alicantes from an intermediate house. Those still hanging on the Vines need looking over twice a week. All is kept as dry as possible, no washing of floors, and decaying leaves are at once removed, and the inside borders are covered with clean, dry straw. Fire-heat is kept constantly on to keep the internal air a few degrees warmer than the outside, otherwise this fog would quickly cause decay of the berries. Flowering plants need quite as much attention in this abnormally dark, damp weather to keep them from injury by damping as does fruit, and to Cyclamens, Primulas, and double-flowered zonal Pelargoniums we have given a little more warmth to prevent this. Fruit rooms we now keep constantly closed, for, having no means in these of drying up damp air, the next best thing to do is to strive to prevent its entry, and air freely when we happen to get a drying atmosphere. Potted Seakale roots for forcing, and also put in warmth the first roots of Rhubarb. Hants.

FRUITS UNDER GLASS.

Pines.

By this time all the plants will be in the positions they are intended to occupy until after the turn of the year, and days being dark, dull, and as short as we may expect to see them, they must be kept as quiet as may be consistent with safety. The fruiting house may be kept at 76° to 80° by day, or perhaps a few degrees higher under gleams of sunshine, when all available spaces may be moistened to soften the atmosphere, as overhead syringing is now out of the question. Plants swelling fruit will require cautious watering, as too much will cause the centres to turn black, whilst want of this element will produce a check which will lead to premature ripening, and most likely the bolting of the suckers when potted and plunged in sharp heat in February. If in good sized pots and deeply plunged in moist fermenting leaves at a temperature of 80° to 85°, the lower roots will absorb a great deal of moisture, and stem roots can be fed by the application of tepid liquid through the syringe, but these means will hardly be sufficient to keep the whole balls in a growing state; therefore such plants as seem to require it must have a liberal supply occasionally. As soon as the fruit has attained its full size, and there is the slightest appearance of a change of colour, the balls must be allowed to become comparatively dry, and a dry, warm compartment being at command, the plants may be lifted out bodily and placed near the glass to ripen. In this position ripe fruit will keep for a long time, but unless some good end can be served, Pines, like all other fruits, should be detached when fully fit for use, otherwise the finest suckers may suffer.

Successions.—If the earliest batch of Queens is still resting, and the plants, by their thick stems and pointed leaves, look like starting, heat and moisture may now be gradually supplied. Where a newly-formed bed in an adjoining compartment has settled down into a steady reliable heat, the change from dry to moist heat will produce the desired effect on a large percentage of the plants, and those which do not start will make a little growth and throw up larger fruit at a very acceptable time. Root-watering and atmospheric moisture will, of course, be necessary, but until the fruit is well up great caution will be needful, as a sudden flush of either at this dead season is sometimes injurious. The general stock of intended fruiters will be kept quiet for some time longer, but it will not be well to let the air or bottom heats fall too low, as the roots of Queens may be injured by starvation and excessive drought.

Young stock potted in September and kept steadily progressing up to the present time should now be looked to, as it is not improbable the extra fire-heat and fermentation combined may have caused the leaves immediately above the pipes to become dry. Should this be the case, steps must be taken to avert the mischief that will follow, either by renovating with a few fresh leaves, or by the application of warm water between the pots, and in quantity sufficient to moisten the lower stratum. The roots also may require a little water occasionally, especially where the beds are shallow and dry fire-heat is near the crocks now full of roots. If growth is to be continued throughout the winter, the plants should be kept well up to the glass, as they must have plenty of light to prevent them from drawing, and in this case will require more top and bottom moisture than if resting. The bottom-heat in such light structures should range from 75° to 80°; the top-heat from 60° by night to 70° by day in favourable weather, and a little lower when dark and cold. In order to secure an approximation to these figures, and at the same time to spare the plants the injurious effect of excessive firing, good covering of some kind should always be provided and carefully used through the night. Shutters are antiquated; mats are untidy, and fast following shutters; but oiled canvas on rollers for running along, not up and down, will be found a cheap, efficient, and neat covering not only for Pines, but for all sorts of plants, especially in pits and frames. It can be obtained any length and width, properly furnished with eylet holes and cords for securing it from wind. Cold rain runs off it on sharp pitched pits before it reaches and chills the glass, and, judging from one year's wear and tear, economy as well as constant neatness and protection will be secured by its use.

Cucumbers.

The weather so far has been favourable to winter plants, which have made good progress under a moderate amount of fire-heat. All plants now in bearing, either in pots or planted out, will require continuous supplies, little and often, of good top dressing to keep the roots active and near the surface. This may consist of light turfy loam, a dash of peat where plentiful, rough, lumpy lime rubble, and charcoal, well mixed and kept in a dry, warm place ready for use as often as the young roots begin to show on the surface. If planted out as formerly directed, and the dry bottom-heat pipes are well covered with a good layer of moist, fermenting leaves, root action will be rapid, and the fruit will swell freely without the aid of solid manure, which, like all other powerful stimulants, forces gross growth of leaf and vine when least wanted. Mild diluted liquid at a temperature of 80° to 85° may be necessary, but this even should be regulated by the condition of the plants, as it is much better to cultivate for firm shoots and medium-sized leaves than to run into the other extreme and be overtaken by canker and mildew. Next to moderate fertile growth under a proper day and night temperature, very important points are cleanliness and the maintenance of a fresh, sweet atmosphere. To this end all surfaces, including the glass, should be frequently washed; not a particle of superfluous or decaying matter, on or off the plants, should be allowed to remain, and air more or less should be admitted near the surface of the bed daily. Add to these precautions thin training, light cropping, and good covering to economise the damaging influence of strong fire-heat, and the plants should continue fresh and healthy until the time comes round for daily syringing. Cucumbers just now are of little value; consequently every fruit that is not likely to be wanted, also all male blossoms, may with the greatest advantage be removed for the present; stopping likewise must be discontinued; and, assuming that close planting has been avoided, full extension training will keep the plants in the best of health where crowding and constant pinching might lead to a collapse just when the fruit is most needed. Mishaps in the best regulated houses no doubt are frequent, and some are beyond the most careful cultivators' control, but by constant attention to every trifling detail and an attempt to nip all diseases in the bud, the most trying month now before us may be tided over. In some gardens the fatal Cucumber disease sweeps all before it for years, and as mysteriously disappears as it first put in its appearance. In others, canker or spider claim their victims, not occasionally, but annually, until perhaps by some trifling change conditions favourable to their development are removed when plants in the same structure may go profitably through the winter with impunity. By some express culture—that is, intense heat—a saturated atmosphere and the exclusion of air is considered the never-failing remedy for, or preventive of, every ill, but I have not had occasion to try it, and so long as my plants continue healthy and fruitful the winter through, I shall follow the doctrine I preach, and advise my friends to do likewise.

Early Peach House.

Unless houses are plentiful and a continuous supply of fruit can be kept up throughout the season, there is nothing gained by starting a permanently planted structure before the first week in December, when, all having gone well, ripe fruit will be forthcoming in May. If wanted earlier than this date, then pot culture, recently referred to, should be relied on, as trees in pots whose chief value is their extreme earliness, can be put aside and replaced at trifling expense in cases of failure. Where the best early varieties are thoroughly established in well made and properly drained internal borders and the houses are light, efficiently heated, and ventilated, December-started trees under careful management can be forced successfully for a great number of years; and when it is borne in mind that their season is as nearly as possible reversed, the veriest tyro will understand that the successful cultivator must be imbued with a large stock of patience. An easily excited tree like the Peach, which naturally starts early, can be forced into flower at almost any time, but unless those flowers are in every way perfect and well in advance of the wood-buds, they will not set, or if they do, many chances run in favour of the fruit dropping when it reaches the critical stage of stoning. To avoid this dilemma and secure full crops really worthy of the size and quality of first-class Peaches, time must be given by starting at a very low temperature, always with air through the day and allow-

ing rest through the hours of darkness. Young trees are less reliable than old ones, but assuming that the latter are in good condition, the borders have never felt the want of water and are now in a proper growing state, fire-heat will hardly be needed during the first fortnight after closing. If artificial heat is required, a good body of fermenting leaves, unless the weather is very severe, should prevent the temperature from falling below 45° at night, whilst under favourable conditions it will range some degrees higher. When the house has been what gardeners term "closed" a fortnight, although practically the ventilators have been open every day and the Oak leaves are throwing off warmth and a steady stream of moisture, gentle fires may be started every morning, always with air to raise the temperature to 55° or 60° under gleams of sunshine. If water through the syringe is considered necessary, this is the proper time to apply it both to the trees and walls, but the first should be allowed to get dry before nightfall, and the fire-heat should be shut off when the mercury registers 50°. Worked on upon this give-and-take principle, the flowers will open strong and perfect; moreover, they will set well; and although a little time apparently may have been lost, they will prove the value of the virtue I have mentioned at the finish. When the blossoms begin to expand, 50° at night and 60° by day may be worked upon as the mean until the fruit is set and swelling out of the decaying flowers, but no hard and-fast line need be adhered to, as Peaches frequently set well under a temperature of 40°. These low heats are not, however, recommended, as warmth from fermenting materials combined with gleams of sunshine and gentle fire-heat which will raise the temperature to 70° will be beneficial, as it ripens the pollen and sets it at liberty when wanted for fertilisation.

Succession houses.—The trees in these should be cleansed and tied in as opportunity offers. Whilst keeping the pruning and training well in advance, we always divide our time between trees under glass and others in the open air, as the men then have indoor work for bad weather, and it is hardly necessary for me to say, get over the greatest possible amount of pruning and nailing when the days are dry and mild. The trees in this, as in all other houses, having been pruned as soon as the crop was cleared, this operation at the present time merely consists of a general dressing over and smoothing of rough cuts as a preliminary to washing. There prevails an impression that extension-trained trees soon become thin in the centre; this I do not find the case, but rather the reverse, as the maintenance of a free healthy balance between the roots and branches gives one the choice of an abundance of fruit-bearing shoots in every part of the tree, and opponents have only to try the system to find out how easily a careful disbudder can command a good supply wherever he wants them. When a regular shortening back to one-third the length of every shoot is adopted, nine-tenths of the young breaks have to be rubbed off and sent after a similar proportion of the flower-buds which might have produced fruit. An extension shoot from 18 inches to 30 inches in length breaks equally well; consequently grossness and confusion are avoided, as a smaller number of fruit-bearing shoots are needed—the first, of course, from the base or lowest bud, the second from about the centre, and the third from the point. These are allowed to grow outwards and onwards to their fullest extent. All intermediate growths are pinched where fruit has set and removed as thinning is proceeded with; where fruit has not set, or its removal is a certainty, they are rubbed off in the usual way. Hard-pruned trees are generally crowded with gross wood which requires much ripening, a decided disadvantage in late houses. Extension-trained trees grow themselves into fertility, and having more room for the full development of their leaves, the wood becomes hard and brown, the buds are large, round, and plump, and being perfectly formed and ripened, the flowers invariably set well.

Late houses.—One of the secrets of success in the management of the trees in these structures is perfect ripening of the wood. When late sorts like Barrington, Sea Eagle, and Walburton Late Admirable are retarded through all the stages of their growth, it is no unusual event to find the wood in a backward state after the fruit is gathered. Fire heat, after the sun has lost its power late in October, many people think is of little avail, but this being the next best element, I always keep the hot-water pipes constantly warm with a circulation of air so long as a leaf hangs naturally upon the trees. When quite clear of foliage, firing is discontinued, as it would be ruinous to push the buds beyond maturity, a by no means uncommon event in very early houses where the trees lose their foliage during the heat of the latter part of the summer. Root-pruning in these late houses is, of course, a telling factor, and should be practised immediately after the fruit is gathered. This work may still be performed, and where fresh trees have to be introduced from reserve walls not a day should be lost in getting them transplanted and their places filled up with young stock before frost sets in. External borders still open to the elements may remain so until we have a change, but frost-resisting materials should be held in readiness for use when wanted. W. Coleman.

Eastnor Castle, Ledbury.

Fruit Garden.

OUTDOOR GRAPES.

Mr. Cornhill (p. 469) is correct in his conclusions as regards failure in outdoor Grape culture arising in most cases from want of attention. The Vine, we all know, is a favourite for training on walls of cottages, and often on those of larger dwellings, but in much the greater number of cases little or nothing is done to secure a fruitful condition, or, if the Vines happen to show the requisite quantity of bunches in spring, to assist the ripening of the fruit within the space of our short and too sunless summers. In place of the shoots being sufficiently reduced in number by thinning as soon as they have made the usual progress, and of stopping those that are retained in the ordinary way and attending to the removal of lateral growth as it appears through the summer, the whole is allowed to go on until a complete thicket is the result, after which an indiscriminate cutting back of the shoots is effected, or the whole are allowed to go on until the leaves fall, when the pruning is done much in the way that one would clip a hedge. So far as I have had an opportunity of judging, the want of attention on the part of those who have Vines on open walls is through ignorance of what is required to enable them to bear and ripen their fruit as they should and would do if properly treated, for it often happens that other things, including bush and other fruits in the gardens where the neglected Vines exist, receive the requisite care. In support of this, it is a common occurrence to hear the owners of these non-fruitful Vines complain of their not bearing or the fruit not ripening, when, on a few hints being given as to the treatment required, they are not only adopted, but followed up in a way by which crops of eatable fruit are secured when the summers are such as to enable it to ripen, which by no means always happens even as far south as London. With fair treatment, a couple of the old white Muscadine Vines, growing on the south side of the house in which I live, show plenty of fruit each spring, but it does not always get ripe enough to eat. This was notably the case the summer before that we have just passed through, when a very late spring was followed by the fine weather being cut short earlier than usual in autumn. This year the spring was later even than in the preceding year; so much so, that the Vines were not in bloom on Midsummer's Day—a condition that has not before occurred during the seventeen years that I have resided in this part of the kingdom. Yet, contrary to what at the time the Vines flowered I thought was possible, the fruit has ripened thoroughly, which shows the exceptionally fine warm autumn we have had, the double advantage of which to outdoor Vines is that the buds for another year are also plumper and better matured than often happens.

Varieties of Grapes that require only a short season to bring them to maturity, such as the Muscadine named and Black Cluster, fairly treated, ripen their fruit in some localities further north than is generally supposed. An amateur with whom I was well acquainted, living in North Lancashire at some eight miles from the sea, had a Black Cluster Vine growing on the south side of his house that used to ripen its fruit thoroughly in fairly warm summers when the weather kept fine well on into autumn. The Vine in question was a strong one, and I have frequently seen it with half a hundredweight of fruit on it black and agreeable to eat. Respecting the absence of the requisite attention to outdoor Vines so generally seen, there are more reasons than one to which it is attributable. The treatment required by Vines is different from that of the common kinds of fruit, such as Apples, Pears, Plums, Cherries, and bush fruits, success with which is attainable more or less by annual pruning carried out at any time during the winter; whereas Vines to do any good must have their shoots sufficiently thinned and the bearing wood that is retained stopped at the right time, with repeated attention in removing lateral growth as this appears. Further than this, Grapes cannot be used in so many ways as most other fruits, and consequently are not worth so much or command the attention which the commoner kinds receive.

In regard to growing Grapes in vineyards in the way that used to be done in England in generations past, much has been written with a view to show that either the climate has changed for the worse, or that giving up their cultivation in this way has been a mistake. Yet those who reason thus seem to express their ideas without reflecting much on the subject, or knowing anything as to the character of the Grapes grown in bygone times. Eatable fruits were then few in number, and vastly inferior in quality to what they have been even at a period comparatively remote from the present day; consequently people were likely to be satisfied with such that now would be rejected as unpalatable. And, so far as I have ever been able to make out, there is no evidence existent that gives any idea what the character of the Grapes grown in English vineyards was. We know that the chief object in their cultivation was for wine-making purposes, to adapt them for which, it is needless to say, it was not necessary that they should have been ripe enough to eat, nor, for the matter of that, even anything near ripe, as unripe Grapes, in common with other kinds of fruit suitable for wine-making, answer for the purpose when much too acid to be eaten. In seasons when the white Grapes I have mentioned do not get ripe enough to eat, we make them into wine by a slow fermenting process, which wine after being bottled a year is little inferior to champagne; no spirit of any kind is added, except such as is contained in the sugar that is used in making it. Doubtless there are many who turn their outdoor Grapes to account in this way, and many more might do the same, if only a thought was turned to making use of the acres of bare, unoccupied walls that exist throughout the land, which, in addition to being vastly improved in appearance, would afford much that would be interesting as well as useful. But as opposed to this, so prevalent is the deep-rooted prejudice against things produced at home, that wine made from Grapes grown in England is not likely to be held in much favour, and this, notwithstanding the well known fact that thousands of gallons of imitation material is annually manufactured and drunk, but which, in spite of the labels on the bottles, has no more relationship to Grape wine than the water that runs down the nearest brook.

As to the re-introduction of the cultivation of Grapes in vineyards in this country, of which accounts from time to time appear, little that is reliable can be gleaned. During the summer one occasionally hears of the prospects of the growing

crop, but, so far as I have noticed, nothing has been said at the time the fruit should have been ripe that was likely to encourage anyone to adopt the system. In fact, it may be accepted as a certainty that in summers when the weather is such as only to just admit of Grapes ripening against a south wall, they will not ripen in a vineyard where the Vines are grown on the ordinary supports. There is one circumstance connected with outdoor Grapes that might possibly be of use to anyone feeling disposed to undertake their cultivation, when Vines are trained on the roof of a building facing the south with the rods secured to strips of wood laid flat on the slates or tiles, the fruit ripens quite ten days earlier than against a south wall. But to admit of the Grapes coming to maturity as early as possible, enough of the sun's rays must reach the surface of the roof, without which the requisite amount of heat will not be thrown off to bring on the crop with as little delay as possible. The way to effect this is to keep the canes far enough apart, so that it will not be necessary to remove too much foliage, to allow the sun to act sufficiently on the roof. Within the limits of such parts of England as are favourable to the cultivation of outdoor Vines there is an immense extent of roof surface covering sheds and low buildings of various kinds that might be turned to account by growing Grapes on them. There is one thing in favour of Grapes over other fruits when grown on a roof in the manner described—that is, the Vines are not brought on into flower by the sun-heat radiated from the surface so early as to get injured by frost in the way that other fruits are more or less liable to in such a position.—T. B.

—— When we called attention the other day to Mr. Harrison Weir's advice to plant Vines out of doors in England, we kept the question clear from that of the growth of the Grape in any artificial structure. He, however, confuses the issue by bringing his doings with ground vineries, &c., into his letter in the *Field*. Seeing a letter of Mr. Weir's in a daily paper of wide circulation among country people, telling them to plant Vines in the open air, we said a few words of caution. More misleading advice we can scarcely imagine to be given than telling people to plant Vines for fruit in the open air; and no one with any pretensions to gardening knowledge has any excuse for giving such advice, because no one with eyes in his head can travel in our warmest counties without seeing the absurdity of it. Mr. Weir speaks of his grandfather and his doings in Grape-growing out of doors fifty years ago—a very interesting reminiscence, no doubt, to him, but not throwing any light on Grape-growing out of doors in our own day. He, however, does not say a word about that experiment of the Marquis of Bute, a recent example which some of us have been to see, and he does not give the name of any place where good Grapes are ripened regularly out of doors in England. The Vine out of doors is always an interesting subject to us, and we have seen some hundreds of gardens within the past three years in which it is grown, but in not more than one case did we see a really eatable berry! Surely it is needless to say to anyone having the least knowledge of gardening that the Vine is a plant which is perfectly unfit for a cold climate like ours without artificial protection. It is no new thing, but one which has been tried for hundreds of years in the most favourable parts of our country, from Norfolk, where it is on every cottage in many of the shore parishes, to the best parts of Kent, Surrey, and Devon. With care and skill a little fruit may be got off warm walls in hot seasons; but the regular and profitable cultivation of the Grape in the open air is impossible. It has been proved to be so in a thousand gardens. Of all possible experiments in cultivation, this has received the fullest trial and the clearest decision. All who know gardens are familiar with the poor bunches of Sweetwater grown now and then under the south gable, and which are often a source of amusement to the owner, but no proof of the fitness of our climate for Grape-growing out of doors—quite the contrary. The wall space given to such trees would be much better given to a first-class winter Pear, or any good fruit that ripens in our climate. In our best gardens, in the warmest districts, no good gardener ever wastes his time and his walls growing Grapes in the open air. Go to Chiswick, and while a variety of experiments may be seen, those in charge know too well the effect of the British climate on the Asiatic Grape to give the subject a thought. With doubtful fruits good gardeners persevere. The severe winters of recent years, though they were so destructive to another valuable exotic fruit—the Peach—have not discouraged good cultivators. At Tortworth, and various gardens in the west, we have seen excellent fruit, and even at Burghley, where the climate is not so good. We say so much to show that where there is any hope, our good gardeners are not slow to try. But the fact is, a number of people have no power to generalise, and if they see a miserable crop of Sweetwater Grapes on the warm side of a house, they fly to the conclusion that everybody should grow Grapes on walls in England. The same kind of men, seeing that a young Gum tree, put out in our flower gardens, made what they thought a strong shoot during the summer, wrote to the *Times*, telling people to plant the Fever Gum tree; and so a few years ago these trees were planted in hundreds of gardens, to live till the first hard frost. Anyone who had seen the fine growth of the tree in a warm temperate climate would not have been deceived by the summer's growth in the sub-tropical garden, and its value for our country was previously well known. We frequently observe that persons who urge these rash experiments ignore the really useful and pleasant planting of the things suited to our climate; and so we ventured to remind Mr. Weir that it would be much better to call the attention of the public to fruits they could bring to perfection, and of which our markets and our tables stand in as much need as they do of Grapes. "No," says Mr. Weir, "the market is often overstocked." This is certainly not the case so far as fruit of the best keeping quality is concerned; and that is the fruit which should be grown on our best wall surfaces. Winter Pears of good quality, the fruit which would pay the best price of any hardy fruit grown in Britain, are not likely to be plentiful for a generation to come. Much very good fruit comes from France, and some from America. Because we had a glut this year of early fruit, that is no reason why we should give up the culture of fruit of the highest class; far from it. The Americans will not cease to send us their Apples, nor the French Duchesse and Easter Beurré Pears, because we had a glut of Plums this year, and because, owing to railways and bad market arrangements, the grower did not get his just profit.—*Field*.

Late Plums.—I have now before me a box of late Plums, grown by Mr. May, the gardener at Northaw House, near Barnet. The variety is Late Rivers, a most delicious dessert fruit, slightly below medium size, round, dark purple, and not unlike the old Purple Gage, to which it is quite equal in quality. It has a very slender stalk, an inch long, and the flesh, firm and juicy, is almost as yellow as that of an Apricot. Growers of the good old Golden Drop, who wish to have a purple companion in perfect condition on the trees as late as the middle of November, will do well to plant this excellent variety. It is one of the many seedlings raised by the late Mr. Rivers, and bore fruit the first time about twenty years ago. Good purple Plums are now perhaps more numerous than white or yellow varieties, and may be had in use from a very early date until after the leaves fall in the autumn. The first to ripen is Early Prolific, an excellent kitchen and market Plum; this is closely followed by that most delicious dessert variety, De Montfort. Then we have Kirke's, a host in itself, one of the best for forcing, and very prolific against open walls or grown as a pyramid. Angelina Burdett is rich, juicy, and prolific. Belgian Purple and Prince Engelbert, free, hardy, and prolific, are invaluable, the first for cooking or dessert, the second for the kitchen and preserving. These should be extensively planted for market purposes. Purple Gage is too well known to require notice. The Czar, a large, early purple Plum, is said to be an improvement on the Early Orleans; and Grand Duke is now making its way as a very high-flavoured fruit, alike useful for market or the private garden. Blue and Ickworth Impératrice are delicious when well ripened against a wall, but they will not do in cold gardens. Plums in the season are plentiful enough, and not unfrequently become a drug; but late sorts, like the excellent subject of this notice, are worthy of the attention of all planters. —W. C.

WINTER PRUNING FRUIT TREES.

Almost everyone who owns a fruit tree professes to be interested in pruning, and is often anxious to know when and how it should be done; but instructions respecting the matter are often badly carried out, and in not a few cases pruning is neglected altogether. Almost all fruit trees will produce a crop whether they are pruned or not, and when their owners see that they fruit, though not pruned, it no doubt makes them careless as to pruning. The quality of the produce of pruned and unpruned trees is, however, very different. On pruned trees the fruit is, as a rule, fully developed, fine in form, juicy and richly flavoured; while that on unpruned trees is always below the proper size, badly formed, dry and flavourless. It is in these respects that the advantage of pruning and the disadvantage of not pruning become visible. If anyone would plant half-a-dozen trees now, prune three of them annually, and allow the others to grow on without being pruned for six or eight years, I venture to affirm that at the end of that time it would be difficult to tell that both lots consisted of the same variety. This applies to all kinds of fruits, from Peaches to Gooseberries, and from Currants to the finest Pears. All trees have a natural tendency to become a dense mass of branches. A Gooseberry bush, never pruned, would soon become so full of wood, that it would be impossible to get one's hand into the middle of it to gather the fruit without being severely scratched. An unpruned Apple tree presents such a mass of foliage at midsummer, that it is impossible to see through it or tell what amount of fruit there is in the centre. But this is not a difficult matter as a rule, because Apples do not form or swell readily in the dark or shade, and trees of this kind have generally a sterile interior; whereas properly pruned trees bear freely and uniformly throughout. In short, if you want a poor crop and small fruit, do not prune, but if you desire a full crop and first-class produce, pruning must be resorted to. In answer to the question, "When is the best time to prune?" the general reply is, "Oh! any time from November until April." I do not, however, believe in such latitude; some pruning may certainly be done in November, though the majority of trees will not be ready for it then; as to April or even March, these months are much too late. It is injurious to prune after the buds have begun to swell. December and January are the two best months in which to prune, the whole of which should be done then. Cut out the decayed branches first, and allow young ones to remain to take their place. Apples, Pears, and Plums fruit most freely on spurs; therefore the young shoots formed during the season should be cut in to 1 inch or so from the bottom, with the exception of those allowed to remain to extend the tree or fill gaps, which may be left 1 foot or more in length. Peaches, Nectarines, and Cherries fruit freely on the young wood; therefore the most fruitful shoots on these should be allowed to remain. Apricots should be pruned on the spur system, and so should Red and White Currants and Gooseberries. Cambrian.

Wintering Strawberries in pots.—Strawberry plants for forcing into fruit in February, March, and April will now be at rest, and they will not grow any more until placed in their forcing quarters. Moreover, the growth made then will not help them; it is upon their development in autumn and the way in which they were matured then that their fruiting mainly depends; part of their success also rests on the way in which

they are kept during the winter, or from now onwards until they are placed in heat for forcing. They are greatly benefited by having a complete rest, and plants kept from frost or cold are not so good as those treated in a more hardy manner until forcing time. It matters not whether they are wet or dry at the root so long as they are cool, but they will bear a good deal of drying off, and if the pots are laid on their sides along the bottom of a wall three or four rows deep, it will be found that they will winter uncommonly well; I would rather treat them in this way than put them in a glasshouse. There is no advantage in plunging the pots in ashes or leaves, as is sometimes done; where there are any spare frames no better place could be had for them, as they can be placed close together in them; the lights may be left off night and day when the weather is mild, and in times of severe frost or much rain, they can be put over the plants to protect them. Plants treated in this way invariably force freely, while they do not suffer in any way from the weather. When left standing wet and exposed to frost, the soil swells and breaks the pots; but were it not for this disaster, there would be no harm in exposing Strawberries to frost. To prevent breakage, and where no protection in the way of a glasslight can be put over them, it is an advantage to put a layer of Bracken or straw over them, but at no time should they be treated as plants which cannot bear exposure so long as they have not been subjected to forcing.—Cambrian.

NOTES ON STRAWBERRY CULTURE.

Wintering pot plants.—Although wintering Strawberries in the open ground seems to be in favour with many, I cannot but think that the best way is to keep them under cover. I have had occasion more than once to winter plants in the open, and the crop of fruit from them never was so great as that from plants which had been well protected. In gardens which lie up well, and where there is no danger of water stagnating round the pots, I do not doubt that thoroughly well-rooted plants may be wintered very well, but I have found that the greatest enemy to them was periods of hard frost, which necessitated covering them with litter for a week or more at a time. When the protecting litter becomes saturated with rain or with melting snow, and then hard frost freezes it into a solid mass, it cannot well be removed, and then the foliage is sure to turn yellow, and decay as soon as the plants are put into the forcing house. We know what the function of the foliage is, and how its health or otherwise acts on the roots. Can it, then, be a matter of indifference whether that of a pot Strawberry be in a thoroughly healthy or diseased condition when, by the application of artificial conditions, the plants are forced into activity? The greener and more abundant the foliage the stronger will the young leaf push. That, at least, is my experience. Given a thoroughly well-rooted plant with a moderate-sized plump crown and several stout deep green leaves, and I always feel that it is an easy matter to get a crop of fruit. I do not deny that good crops may be got from plants which are but naked crowns when started into growth, but I contend that it is not good policy to bring them into this condition, and I know that a considerable amount of skill and much care are indispensable to keep them from getting into a bad condition. The first stage of forcing when the plants are called upon to make an effort under more or less unnatural conditions is always fraught with danger, and many thousands of plants are annually ruined at this time through careless handling, or the plants not being in a fit condition. One great risk lies in over-watering; once the roots get injured, more or less of a failure is likely to follow. I have the word of an excellent grower that his greatest difficulty is to keep his plants from being overwatered. Good healthy foliage preserved intact fresh and green through the winter, minimises this risk very considerably. Some draw their conclusions from the behaviour of plants that have been wintered on shelves, but this is not a good place for them, as unless they are carefully attended to they are sure to suffer from want of water. It is just as bad for a Strawberry to become very dry in the winter as to be soddened with moisture. In cold frames standing on ashes they are in a position to keep them in good health. One mistake, often made, is over-haste in getting the plants under cover. As soon as the first heavy rains come toward the end of September, they are frequently put into their winter quarters, and are thus deprived of the benefits of abundance of pure air and refreshing autumnal rains. If a plant has been well grown it will not fear, but will rejoice in the occasional drenching rains of autumn. It is often said that the Strawberry has completed its growth by the middle of September, but this is wrong. There is a considerable increase of bulk up to the middle and, in some years, to the end of October. It is the autumn weather that does this, and we are, therefore, not justified in depriving plants of its beneficial influence. I am sure, and many of your readers will endorse the statement, that Strawberries this year made more growth in the six weeks following the first week in September than during the whole of the summer. This often happens after a hot, dry season. When plants are stored away so early, they are apt to get dry frequently, but if they are not wintered till the end of October, and are stored away when quite wet, they will rarely need looking to till they are required for forcing. They remain in an equable state of moisture through the winter.

Plants several years in the same pots.—The possibility of getting good crops of fruit from plants that have had no change of soil for several years has on several occasions been questioned in The Garden. Some years of experience have proved to my satisfaction that in quantity and quality, the produce given by old plants is quite equal to that given by young ones. Of course, they must be rightly managed; there must be some labour expended on them, but so there must on young plants. It happened some years ago that we had not the means of obtaining a sufficient number of young plants, and we were obliged to keep some of the old ones. These we found answered so well, that we did not trouble to get any great number of runners. The treatment given was as follows: Early in June the foliage was cut off, thus getting rid of red spider. It is noteworthy, that as soon as the old leaves are cut away new ones immediately begin to develop; whereas, when left on, the greater part of the summer passes before fresh foliage is made. As soon as each crown has two fairly developed leaves they are thinned out to one good crown to a pot, and they then get a top dressing of some kind. They are then placed on a bed of free, rather light, soil, and are not disturbed until September. During this time the roots push through the bottom of the pots, and this gives a great impetus to top growth. About the first week in September they are broken off, the roots that have been made in the soil are cleared away, and if there are any signs of mildew, they are dipped or well syringed with soft soap and sulphur. They then get a top-dressing of three parts soot and one part sand, the latter being added to set the soot and keep it from floating off when watered. This, being well watered in, binds firmly on to the surface, gives a fine colour to the foliage, and prevents the formation of Moss all through the forcing time. The destruction of the roots when the pots are disturbed would seem to be likely to be fraught with disastrous results, but if the plants are kept well moist for a week afterwards, they sustain no check. It is also curious that the breaking off of the roots at the bottom is immediately followed by the production of new ones from the crown, and as well as from the old roots composing the ball. In the course of a month the pots are again filled with new fibres, and the roots from the crown, which are much stronger than those produced by young plants, will have reached the bottom of the pots. Occasionally I have shifted some of these plants during July into 8-inch pots, and they then made specimens about like what old stools in the open air are when doing well. I have had plants of Sir C. Napier with more than a dozen good flower-spikes on them. Such plants will not do for early work, but they are good for bearing a heavy crop of late fruit, say, early in June. A friend of mine has adopted this system with a modification. Instead of letting the roots go through, he shakes them partly out in August, gives fresh drainage and a little new soil. This is the way I should recommend if any reader of The Garden wished to grow on the old plants, and this is the way to get the best rooted and strongest plants that can be grown. Such plants are more sure of fruiting than young ones—that at least is my experience. I have compared old plants with young ones both in respect to heaviness of crop and quality of berry, and I can conscientiously say that I have never found any difference. There need be no surprise that this should be the case; it does not matter what the age of the plant is if it has the requisite strength. I do not suppose that many readers of The Garden will care to grow on old plants, but if through circumstances they should be obliged to do so, they may rest assured as to the results if they will give them proper treatment. It will perhaps be said that it is quite as easy to get young plants as to grow on old ones. Those who find this to be the case, need not, of course, trouble about retaining old ones; but where there is any difficulty in procuring good strong runners, I would advise the best of the old plants to be kept.

Strawberries after fruiting.—One reason why plants collapse after having yielded one or two crops of fruit is that they do not get any particular attention after the fruit is gathered. The Strawberry probably bears a greater weight of fruit in proportion to its size than any other hardy fruit, and whilst this is ripening off there is a great strain on the plant. This is especially the case with large-berried kinds, and when very dry weather accompanies or immediately follows the ripening period. During the time that the fruit is swelling, a Strawberry plantation is a source of much interest; the eye of the grower is constantly upon it; but this supervision often ceases with the ripening off of the crop, and the plants frequently get no attention for a month or so. It is, however, just at that time that a little attention is much needed; a day's work would often save the plants for another year. In the first place, some of the old foliage should be cut off, and where there is a mass of crowns they should be thinned out to three or four. Then give a top-dressing of some kind, and a thorough soaking of water if the weather is dry. It is surprising what this does for the plants: the partial defoliation and thinning of the crowns give them a new lease of life, and by the end of the autumn they will have made seven or eight good substantial crowns, very different from the mass of more or less weakly ones that are often to be seen on old stools. Early in autumn a good dressing of soot is very beneficial, as it gives great substance to the foliage. J. C. B.

APPLES FOR PROFIT.

There never was a more encouraging time for making a start in Apple-tree planting for market than at present. It needs but a glance into our markets to convince the most sceptical that we can still get the highest price for home-grown Apples, no matter how many may be on sale of foreign growth. Thus we have the first three months of the Apple season without any rivals in which to dispose of our early free-bearing sorts of the Codlin type, and after that we must be prepared with sorts that will bear comparison with anything foreigners are likely to send. Some say we have too many orchards already, but let it be remembered that one-half of the orchards now in existence are worthless. Good fruit cannot be expected from trees prematurely old through neglect. No wonder that the produce of trees that ought to be grubbed up and burned is specked, worm-eaten, and unsaleable; yet Apples only need common-sense

culture. Blenheim Orange, Cox's Orange Pippin, Wellingtons, Ribston, Queenings, Russets, and a few others are sufficient for the largest orchards that are likely to be planted. I should like to see for once a large orchard of Blenheim Orange, a variety that always sells well. The expense of planting is not so great as many imagine, and the idea that a young orchard produces nothing for the first few years is wholly a mistake. Whether planted with standards or dwarfs, the land should be cultivated and manured, and such crops as Potatoes grown between the rows, but do not plant bush fruits; they are too exhausting and there is plenty of them already; do not crop close up to the trees; on the contrary, give them a clear space all round for their roots. Apple trees do not require a great deal of manure at planting time, *i.e.*, if the soil is rich enough to grow good vegetables, or Corn, but after planting the roots should be mulched. The mulching keeps them warm in winter, saves them from drought in summer, and provides food for the rootlets near the surface. On a large scale in the case of orchards laid down with Grass, the only way of supplying the roots with food is by grazing the orchard with sheep in summer, and winter dressing with farmyard manure. Every shoot must be fully exposed to light, and the bark must be painted with paraffin oil to free it from insects, Moss, and other parasites. If dwarf trees are adopted, let them have the soil entirely to themselves; do not choke them with bushes of any kind. J. G.

Books.

APPLES AND PEARS AS VINTAGE FRUITS.*

This handy little volume of some 250 pages has been published soon after the completion of the last part of the "Herefordshire Pomona." The Woolhope Naturalists' Field Club, at the head of which was the late Dr. Bull, spent nine years in getting up the "Pomona" with its 430 beautifully coloured plates, but, fully alive to the fact that the work was too expensive for the masses, the club determined upon publishing a selection of papers from it, with sections of fruit, at a price that should at once place it within the reach of every cider grower in the kingdom. This the society did not do one day too soon; the crowning work of the editor's life was the re-writing of the papers which he had selected, and the drawing with his own hand of the sections of fruits with which the book is illustrated. This statement alone should recommend the book, for the editor, a keen observer, spent many years of his life in the centre of the richest cider district in England; he also gained much useful information from the French during his visit to the Congress at Rouen in 1884, and the outcome is a mass of useful matter in a very convenient form. In these days of agricultural depression, when landlords and tenants alike are suffering, when the colonist, aided by brighter climes, is beating us out of our own markets, when even our own railway companies are dead against us, this carefully written book should be read by everyone engaged in the culture of the Apple, its scientific management and conversion into a beverage more wholesome than much of the wine now imported into this country. So thoroughly practical indeed are the short chapters on soils, manures, and general culture, that we have no hesitation in saying that this little volume may be perused with profit by every horticulturist who wishes to keep abreast of the times in the production of culinary and dessert fruit for the English market.

The first part of the work is divided into short chapters on the orchard and its products, *i.e.*, cider and perry, and a most interesting and instructive portion it is. Then follow chapters on the orchard generally, orchard trees, fruit management and fermentation, chapters which should be made prominent subjects in every rural elementary school and agricultural college, especially those in cider districts. Then we have a chapter on the orchard in its commercial aspect, no trifling matter when it is estimated that the produce of one county (Hereford), with its 27,000 acres, principally of Apples and Pears, is worth £127,000 per annum. A very important chapter in the "Pomona"—renovation of the orchard—is too lightly treated, as much may and must be done in this direction before growers can discuss with any degree of satisfaction or comfort our future orchard prospects. The writer's remarks under this head run as follows:—

English agriculturists have now to meet the competition of the world, and it is desirable on every account that they should enlarge their sphere of action. Instead of confining themselves so much to Corn and cattle as they have hitherto done, they should pay closer attention to the growth of other products which will command a constant and lucrative market in our own populous and wealthy towns. . . . . Happy in these times are they who, living in districts especially adapted to the growth of hardy fruits, can turn their efforts in this direction. Our orchards ought to supply economically and profitably the markets of our cities and towns with an abundance of Apples and Pears, and to be able to meet successfully, moreover, an active competition from the continent of Europe, from America, and even from Australia.

Herefordshire, Devonshire, and Somersetshire, and other districts capable of producing cider and perry of good quality have a peculiar advantage in the possession of a branch of agricultural industry that may be made very remunerative. It is one of the least likely to be interfered with by the fluctuations of ordinary trade, and has therefore, with proper care, only the seasons to contend with. The present state of our legislature is most favourable to its extension, since there are no longer any restrictions on its produce by taxation, nor yet on its sale direct from the orchards; whilst as regards foreign competition, there is no probability that the supply for our home consumption can be seriously interfered with for this, if for no other reason, that beverages which only contain so slight a proportion of alcohol are readily susceptible of re-fermentation caused by the constant shaking incident on conveyance from a distance.

Landlord and tenant are alike interested in the utmost development of our home industries. The greatest attention must be paid to the special products of every district. Great competition must be met by high cultivation, by economy, and by intelligent, persevering industry. The land must be managed, if not in the letter, yet in the economic spirit of John Stuart Mill, who pointed as an illustration to the Cabbage of the French proprietor, so carefully dug round, watered, and manured; so individualised, in short, as though the whole profit of the farm centred in that one single vegetable. By thus paying greater attention to minute details, the farm may become, what it ought to be in these days of competitive agriculture in both hemispheres, a duplicate of the garden on a large scale.

Turning to the editor's opinions upon pruning, we have (p. 30)—

The necessary pruning in the orchard is very apt either to be neglected altogether, or to be carried out in excess. In the one case the boughs grow matted together, and bear their fruit small in size and deficient in quality; or in the other, whole boughs are mercilessly lopped off close to the trunk, leaving those great round scars commonly called "owl's faces," to offend the eye of every good orchardist, since they show how deeply the trees have been injured. It would sometimes seem as if the want of fagots suggested "a turn at pruning," when the poor trees are mercilessly attacked, at the cost of their strength and vigour.

The trunk of a tree is fed by its branches, just as a river is fed by its tributaries. It is not nourished by the sap taken up by the roots from the soil until it has been acted upon by the atmosphere in the leaves; and thus its growth is downward from the foliage, and not upwards from the roots. Every branch of a tree has smaller branches of its own, and is in fact to them a tree. Now, supposing a branch to be condemned, instead of proceeding by capital punishment (which admits of no repentance except to the inflictor), the humane process is this. Select a branchlet which happens to grow in the most favourable direction, and at the point where it springs cut off the main branch obliquely in the direction of the growing branchlet, undercutting at first to prevent spalteiing, and prune the wound as much as possible into symmetry with the direction of the new leader. In another year or two serve the new leader in the same way, and the process may be repeated if requisite. The result is this. The growth of the original condemned branch is entirely stopped without its being itself killed, and as the trunk of the tree increases its size gets less in proportion, and may generally in a few years be moved entirely without injury or eyesore close to the stem; that is to say, when the proportionate size of the scar to the stem is such that it will heal perfectly in two or three summers.

Thoroughly at home as a microscopist, Dr. Bull's papers on fungoid growths, insect enemies, and diseases will be found alike useful to the farmer and the gardener. His remarks and quotations on gathering, storing, and managing ripe fruit may also be read by both with mutual advantage. To the owners of old orchards, in which nomenclature has been lost or muddled up with local or outlandish names, the latter part of the book, embracing 150 pages, will be found of immense value, as it not only contains faithful sections, by means of which the names of all leading varieties of Apples and Pears can be determined, but it also briefly gives the history, where known, the locality which suits them best, a minute description of the fruit, wood, and flowers, as well as a chemical analysis of the juice. Take, as an example, the Foxwhelp, which may be considered the king of Cider Apples:—

Density of fresh juice	1·068
Do. after 24 hours' exposure to air ..	1·070
100 parts by weight yielded of sugar ..	14·40
Tannin, mucilage, salt, &c.	8·50
Water	77 100

If space admitted, we might quote more or less from every page, but quite sufficient has been said to show that the owners and occupiers of the soil are indebted to the Woolhope Club and its late leader for a valuable book, which comes within their reach at an opportune time, and which should be read by all who wish to elevate our orchards to their proper commercial position. The type is bold and the paper good, and the work, upon the whole, is worthy of the editor of the "Herefordshire Pomona." W. C.

NOTES ON MARKET NURSERIES.

The speciality of Messrs. Drovers' nurseries at Fareham is flowers for cutting, and notably white flowers, with which house after house is packed until there is hardly space to get amongst the plants. Chrysanthemum blooms and white Camellias are just now magnificent, and every shoot is surmounted by great bunches of buds and blooms in various stages, that will keep up a supply for months. They are gathered every morning and sent to all parts of the kingdom by post or rail, as the case may be, and as only the blooms are picked, no wood being cut, the bushes soon attain a large size. They are planted out in a border all round the house, and there is in addition a large central bed. The house, which is low, is span-roofed, and exceedingly well adapted to the purpose. Gardenias are grown in several houses exactly similar to the Camellias, each bush being on a large hillock of the best peat, and they are really a sight worth looking at at any time of the year, but especially when covered with thousands of buds, for

* "The Apple and Pear as Vintage Fruits." By H. G Bull, M.D., &c. Hereford: Jakeman & Carver. 1886.

the picking is too closely followed up to allow of many fully expanded blooms being seen. The roofs of these houses are covered with Stephanotis, planted out, and from which flowers are procurable in one or other of the houses nearly the whole year round. These houses get copious drenchings of soft water; the latter feeds the Gardenias, and enables them to produce quantities of blooms of good substance and purity. Keeping such houses free from mealy bug is a heavy item of expenditure, several boys being employed almost continuously in sponging and brushing.

The Arum Lily house is a grand sight at certain times, 1000 pots being ranged in it as thickly as they can stand, and all containing good stocky plants that have been plunged in the open ground all summer. They keep very dwarf and sturdy in foliage, and throw up fine spikes. Five-inch and 6-inch pots are the sizes used, and the supply lasts from October until Easter, when they are cleared out and some other kind of plant introduced. The spikes of this Lily are always in request for church decoration, funeral wreaths and crosses, &c., and they last a long time in a cut state.

Double Primulas and winter-flowering Pelargoniums are both well grown, also Maiden-hair Ferns in countless numbers, the demand for this being an all-the-year-round one. Adiantum cuneatum is the kind grown most largely, being liked best by bouquetists; but the slender-leaved A. gracillimum is also used for special purposes.

Roses planted out, trained on wires like Vines, and grown in other ways, fill many houses. Gloire de Dijon, Maréchal Niel, Niphetos, and a few brilliant-coloured ones, good in the bud state, are produced in quantity, and most of the Tea sorts, such as Safrano, Marie Van Houtte, &c., are coming on in pots. Greenfly, so destructive to Roses, is kept in check by timely and constant light fumigations.

Christmas Roses in pots and boxes were plentiful, as were also Deutzias and other hardy material for spring flowering in cold houses.

All the rain-water that falls on the houses here is stored for use until required, by means of converting every alternate pathway into a cemented tank, and running all the surplus rain-water into them.

Kitchen Garden.

TOMATOES IN AMERICA.

Perhaps no fruit or vegetable shows the result of careful selection so much as the Tomato. Within the last few years it has made rapid advance towards perfection. Solidity, medium size, thinness of skin, perfect shape, and prolific bearing have been the standard aimed at, and has, I think, been attained. The best are Cardinal, deep red, perfectly round and smooth; Acme, pink, perfectly round, smooth and early; Beauty (Livingston's), an improved Acme; Perfection (Livingston's), red, quite round and smooth; this kind is exceedingly prolific, bearing medium-sized fruit, and is a really good market kind. Trophy is of good repute, but to my thinking does not come up to any of the others, except, perhaps, in flavour. The fruit is larger than that of any of the above-named (which are medium-sized). It is orange in colour, slightly flattened and lobed, and not such a heavy bearer, or so early as some. Last in my list comes the new Mikado, sent out last season by Mr. Peter Henderson, of New York, and Burpee, of Philadelphia—the latter under the name of Turner Hybrid. This is a new departure altogether, and, judging from our first year's results, not quite satisfactory. In growth, its Potato-leaf and vigorous habit are its distinctive features. Not only are the fruits large, but very ugly, nor do they ripen evenly or fully. In our patch of something like sixty plants, one only bore perfect fruit. These were red and large, though not so large as the uglier ones. But the great point was the quantity of fruit that one plant bore. I shall scarcely be believed when I state that I picked over half a bushel off one plant, which covered 4 square yards, though some others were even more gross. I did not neglect to save all seed of that plant I could find, and something else I did—I got a batch of nicely rooted cuttings, and it seems to me I could increase my stock to almost any extent in that way.

T. D. Hatfield.

VEGETABLE FORCING.

Hotbeds are useful at all times, as the bottom-heat which they afford is valuable for rooting cuttings, in growing plants which require heat at the root, and also for forcing vegetables. It is in the latter respect that they are in demand at this season, and with a good hotbed or two, vegetable forcing becomes a simple matter. Asparagus and Rhubarb especially are easily forced with the aid of a hotbed, and early Potatoes, Radishes, and such like grow freely on hotbeds in the early spring months. To ensure success, however, with any or all of these, a good bed is necessary, and as they cannot be re-made after being once planted, care should be taken that they are satisfactory at the beginning. When made up hurriedly or imperfectly, they generally heat violently for a short time; then the heat goes down and their usefulness ceases. When the produce is only half grown at this time, the decline of the heat causes it to fail, and the whole of the expense of making the hotbed as well as putting in the crops is lost. It is the danger of this occurring which should make everyone most careful in forming their hotbeds. The best hotbed materials are litter from the stables and leaves. Two parts of the former to one of the latter make a good mixture. The droppings may be shaken from the manure to form Mushroom beds, and the long material should be well mixed with the leaves. They may be thrown together roughly at first, but they should be turned daily for a week or more, and when finished the whole should be thoroughly well mixed together. It is in this the main part of a good hotbed resides, as a bed composed of hot manure alone soon cools down, while one made entirely of leaves fails to heat sufficiently; but a mixture of the two holds the heat for a long time and answers the purpose admirably. In making a hotbed up to last for any length of time, it cannot be too firmly put together. A loose heap never retains the heat more than a week or two, but a firm bed will keep warm for two or three months. The bed should always be made 1 foot or more wider all round than the frame which is placed on the top of it, and when the heat goes down the outside part should be taken away and a warm lining substituted. A temporary bed need not be more than 18 inches high in the front and 2 feet at the back; but a three or four months' bed should be 2 feet 6 inches in height at the front, and 4 feet in height at the back, and as building goes on, the whole must be trodden down frequently from bottom to top. Cambrian.

Two good Potatoes.—Among the numerous novelties sent out of late years there are few that will long be cultivated. Two noteworthy exceptions will, however, be found in Sutton's Seedling and Abundance. The former, which is of moderately strong growth, is very prolific, and the majority of the tubers are handsome enough for exhibition, while all are of excellent table quality. It belongs to the white kidney section; in shape not unlike a good Woodstock Kidney, only the skin is rougher, and some of the tubers tend to roundness. Abundance, a white round variety, grows strongly, and gives promise of being disease-resisting. It crops heavily, the tubers are rough-skinned and clean in appearance, or such as would sell readily, and no fault can be found with the quality. At Draycot Manor, near Chippenham, a considerable number of varieties, new and old, were tried this season, and among these Sutton's Seedling and Abundance stood out pre-eminently good.—W. I.

Autumn-sown Peas and Beans.—Although the custom of sowing Peas and Beans in autumn has of late fallen into disrepute, it has many things to recommend it. It is, I think, specially well suited for dry, poor soil, such as prevails largely on the south coast; under such circumstances both Peas and Beans get much more firmly rooted than they do in spring, and are able to defy a spell of dry weather should it set in early in the season. If not already done, this is a good time to sow, and the advantage of getting such work done in a comparatively slack time will be helpful in spring. The Early Mazagan and Long-pod Beans are very hardy, and are never more useful or appreciated than when got in early in the season. Of Peas there are many, both white and blue, that answer well for the purpose. Ringleader is a capital kind. One of the things in which old gardeners firmly believed was sowing early in winter, and, singular to say, in spite of the endless kinds sent out, we have not gained anything in point of earliness in the days when our forefathers depended principally on early sowing for their early gathering. In the flower garden I find sweet Peas sown now answer admirably; they get deeply rooted, and will be in full bloom from May throughout the entire season, provided the pods are kept picked off before they exhaust the plant by seed-bearing, as no plant can perform such double duty for any length of time. —J. G., *Hants.*

AN ENGLISH CELERY SHOW.

Many of the hardest workers and those whose work is of the most cheerless description are enthusiasts as regards some hobby. These are notably coal-miners and mill operatives, whose productions in the direction of the humbler varieties of fruit, flowers, and vegetables vie with the efforts of great gardeners. Especially is this so in the counties of Lancashire and Yorkshire. Fruit and vegetable growing there is universal. At one time Rhubarb was the plant which everyone grew. Then came Gooseberry culture, when big Gooseberries were not merely the autumnal production of newspaper paragraphists, but could be seen in dozens as big as Victoria Plums at shows. Afterwards came Cabbages and Cauliflowers, whose dimensions and weights would be regarded as fabulous did I name them. And now the rage is Celery-growing. Each of these hobbies has yet many followers, but fashion changes. With these there are flowers which receive a like attention. Pansies, Gladioli, and Asters appear to be the favourites just now, though Pelargoniums and Fuchsias are always popular.

In a Lancashire town, which shall be nameless, I recently saw the advertisement of a Celery show, and a unique advertisement it was. Projecting from the upper window of a public-house, called the "Shoulder of Mutton," was a flagstaff, upon which were hung a dozen copper kettles, and at the extreme end a big bunch of Celery. Nothing could be more suggestive, and it combined two eminent necessities in successful advertising—prominence and effectiveness. I learned that the show was to take place that evening; it was Saturday, and in due course I paid my twopence—which, by the way, was good for a pint of "drink" as I came out—to find the show in the long room of the house. Here was gathered together a remarkably good collection, not only of Celery, but of Potatoes and Pansies, of Cabbages and Cucumbers, of Fuchsias and fruit, vegetables and flowers. But the Celery was decidedly in the ascendant. Behind the winning lots of this latter edible were the copper kettles, or the britannia-metal teapots, the latter given as second prizes. The winning lot of untrimmed Celery weighed 14 lbs. 4¾ ozs., and the corresponding victor in the trimmed class 9 lbs 8¾ ozs. These weights will give some indication of the size, and from what I could see of the bunches, they were tender and beautifully white.

Nights and days had been spent in their culture; heaps of manure had been supplied to the ground around them, and doubtless during the week previous to the show, the grower had worked by day and sat up all night watching his plants against the designs of some unscrupulous opponent. It is no uncommon thing for Gooseberries and flowers to be watched day and night previous to a show, lest some evil befall that which it is hoped will secure the copper kettle, the height of the competitor's ambition. A Lancashire house is never complete without one of these utensils; and polished as only Lancashire women can polish—that is, with plenty of the stuff known as "elbow grease"—they are brilliant ornaments in the

kitchen, or "house," as it is usually called. Many of those to be seen in Lancashire houses have been won at such shows as this one. A young fellow feels impelled to win a kettle either before or after his wedding, in order to maintain his claim to manhood. But there is a reverse side to the shield. Held in public-houses promoted by publicans, they are a direct incentive to drinking, especially with the drink tickets. We were regarded as strange mortals indeed, because we did not use our privilege and "hev a soop." Some of the prize-winners were already, at the early hour on which we attended the show, far gone, and probably the kettles which they had won would be very expensive articles ere they got them safely home.—S. B., in *Country Gentleman*.

GARDEN DESTROYERS.

CLOUDS OF APHIDES.

The most singular thing about those described by G. B. Buckton (p. 502) is the lateness of their appearance. In East Anglia such swarms, so far as I can remember, have not appeared later than September. I think I alluded in The Garden, some years since, to a dense cloud of aphides that lasted three days. It came from the east, and was thought to have come from Germany. Several of the movements described by Mr. Buckton were observed, though in a less definite degree. But the chief feature of the living cloud was its density and its movement nearly, I believe, from east to west. It was also mainly migratory, very few of the aphides remaining behind after the mass had passed over.

So far as I am aware, no one has attempted to measure the area of such swarms, which must be, indeed, immense, as measured by their rate of progress and the time needed to sweep past a given point. Their speed, however, appears to vary greatly—now being whirled along by some inscrutable impulse, and anon hanging on sluggishly to the tail of the air-currents. In other words, no one can watch an aphides cloud for long, or feel the impact of their mass upon his face or hands, without realising that the myriads of insects have their active and passive moods; now using their wings to quicken their speed, and again folding them to be calmed into rest or floated on the wings of the moving air.

The most singular thing about these clouds of aphides is their erratic and intermittent character. Did the swarms come and go annually, they would be accepted as incidents of breeding, transportation, or change of climate just as easily explained as the migration of swallows or other birds. But it is just otherwise with these clouds of aphides. For years there are none, or none of any noticeable extent, and then they appear quite suddenly and unexpectedly; but however widely they spread they never seem to expand to anything like universality over the entire country, but seem to originate in and to be confined to local centres, however wide their circumferences may be. Have they, like the locust, found all before them fair as the garden of Eden, and left all behind bare as the barren sand? And has hunger and starvation in their rear forced them on to the wing? Possibly our entomologists may be able to instruct us on these points, or explain on some intelligent hypothesis those marvellous flights and swarms of flies which are among the most curious and interesting phenomena of Nature. D. T. F.

Mildew on Roses.—In The Garden of November 20 there is an article by Mr. Cornhill on Grapes in the open air, in which he recommends an application of sulphur and soft soap for mildew. I shall be obliged if Mr. Cornhill would inform me how much sulphur is required to the gallon of water, how dissolved, and if the water should be warm. My requirement would be for Roses in the open, which this season were badly mildewed, and in no way lessened by two applications of sulphide of sodium, so often recommended of late. Perhaps I allowed the mildew to get too far ahead.—Jacqueminot.

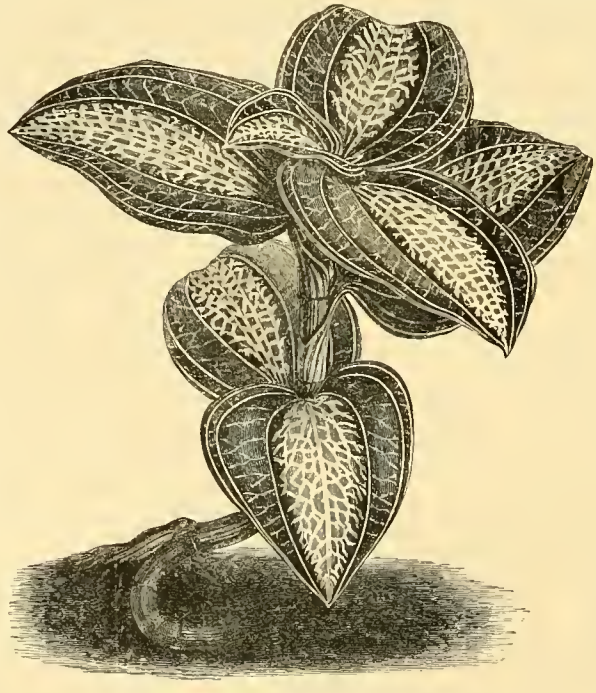
Bulb-destroying insects.—Kindly name the accompanying maggots, and tell us the best way to kill them. We find them round the base of our Hyacinthus candicans just lifted. Gladioli growing close to them they do not touch.—C. B. G.

*** The grubs now forwarded are those of a fly. The only means I can suggest of killing them, except lifting the plants and picking them off, is burying small slices of Turnips, Carrots, or Potatoes, with a small stick stuck into each to show where they are, near the plants. These traps should be examined every morning. Any insecticide applied in sufficient strength to be detrimental to the grubs would, I am afraid, injure the plants.—G. S. S.

ORCHIDS.

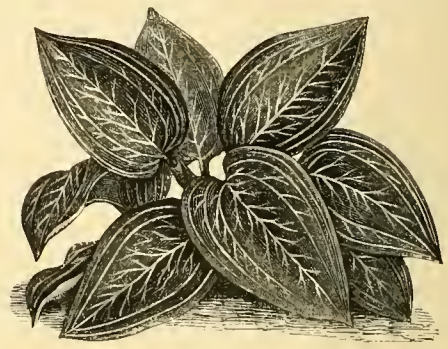
VARIEGATED ORCHIDS.

So much attention has been paid of late years by Orchid growers to showy flowering Orchids, that those with fine foliage have been overlooked, and yet the leaves of Anæctochiluses, Goodyeras, and Physuruses far surpass in beauty those of other variegated-leaved plants. In several gardens these plants, we are glad to see, are again receiving the attention which they deserve, and which they formerly received at the hands of Orchid growers. A few years ago we



Anæctochilus xanthophyllus (natural size).

cultivated very successfully considerable numbers of these plants. The Anæctochili are slow growers, and one need never expect to get large specimens of them. Nor are they naturally very long-lived. They are renewed from seeds from time to time, which they produce very freely, but their period of existence under cultivation may be much prolonged by frequently cutting them into pieces, by which means they are also increased in numbers. This cutting up likewise tends to check their propensity to bloom, which under cultivation too frequently has a disastrous result, inasmuch as the effort to produce flowers exhausts the plants, and in most instances no seed is perfected. We have cut these plants three times in one season, an operation which greatly increased our stock, and at the same time benefited the plants. The stem should be cut about half-way through, just



Goodyera Dawsoniana.

below the second joint; the cut should be covered with sharp sand and living Sphagnum Moss, when it will speedily throw out roots. At this stage the top should be taken off entirely, potted, and placed in a somewhat close atmosphere, and in about a week it will have become established. Soon after the top is removed the old plant or stool will push out one or more lateral shoots, which, in their turn, must be cut and treated in a similar manner. Anæctochili and their allies, the Goodyeras and Physuruses, require just about the same treatment, but of the three the Goodyeras are the most robust. They are frequently killed by too much heat and moisture, and by the total exclusion of external air, by being shut close in under bell-glasses. The temperature in which they thrive best varies from 70° to 75° in summer and from 60° to 65° in winter. The atmosphere should be well charged with moisture, and a fair amount of air should be admitted at all times; they must never be exposed to the sun's rays, but must be kept rather heavily shaded. We have known some of the East Indian Anæctochili to live (but not grow) through the winter in a temperature as low as 40°, but this practice we do not advise. We do not like covering these plants with bell-glasses, but prefer a shallow frame in which the pots may be plunged in living Sphagnum Moss. This frame should be covered with loose panes of glass, and thus more or less air may be admitted without suddenly drying the leaves. The soil for these plants should be a mixture of chopped Sphagnum Moss, small nodules of charcoal, a little fibrous peat, and some sharp silver sand, whilst the drainage must be kept exceptionally free.

Re-potting should be done early in February; by this we do not mean they will require much larger pots, but all the soil by which they have been surrounded throughout the winter must be carefully removed, and be replaced by clean drainage and fresh soil. Do not pot firmly, as these plants have thick, fleshy, woolly roots, and thrive best when these can easily penetrate the soil. The surface should be neatly covered with chopped, growing Sphagnum, which not only tends to keep the roots moist, but sets off the foliage to advantage. After growth has commenced, let them have a fair amount of moisture, and as the days lengthen the supply may be increased up to about the month of October, when

the quantity given must be considerably reduced until the re-potting season comes round, but at no season must water be entirely withheld.

There have been a goodly number of Anæctochili introduced during the last twenty-five years, more especially in the first half of that period, but many of these are no longer to be found in this country. Amongst those lost we fear are A. Ruckeri, Nevillianus, and Bulleni, which were introduced from Borneo by the Messrs. Low, of Clapton. The following are truly handsome, viz., xanthophyllus, concinnus, Petola, hieroglyphicus, intermedius, Roxburghi, Lowi, Dayi, and Lobbi, which differ more or less in the intensity of their marking, and various forms of setaceus, which latter obtains the name of "Wana Rajah," or "King of the Woods," in Ceylon, on account of the brilliant golden reticulations which cover the dark velvety bronze-green of the leaves.

Goodyeras much resemble the last-named family, of which the illustration of G. Dawsoniana, here given, serves to show. Other kinds are G. Veitchi and Dominii, both garden hybrids of great beauty; G. Rollissoni, a very handsome kind, blotched and striped with creamy-yellow on a dark velvety-green ground; and G. rubrovenia, the surface of the leaves of which are bronzy velvet striped with fiery red. Another section of this genus thrives admirably in the coolest house with the Odontoglossums, and consists of natives of Japan. The best of them are G. macrantha, having dark velvety-green leaves, streaked and netted with pale green, its variety, luteo-marginata, having an additional attraction, through its leaves being bordered with creamy yellow; and G. velutina, with velvety leaves of an intense green, with a broad metallic-white band along the centre.

Physuruses are for the most part plants with light green leaves and silvery markings and reticulations, and have the same habit of growth as the Anæctochili, the bronzy-green and gold foliage of which contrasts well with that of the Physurus. The most notable of this genus are P. argenteus, querciticolus, nobilis, pictus, and maculatus, the latter species being discovered by Cross on his first Cinchona expedition.

W. H. G.

Well-grown Phalænopsids.—The collection of Phalænopsids at Heaton House, Cheshunt, is equalled by very few and excelled by none in this country. The species in the collection are P. amabilis, grandiflora, Sanderiana, Esmeralda, Lowi, leucorrhoda, casta, violacea, Stuarti, cornu-cervi, rosea, and Luddemanniana, each being represented by numerous plants, and of such kinds as P. grandiflora and amabilis there are grand specimens bearing nine, ten, and thirteen leaves upwards of a foot in length and 7 inches across; quantities are throwing up flower-spikes innumerable, whilst some of the plants of grandiflora and amabilis have as many as sixty flowers on each plant fully expanded at the present time. It may be thought by some that these plants have been stimulated into an unnatural growth, and that during the winter they will melt away like snow before the sun. This, however, is not the case, as the plants are grown under cool treatment, not the cool system as applied to Odontoglossums, but upon a plan which supplies them with a continuous circulation of fresh air, which keeps the house in such a genial condition that I was surprised to find the thermometer standing so high as 70°, so cool and genial did the atmosphere feel. All the plants in this collection of Phalænopsids are without spot or blemish; they have bold, hard, rich green leaves, which are persistent; even the fickle, but beautiful P. Lowi cannot resist the seductive influence of the atmosphere, for it does not part with its leaves through the winter months. There are one or two lessons to be learnt from an inspection of Mr. Partington's Phalænopsids. The Phalænopsis house here is a lean-to (but the shape of the house we do not consider as being of great importance); a side stage extends all round the house, leaving the centre open, over which Phalænopsids are suspended in baskets. The side stage is covered with a layer of sand, which is kept damp. Over this and a few inches above it is an open lattice-work stage, upon which the plants are placed. They are in baskets filled with pieces of broken pots, with just the thinnest coating of Sphagnum upon the surface. The baskets are again set upon pots, with the mouth uppermost, and into and over these pots the roots extend in a marvellous manner. This system does not smother the roots with sour Moss, neither are they bleached and reduced to such an enfeebled state of health as to fail to keep the plant in a healthy condition, but are hard, firm, and wiry. The hot-water pipes are under the stages, and air is constantly admitted from the front, which has to pass over the pipes, and thus becomes heated before it rises amongst the plants. There is a marked absence of that moisture-laden atmosphere which is usually so characteristic of the houses in which Phalænopsids are grown, but yet there is sufficient moisture to prevent the current of air from absorbing it to the detriment of roots and leaves of the Phalænopsis. There is a total absence of metal and stone in this house, which, we believe, is too prevalent in most Orchid houses. The latticed stages are wood (the hot-water pipes are, of course, iron), and the floor of the open centre of the house is composed of a bed of loose, fine shingly gravel, kept moist, and from which there is always a gentle but imperceptible exhalation of vapours which is so coogenial to these plants. This produces no drip, and, together with the free admission of air, tempers the atmosphere, and renders it quite enjoyable both to plants and visitors. The temperature in which these plants have thus thriven is 60° at night and 65° to 70° during the day in winter, and 70° upwards during the summer months.

Odontoglossums at Cheshunt.—In Mr. Partington's garden at Heaton House, the cool system of growing Orchids is well carried out, and the robustness of the plants shows how beneficial a cool atmosphere and an abundance of air are to the majority of Odontoglossums. We were somewhat surprised to find the doors of these houses standing wide open on the last day of November. Under these conditions, Odontoglossum crispum and most others of the genus appear to grow and flower most profusely, the majority of the plants bearing branching spikes. For instance, one plant of O. crispum, growing in a 7-inch pot, is now bearing a tall spike having seven lateral branches, the whole forming a large and dense panicle of bloom, sixty flowers being expanded; another plant of the same species is bearing a fine five-branched panicle of its lovely blooms, and several other branching forms are not yet open. A specimen of a very fine variety has produced two spikes from one bulb, one being simple, the other having five branches, bearing in all thirty-two large flowers; another plant of the same species is bearing two unbranched spikes from one bulb and is carrying twenty-seven superb blooms. The robust health of these plants, and the numerous spikes of bloom they are just beginning to push up, give promise of a magnificent display throughout the winter. It may be supposed that these grand branching forms of O. crispum are the result of careful selection from established collections of Orchids; this, however, is not the case; they have been bought as imported plants, some of them being from lots which were sold three or four years ago, in bags of twenty-five together. This fact goes to prove that the success obtained is due to the rational conditions under which they have been grown.

Saccolabium giganteum.—Most of the members of this genus produce their flowers during the summer months, but this species and its near ally, S. violaceum, always produce their long racemes of waxy white and violet-purple flowers during winter. We recently saw a fine display of it at Selborne, Streatham.

Anæctochilus Lowi.—This beautiful variegated leaved Orchid is just now thriving well with Mr. Laing at Forest Hill, where it is kept under bell-glasses, but with air always admitted. We have also seen it in other gardens growing vigorously amongst other East Indian Orchids, exposed to the ordinary atmosphere of the house.

NOTES OF THE WEEK.

National Auricula and Carnation and Picotee Societies.—The annual general meeting of these societies will be held in the East Crush room of the Albert Hall as soon after 12 o'clock as possible, on Tuesday next, December 7. The business of the meeting will be the election of officers and committee, receiving the secretary's and treasurer's report, the election of judges for the ensuing year, and other necessary business.

Plumbago rosea.—This plant is again coming into favour after having been subjected to some years of neglect. It should be grown from cuttings every season, as young plants produce longer racemes and brighter flowers than old plants. Its rosy red blossoms are now making a fine display in many warm greenhouses round London.

Chrysanthemum Mrs. Norman Davis.—We have received from Mr. Mizen, of Mitcham, flowers of this variety, which is a sport from the well-known Princess of Teck; the colour is rich golden yellow, and the petals are beautifully incurved. Judging by the beauty and freshness of the flowers just sent to us, it would appear to be a late bloomer, and, if so, an acquisition.

Winter-flowering Flax.—As a brilliant, clear yellow this Flax (Linum trigynum) stands unequalled as a stove or warm greenhouse plant during winter. It may be grown into good-sized plants in one season from cuttings, but it should be kept in an intermediate house during summer, and freely syringed, in order to keep down red spider, its greatest enemy. We saw it in great beauty recently in the Forest Hill Nursery.

Celsia cretica.—I send herewith a piece of a plant of Celsia cretica, a self-sown seedling. You will perceive that the habit of flowering is quite different from that of the ordinary form—at least, as far as I have ever seen it. It generally runs up in a long spike without any foliage, while in this there are leaves amongst the flowers all the way up the spike. There is no difference in the flowers.—Delta.

The winter Cherry.—This fine old-fashioned annual is now in great beauty in various rock gardens in the suburbs of London. The calyx, which increases in size after the flowers have fallen to that of a small orange, is rich orange-scarlet, a colour which renders this plant, when seen in a mass, very conspicuous. No more interesting plant can be grown for outdoor decoration at this season than this winter Cherry, the Physalis Alkekengi of botanists.

Yucca gloriosa.—We have received from a correspondent, who does not give his name, a beautiful photograph of a Yucca. The stately grace and the beauty of form of the flower of these plants are not surpassed among hardy plants, and it is only the fact that we have engraved this Yucca so often that makes us hesitate to reproduce this photograph also. It is a good thing for our gardens that we are able in our cool country, owing to our mild winters, to grow such fine semi-tropical forms of plants.

Royal Botanic Society.—The following are the dates of the exhibitions of this society during 1887: Spring shows—Wednesdays, March 23, April 20. Summer shows—Wednesdays, May 18, June 15. Evening fête (probable date)—Wednesday, July 6. Exhibition of American plants, by Mr. Anthony Waterer, Knap Hill, Surrey—daily during June. Promenades—Every Wednesday from May 4 to July 27, excepting May 18 and June 15.

Dahlia imperialis.—Some years ago for a brief period this Dahlia attracted a considerable amount of attention, but it did not long retain its popularity, owing partially doubtless to the fact that a lofty structure is required for its full development, and also to the circumstance that single Dahlias were at that time regarded only as fit for the rubbish heap. This Dahlia needs a structure from 12 feet to 15 feet high, or even more, and where this can be had there are few more imposing subjects for flowering during the autumn and early winter months, especially if the temperature be an intermediate one. In such a house the blooms become better developed than in a green-

house. This Dahlia flowers freely every year in the Palm house at Kew. Out of doors is its proper position during the summer months; indeed, plants so treated are more sturdy than when grown wholly under glass. For the introduction of this Dahlia we are indebted to M. Roezl, who found it in Mexico about twenty-five years ago.—T.

London parks and gardens.—Next session a Bill will be introduced into Parliament having for its object the transfer of several public parks and gardens in London from the department of Works and Public Buildings to the Metropolitan Board of Works. The parks and gardens which will be affected by this arrangement are the following: Battersea Park, Victoria Park, Kennington Park, Bethnal Green Museum Garden, and the Chelsea and Westminster Embankment Gardens. It is proposed that no material alteration shall be effected in regard to the management as far as the officers and servants attached thereto are concerned.

Outdoor Chrysanthemums.—Herewith I send a few spikes of Chrysanthemums gathered from plants growing out of doors and trained on a south wall. Each plant is bearing about twelve spikes such as those sent. Such flowers show what grand subjects Chrysanthemums are for outdoor as well as for indoor decoration.—E. Molyneux, *Swanmore Park, Bishop's Waltham.*

*** Grand flowers in every respect, and that, too, in the last week in November.—Ed.

Open-air flowers and leaves.—Herewith I send you a collection of seedling Chrysanthemums and green leafage from the open borders. This has been, so far as December 1, an ideal season for Chrysanthemums of all kinds, but these seedlings are so dwarf and sturdy, so hardy and withal so distinct and variable, that I consider they have before them quite a future as open-air flowers. They bloom so profusely and in such quick succession, that one can cut and come again for one's flower baskets. For leafage we use Ivy and Smilax latifolia or S. aspera, tamnoides or mauritanica, shoots of Veronica Andersoni (also in flower), Garrya, true Laurel, Acanthus, but darker, fresher, and more endurable than all, Ruscus racemosus and common Butcher's Broom. This last (R. aculeatus) is a grand plant for open woods, and its fresh growths cut long endure fresh for weeks indoors.—F. W. B.

*** A most interesting collection, bright and varied in colour, and a good illustration of the effect produced by the fine autumn with which we have been favoured. In the neighbourhood of London, too, Chrysanthemums are still in great beauty.—Ed.

THE POTATO TERCENTENARY EXHIBITION AND CONFERENCE.

December 1 to 4.

A celebration of the introduction of the Potato into England 300 years ago is being held in St. Stephen's Hall, Broad Sanctuary, Westminster. It consists of an exhibition of the Potato, of the products obtained from it, of appliances for cooking it, of books relating to it—in short, everything that could have the remotest connection with the Potato has been brought together on this occasion. The object of the conference appears to be the discussion of the origin, history, culture, uses, and diseases of the Potato, and the following list of papers read and discussed shows that the Potato has been well considered, whatever may be the practical outcome of it all. The first of the papers was the—

"Historic consideration of the question whence came the Potato to England," by W. S. Mitchell, M.A. Mr. W. H. Pollock's paper was "Drake's Expedition of 1586." The "Cultivation by the Incas and other Andean Nations" was dealt with by Mr. Clement R. Markham. "The Introduction of the Potato into France" was the subject of a paper by M. Henry L. de Vilmorin, of Paris. "Distinct Wild Species of the Potato as at present recognised" was dealt with by Mr. J. G. Baker, of Kew. Other subjects were "The Potato Disease;" "The Production of Varieties by Cultivation," by Dr. Masters; "Methods for Using Partly Diseased Potatoes," "Methods for Storing and Preserving Potatoes," and lastly, a conference of cultivators on rates of transit of Potatoes, a paper respecting which was read by Professor Hunter.

The botany of the Potato is well represented by illustrations and dried specimens. By far the most important is the exhibit from Mr. Baker, F.R.S., who, as is well known, has so long identified himself with the Potato question. He exhibits beautifully coloured illustrations of nearly all the tuber-bearing Solanums, of which there are five distinct species, while there are no fewer than sixteen geographical forms of S. tuberosum. The latter is, without doubt, the origin of the garden Potato, and a most variable plant it is. The two species most concerned in the Potato experiments are S. tuberosum and S. Maglia, and these are admirably portrayed in these drawings, the distinguishing characters of each being visible at once. The illustration of S. Maglia is from Sabine's drawing, and besides illustrating the foliage and flowers, the plate shows a tuber about the size of a marble, drawn from a wild specimen, and a larger tuber, the size of a hen's egg, produced, after having been cultivated one season. The great difference in the way of size between these two tubers, after having been grown one year, shows plainly what may be effected by means of cultivation.

The geographical distribution of the Potato is indicated by numerous charts and maps, including several quaint Elizabethan prints and an enlarged map of the western coast of South America. The exact locality of the wild Solanum tuberosum is indicated plainly, thus enabling the audience to follow the lecturer when dealing with the native countries of the tuberous Solanums.

Potato literature is very profuse in the exhibition, there being a large number of old works in which the edible Potato is figured and described. Those interested in old garden books may revel in rare copies of Gerard, Parkinson, L'Obel, Dodonæus, together with the life histories of Drake and Raleigh, both being intimately connected with the introduction of the Potato into this country. The exhibition, on the whole, is interesting, and should any practical result arise from the discussion of the various Potato topics at the conference of botanists, historians, and Potato raisers and growers, the tercentenary will not have been celebrated to no purpose.

The competition was on a very limited scale as regards the classes, there being but two—the first for a collection of not less than six, and not exceeding twelve, varieties; the second, for the best new seedling Potato. Three prizes, consisting of a gold, silver, and bronze medal, were awarded in the first class; while there was but one prize (also a medal) awarded in the class for new sorts. There were about thirty collections of twelve dishes shown, and these made a large display. On the whole, the quality of the tubers was fairly good, but it was evident that December is not the most favourable time for a Potato exhibition, as the tubers lack that fresh, plump appearance they have in September. The judges had no difficulty in awarding the gold medal, but it was a difficult matter to award the other prizes, and so many collections were nearly of equal merit. The gold medal for the best collection of twenty-four dishes was won by Mr. E. Chopping, Milton, Sittingbourne. This was an excellent collection in every way, the tubers being uniform in size, large, of good shape, and clean. The sorts were Adirondack, Schoolmaster, Reading Russet, The Belle, Purple Perfection, The Colonel, Chancellor, White Elephant, Reading Ruby, Sutton's Abundance, Village Blacksmith, and Rufus. The silver medal was won by Mr. J. H. Diver, Pitshill, Petworth, who also showed a capital collection, the sorts Washington Hero, Mr. Bresee, Vicar of Laleham, Reading Giant, The Dean, Purple Edgecote, and Snowflake being the finest dishes. The bronze medal was taken by Mr. W. Kerr, Dargaval, Dumfries, a well-known Potato grower. His best dishes were of Chancellor, Mammoth Pearl, Adirondack, Eclipse, Queen of the Valley, Mr. Bresee, Schoolmaster, Blacksmith, White Elephant. The other exhibitors in this class came from all parts, and prominent amongst them was Mr. Fidler, of Reading, who had three or four collections of twelve dishes; and Mr. Watkins, of Hereford, who showed no fewer than 150 dishes, not for competition.

There were but few new seedlings exhibited, and the judges in awarding the prize put the tubers to the cooking test, the result being that the medal was awarded to Mr. J. Lye, Cliffe Hall, Market Lavington, for his seedling named Clipper. This is a large, handsome, white, round tuber, considered by the judges to be of first-rate table quality. Amongst other new sorts, Messrs. Carter, High Holborn, showed their new Liputian Potato, a cross between Ashtop Fluke and Champion. Messrs. Vilmorin, of Paris, sent about a dozen French sorts of Potatoes including some sprouting tubers ready for forcing. Messrs. Hooper, Covent Garden, had a large collection of Potatoes, but the other great trade growers which usually show extensive collections were conspicuous by their absence.

OBITUARY.

CHARLES GREEN.

Many will learn with regret of the death of Mr. Charles Green, which occurred recently at his residence at Reigate. Few men of the present day possessed such an extensive knowledge of plants as Charles Green, and his love for all kinds of plants, especially those out of the ordinary run, was only equalled by his skill in growing them. For upwards of thirty years Mr. Green has been known in connection with garden botany. He was first gardener to the late Mr. Borrer, at Henfield, a prominent botanist at that time, whose garden contained one of the finest collections of plants, particularly of hardy perennials, then existent. Subsequently, Mr. Green had the charge of that famous garden at Hillfield, Reigate, in which the late Mr. Wilson Saunders had perhaps the most extensive botanical collection that has yet been seen in a private garden. Until within the last few years Mr. Green had charge of Sir George Macleay's garden at Pendell Court, Bletchingley, which also contains one of the richest private collections of plants in Europe. Unassuming in his manner, ever ready to impart information about plants, he won respect from everyone. His death is a real loss to horticulture, for it may truly be said that he was the means of preserving many a plant that would have been cast aside in accordance with the vagaries of fashion, and of rescuing other fine plants from the oblivion into which they had fallen. The records of the Royal Horticultural Society contain evidence of this, for many are the plants which Mr. Green used to bring to the meetings from Hillfield and Pendell Court.

The death is recorded of M. Auguste Van Geert, one of the oldest and best-known nurserymen in Belgium. For many years he has been a prominent figure in all that concerned Belgian horticulture, and was as well known in this country as our own nurserymen. He began to learn his business in the Chelsea nursery of Messrs. Knight and Perry (now Messrs. Veitch). He was sixty-eight years of age, but had retired from business for some years.

QUESTION.

5532.—**Romneya Coulteri.**—Would anyone kindly advise me how to grow Romneya Coulteri (Tree Poppy)? I have two plants in 5-inch pots in a cool house. They are certainly making some fine young shoots, but the leaves drop off the old shoots and the plants look unhappy. I have a very warm wall and a mild climate. Should I plant them out or plunge them in a cold frame? Iris stylosa, Gentiana acaulis, Primroses and Hellebores have been in bloom here for the last six weeks. Hepatica buds are showing colour.—C. O. Miles, *Sunnyhill, Shirehampton.*

Secateur (*G. T.*) is the proper way of spelling this word.

Cox's Orange Pippin is said to be realising 9s. per bushel in Covent Garden Market, and the supply of it is insufficient for the demand.

Names of plants.—*C. Dalby.*—1, Myrsiphyllum asparagoides; 2, Casuarina quadrivalvis; 3, Santolina incana.——*J. F. H.*—Common Spindle tree (Euonymus europæus).——*H. D.*—Scutellaria Hadweni.——*J. R.*—1, Blechnum cognatum; 2, Lastrea aristata; 3, Libonia floribunda; 4, Epiphyllum truncatum.——*R. Davies.*—Possibly the plant you send is an Armeria, but it is difficult to name accurately without further material. Send when it flowers next year. We thank you for the hint you give.——*Alpha, Rotherham.*—1, Davallia solida; 2, Lastrea glabella; 3, a form of Athyrium Filix-fœmina; 4, Asplenium bulbiferum.

Names of fruits.—*C. Earl.*—2, Beurré Bosc.——*Kidderminster.*—1, Beurré Clairgeau; 2, Madame Eliza; 3, Comte de Flandre.—*D. C. F.*—Numbers all detached from the fruits and mixed together, so that we cannot tell which is which. This is due to careless packing.—Others next week.

WOODS & FORESTS.

HOW TIMBER IS VALUED.

The note in last week's *Woods and Forests*, from "The Forester on the Duncombe Park Estate," is not sufficently explicit. I am prepared to admit that if his other expenses connected with the disposal of his Larch are as low as his felling price, viz., less than one farthing per foot, his profits may be larger in his neighbourhood than I estimated was the case, for I should think a lower, if as low a figure is not paid anywhere else in England. Your correspondent's frankness in these matters is, however, more apparent than real. There is much Larch in the neighbourhood of Helmsley, whoever it belongs to. Extensive lots of the same have been advertised publicly and by private circular and been sold, and the same has afterwards been delivered in South Yorkshire from one timber merchant to another, to sell again, at 1s. per foot, and who have re-delivered it at collieries near here by wagon or rail for 14d. or 15d. per foot—about the very highest figure given hereabouts for eighteen months back or more by the consumer. Now "The Forester on the Duncombe Park Estate" does not dispute the cost of transport from Helmsley to South Yorkshire by rail given by me, viz , 5d. to 6d. per foot, nor the cost of transport to railway stations at his end, both of which he knows as well or better than I do, although he only "hopes the figures I give" on that point "are reliable," and your readers may therefore reckon for themselves what the vendor gets for his Larch in the wood. When you take eightpence or ninepence out of a shilling, the remainder is threepence or fourpence, I presume. How, under these circumstances, the Duncombe Park prices for Larch have "not been anything like the ridiculously low price per foot I named," I leave the Duncombe Park forester to explain. It occurs to me that if the price had been much more than what I said it was, he would have told us the exact figure and not have left us to guess from his vague negatives. This is what I call going into "details;" let your correspondent follow suit if he can. I beg to correct an error of mine the week before last in reference to the lot of Larch which was being delivered here lately, as I understood, from near Helmsley, at 1s. per foot. This particular lot did not come from there, but from the neighbourhood of Scarborough, some 40 miles further north still, thus bringing the price still lower to the vendor in the wood than I stated. It should be known that the Larch growers in North Yorkshire depend largely for their market on South Yorkshire; hence, I suppose the keen cutting in prices amongst them. I may add, too, that under similar conditions vendors sometimes allow very ample measure when large lots are purchased, as well as discount, in which case the prices and quantities given can only be considered as nominal. In conclusion, it may interest "The Forester at Duncombe Park" to learn that two large purchasers, at least, that he deals with, from the neighbourhood of Huddersfield and Doncaster, dispose of his timber round here, and I know what price they deliver it at, so that by reckoning back to the wood I need not be far wrong as to the vendor's price. Y.

Are squirrels injurious?—The squirrel is one of the liveliest little animals we have; whether seen leaping from branch to branch, or on the ground, he is always engaging. It is said that this little animal lays up store for winter. I doubt this; though he may hoard up a few Nuts or Acorns, that can hardly be called a provision for winter, for, if he had nothing else to depend upon, he would soon fall short. By instinct, however, he inhabits woods that afford him ample supply in winter. The seed in the Fir cones are his favourite food, and in summer the young shoots of the same kind of trees, especially the Spruce Firs; and frequently much damage is done to the trees by losing their tops by these nimble animals. As the summer advances the shoots of trees get too hard for the squirrels: they then visit the orchard and garden in search of food. Their thefts in the former may be looked over, except there are Nut bushes, but not in the latter; for Apricots, that have escaped the frost, the grub, and decay at stoning-time, are too valuable to be carried over the wall to be eaten on the top of an adjoining tree; but the mischief does not end here, for the net that preserves Cherries from blackbirds and thrushes is of little consequence to the squirrel's sharp teeth; and, if not protected in time by trap or gun, there will be nothing left of a fruitful crop except stalks and Cherry stones. In justice, however, to the squirrel, I ought to mention that those misdeeds of his only happen when he is driven by necessity from the woods; and, except at nutting-time, he seldom approaches the garden; but the damage he does then is incalculable.—G.

PRICE OF TIMBER AND BARK ALLOWANCE.

I have been interested in "W. B. H.'s" notes upon timber measuring, but I do not clearly understand what he means when speaking of allowance for bark by saying that he was not aware that any allowance was made on any of the hard woods except Oak. If he really means that in the district from which he writes the merchant buys "bark and all," that is, takes such as Ash and Beech at the gross quarter girth without any deduction, it only shows how customs on matters of this sort vary in different parts of the country. Such a thing here, so far as I know, has never occurred, or has ever been contemplated. Wherever timber is felled with the bark upon it a proportionate allowance according to the kind is always made.

As a general rule, an inch deduction from each foot of quarter girth is what is taken, and this is the basis upon which the railway companies buy their round timber. Too strictly adhered to, however, such a deduction is unfair, as it is obvious that between large, rough-barked Elms and thin and smooth-barked Ash or Beech there is a wide difference. When the bark is allowed off each individual item as it is taken down, there is some difficulty in adjusting the figures to a nicety. A much better plan, and one which I have followed when possible, is to take the gross measurement upon the bark, and then deduct a certain percentage from the total number of cubic feet. It is not an easy matter to fix upon what this percentage on each kind of timber should be without taking into account the size of it and the character of its bark. Ash, for instance, would differ greatly. I may say, however, that on the average the following will be fair allowances: Oak, winter cut, with bark on 15 per cent., Elm 15 per cent., Poplar 15 per cent, Beech 10 to 12 per cent., small Ash 8 to 10 per cent., large, rough-barked Ash 15 per cent., and other woods in proportion, according to the nature of their bark.

With regard to the question of prices, I think it is a great pity that such statements as that to which "W. B. H." refers about the price of Ash in Sussex should be put forth. I happen to know a little of what Ash is worth in Sussex, as well as here in Wiltshire, and it cannot but be embarrassing to foresters who are doing their best for their employers to be told that such and such prices are obtained on such and such estates, when everybody who understands the business knows perfectly well that such a difference is impossible. I do not deny that now and again a merchant may secure a lot at a lower figure than usual when the sellers are not well up in the market value, but it is scarcely likely the converse will occur, and that the merchants who have values at their fingers' ends will be caught napping to the extent of 40 or 50 per cent. This must be the explanation if the prices talked about are really obtained, but I will at once say that they are not. A wheelwright who has the work of the estate to do, or a tradesman who has a chance of making it up in some other way, may possibly give a long price for a few trees, but it is quite certain that merchants will not give any such price as 3s. 6d. per foot, for the simple reason that they cannot. From what I can glean of "W. B. H.'s" figures, the values of timber with him are much the same as they are here, save and except that we allow for bark, whilst it appears he does not. In Sussex good Ash may be 20 per cent. higher, but certainly not more, and much of this difference may be accounted for by the greater part of the wood which grows in the plantations there with the Oak being tough and fit for cleaving, and therefore intrinsically worth more. D. J. Y.

TRUNK V. LIMB.

This is what the controversy, "To thin or not to thio," virtually resolves itself into, viz., thin if you wish to grow limbs; do not thin if you wish to grow timber. Of course, everyone must follow his own judgment, but to the ordinary mind it would appear more reasonable to grow that which there is some prospect of selling when it is grown. It is all very well to argue that the greater the leaf surface the greater the woody tissue deposited; but if it turns out in the end that the extra wood so grown is of little or no value, and seriously injures the parent stem, where is the advantage? It has been estimated that in the case of an ordinary isolated tree only a fourth of its bulk or weight is really trunk or first-class timber. This, of course, cannot mean that only a fourth of all that is large enough to be measured is of the first class, but includes, without doubt, the smaller branches and leaves. In practical calculation it is hardly fair to include the leaves and very small branches, but, at the same time, it cannot be denied that it is a great waste of Nature's energies to produce growth which is of little or no value when good timber may be raised instead. Leaving this, however, for the present, and only looking at the proportions of what is really wood, it will not be wrong to say that, in the ordinary tree which has been allowed free lateral development, not more than one-half will be really the best class timber and free from knots. Take an instance of a tree which, everything measured down to the smallest branch, contains 100 feet. Not more than 50 feet will be first-class timber; 25 feet to 30 feet will be top and limbs, and the remaining 20 feet or 25 feet too small for anything but firewood. On the other hand, we get a tree which, owing to having grown closely, has put on no lateral branches, and consequently has had less leaf-surface and only grows to 80 feet in the same time. Out of this 80 feet 70 feet is first-class timber, and the remaining 10 feet of very little use but for the fire. Suppose this to be a Beech, at 1s. per foot. In the first case we get £2 10s. for the first-class wood, and say a third the price for the 30 feet of top or limbs, viz., 10s. more. This makes £3 as against £3 10s. for the closely-grown tree, outside the very important matter of growing twice as many upon the same space of ground. It will be seen that on this calculation 20 per cent. has been allowed for the disadvantage the closely-grown tree has been placed in through not being able to throw out lateral branches, but in practice I do not think this would be so much.

I do not see how such logic as this can be argued away, as even if the closely-grown tree only put on 50 feet, whilst the isolated or thinly-planted one reached 100 feet, the balance would still be in favour of close-growing, assuming two trees to occupy the space of one. One wishes that for the time being the advocates of thin planting and pruning could be turned into merchants, or connected with the various businesses where timber has to be cut up and used. I venture to say that he would return to his duties a sadder and a wiser man, and very little would be heard of greater deposition of woody tissue from more extended leaf-surface. The theoretical must give way to the practical, and this is another instance of it.

D. J. Y.

Thinning plantations.—In thinning woods care should be taken to mark all the inferior, unhealthy, or badly-shaped trees that are likely to interfere with the full development of the better ones that are intended to stand permanently. In cutting young plantations for the first time, great care should be taken to use only good cutting tools and to finish off the work well. In thinning screen plantations the workman must, to a great extent, be guided by the depth or thickness of the belt. When it is narrow the removal of any considerable number of trees would mar its effect; but when its extent will permit of such treatment, the best way to secure a perma-

nent screen is to keep the front trees well thinned out from the commencement, so as to allow them to branch low. By such means also a gradual increase in the height of the trees from the front line to the centre is secured, as those in the interior, from being more crowded, are the more rapidly drawn up.—B.

DRAINING LAND FOR TREES.

The thorough and efficient drainage of land takes, or rather should take, precedence of all other estate improvements, and if the work is well done and conducted with skill and judgment, the capital spent on such work could not be better invested. On the other hand, should the drains prove defective from whatever cause, the capital spent will be merely thrown away.

In draining stiff clay land we have always derived the most satisfactory results by covering the pipes with about 12 inches in depth of small stones. These should be put into the drain carefully, and nicely packed and levelled on the top; then a tough surface sod, or Heather scraw, when it can be got conveniently, should be laid on the top of the stones, with the Heather side undermost, and the work finished by filling up the drains with soil. This makes a very efficient lasting drain, but in cases where stones cannot be had the drains should be filled up with soil of a loose open texture, by which means the surface water will be absorbed and get away, which is the principal point to be aimed at in thorough drainage. When the drains are filled with stiff clay the surface water is thereby prevented from percolating and passing through the adhesive substance and reaching the pipes, so that I have seen surface water lying in pools in hollow places right on the top of such drains, which was only removed by gradual evaporation. Such drains may, however, be used where it is only necessary to tap a spring and simply run off the water.

In the formation of drains in the vicinity of trees in the park or on the lawn, socket-pipes should be used opposite the trees, and the connections carefully filled with cement, in order to prevent, as far as possible, roots from entering and choking the pipes. This, however, does not always answer that end, as I have seen drains so constructed with great care become completely choked up by the roots, so that when the latter were pulled out of the pipes, they presented the appearance of thick ropes the exact size of the interior of the pipe. When once a root penetrates a pipe (which I cannot say I have ever been able altogether to prevent it from so doing), although it is only about as thick as a common thread, yet such a root will throw off fresh branches so rapidly, that the drain will soon become useless. It is sometimes necessary to build a tank here and there to catch mud and sediment. These should be occasionally examined and cleaned out, which will aid in keeping the drains clean and in proper working order, especially in cases where the water is impregnated with oxide of iron, which tends to close up the pipes if not removed, rendering them unworkable. The outlet of the leader drains should be built with stones or brick and lime mortar, and a brander fitted on the same to prevent rabbits from making burrows and destroying the drain. These should all be numbered, and a map drawn out indicating all the leaders and branches belonging to the same, and the positions occupied by the principal trees in the grounds marked by a small circle, thus O, and their names added. The distance between the trees and nearest drains in their vicinity should be measured and recorded on the map, so that when anything goes wrong with the drains, their position can be found at once without trouble or expense, and the defective drain opened at the exact spot, and the necessary repairs of whatever nature carried out. J. B. W.

Timber measuring.—"Young Forester" cannot perceive how the real contents of a tree or piece of timber 12 feet long and 19 inches the quarter-girth can contain 38¼ cubic feet. The problem is one of the simplest in mensuration. Should we measure this piece of timber as the frustrum of a cone, the operation would be somewhat elaborate, but if taken as a cylinder, 12 feet long and 76 inches in circumference, then the computation is simple and easy. The area of a circle whose circumference is 1 is ·0795. Now the square of 76 inches is=5776. And these figures, multiplied by the decimal ·0795, gives 459·192, and this multiplied by the length (12 feet), and the product divided by 144, the number of square inches in a square foot, gives 38·266, or a little over 38¼ cubic feet.

—A. P.

THE FUTURE OF SCOTCH FORESTS.

In the report which followed the visit of the inspector of French forests to this country, M. Boppe says: We venture to predict a great and prosperous future for the Scotch forests. It does not need that one should be a very great prophet to predict this for a country where the Oak and Beech, the Scotch Fir and Larch, flourish with equal vigour, and where the Abies Douglasi, Abies nobilis, and Abies Menziesi, the Sequoia, and the Cedar form mighty trees, in company with the Araucaria and various exotic shrubs, which only languish miserably under the climate of Paris. We would fain add a word of advice, for the moment appears to us a propitious one for deciding on the future welfare of the forests, which, owing to the rapidly increasing value of timber, runs great risk of being compromised. Ordinary Fir timber now fetches 8d. per cubic foot. Larch is worth nearly double that amount. We ourselves visited a forest of Scotch Fir which, at this rate, would be worth £120 an acre, and another of Larch worth considerably more; whilst a third forest of 1600 acres, composed of Scotch Fir, was purchased a few years ago for £52,000, or only about £30 an acre. The plantations on the Culbin Sands, near Forres, would readily find buyers at £50 an acre at the age of forty-five to fifty years. The very day we were at Grantown, the agent for the Strathspey Forest concluded a bargain to furnish Birchwood to the amount of £2000. All these figures are fraught with extreme significance for the future, and the large forest owners of Scotland will do well to pause before allowing their forests to be "overworked." No doubt, people are often frightened by the long names and big words they find in treatises on scientific forest management, but they may very well neglect the text if only they will adopt some of the principles which they contain. Let the owner of a forest, after having made a careful and detailed inspection of it, divide it off into blocks or compartments so arranged that they should be uniform as regards conditions of soil and of planting, and then proceed to count and measure all the trees of 3 feet girth and upwards, classing them in categories according to their diameter. He should then open a debit and credit account for each compartment, placing on the debit side the actual volume of the standing crop, and on the credit side the volume of timber removed at each successive felling. This register should always be consulted before undertaking any forest operation, and when the annual fellings fall due, it will show which compartments can best support the withdrawal of timber, and which require to be left untouched. Moreover, the balance-sheet will render an exact account, favourable or otherwise, of the condition of the forest. Ten years of such systematic treatment would form in itself the basis of a regular forest working plan, and the doctor's prescription would no longer frighten the patient with its long words.

AUTUMN FROSTS AND TREE FOLIAGE.

The question of the effects of early frosts upon tree foliage, more especially in relation to their influence on the colour of the leaves, has, on one or two occasions, elicited some interesting remarks in the pages of *Woods and Forests*. In the course of one paper the writer asked, who has not been struck with the beauty of the woods in autumn? and then goes on to describe the effects of a single night's frost in changing the uniform summer green to the varying colours of autumn. To this Mr. Hovey, of Boston, demurred, and, in support of his views, gave an instance as to the way in which the foliage of the Maples and other trees had changed colour in a very mild autumn. I think if any doubt remained as to the necessity of frost in the production of autumn leaf colours, it must have been dispelled during the last two or three months. A milder September, October, and November it has seldom been our lot to witness, yet the same changes have gone on in the same slow, but sure way, and now at the end of November there are few leaves left except in the Oak woods. This much, then, as to the effect of frosts upon leaf colouring, but there can be no doubt that they have their influence in another way, and that it expedites the process of detachment. To the mildness of the autumn, therefore, may be attributed the presence of leaves upon the trees later than usual this year. What slight frosts there have been have been duly recorded, as each morning, as soon as an appreciable rise in the temperature has taken place, whether the air is at rest or not, a greater leaf-fall than ordinary has been the result. If there is any considerable movement in the air, the effect of the frost is more marked, but the question of the influence of wind in connection with frost is only one of degree, the action of the former merely accelerating that of the latter. Independent of either of these agencies, it is perfectly certain that the leaf-fall would take place, but it would be very much more protracted. As the precise action which a fall in the temperature to below freezing point produces upon tree foliage does not appear to be too well understood, the present autumn has afforded a good opportunity for observing the way in which the fall occurs in the comparative absence of frost. That frost is not the cause of the production of autumn tints has been clearly demonstrated. Rustic.

Trees in parks.—There is nothing that adds so much to the importance and beauty of an estate as fine tree growth. A park surrounding a mansion unembellished by fine trees should never be seen in this country. Yet we could cite many examples of such. With our present wealth of trees so readily obtainable at almost a nominal cost, a treeless park should be a rarity, for if not favoured with patriarchal tree growth such as surrounds our noblest and oldest country seats, there is now such a choice of ornamental trees for every locality and soil, that there is no excuse for not planting. We have plenty of tried subjects for planting among our English forest trees without resorting to doubtful novelties. Compare, for example, the common Silver Fir and the common Spruce with some rare species. Neither the Silver Fir nor the Spruce is reckoned of much account as an ornamental tree; nevertheless, when planted in suitable situations, in a damp climate, and in a tolerably moist soil, either of them—especially the Silver Fir—far surpasses some of the more recent and popular introductions. Both are perfect in their shape, grow nearly 100 feet high, and retain their branches, even when grown thickly together, down to the very ground. Thousands of such examples are to be seen in the valleys of the west of Scotland. Then among other park trees we have the Holly; it will grow 40 feet high, and nearly half as wide, if it have room, and be perfect in shape, and when covered with fruit it cannot be surpassed.

Walnut trees.—We have a prime old Walnut tree here that we intend to dispose of. Would some of the readers of The Garden give me some idea as to its value. Its height is 13 feet, girth 8 feet 6 inches at 3 feet from the ground, and 6 feet 6 inches at 11 feet from the ground. Any information on this subject will be gratefully received.—Juglans.

No. 786. SATURDAY, Dec. 11, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

GLOUCESTERSHIRE ORCHARDS.

I SEND you a sample of our west midland Blenheim Orange Apples. They are not picked specimens from the produce of cordon trees under high culture, but a good selection from orchard standards planted thirty-five years ago. The grower, Mr. Phelps, Tibberton, near Gloucester, assures me that the trees growing on what I should term rolling or upland ground, deep and heavy, receive no special treatment beyond the annual thinning and manuring by young stock which is allowed to graze in his orchards. Further, he says—and having adjudicated at Gloucester for many years, I can substantiate his statement—that his fruit this year is far below the average in point of colour and regularity of outline. Want of colour this season is a general complaint, and imperfect shape all pomologists agree in thinking is due to the checks and chills to which the trees and fruit were exposed throughout the early part of the summer. Notwithstanding these defects, I think you will agree with me in saying that the sample sent is highly creditable to a Gloucestershire farmer who is by no means an isolated exhibitor. I assure you, with fruit very much better coloured, he was this year very closely run by several competitors. Sending samples of fruit to THE GARDEN is akin to sending coals to Newcastle, and as few act in this way without an object, I may as well, once for all, make a clean breast by harking back to statements which have been published in some of the horticultural journals. In some of those communications our west country orchards have been described by clever men, who must have wielded their pens upon hearsay, as wretched Moss and Lichen-clad relics of the past, as cumberers of the ground only fit for the faggot heap. Instead of holding out a helping hand the farmers have been told that their case is hopeless, and the sooner they clear out of the markets to make room for the colonial growers, the better will it be for the public. I do not for a moment lose sight of the fact that foreign growers have got the start of us, and we have powerful opponents to contend with, but I still assert that our soil and climate are favourable to the growth of excellent Apples; if not quite so bright and highly coloured, in density and quality they are certainly superior to those imported from Canada. Fruit growers in this and the adjoining counties are not only renovating their old orchards, but they are planting young trees by the thousand. Exhibitors like Mr. Watkins, of Withington, a cold, low-lying locality, are showing the public what can be done under adverse local and climatal conditions, and scores besides him, who do not venture into competition, are quietly working in the right direction. To these and all who own or rent an orchard, I still say, prune and cleanse, drain, subsoil, and top-dress. Cut down old and graft inferior sorts, and your ancient, Moss-clad plantations will yet pay their way. Do not rest at the attainment of this point, but supplement your old by planting young orchards on deep, suitable soils resting on the hillsides well above the line of fog and frost. Avoid endless variety, but plant in duplicate the best sorts for market or vintage purposes, those especially which do well in your own immediate localities. Do not be content with the old rule-of-thumb systems followed by your forefathers, who were safe from foreign competition, but study the modern theory and practice of culture, gathering, storing, and packing for market, selecting, blending of different sorts, and scientific conversion into genuine cider. Good books are now plentiful and cheap. Nurserymen's catalogues even contain a vast amount of information alike useful to the gardener and the farmer. Gardeners study their contents; farmers, their sons, and their managers should do the same. They will then soon discover that the wonderful crops grown by the former are neither more nor less than the outcome of well-directed skill and intelligence, which every farmer may imitate, not only to his own advantage, but also to that of the community.

Eastnor Castle, Ledbury. W. COLEMAN.

*** Excellent fruit of this useful Apple.—ED.

INDOOR GARDEN.

AMARYLLISES AND THEIR TREATMENT.

WHEN I last ventured to make a few observations on Amaryllises in THE GARDEN (p. 285) they had gone to rest, and, up till now, the soil in the pots has not received any water, nor has the temperature exceeded that of an ordinary greenhouse. The resting period, and also that of growth, may be altered according to the requirements of the cultivator. This is well known and understood, not only by growers of the present day, but the earliest cultivators of exotic plants. In Dr. John Hill's "Eden," cultural directions are given for the Amaryllis, and the time of "absolute rest" is put down as the end of May, June, and the beginning of July. Under this treatment the plants would flower late in autumn, and winter growth would be made in winter and spring; but at that early date, 1773, the species must have been few, and the natural habits of the plants but ill understood. Hill states that they never failed to do well in a hotbed consisting of tanner's bark; and his potting material was one-half mould, one-quarter rotted wood, and one-quarter sand. Another cultural detail was to shake the roots out of the soil, and to dry them for about two months. This has been practised at a much more recent date than that on which Hill wrote, but it is one that cannot be recommended. The fibrous roots shrivel and part from the base of the bulbs, which they do not do under the best cultural conditions. At no time has the Amaryllis been so well grown as during the last few years; but the advance in cultural requirements, great as they have been, has not kept pace with the rapid improvement that has taken place in the quality of the flowers produced. Some remarks on this subject were given in THE GARDEN (p. 285). My object now is to remind cultivators that preparations for repotting should be made at once where a collection of varieties is grown. Every bulb should be examined; all decaying matter near the crown should be removed and burned, as it may contain the eggs and, perhaps, live specimens of insect pests. The next process is to wash every part of the wood and glasswork of the house outside as well as inside. We mix the potting soil about two months before using it, in order that its constituent parts may be more thoroughly incorporated. From the beginning to the end of January the plants may be repotted; we shake off all the old soil, and during repotting half the bulb is left out of the soil, the mould being pressed in firmly amongst the fibrous roots and round the base of the bulbs. The potting soil being moderately moist, we do not give water until fresh roots have been formed. The pots we plunge in tan or in some other fermenting material, which will furnish a bottom-heat of about 85°. The bulbs will do as well in an early vinery as in any house specially set apart for them. It is a good old fashion to make up a bed of fermenting material in the early vinery, and in this the Amaryllis bulbs are plunged. The temperature of the house, which ought to range from 45° to 50° as a minimum, just suits Amaryllises starting into growth. It is also very desirable that the bulbs should be clean, as thrips, bug, or even red spider might spread from them to the vines and do much mischief. The temperature will, of course, be increased after the first two or three weeks, and by the time the Amaryllises are in flower, 60° as a minimum will be reached. Some varieties more so than others have a disposition to produce their flower-scapes before the leaves make their appearance; this occurs amongst crosses from Hippeastrum pardinum and A. Chelsoni. The heat from the tan bed will promote root action, and without this the flower-scape will not be strong, even if the leaves are produced with it. The careful cultivator will always maintain reciprocal action between the roots and leaf development, and will readily ascertain whether the root growth has been sufficient to admit of the plants being forced into flower at an earlier date than was intended at first without any falling off in the quality of the flowers. An Amaryllis bulb will produce a flower-scape even if scarcely any roots have been formed, but the flowers would be of very poor quality, and the bulbs, which are much exhausted by the production of the scapes even under the most healthy condition, would be greatly injured and perhaps killed outright.

Sometimes we are called upon to deal with certain choice varieties which are also scare and valuable; rootless bulbs of these would not be allowed to develop flower-scapes if they produced them. Good management under such conditions consists in removing the scapes in the very earliest stages of their growth, so that the entire force of the new root action would be spent in producing leaves, which, in their turn, if maintained in a healthy condition to the end of the growing period, would perfectly mature the bulbs and bring them up to a flowering state for the following season. It is most interesting and instructive to examine a bulb of an Amaryllis when the flowers on the scape have arrived at full development. The substance of the bulb has almost disappeared; it has been used up in the production of the scape or scapes, and the outer coatings of the bulb hang loosely over the internal remains. Usually the plants are well furnished with healthy roots and leaves, and no sooner are the scapes removed than the process of filling up commences. Root action has to be well kept up, and a warm, moist atmosphere is necessary to keep up a satisfactory relation between roots and leaves. The plants will take plentiful supplies of tepid water, as vigorous growth is most desirable, and any plants that may become dry at the roots receive a check from which they do not speedily recover; should they become over dry more than once the chances are that the leaves will prematurely lose their colour; decay having once set in cannot be arrested, and the bulbs will consequently ripen before the whole process of the internal formation is completed. The flower-buds are there in embryo; so are the leaves, closely embedded and secure from harm in the centre of the bulbs. Even after the leaves decay and are removed the period of absolute rest is very short, for changes are going on in the bulb all through the resting period, and with the first touch of heat and moisture, leaf and flower, or flower and leaf, burst forth with a rapidity truly marvellous.

Great Gearies, Ilford. J. DOUGLAS.

Flowerless Violets.—A too shady position and an insufficient circulation of air are generally the cause of Violets producing foliage out of proportion to the amount of blooms which they furnish. The flower-buds are, of course, formed on the crowns, and these cannot mature sufficiently if too much hidden by foliage. Thick planting, in conjunction with a rich soil, will drive out floriferousness, and this is one reason why old plantations often become sterile. When Violets are grown in fields in the open air, where they get an abundance of light, and where the breezes of early autumn play freely on them, they rarely prove flowerless. It is only in the confined precincts of a garden that they do

so. The remedy for a flowerless condition is plenty of room in which to grow, a moderately rich soil, and a position where the plants get abundant light. There may, of course, be other causes for the non-production of bloom, such as starvation, an over-dry atmosphere, and the attacks of red spider. The condition of the foliage will surely indicate if any of these adverse influences are the cause of infertility. Poverty is easily remedied by a top dressing of decayed manure in spring, and an occasional soaking of water in hot, dry weather will help to ward off insect pests. It is certain, however, that Violet-culture in some localities offers more difficulties than in others. In some places soil and climate combine to render Violets happy; in others it is only the care and skill of the grower that can do so. Violets are so fresh, so pleasantly fragrant, and so welcome during gloomy winter days, as to be worth any reasonable amount of pains to obtain them.—Byfleet.

Miniature Orange trees.—These are most useful in the case of those who have to supply plants for table decoration in winter. A few neat little bushes of Tangerine Oranges will last several years in serviceable condition as regards size with a very moderate amount of care. A temperature a little above that of an ordinary greenhouse suits them perfectly, and sponging the leaves and careful attention to watering constitute the rest of their requirements. In spring we turn them out of their pots and give fresh drainage, for if the soil gets water-logged they soon lose their roots. A good layer of fine crocks, and a soil consisting of turfy loam, a little leaf-soil, and sand, suit them exactly. When fresh potted, put them in a vinery just started. Thus treated, they will flower freely from every spray, and when in bloom look well in the conservatory. They never fail to set a quantity of fruit, which we thin out to a number sufficient for the bush to bear. In any of the vineries or Peach house these little bushes will perfect a capital crop of pretty little fruits; and a bush bearing a dozen or more of them, accompanied by bright shining foliage, looks well in a rustic vase on the dinner-table or sideboard. When flowering plants are scarce and fine-foliaged plants have become monotonous, a reserve of fruit-bearing plants such as these little Oranges are is most welcome. Where old-fashioned orangeries still exist, some of the large-fruited Oranges, cut off with sprays of foliage, make pretty table ornaments. Many fail with Oranges from want of a little timely attention to the roots; as long as they look fairly healthy they are allowed to remain in the same pots, but under such circumstances they often drop their leaves and show signs of distress. In such cases it is advisable to shake the plant out of the soil in which it is growing and repot in a smaller-sized pot, using rather lighter and more sandy soil than before, until fresh roots are emitted. A moist, genial temperature and frequent syringings will be helpful until a fresh growth of young leaves makes its appearance.—J. G. H.

FRUIT ROOMS IN WINTER.

The perfect preservation of fruit in winter is a subject in which all who have any fruit to preserve are interested. Apples and Pears are the most important occupants of fruit rooms in winter, and although it is difficult to destroy late-keeping varieties, attention is required to keep those in season good as long as possible, and it is important that they be kept in such a way as to retain their flavour in perfection. This is a point not always taken into consideration, the main object with many being merely to prevent decay. Apples and Pears keep well in close places; if this was not the case we would not see such fine specimens turned out of American barrels as we now do; but an Apple kept for some months in a close room and one kept in a sweet atmosphere are widely different in flavour, and Pears are still more liable to be affected by the state of the atmosphere; they absorb the impurities of close air and part with their own exquisite flavour. A fruit room which can be gently heated now and then in damp weather is very useful, and where no heat can be applied, it is of great advantage to admit fresh air on fine days. A dry atmosphere is very desirable, and no opportunity of securing one should ever be allowed to pass by. Decayed fruit should not be allowed to remain in any fruit room, as it creates damp and contaminates the air. The whole of the stores should be looked over weekly in order to remove bad fruit, and if the windows can be kept so close as to exclude damp, they need not be opened during December or January, unless the weather is very brilliant. Frost must be excluded, as if once fruit gets slightly frosted, much of it will decay before it is ready for use.

Cambrian.

NOTES OF THE WEEK.

West Indian Blood-flower.—Although tolerably well known as a plant for summer decoration, this Asclepiad is but little grown for winter display. It is, however, used with good effect for this purpose in Canon Bridges' garden at Beddington, where we recently saw it. It is the Asclepias curassavica of botanists.

Cestrum aurantiacum.—This is a yellow-flowered form of the plant better known as Habrothamnus elegans. It is a lovely object trained either upon pillars or rafters, and it makes a good bush in a conservatory bed. We saw it recently in full bloom in the Royal Gardens at Kew.

Australian Bean-flower (Kennedya Marryattæ).—This is an old-fashioned greenhouse climber too seldom seen now-a days in our plant houses, more especially as its bright red Pea-shaped flowers are produced during the months of December and January. We saw it recently at Kew, where its branches hang from the roof in beautiful festoons.

The blue Marguerite.—Blue flowers are not, as a rule, over-plentiful in winter, and therefore we were somewhat surprised to find this plant a few days back blooming profusely in one of the greenhouses at Kew. The species in question is the old Agathæa cælestis, a dwarf, compact plant, with opposite entire leaves and terminal flower-heads, the ray florets being bright blue and the centre yellow. It is a native of South Africa.

Luculia gratissima.—This in now flowering in great profusion at Kew, filling the whole greenhouse in which it is placed with its delicate fragrance. It is also blooming in perfection in the York Nurseries, planted at the north end of an old Camellia house. The plant in question is bearing considerably over a hundred heads of delicate pink blossoms. Its Hydrangea-like heads of bloom last several days in water after being cut. This grand old plant has been too much neglected of late years. A fine bush of it which flowered annually grew in the conservatory at Chiswick before it was converted into a vinery.

Cotoneaster affinis.—I have enclosed a few fruit-laden branches of this Cotoneaster. Imagine groups 40 feet or 50 feet across and 12 feet to 20 feet in height literally loaded with fruit and foliage, and you realise the value of this splendid shrub.—W. Coleman, *Eastnor Castle, Ledbury.*

*** Uncommonly fine specimens of what must be considered the most ornamental hardy tree of the season. The profusion of bright scarlet berries must, as Mr. Coleman remarks, produce a splendid effect at this season. Both C. affinis and its closely allied relative, C. frigida, are among the select shrubs or small trees that no planter should neglect. Both are natives of the mountains of Nepaul.—Ed.

Reinwardtia tetragyna is an old plant with a new name, it having been grown abont a century ago in English gardens under the name of Linum. It had, however, long since disappeared from cultivation, although it is a common weed in some parts of India, and has recently been re-introduced by Messrs. Veitch, and also by Kew. Another member of this genus is the old favourite winter-flowering plant commonly known as Linum trigynum, these two constituting the genus as described in the "Flora of British India." R. tetragyna is as good a garden plant as the better-known R. trigyna, its flowers being 2 inches across, sulphur-yellow (those of R. trigyna being almost orange); the petals crisp-edged and spreading, and they are borne in terminal umbels, strong shoots bearing as many as twenty flowers in a head; they open one or two together. In the other kind the flowers are produced on short axillary branches all along the main shoots. The plant is woodier than R. trigyna, and the leaves are 7 inches long, lance-shaped, with crenate edges. R. tetragyna is distinct enough from its better-known relation to be worth growing along with it. We saw a batch of it in flower in the **T** range at Kew, and in the greenhouse (No. 4) R. trigyna is also flowering freely.

East Indian Morning Glory (Ipomæa Horsfalliæ).—This very fine climbing plant is somewhat difficult to propagate, and hence it has never become plentiful, although always a favourite. The most successful method of increasing it with which we are acquainted is by root-grafting. The foliage is deep green, the leaves being somewhat hand-shaped, whilst the trumpet-shaped, bright rosy flowers are produced in showy panicles. In stoves here and there it is at the present time finely in flower.

Canary Island Bellflower.—We recently saw this plant flowering in a greenhouse at Kew. It cannot be called a very showy plant, but its large drooping, bell-shaped flowers are yellowish red—a remarkable colour amongst its near relatives, the Campanulas. The plant in question is called Canarina campanulata; it has a thick, tuberous root, which used to be dormant at this season; the stem is stout and branching, swollen at the joints, and the thin leaves are somewhat heart-shaped.

Ghiesbreght's Tree Groundsel (Senecio Ghiesbreghti).—The Groundsels constitute perhaps one of the largest genus of plants known; many of them are worthless weeds, but this plant which we recently saw in the greenhouses at Kew is a veritable Anak amongst its fellows. It is shrubby in habit, attaining a height of from 4 feet to 5 feet or more, and bearing large, alternate, dull green, coarsely toothed leaves; the summits of the stems are crowned with large, flat, corymbose heads of yellow flowers, which render it conspicuous at this season of the year.

Finely-grown Calanthes.—I have sent you a few spikes of Calanthes. Our mode of treatment is much the same as that given in The Garden last week by "Veronica." The only difference is, that we put the majority of our bulbs five in a 10-inch pot. I have at the present time one such pot with twenty-two spikes, with an average of thirty-two flowers to a spike.—H. Carter, *Downhill, Coleraine.*

*** The Calanthes received are very fine examples of culture, the spikes being some 4 feet in length, bearing three dozen flowers of exceptional size and colour. The varieties sent are C. Veitchi and the red and yellow forms of C. vestita. The colour of C. Veitchi is very rich, the result probably of such excellent culture in pure country air.—Ed.

Cattleya Mastersoniæ.—This beautiful new hybrid has recently flowered at The Dell, Egham, in Baron Schroeder's collection. The habit of the plant is in the way of Cattleya Loddigesi, but the bulbs are somewhat shorter and thicker, leaves being round and dark. The flower stands out bold, and has the distinct character of Cattleya Loddigesi, but much larger, partaking of its parent's rich hue; the sepals and petals are deep rose; the lip is a rich crimson, as in the old C. labiata, but is shorter and not so much fringed. It is a splendid hybrid, and a close rival to Cattleya exoniensis, if it does not actually surpass it.

Begonia socotrana is gay with flowers now, and is altogether a pretty and interesting species, which will be sure to hold favour as a winter-flowering stove plant, and one which is peculiarly attractive on account of its large Tropæolum-like leaves and singular habit. When this plant was first introduced we were doubtful as to its lending itself to the production of hybrids by crossing with other kinds; but all doubts have been removed by the Messrs. Veitch, who have already raised several distinct hybrids from B. socotrana and others; and success in the same direction has also rewarded several Continental growers. But the children of the Socotran Begonia may be left to speak for themselves; we wish here to

point out that wherever bright rose-pink flowers are wanted in winter, flowers, too, which among Begonias have the exceptional character of lasting well when cut and placed in water, B. socotrana is deserving of favour. It is a little peculiar in its cultural requirements, but particulars on this point may be found in The Garden, along with a coloured picture of the flowers, in Vol. XXI., p. 162. Several groups of well-flowered examples of this plant may now be seen in the T range at Kew.

Agathæa cælestis, or the blue Marguerite, is most useful when grown in pots out of doors all summer and not allowed to flower till winter, when it will produce a good crop of its delicate blue, Daisy-like flowers with bright yellow centres and of good lasting qualities. A batch of these plants, well flowered and very pretty to look at, may be seen in the greenhouse (No. 4) at Kew, and they are rendered still more attractive by being mixed with the Paris Daisy, the two going well together.

The Order of the Chrysanthemum.—The most exalted Order of the Japanese Empire is that of the Chrysanthemum, and this, with but one exception, has previously been bestowed upon reigning sovereigns only. On Tuesday last the Order was conferred upon the Prince of Wales by Prince Komatsu, the envoy of the Emperor of Japan. The Order of the Chrysanthemum is described as consisting of a star and collar, the former being in the form of a silver-fluted cross with a large ruby in the centre, and the latter being a "blaze," with a ruby, hung round the neck by a riband.

Strobilanthes Championi.—Although a large genus of Acanthaceous plants, and one which is said to comprise many ornamental flowered kinds, only very few species of Strobilanthes have found their way into gardens, and we may say not one has found much favour among cultivators. The genus is related to the Ruellias, and is mostly blue-flowered. Many of the species form large, handsome, herbaceous shrubs, and some of these have the peculiar habit of growing for an indefinite period without producing flowers till the flowering time comes, when they expend themselves in making a fine display, and then perish. Several of these are now represented by large plants in the stoves at Kew, but they are not yet showing any disposition to flower. S. Championi is a recent introduction from Hong Kong, and is now in flower. In habit it is suggestive of Dædalacanthus, being a stout herb with quadrangular stems, ovate-toothed leaves 5 inches long, and flowers in erect terminal racemes, each flower being tubular, curved below, spreading above like a Pentstemon, and about 1 inch across; the colour is pale violet with purple veining. Only two or three flowers open at once on each spike. Height of plant, 2 feet.

Garden Destroyers.

EUCHARIS MITE.

"J. C. B." publishes (p. 501) an experiment which he made in reference to the Eucharis mite, or what he presumes to be that destructive little pest, but the conclusion at which he has arrived, viz., that it can be successfully eradicated without the loss of the bulbs, is scarcely borne out by the facts which he gives. The remedy stated might have been effectual enough in the case of the Vallota, but, as he admits, it might, in the case of the more delicately constituted Eucharis, prove destructive to both bulbs and mites; consequently he is somewhat premature in asserting that there is yet a better plan than that proposed by me (p. 394). Then, again, the mite that "favours" the Vallota with its attention may be different from that which affects the Eucharis. We all know that the smallest forms of aphides are the worst to exterminate, and on these grounds I am reasonably sceptical of the success of the experiment recommended by "J. C. B." when it comes to be tested on the Eucharis mite properly so called. Any effectual remedy would be welcomed by all who suffer from this destructive mite; but until this is forthcoming and proved, I must still hold that a thorough clearance of the stock is the surest method of getting rid of it. Such a radical remedy may at first sight appear uncalled for, but when it is taken into consideration how much time and space have been taken up by experienced cultivators in their futile efforts to destroy this mite, it will perhaps be conceded that no better plan has yet been found. Mr. Cypher, of Cheltenham, one of the most extensive cultivators of Eucharis with whom I am acquainted, unfortunately imported the mite into his collection, and this soon spread. Every known remedy that has been tried and recommended by other cultivators has been given a thorough trial, and some that occurred to those in charge were also tried, but in every instance without an effectual clearance of the mite. The conclusion arrived at was that many who profess to have effectually exterminated the mite could not have had the true pest to deal with. Believing, therefore, that there is no remedy other than a thorough clearance, they burnt their plants; the houses were thoroughly purified and furnished with fresh stock. At present, therefore, they have a grand lot of Eucharis, and not a trace of the mite discernible. Nor need other cultivators hesitate to follow this example. A few healthy strong potfuls of bulbs may be rather expensive to buy, but then these may be rapidly increased by division. W. I. M.

Diseased Eucharis bulbs (*S. N.*).—Your Eucharis bulbs are attacked by the bulb mite (Rhizoglyphus echinopus). It is a very difficult pest to destroy. "J. C. B.," in The Garden of November 27, mentions that he has been successful in killing this mite with a strong solution of sulphide of potassium. No doubt, as he says, if the mixture be strong enough it will do so, and he has found that 3 lbs. dissolved in a gallon of water will kill the mites, and not injure the bulbs of Vallotas. Eucharis bulbs, as he suggests, might not, however, stand such a strong dose. The bulbs should be allowed to soak for some time in this mixture, as the mites often work down from the base of the leaves between the scales for some distance, so that no washing or dipping would bring the solution into contact with the mites. "J. C. B." is much mistaken if he thinks he is the first person to use sulphide of potassium for this purpose. Mr. E. Cameron, of Moffat, wrote to The Garden last year, on December 12, saying how successful he had been in killing these mites with it. Another correspondent recommended it in April, last year, for the same purpose. I am of opinion that the cure will be found in immersing the bulbs in hot water of 115° and 120° Fahr. This, as far as I have been able to experiment, will kill the mites, but I am uncertain as to the effect on the bulbs. I have not yet heard the result of some trials which are being made to test this theory.—G. S. S.

THE POTATO TERCENTENARY.

The conference which formed a part of the proceedings of this celebration had many features of interest, though the attendance was, unfortunately, during all its stages extremely poor. This probably arose from the fact that there was a kind of mystery attached to the preliminary proceedings, and many held aloof because the names of the promoters were kept a studied secret. It was not until the eleventh hour that a few well-known Potato raisers and cultivators were invited to assist. Still, a great deal of very valuable information came out in the course of the discussions, and it is a pity that a larger number of professional horticulturists was not present.

The conference opened on the morning of the 2nd instant, Mr. William Carruthers, F.R.S., presiding. The first paper read was by Mr. W. S. Mitchell, M.A., on "The historic consideration of the question, whence came the Potato to England?" The tenor of this paper was to show that the Potato, though regarded as a Virginian importation, could not be so. He believed that the Potato had been introduced into England by Sir Francis Drake in 1586; that he obtained it on the coast of South America, either by purchase from the natives, or by plunder from some Spanish ship, and conveyed it to England on the conclusion of the voyage in which he relieved Sir Walter Raleigh's colony in Virginia. Then followed a paper prepared by Mr. W. H. Pollock, M.A., on "Drake's Expedition of 1586," read by Sir R. Pollock. This gave an account of Drake's voyage in 1586, showing the various places he touched at and the enterprises carried out, and that in some of the places touched at in the Pacific Ocean it was possible he took in a supply of Potatoes for his crews.

Next came a remarkably able, complete, and highly interesting paper by Mr. Clements B. Markham, C.B., F.R.S., on "The cultivation of the Potato by the Incas of Peru and other Andean nations." It is impossible that any abstract can do justice to a paper that should be read in detail, so full of information of a specially appropriate character was every part of it. Mr. Markham said that the original home of the Potato was in the Cordilleras of the Andes, in South America. There it had been cultivated from time immemorial over an extent of 3000 miles. When the Spaniards first arrived, the Potato was a domesticated plant in the kingdom of the Chilchas, in the province of Quito, throughout the empire of the Incas of Peru, and in Chili. This fact of its immemorial cultivation rendered it difficult to ascertain with certainty the localities where the Potato was indigenous. It was most probable, on the whole, that the Potato originally grew wild in suitable localities throughout the Cordilleras of Peru and Chili. A description of the physical geography of these districts, and of the system of government under which the inhabitants lived, then followed. Mr. Markham observed that the government was practically a theocratic socialism, which secured an almost complete absence of distress and pauperism among the people, and under which the Potato became a cultivated plant. The Potato was unknown further than the highlands of Bogota, in Columbia; and it was there that one of the three American civilisations had its root, viz., that called by the Spanish conquerors the Mysca nation. Its people spoke a language called Chileha, which is now extinct. But vocabularies have been preserved, and they revealed the fact that the ancient people of Bogota cultivated the Potato extensively, and had produced several varieties.

Mr. J. G. Baker, F.R.S., of the Royal Gardens, Kew, contributed an interesting paper on "The wild species of the Potato as at present recognised." He said that the well-marked, thoroughly distinct species of tuber-bearing Solanums were five in number, and were all natives of America, viz., tuberosum, Commersoni, cardiophyllum, Jamesi and oxycarpum. The Potato of cultivation originated from the first-named species. S. tuberosum, in one form or another, extended down the western side of the American continent from the Rocky Mountains, the latitude 30° north, to the Chonos Archipelago, off the coast of Patagonia, in latitude 45° south. Within this area there were found no less than sixteen forms, so far different from one another that they had been named by some botanical writers as distinct species. They were not so, however, in any comprehensive sense. S. tuberosum was therefore one of those polymorphic types, of which we have very similar examples in the old world in the genus Rubus—Raspberry and Cloudberry—and in R. saxatilis. The extreme forms looked very different from one another when they were placed side by side, but in the whole series there was to be found no very decided gap of character. Though the Potato had been cultivated in Europe for 300 years, we knew very little about the deterioration that might be produced in the distinguishing characters by changes of climate and soil. He wished that someone would undertake to monograph the tuberous Solanums in the same thorough way that Mr. George Maw had just monographed the Crocuses. We did not know whether S. tuberosum, the commonly cultivated esculent, was really an original type or a form produced by man's agency, and in investigating the relation to it of the other fifteen types that were regarded as non-tuberous, there was scope for the labour of a lifetime. He would add that Mr. Markham's paper was of exceptional value and interest, and, if nothing more came from the conference, a new era in the history of the Potato had been inaugurated by Mr. Markham's contribution. It contained an enormous flood of information which would put the botanical and historical bearing of the question in an entirely new light. Botanists had not had the least idea of the large extent to which it appeared the Potato was culti-

vated at the very early period Mr. Markham had mentioned. Mr. Baker illustrated his address by coloured illustrations of as many of the reputed species as he had been able to obtain.

The conference adjourned to the afternoon, when Mr. J. G. Baker presided. Mr. George Murray, F.L.S., of the British Museum, read a paper on "The character and operation of the Potato disease," his remarks being illustrated by a number of diagrams of the fungus in its various stages. He said that the history of the disease was a recent one as compared with the history of the Potato itself, notice having been first called to it in 1845, when it was probably brought to this country from Belgium. After describing the nature of the fungus, Mr. Murray said he had satisfied himself that the disease was propagated by the spores being distributed by the wind. A number of glass slides, such as those used with a microscope, having been covered with glycerine and placed on the lee side of a field of infected Potatoes when a slight breeze was blowing, it was found, after an exposure of a few hours that the slides each contained a number of these spores. From continuous microscopic investigation it had been seen that the complete fungus was produced in three hours, and this accounted for the sudden and disastrous spread of the disease. No system of earthing up Potatoes could, he believed, be efficacious in checking the disease; neither could confidence be placed in any legislative enactments regulating the planting of Potatoes.

Earl Cathcart said that it would be interesting to know whether the Potato disease was an effect or a cause. With regard to the degeneracy of the Potato, he might mention that it was a fact that no supposed standard Potato had ever existed. That in itself he considered to be an argument in favour of the theory that plants are liable to degenerate when over-cultivated.

M. Henri L. de Vilmorin, of Paris, then read a paper on "The introduction of the Potato into France." M. Vilmorin said that the Potato was first introduced into the Dauphiny from Switzerland. At first it was not extensively grown, and was used as fodder for cattle, and there existed a strong prejudice against it. But a bouquet of its flowers being presented to the king, who greatly admired them, the prejudice was gradually overcome, and the Potato became more generally grown. In 1830 the Agricultural Society of Paris sent to him a large collection of known varieties which were grown and compared, and resulted in their reduction to 120 distinct kinds. Since then some 2000 named varieties had passed through their hands, and they had reduced these by about 550 distinct sorts.

The conference was resumed on Friday, the 3rd inst., Mr. Mitchell presiding, when a paper was read by Dr. Masters on "The production of varieties by cultivation." At the outset, he said the methods now resorted to for the production of new varieties were not of a nature to reach the end sought. One general method of obtaining new varieties was by selection, but he was of opinion that nothing could be derived from this method. Another process was that of cross-breeding, or the production of new varieties by the application of the pollen of one variety to the stigma of another. The third method was that of hybridisation proper, or the crossing of two reputedly distinct species. This process had not been much attended to in England until it was adopted by Messrs. Sutton, Reading. There was yet another mode by which new varieties might be obtained—namely, by grafting. Very many cultivators absolutely denied the possibility of anything like grafting, but he believed it to be a practicable idea. He had himself obtained intermediate forms by the process, and he had seen remarkable results follow the grafting of the Potato on to the Tomato and other species. These were all the methods at present practised for gaining new varieties of the Potato; there might be more, but he did not think it probable. What he would wish to emphasise is the fact that all these modes, except that practised by Messrs. Sutton, were merely "ringing the changes" on the old varieties over and over again. If any really important result was to be obtained in the future in point of greater adaptability to our climate, power of resisting disease, or general robustness, we should have to infuse a new strain into our varieties; the only way to do this was by hybridisation of species. It was not necessary to confine the experiments to tuberous Solanums only, but other hardy species might be put under requisition. The process, however, would be very long and tedious, and it would hardly be within the power of private individuals to undertake the experiments, which would require quite twenty years of patient attention.

Mr. A. Dean, Bedfont, said, with regard to the process of obtaining new varieties by selection, he could say, as one having much experience in the matter, that the only practical result was obtaining a slightly better stock for a year or two, which, however, would soon degenerate. The only real means by which distinct varieties had been introduced was by cross-breeding, and by this means, from a simple Solanum tuberosum, a thousand distinct varieties had been obtained. They had also produced many varieties entitled to be termed disease-resisting, and had put themselves in the position to say that Potatoes were never better or cheaper than at present.

Mr. Arthur Sutton, Reading, said he did not wish to claim for his firm any credit for having originated the experiments referred to by Dr. Masters. The idea had emanated from Lord Cathcart, and he believed that in its execution they had a pleasing example of the union of scientific and practical knowledge. He had never known any new variety to be originated by selection, and he believed such a thing to be impossible.

Mr. William Earley stated that while he did not assert the possibility of obtaining new varieties by the process of selection, the fact was not to be overlooked that by continually choosing the best specimens of a variety, a better standard of excellence was maintained.

Mr. R. Dean, Ealing, said that on the previous day he had asked Mr. J. G. Baker whether it would be possible to carry out a series of experiments at Kew with the different species of Solanum, but he said it would be practically impossible to do so, as a new department would have to be created; and there was the further disadvantage that a constant change was going on in the personality of the staff, which greatly interfered with the continuity of such work.

Mr. Charles ap Thomas said that he had resided for twenty-five years in Chili and Peru, and was conversant with the edible plants there. There were three varieties of the Potato, one of them, the Yellow Potato, being very suitable for introduction to England. Its name was given to it on account of the colour of its flesh, and it was very similar to the Rector of Woodstock variety. It was indigenous to the soil, and had been found in the country by the Spaniards when they first arrived.

Mr. R. Dean, Ealing, then read a paper on the "Cultivation of the Potato," recommending autumn manuring and trenching, a choice selection of sets, and care in the process of earthing-up. Mr. A. Dean, Bedfont, followed on "Raising new varieties," detailing the various crosses he had attempted, and the character of the varieties he had obtained therefrom. Mr. W. Earley, Ilford, read a paper "On the advantage of early lifting of the crop as a preventive to disease," and illustrated the same with samples of tubers.

At the evening sitting, the subject considered was the rates of transit of Potatoes by railway. The chair was taken by Mr. T. H. Bolton, who said that it was generally admitted that the railways had hardly answered the requirements of the public, either as to accommodation or cheapness of transit. In the last Parliament a measure had been introduced, on the responsibility of Mr. Gladstone's Government, to place the railway companies under greater supervision, and to require that they should more fully discharge the duties which had, under Parliamentary sanction, been entrusted to them. The measure was not then carried through, but its passing into law was only deferred, and the railway companies would have finally to submit to Parliamentary control. There existed great reason to complain of the unfair preference that was practically given to foreign producers in connection with the main trunk lines unto the great cities. It was useless for the railways to plead that they could not afford to satisfy the demands of the public, for it could be seen from returns that most of the chief lines were paying good dividends.

Prof. W. A. Hunter, M.P., then read a paper on the subject under discussion. He said that the subject of railway charges for the conveyance of Potatoes might be considered under the following heads: (1) preferential charges in favour of foreign as against home-grown Potatoes; (2) irregularities in the charges compared with the service rendered; (3) charges by railway companies exceeding the maximum; (4) excessive proportion of the charges to the value of the article; (5) suggestions for cheapening the rates for conveyance. With regard to the last consideration, could cheaper rates be obtained? It was first to be remembered, that as it stood now the law could do nothing to help the Potato grower. On the Brighton line the rate charged per ton per mile, exclusive of collection and delivery, varied between 4d. and 6d., while in America the Pennsylvania Railway Company charged less, and ½d. per ton per mile on the average of its whole goods traffic. This was lower than the English average for the coal traffic only. The secret of the low American rates was not in the unremunerative character of the work done, but in the mode of conducting railway business. What was required was a truck rate as well as a tonnage rate. By such an arrangement the trader could have the option of sending by the present system, or of having a truck and loading it as he pleased and with what he pleased up to the full carrying capacity of the wagon. At a rough guess he would say, then, an 8-ton or 10-ton truck ought to be charged 6d. per mile for short distances (say under forty miles), and a diminishing rate for long distances; so that for 200 miles it ought not to exceed 4d. per mile. It might be said that, though this system would be beneficial to the large trader, it would not be so to the small trader. Indirectly it would, however; for the moment a fair truck rate was established, a class of carriers would spring up who would collect the traffic of small men and make their profit by sending full truck loads. Under the present system the independent carrier had been exterminated, and the railway companies had established a monopoly. If a truck rate were fixed the business would be made more profitable to the companies, and, at the same time, the railway monopoly would be smashed.

A lively discussion ensued, a general agreement being expressed with the conclusions drawn by Prof. Hunter.

A COTTAGE DOOR.

There is a charm about an English cottage home with its little strip of carefully tended flower border, that no other country can show its travellers by road, and that this is not a vain insular boast is frequently proved by the pleasure expressed by our foreign visitors at the pretty pictures, such as the one we now engrave, so frequent in our villages and scattered by our country roadsides. The double flower border, leading from the road to the Vine-clad porch, is filled with good hardy flowers, tended with watchful care by the mistress of the little dwelling—the home of an honourable family of labouring people. Next the flower border is a line of fruitful Gooseberry bushes, and then a good bit of vegetable garden and Potato ground, or, according to the local wording of the older folk, "a bit of ground to grow sauce in."

QUESTIONS.

5533.—**Market Hydrangeas.**—Would some reader of The Garden kindly give me a hint or two on the culture of common Hydrangeas for market, also the best means of propagation?—E. F.

5534.—**Open-air Chrysanthemums.**—Will some reader kindly give the names of the best sorts of Chrysanthemums suitable for open-air planting? Locality, Lancashire coast.—J. R.

Book.—Rivers' "Orchard House"; obtained of the author, the Nurseries, Sawbridgeworth.

Rose Garden.

PLANTING ROSES.

In a general way Roses are planted at any time between the 1st of November and the 1st of March; but as regards standard Roses, I think, when November is over and the work of planting not completed, it is better to defer it until the severity of the winter is over. If we could depend on the winter not being severe, I should say there is no reason to wait; on the contrary, I should say plant at any time when the weather is open from November to the beginning of March; but when planting has been delayed to mid-winter, and the position the plants are to occupy happens to be an exposed one, I say by all means wait until the end of February. My reasons for advocating delay in such cases is, that recently planted standard Roses are sometimes seriously injured by severe frost, and not unfrequently great losses are experienced when they are standing in nursery quarters. It is not, therefore, difficult to understand that when they are subjected to removal and planted out singly in exposed situations that they should suffer if overtaken by unusually severe frost. I have never known 20° to injure Roses to any serious extent, but on more than one occasion I have seen a good deal of the young growth killed by 26° of frost. I have known long lines of standard Roses in fairly sheltered places to escape unharmed, even when the thermometer had been down to zero; therefore I am not in any way anxious about the safety of established plants. It is newly planted Roses about which I am most concerned, and if I resided in the north of England, I should adopt some plan of protecting them, *i.e.*, if I was compelled to plant before severe weather had left us. My advice is, therefore, that those who have delayed planting should get their plants home and prune them as soon as received. They may be pruned just as well before being planted as afterwards, and by doing the work now the wounds made will have time to heal, and when planted they will have nothing to do but to start into growth. As soon as pruned, a fairly sheltered border should be selected to receive them where the soil is light and moderately fine. Where some fine leaf-soil is at command it should be preferred to anything else in which to lay the roots; any way, the plants must be laid in very carefully. The stems should be nearly upright and sufficiently far apart to keep the roots of one plant from touching those of another. There is no need to tread the soil about them very much; if it lies about the roots close enough to prevent the ingress of air, that is all that is wanted. It has been stated more than once that root-disturbance means root-formation, and in no instance have I seen the statement better exemplified than in the case of some Roses which, owing to some alterations, I was once compelled to move early in November, and for the same reason they could not be replanted until quite late in the spring. In the meantime they were well cared for, the roots were laid in in a heap in some rich soil, and when the time came to plant them they were bristling with long white fleshy fibres, which being carefully planted enabled the plants to quickly lay hold of the new soil, which they did, and soon started into growth, yielding the same season quite a satisfactory number of flowers. Deferring planting also affords an excellent opportunity for the thorough preparation of the soil. With regard to positions for Roses, I do not agree with draining them, except where absolutely necessary, for, in a general way, during the summer Roses suffer more from want of root-moisture than from an excess of it; at the same time, I admit that in low-lying situations, where the soil inclines to clay, it is desirable to provide moderate drainage.

A cottage door in West Surrey. Engraved for The Garden from a photograph.

Planting Roses on dry banks and in raised beds is another feature in Rose culture to be avoided in the majority of cases, more especially where the soil is naturally light and well drained. In regard to the height of the soil above the surrounding surface, there is a happy medium to be aimed at, and that is, the surface of Rose beds should be on a level with the ordinary surface of the ground, except in the case of Tea Roses; these, on account of their being more tender and less vigorous in growth than Perpetuals, require a drier and warmer medium for their roots; therefore, in some cases it is desirable to raise the surface of the Rose bed to from 9 inches to 1 foot above the surrounding level.

Manure for Roses is a question that often perplexes the inexperienced cultivator, and I think unnecessarily so. There can be no doubt that well-rotted farmyard or hotbed manure is best; but even this must be used with discrimination. A soil that is already fairly rich should have less than one that is deficient of sustaining matter. The practice of putting a little manure round the roots and leaving other parts of the bed without any is not the way to ensure lasting and satisfactory growth. The manure should be distributed regularly all over the bed, and in the case of a poor soil plenty of it should be used; a good quantity of it should be mixed with the soil 1 foot below the surface. As a general rule the roots of vigorous-growing Roses are few in number, but when they have a good deep soil to grow in they travel a long way in search of food. It is, therefore, important that they should find plenty of it in whatever direction they may take. This they cannot do if the manure is only placed in certain places and the bulk of it near the surface.

J. C. C.

Rose stocks.—I was surprised to see (p. 497) that "D. T. F." had so much affection for the Manetti as a stock for Roses. He still clings to the idea that Roses worked on the Manetti root as freely from above as from below the point of union. They certainly do so, but in a much less degree than "D. T. F." gives them credit for. Such is my experience, and if that is incorrect, how comes it that so many thousands die annually? Too many have, I fear, started with the idea of forming own-root Roses on the lines "D. T. F." has delineated, with the result that at the end of three years the beds or borders have been terribly thinned by the natural propensity of the stock to die before it has fulfilled its mission. That the Manetti has been the means of carrying the Rose into thousands of gardens, into which it could not otherwise have found its way, I am willing to admit, but, although it has done so, it has not been an unmixed blessing. I knew of instances in which gardeners have been blamed for neglecting their Roses, when, in fact, the blame rested entirely with the stock. No one knows better than "D. T. F." that when once the Manetti refuses to sustain the Rose worked on it, no after treatment, however skilful, will save the Rose from its inevitable doom—death—unless the Rose has made roots of its own. My advice to those who are about to plant Roses worked on the Manetti is, that at planting time they should peg down the strongest and longest Rose shoot and bury a portion of it 3 inches under the surface; then, with a stick and a tie, bring up the point of the shoot so as to raise it several inches above the soil. The buried portion of the branch will in time emit roots, and ultimately form a plant of itself, so that in the event of the stock dying, a plant on its own roots

will be secured, and thus disappointment be prevented. Should the stock live and the Rose develop into a vigorous plant, that raised from the branch can, if desired, be taken up and planted elsewhere. Such a course is quite practicable, and has to my knowledge been successfully carried out in large beds first planted with Roses worked on the Manetti, but now converted into own-root plants, and as vigorous as anyone could desire.

TAUNTON.

GRAFTING ROSES ON THE MANETTI.

APROPOS of the value or otherwise of the Manetti stock for Roses, it may be well to direct attention to the amazing rapidity with which Roses may be grown on it through grafting. The simplest mode of procedure in this, as in many other matters horticultural, is no doubt also the best. Procure any number of Manetti stocks one or two years from cuttings. Size is of little moment, provided they are rooted. Trim off the tops and bottoms, *i.e.*, roots and shoots, so as to leave the whole of the stock from 6 inches to a foot long; some would even prefer stocks shorter. So soon as trimmed, lay the stocks in by the heels, covering the whole overhead, or leaving an inch or so of the upper extremity exposed. Leaf mould or a mixture of equal parts leaf mould and loam is the most suitable plunging material. The place to plunge for the mode of procedure now under notice is a pit or house with a bottom heat of from 65° to 70°. Leave the stocks plunged for ten days or a fortnight; at the end of that time, under such forcing conditions, the roots and tops will be beginning to move. The cut roots and tops will also develop symptoms of beginning to callus. The stocks are then ready for grafting. Scions should have been taken off the Rose bushes about the time the stocks were laid in by the heels in heat, or indeed earlier. But assuming the stocks were trimmed and set to work in January, the scions should have been cut off, the useless parts removed, and the whole of the portions fit for scions buried in the ground in the open air, there to remain till wanted, which may be a fortnight, three weeks, or a month, according to circumstances. The stocks and scions being thus both prepared, the simplest and safest mode of uniting them is as follows: Choose the two of about equal dimensions, if practicable, and whip-graft on to the root or root-stock. Tie the stock on to the scion with from three to five rounds of bast or matting. The tie should be firm, but the tying material by no means close. The reason for this will appear as we proceed. Before fitting the scion on to the stock, a thin slice should be taken off the bark on one side of the scion. So soon as the scion is placed, replunge the stock and scion, only leaving one or two buds of the scion exposed. The stock will at once proceed to form roots almost as rapidly as if it had not been disturbed. While this process of rooting is proceeding, the scion along both sides often, but especially on the side from which the thin slice of bark is removed, will also be callusing for roots; so that by the time the union of scion and stock is perfected, the embryo Rose plant will already be furnished with two sets of roots either in embryo or in fact. At this stage stocks and scions may be manipulated at will. The one bud or more that may have been left on the stock beyond the Rose scion may be removed, and the stock, in fact, cut back bodily to the scion. The bud or buds on the latter will now be breaking, and, as already seen, will be furnished with roots sufficient to furnish it with supplies of food. It is possible even to dispense also with a portion or a whole of the Manetti roots at this early stage, though safer to leave them till afterwards. At this stage the plants should be potted up, keeping the point of union between scion and stock wholly buried. A mixture of leaf-mould and light sandy loam, with a sixth part of rotten manure, is the most suitable for this potting; but any light soil that encourages free rooting will answer; 4-inch or 6-inch pots will suffice, and they should be plunged after potting in a hotbed of 60° or 65°. The tops of the plants may be kept a few degrees cooler but the great object at this stage is to encourage rapid growth of roots, so as to complete and consolidate the union, and encourage the rapid emission and multiplication of roots, especially from the sides and base of the scions.

As these processes are completed and the Roses get established, the temperature may be gradually lowered and more air admitted. Under such treatment, Roses on the Manetti may be rushed forward into well-established plants and planted out in the open air within less than six months from the time of working. There are many other different modes of procedure, such as graft-budding with a single bud with the wood intact; also a species of saddle-grafting, by which all the raw edges of the scions may be utilised more effectually to force the independent rooting of the scions. But the illustration given will suffice to show with what amazing rapidity Manetti stocks may convert Rose scions or buds into Rose plants on their own roots or otherwise.

HORTUS.

Own-root Roses.—I have been preparing a large quantity of cuttings of Maréchal Niel for making own-root Roses next year. I have had very fair luck with cuttings of this kind in previous years, but this season I shall keep them laid in thickly in a frame, at least until after the severest frosts are past. Without doubt a warm south border is the most fitting place for such cuttings during the winter, but it is rather too hot in summer; hence I shall put out the cuttings towards the end of March on a west border, where they will be encouraged to make good growth during the summer and be protected from the keenest winds. Maréchal Niel, budded on strong kinds such as Lamarque and Madame Berard as well as on the Brier, makes great growth here and affords an abundance of stout wood for cuttings. I find Reine Marie Henriette to be the freest rooter; indeed not one cutting of this seems to fail; these soon make capital plants. Apart from its value as a climbing Rose, either for house or wall, the latter especially, it should make a good stock for weaker growing trees, as it strikes freely, thus enabling anyone having a strong plant always to command stocks. Early buds of this Rose, especially those under glass, seem to rival buds of General Jacqueminot in depth of colour. It is without doubt, if a robust grower, a beautiful blooming kind, and especially merits wide culture.—A. D.

LANCASHIRE GARDENING.

THE remarks made under the heading "An English Celery Show" (p. 527) brought to my mind some pleasant reminiscences of visits paid to various small gardens owned by working men in Lancashire. Copper kettles are favourite prizes in that county, but these and Britannia metal tea-pots are not the only prizes. The districts visited by me were Rochdale, Oldham, Middleton, and neighbouring towns, the mill operatives of which labour under considerable disadvantages, which, however, do not prevent them from following garden pursuits with a zeal far too uncommon elsewhere. The gardens are necessarily small, but large enough for a man to manage during his spare hours. In winter he has not much daylight, except on Saturdays; he therefore has to do the best he can by the aid of moonlight. The spirit of rivalry amongst the operatives is fostered by the numerous exhibitions that are held, and, as far as I could judge, gardening had a much firmer hold amongst the men than other amusements of a questionable character. In many districts fruit does not produce satisfactory results, *i.e.*, with the exception of Gooseberries, which are not influenced so much by the impure atmosphere as Apples and Pears. Hardy flowers are well understood and tended with great care. Celery and Onions are the principal vegetables grown. I was carefully instructed in the art and mystery of Onion and Celery culture by Mr. James Fallows, one of the workmen in the Stakehill Works of Mr. Samuel Barlow. Fallows uncovered a head of Celery to show me the process of blanching. None of the exhibition Celery is earthed up. It is grown on level beds of deep, rich soil, and the art of watering consists in giving enough without overdoing it. Too much water causes it to become pithy. Every plant of Celery in the garden was swathed separately in several sheets of brown paper, and, as it was near the time of exhibition, it was perfectly blanched, clean, and in capital condition for use.

Onions are equally well cared for. In each case there is ample space for the plants to develop themselves; all the leaves are tied up to a trellis to prevent injury to them. Onions, like the Celery, must be watered by someone who knows when they have enough and when too little, as an overgrown Onion will burst, and its chance of success on the exhibition table is then at an end. Exhibition Onions must be sown in the same year in which they are exhibited. The seeds may be sown on the first day in January, but not earlier. The exhibitions, of which I have notes, were held one at Middleton, and the other more recently at Failsworth. They are either held in a public-house, or in premises adjoining one. Red Onions seemed to be merely a selected strain of the blood; but many good gardeners will be surprised to learn that single specimens have been grown to weigh 36 ozs. after the roots and tops have been removed. Ten prizes were awarded for red, and the same number for white, Onions at the Middleton exhibition. Mr. Job Siddall, Crab Lane, Blackley, gained the first prize with a specimen weighing 32 ozs. In white Onions the heaviest was 19½ ozs., and the lightest 8½ ozs.

The Celery was very fine indeed; I have not a note of the weights, but Mr. Barlow told me that three heads have been known to weigh 40 lbs. untrimmed. Mr. Thos. Kay, of Stakehill, gained for Celery the first prize, which was half a load of flour. A recent exhibition, held in the Sun Inn, New Road, Failsworth, was visited by 1200 people who paid for admission. On that occasion forty-six red and white Onions were exhibited and won prizes. None of them weighed less than a pound; the heaviest red weighed 34 oz., and the heaviest white variety 24 oz., the prizes being useful articles or cash.

Roses are the favourite flower of some of the cottagers; and it is worthy of remark that the Rose does not flower well in the usual midsummer flowering-time, but does well in September, the flowers being large, and the plants healthy and free from mildew. The little bit of garden is made the most of. The ground where the Roses are planted is deeply trenched and well manured, pig manure being easily obtained.

I spent some time, also, amongst the Auricula growers. Some of the most enterprising cottagers would grow many different varieties of the choice garden varieties of the Auricula, Tulip, Carnation, Pink, Ranunculus, &c. In many cases the rude structures, covered with wooden shutters instead of glass, have been done away with, and good houses put up in their place. Some of the growers are adepts at propagating scarce varieties, which are so because of their seldom producing offsets. The plan, first adopted, I think, by the Rev. F. D. Horner, of cutting off the head of the plant and encouraging the stumps to sprout effected quite a revolution in the propagation of slow-growing varieties.

The showy, late-flowering Tulips are still greatly valued, and as well grown as they used to be in the palmy days of this noble flower. Mr. David Jackson, an excellent representative of the silk hand-loom weavers and Tulip growers of Middleton, is still alive. Their ambition was to win premiums at the annual Tulip show with their carefully tended blooms, and their occupation of hand-loom weaving in their own houses gave them an excellent opportunity to attend to all the details of their work at the right time. Many of them are also seedling raisers, and to their industry we owe many of our choice named garden varieties. The Auricula, Carnation, and Tulip exhibitions are held under the auspices of the Botanical Society of Manchester. The council give a grant of money to each and find a place for

the exhibitions, which are held either in the town hall or in the gardens of the society at Old Trafford. In these days of special societies it is just probable that a society formed for the special culture of Onions and Celery having its centre in Manchester would be very successful. The growers could take their products to the town hall, and at the usual date at which such exhibitions are held, a goodly number of visitors would be expected to attend. It would at least have the charm of novelty, and that would be something in these days. I would object to anything that would take working men inside a public-house, however laudable in other respects the object might be.

J. Douglas.

NOTES.

Primroses, or Peas.—Mankind has been divided in many ways, but I sometimes think there are two classes only—those who like Primroses, and those who prefer Peas. Sentiment is in favour of beautiful Primroses, but those who pride themselves on their sterling common sense select the Peas, all of which signifies merely this, that the one prefers utility, and the other things wholly beautiful. There is a quiet, unpretentious, middle-class set of people who say nothing, but enjoy both. "I remember once seeing a white satin spencer of Queen Elizabeth's, embroidered with butterflies and Green-Pea pods half-open to show the rows of Peas within," and there are "Pea-pods beautifully sculptured on the great bronze gates of the cathedral at Pisa" [E. V. B.]. So that, even the prosaic Peas of the kitchen garden have a higher use than the mere pot-boiler can put them to. But when we come to the sweet hedge or wood Primrose, what shall we say of it? It is the most lovely of all our flowers of spring, and the latest of all flowers taken as a party badge or ensign. Lilies, Irises, Broom, Crown Imperials, and Violets, to say nothing of the Rose, have each and all been degraded in their turn as party symbols. Somehow one must regret the fate of any wild flower that is singled out in this way to be torn up by the million, and then brought into the towns to fade and die. Alphonse Karr tells us something of the political flowers as used in France, all of which were in turn proscribed and recalled, or multiplied to excess, or piteously rooted out of the flower beds in the Tuileries garden. Gone now the Violets and the Crown Imperials which are painted on the old state coaches at Versailles, and those who planted them carefully are gone along with those who proscribed them and threw them away, and yet every year they return in private life, and are quite as happy, certainly much less tormented, than when at the zenith of their political power.

Ruskin's garden at Denmark Hill.—Mr. Ruskin, now of Brantwood, thus describes in his "Reminiscences" the garden he inherited on the death of his father. "I have round me here at Denmark Hill seven acres of leasehold ground. I pay £50 a year ground rent, and £250 a year in wages to my gardeners, besides expenses in fuel for hothouses and the like. And for this sum of £300 odd a year I have some Peas and Strawberries in summer, some Camellias and Azaleas in the winter, and good cream, and a quiet place to walk in all the year round. Of the Strawberries, cream, and Peas, I eat more than is good for me, sometimes, of course, obliging my friends with a superfluous pottle or pint. The Camellias and Azaleas stand in the anteroom of my library; and everybody says when they come in, 'How pretty!' and my young lady friends have leave to gather what they like to put in their hair when they are going to balls. Meantime, outside of my fenced seven acres numbers of people are starving; many more dying of too much gin; and many of their children dying of too little milk." I know not whether Mr. Ruskin has a garden at his present home or not, but certainly no man of our time has in his speech and writings shown deeper sympathy for beautiful trees and Grass and flowers than he has. His definition of the vegetable kingdom is quite different from the definition of botanists generally, but perhaps not on that account less true. "Corn for the granary, timber for the builder's yard, flowers for the bride's chamber, and Moss for the grave." In a word, food, shelter, and beauty for all of us, living or dead, are the sum total of a world's vegetation.

Impatiens coccinea.—Can anyone learned in garden plants tell us where seeds of this old rosy-flowered Balsam can now be obtained? It is a tender annual introduced years ago from India by the late Dr. Roxburgh, and it is figured in the *Botanical Magazine* (t. 1256). It was cultivated by Mr. Salisbury, who grew it along with many other rare and beautiful plants in his botanical garden in Sloane Street, but is, as I now apprehend, extremely rare in gardens, even if it exists therein. The flowers are large in proportion to the leaves and slender stems, and at first sight colour and leaves alike remind one of Begonia Marti, another lovely species not so often seen as it deserves to be. So far we have no Impatiens so free and floriferous as is I. Sultani, but, judging from the *Botanical Magazine* figure, as cited above, this I. coccinea would run it very hard in the favour of cultivators generally. I. Hawkeri bears magnificent individual blossoms, brilliant in colour, but it is by no means so free as I. Sultani. If Impatiens coccinea does not exist in gardens, we must ask our Indian friends at Calcutta, Bombay, or Madras to look it up for us, and to send us a few of its seeds.

Vegetative vigour *v.* fertility.—The very foundation of good gardening depends in a great measure on our distinguishing sexual vigour from mere vegetative growth in the garden. We find the rankest of wood and the largest of leaves on young trees or seedling plants that rarely, if ever, yield a flower or a fruit. This is vegetative vigour, and the natural result of a plentiful supply of nutrition of plant-food in the soil. Now, if we find this rank woodiness in our fruit trees, what does the gardener do? He root-prunes, or he plants the trees in a restricted area or in poor soil, or he engrafts scions on a restricting stock; in a word, he withholds all superfluous nutrition until the flowering and fruiting limit of fertility is ensured. Nature obtains the same results in other ways, not being in a hurry for results, as we generally are in the garden. So we manure the ground heavily when we want fine leafage, but if we want fruit or flowers as early as possible, we curtail the root supplies until such time as we are sure of a crop. We must never forget that there are two kinds of vigour present in every plant, and one of these forces is apt to counteract the other. By systematic starvation a Chinese gardener will grow half-a-dozen little fruit trees, and present them to his admiring employer on his birthday, all growing and flowering or fruiting in a punch-bowl; while, in Japan, an Umbrella Pine, fifty years old, is often seen growing in a half-pint bit of porcelain. In a word, a free larder in the garden practically means leafy growth, but if supplies are by any means kept down to the right limit, flowers and fruit will be obtained years earlier than when free-root scope is allowed. Every plant has its fertility line, and it is the business of the gardener to find this line by wasting as little vegetative growth-force as is possible.

Scented-leaved Pelargoniums.—It is now a long time ago since these were novelties, and, in consequence, much run after in gardens, to which they had been introduced from the Cape. But after passing through the dark ages of neglect it is now pleasant to know that they are again being valued at their true worth. They are for the most part evergreen, and so always fresh, sweet, and many of them are very distinct and beautiful when in flower. All the old Stag's-horn forms are useful for cutting, affording fragrant fine cut leafage for grouping along with cut flowers. Then the peppermint, lemon, and rose-scented kinds are not less valuable in their way. A cool greenhouse temperature suits them, and they are easily propagated from cuttings or slips inserted in sandy soil. For window culture they are admirable, although not now so popular as formerly amongst the cottagers and others, who threw them away to make room for the large-blossomed Pelargoniums of Hoyle, Foster, Beck, Turner, and other raisers. There is to-day, however, a deep-laid desire for fragrant leafage of all kinds in most good gardens, and so these old favourites are again valued, and are brought back to the greenhouse and garden along with the thousand-and-one old-fashioned flowers of other days.

Outdoor Grapes.—I am glad this subject of Grape-growing in the open air has again been opened, believing as I do that within certain limits much may be done with Grape Vines in particularly warm and sheltered places. The sorts are a most important consideration. Black Cluster and Chasselas de Fontainebleau are two of the best, and these generally do well if duly trained, pruned, and tended on sunny walls or in sheltered warm yards in Southern England. Restricted root-space and frequent watering with liquid manure also go a long way in the race for a good crop. Even in the cold midland counties of England I have seen good crops of outdoor Grapes. I remember a Vine—Black Cluster, I believe—which grew on a mud wall in a garden alongside Petch's tanyard in the town of Melton Mowbray, and I have often seen it laden with Grapes of really good quality. They were good to eat, but the bulk was made into wine. If open-air Vine culture should revive, we must rear hardy seedlings, as the Americans did years ago. We have in recent years lost our luck, I am afraid, in the careful culture of other open-air fruits as well as Grapes—gone now the old flue-heated fruit-tree walls, and I wonder how many young gardeners of to-day thatch down the Fig trees every autumn as I had to do when a boy. The introduction of cheap glass structures is "mighty convenient," to use an effective expression; but they have led to the neglect of many efficient practical dodges by which fine wall fruits were secured in days gone by. If we took as much care of our Vines as they do at Thomery, and attended to our Peach walls as they do at Montrieux, we should succeed in getting good fruit. As it is, an open-air Peach is a luxury, and the Vine and Fig tree make us afraid.

Satisfactory little gardens.—I am very much obliged to "North-west Cheshire" for giving us all such a very interesting account of what I am quite sure is a very satisfying garden. Great gardens are, like big books, a great trouble, and great gardeners, I feel fully assured, are by no means the happiest ones. Some of the most interesting gardens I know are those managed by ladies, or gentlemen themselves, with the assistance of a gardener now and then or of a labourer for digging, and who will do carefully all that he is told. Of one thing "North-west Cheshire" may rest fully assured, and that is that no great gardener who reads his description on p. 511 will depreciate his well-directed endeavours to make a good and produc-

tive garden around his house. Personally, my own feelings in the matter are that he has made good use of his opportunities, and I am sure possesses a garden worth the seeing and of which he may well feel proud. Some of the most satisfying of gardens are small ones, where a few good things are focussed as it were instead of being scattered and dribbled over acres and acres of space. In little gardens you can concentrate both labour and growth force, and I trust the pleasant picture drawn at p. 511 will prove an encouragement to those who are ever longing for an angel's wings—that is to say, for more space or more labour power in the garden.

Names *v.* things.—"What's in a name? That which we call a Rose, by any other name would smell as sweet;" and this is, after all, a truth demonstrated in the garden every day in the year. Call a plant this or that, superbissima or tristis, but the plant so called is yet the same, despite all our naming and awarding of honours. The Arabs have a proverb, "Man gives names, but the Creator gives things;" and we may differ over names like the *savans* in one of Molière's plays, but Nature never changes from her purpose, call her children whatever we will. One may freely grant the scientific minority the right to use Latin or Greek names in so far as these are understood all the world over, but the use of dead languages of this kind will always prevent the majority of readers from understanding anything of botany as so described. We say to the *savan*: Use Latin if you will, but give us at least the crumbs which fall from the table, viz., plain English also, for plain people. The use of Latin may inform foreign botanists; but think how many people at home are blinded by its use. As it is, more botany is concealed than is revealed. Latin, as used in science, becomes a locker, of which only a few hold a key. The business of real students of Nature is to interpret her secret writing and to publish her mysteries simply and plainly, so that all who run may read. People who are not botanists do not care to ascend the difficult winding stair of Latin and Greek words in order to look at a Daisy in the Grass. We have in plants the most pleasant of all the sciences, but we are asked to study them barefoot and among thorns.

Dahlia imperialis.—Someone has written the couplet—

> To grow in size just like a tree
> Does not make things better be;

and the same applies to this gigantic species of Dahlia from Mexico. Soon after its introduction it flowered at Chiswick, but I think it was the late Mr. John Salter of Chrysanthemum fame, then of the Versailles Nursery, Hammersmith, who solved the difficulty of flowering it at 5 feet or 6 feet in height, and this was effected by grafting scions of D. imperialis on to the tubers of a Dahlia of the ordinary dwarf-growing kind. As a noble-flowering plant for a warm, airy conservatory this giant Dahlia deserves notice, and it is to be hoped that by the more general adoption of Mr. Salter's expedient this plant may be more often seen. Dahlias generally, and this rampant species in particular, become too gross and leafy if grown in deep, rich soils. A compost of lime rubbish and road scrapings, or any poor sandy loam is better than a richer compost. The plant should be grown in a sunny position in the open air, and just as the flower-buds appear a little liquid manure may be given with advantage, but not before the buds are seen. Its flowers are as big as those of white Lilies, and are very effective late in the year.

Ferula conspicua.—This is an ornamental plant of the Carrot or Hemlock tribe totally unknown to me except by name. I find it described as "a lovely gigantic evergreen Fennel," and as retaining its bright foliage for three or four consecutive years. It is further described as a picturesque plant on the lawn, withstanding the roughest weather. Height 2 feet to 2½ feet, and the same in diameter, and the flower-spike of the third year is said to attain a height of 8 feet. All the Ferulas are noble plants, and I trust that some kind reader may be able to inform me as to the above. Years ago, in the old college gardens at Dublin, Mr. John Bain used to grow a very beautiful plant under the name of Ferula persica (see *Botanical Magazine*, vol. xlvi., t. 2096). The plant was, I believe, unique, and, so far as I now know, is unknown in gardens to-day. F. communis and some other kinds are just commencing their growth, and during the early months of spring, when Crocuses, Snowdrops, and Daffodils gleam out here and there from the fresh young Grass, these finely-cut Ferulas are as beautiful as the Crape Ferns or Todeas, and, moreover, much less difficult to cultivate. We sow Ferula seed every year from various sources, but to ensure the best results it should be sown during the late summer months as soon as ever it ripens. Some of the seed collected in Asia Minor by the officers of the Russian army, which reached us through Dr. Ed. Regel, of St. Petersburg, has grown well, and the seedlings are of great promise. I wish some traveller in the north-eastern parts of Asia would send home seeds of the gum-producing Umbellifers, such as the true Narthex asafœtida, Euryangium Sumbul, and Darema of various kinds, all of which would be most welcome additions to many modern gardens.

Veronica.

Flower Garden.

HARDY SPRING-FLOWERING PLANTS.

There seems to be a lack of information, especially amongst owners of small gardens, as to the best way in which to fill their beds or borders with spring-flowering plants. The popular notion of bedding is straight lines of different coloured Violas, Daisies, or fine-foliaged plants. The garden of which I have charge is a very large one, and contains thousands of spring-flowering plants, but none of them are planted in straight lines, angles, crescents, circles, or parallelograms. Hardy plants of all kinds in a state of Nature grow in masses. For instance, the Cushion Pink (Silene acaulis) has been found on the Westmoreland mountains forming tufts, or rather beds, 5 feet across, and the wood Anemone (A. nemorosa) may be found besprinkled in English woods in great masses. Some of our best gardeners have disregarded Nature in this respect. I have been recently reading a work on spring flower gardening, by one of the foremost of British gardeners, and in that we are told that the old-fashioned Crown Imperials are excellent for back lines. The striped-foliaged Iris we are also told "is a very ornamental plant, admirably adapted for back lines in ribbon borders, panels, and centres of large beds." Even concerning the planting of the Snowdrop, the loveliest of all our vernal flowers, directions are given which no one with any love for natural beauty could adopt; on grass it is said it may be planted in stars, crests, and in numerous other designs, by making holes 4 inches deep with a dibble, and dropping in a bulb or two. It is also added that "few plants remove better than Snowdrops, and when planted as edgings or lines, they can be lifted immediately they have done blooming with balls, and be put in any out-of-the-way corner to mature themselves." It is scarcely necessary to state that Snowdrops removed twice a year will give no satisfaction. Like most other spring-flowering plants, they like to be undisturbed. Plant them in a suitable position at first, and they need not be moved for a decade at least. I dislike double-flowered Snowdrops; some, however, like them best, and as they are as cheap as single ones, it is easy enough to obtain them. Our mode of treating Snowdrops is as follows: We selected a part of the lawn that could be left unmown up to the end of May, and as it was also an uneven part, we stripped off the turf, levelled the soil, and added some fresh material. The whole of it was planted with Snowdrops, Crocuses, and winter Aconites in masses. The roots were merely pushed into the soil, scarcely covering them, and the turf was rolled over them and beaten down quite level. They did not flower well the first year, but they were better the second; and last year, though the season was unfavourable, they flowered most profusely. We grow also in isolated clumps in the borders four other species of Snowdrops, viz., Galanthus Redoutei, G. plicatus, G. Imperati, and G. Elwesi. The last named I consider the most beautiful of all Snowdrops. When planted in borders there is no need to remove them. The leaves die down naturally about the end of May, and if summer-flowering plants are required to take their place, they may be planted close to the clumps of Snowdrops, over which they will spread and do no harm whatever to the bulbs underneath.

Another favourite spring flower is the Wallflower. Of this sweetly perfumed plant we grow thousands, and as there are numerous beds which have to be filled with summer and autumn-flowering plants, we fill them in the autumn with Wallflowers, which are removed in May when their flowers are over. Two varieties are grown (both dwarf); one has golden yellow flowers, the other blood-coloured ones. It is easy to save seeds of Wallflowers, but only one kind should be seeded in the same year, and by keeping the dwarfest and brightest flowering varieties for seeds a strain of great excellence can in a few years be obtained. The Wallflower is quite at home on old crumbling walls, in the crevices of which seeds may be sown, the result of which is better than that from transplanted plants.

Double Daisies, white, pink, and crimson or deep red, are lovely in beds; they like rich soil and frequent transplanting. In dry, light soils they have a tendency to die off during hot weather. This tendency can be overcome by giving them deeply-worked soil to grow in and a fair supply of water at the roots. I do not know whether Christmas Roses may be admitted as spring flowers. They are decidedly winter-flowering plants, beginning as early as the last days of October and flowering well into the new year. Helleborus altifolius and H. angustifolius are our two favourite varieties, and most lovely they are. We tried some of them under handlights, and others without them, and the uncovered plants were the most healthy. It takes a sharp frost to harm the flowers, protected as they are by a canopy of noble foliage. Christmas Roses are best left undisturbed for years and years in the same place.

Anemone apennina and the earlier flowering, as well as more beautiful, A. blanda are charming plants for masses. They both increase most rapidly, and can be speedily multiplied a hundredfold in deep, well-worked soil. In borders we leave them alone for about five years; the leaves die off, early summer-flowering plants are planted over them, and as the ground where they grow was trenched at planting time about 18 inches deep and well manured, it does not require more than a light surface dressing of rich soil once a year. There are no such lovely blue flowers as those of these Anemones to be found, and they open well in cold weather. I have seen them when in full flower covered with snow, and when it has melted and disappeared they have come out in the sunshine as bright as ever. The white form of A. apennina is now plentiful, and, notwithstanding the fact that some of the plants revert to the normal blue form, the mixture of blue and white is very pretty. The double form of the common wood Anemone is a charming plant. The yellow wood Anemone (A. ranun-

culoides) has rich yellow flowers that are freely produced, and which can now be easily obtained. The numerous hybrids of A. coronaria, especially those which produce self-coloured forms—scarlet, purple, rose, violet, blue, &c.—are most valuable. They are the most charming plants imaginable, and mixed varieties of them can easily be raised from seeds. Who, too, would be without the pretty little Adonis vernalis, which produces its pretty yellow flowers freely in light, deep soil? That earliest of spring flowers, likewise the little winter Aconite, grow like a weed on Grass or in borders. It grows well on bare banks, and covers them with a golden sheet of glistening colour before the Snowdrops appear. The Aubrietias are much esteemed for filling beds in early spring, but they require occasional curtailment. Indeed, I saw a rock garden entirely overrun with A. Campbelli, everything else being smothered.

Another spring flower beloved by everybody is the Hepatica—red, white, and blue. The double red is easily grown, but the double blue does not take kindly to ordinary culture, although it can be grown freely in some places. H. angulosa grows as freely as any of the Hepaticas, and is surpassed by none of the single forms of H. triloba.

Chionodoxa Luciliæ may now be grown in every garden and can be plentifully raised from seeds, which vegetate as freely as those of Onions. The seeds scatter of their own accord, and the young plants appear very thickly round the parent bulbs. Tulips, Hyacinths, and Crocuses may be grown in quantities. I cannot conclude without a word in favour of late-flowering Tulips—the bizarres, byblœmens, and roses of the old florists. They are the gayest flowers of the spring garden, and require no great care to produce a grand display. We plant the bulbs early in November in rich, deep soil; when grown somewhat, a mulching of decayed manure is placed over the surface, and they need no more attention. The bulbs are ready to be dug up about the middle of June; the places in which they were grown are forked over and planted with Asters. I have omitted Pansies and Violas of many colours; also Forget-me-nots, Narcissi, Grape Hyacinths, Squills, Saxifrages, Primulas, and alpine Auriculas, none of which need the least assistance from glass. J. Douglas.

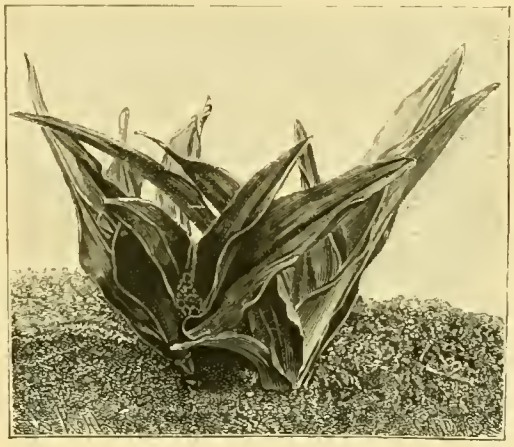
Salvia Pitcheri.—Good blue flowers are so scarce in autumn, that this Salvia ought to be found in every garden. I do not suppose that it is quite hardy in any part of the country, but it is so nearly so, that if wanted it can be easily protected during a severe winter. Here it has not been exposed to more than 22° of frost, but that amount of cold has done it no harm. It commences to flower at the end of September, and remains in bloom for several weeks. In our strong soil it grows to a height of 4 feet and requires supports. The spikes of flowers are sometimes 9 inches long.—Taunton.

Are Centaureas hardy?—Inquiry was recently made in The Garden as to the power of Centaureas to stand the winter out of doors. In the west of England I find that when left out of doors they are not hardy enough to be depended upon. I have known them to pass through a mild winter unharmed in a well-drained soil and in a sheltered situation, but in our elevated position they cannot be trusted. In our case damp kills them before frost has touched them. We had more than a score of plants in the centre of a bed of Verbenas this year, but the Centaureas were all dead by the middle of October, although the Verbenas kept healthy and full of vigour.—Somerset.

—— In some districts, no doubt, this plant will withstand the winter out of doors; two years ago in the lower part of Suffolk I saw some very fine plants of it which had been out for three or four years. I have tried leaving it out myself, but have found the result anything but satisfactory. Some plants of it generally die off during winter, and when replaced by young plants the plantation looks uneven and does not compare favourably with annually propagated stock. Some years ago it was customary to propagate Centaureas in autumn in the way in which Calceolarias are propagated, but the best way with which I am acquainted is to save a few plants of the previous year's stock and pot them in 5-inch or 6-inch pots, grow them out of doors during summer, and late in autumn and winter they will be useful in the conservatory. Early in spring place them in a higher temperature and remove the tips of the shoots; the result will be an abundance of cuttings, which, if taken off with a heel, will strike root quickly. "Cambrian" appears to think that the plants stand the winter better as they get older, but my experience is just the reverse with both Centaurea ragusina and Cineraria maritima. While young the plants seem to stand the winter fairly well, but as they get older they go off wholesale, even though the weather is not severe. —E. B. L.

ROHDEA JAPONICA.

Though devoid of flower beauty, the varieties of Rohdea japonica deserve a place in the garden as dwarf foliage plants. The leaves are of great substance, and of a fine glossy, deep green colour,



Rohdea japonica. Engraved for The Garden from a photograph.

boldly waved at the outer edges. There is a large kind, and one or two variegated. It likes a warm nook, and looks well about the lower parts of rockwork.

Border edgings, Speedwells, &c.—I do not know whether Gaultheria procumbens has ever been suggested as an edging for a border. I tried it a year or two ago at Oakwood round a bed containing principally deciduous plants, and now at this dead season the bright red berries and glossy green leaves have a very pretty effect. I was struck with the frost-resisting power of a Veronica with narrow leaves and white flowers which I have as V. salicifolia, but which a good authority tells me is wrongly named. The thermometer at Oakwood last night went down to 23° Fahr., yet I could cut sprays from plants in full exposure perfectly untouched. The narrow leaves and feathery white flowers made a useful addition to a table nosegay, chiefly consisting of Pernettyas with different coloured berries and the open seed-pods of Iris fœtidissima, both very pretty, but rather solid.—George F. Wilson, *Heatherbank, Weybridge Heath.*

Balm of Gilead.—This old-fashioned, scented-leaved plant is wonderfully green and fresh this autumn. I never remember having seen it looking so well at the end of November as it does this year. Absence of frost is, of course, the cause of this, but there are many other much hardier plants that are not looking so well. We have kept a few plants of it for some years by taking up the smallest before frost reached them and placing them in the greenhouse during the winter. Where much greenery is required to mix with cut flowers, a few sprays of this Balm are always appreciated on account of its agreeable fragrance. With us it seeds freely in the open borders.—J. C. C.

HAWKERS' "ROOTS."

A somewhat favourite resort of these peripatetic dealers is in and about the village of Feltham, situated between Hounslow and Staines, and where not only certain trade or market growers produce "roots," as they are called, specially in large quantities, but even many of the cottagers utilise their gardens profitably in the growth of certain recognised things, which, if cheap, are easily raised, and they usually find ready buyers. A few rods of ground only in each case may be so devoted, perhaps, to double Daisies, Pinks, Sweet Williams, or Pansies, but several hundreds of plants are perhaps grown upon so small an area, and it pays better than Cabbages or Potatoes. One of the largest growers has several acres of land filled entirely with all kinds of hardy "roots," and that his trade is very considerable is evidenced in the breadth of single Carnations, *alias* Jacks, annually laid down. These are, of course, raised from seed sown in April, the result usually furnishing many thousands of extra strong plants at this time of the year. Differing from the commoner forms of double or continental Carnations, which have long, narrow leafage, these Jacks have usually broad, reflexed leafage, which imparts an air of quality to the plants. The bloom is, however, very disappointing, as it is but single and small. The growers of these make no pretence whatever that these Jacks are better than they really are. They are sold cheaply, at perhaps about 6d. per dozen, but there are found not a few dealers, gifted with strong imaginations, who think these single Carnations look like good doubles, even if they are not, and do not refrain from selling them as such to unwary purchasers. At 6d. per dozen Jacks are not dear, but at 4s. per dozen they are very expensive. Still, it is a fact that many thousands of these find purchasers every year. There is a class of clever people who apparently like to be "done," and these seem to be fond of single Carnations. At present the root trade is not brisk in spite of the fact that the season has been very open and the material is wonderfully good. We have, indeed, rarely seen it better. Of course, the spring is the chief sale season, but some considerable trade is usually done before Christmas. Possibly the usual purchasers of hardy plants have of late devoted their spare pence to the purchase of Orchids, as these seem to be the fashionable flowers of the day.

How good the roots are may be evidenced by a look over the Pansy breadths, the plants being strong, and in some cases fancies and yellows considerably in bloom. We do not often meet with such fine strains of blotched or fancy Pansies as are seen here, except at some of our leading trade growers'. If the crafty dealer in Jacks would drop them and turn his attention to fancy Pansies, naming them right and left from the Queen down, he would at least find in them good things to offer to his patrons. These plants are all from seed, the best being selected and divided, pulled apart again and replanted more than once in the year, and are now first-rate plants. Then come in large quantities of commoner or second-rate material, the flowers of which are good and showy, but not first-class. Still follows a big belted kind, named Goliath, for it is a huge flower; and Aurora is another, less in size, but very showy and free. These seem very popular sorts, as they are found in large quantities. The best of the self-coloured kinds are Pride of Rufford, really a selected seedling—so named and better than its old namesake—and Golden Prince, both fine yellows; Primrose Queen and Sulphur Gem, good lemon hues; Dickson's

Queen, a good white; and of blues, Blue King and The Tory, both very early and free. Violas are not extensively grown, but the two most favoured are Yellow Gem and Blue Bell. The chief self-purple flowers are Cliveden Purple and Annetta, both good of their kind. Daisies are well represented by the Double Giant, white, red, mottled, and crimson or blood-red. Other forms or colours do not find favour, although some of the pink-flowered kinds are very pleasing. Forget-me-nots are the common blue sylvatica and the white and blue forms of dissitiflora; but these two latter are much less satisfactory growers than the former. Pinks, really good double kinds, are in great force, that very fine white, Mrs. Sinkins, being specially so; so also are the old white and pink-flowered kinds, and also the once highly-favoured Anne Boleyn. Some other kinds tried have not proved sufficiently robust, as it is obvious that only stout, free-growers will thrive under the field culture here given.

The old red Clove is very abundant, and there is also a good selection of double French Carnations. Violets are very largely grown, especially the singles, such as Czar and Russian Superb; these are hardly favourite hawkers' plants, as they lack showiness when in bloom, but some firms purchase largely of them, and specially so of the double kinds, of which the plants are very good indeed. Of whites there are fragrantissimus, flore-pleno albus (reputed the best white), Belle de Chatenay, and Queen of Violets; Marie Louise and Neapolitan, mauve; and King of Violets, deep blue. All these thrive well out in the open field, being much aided during the summer by ample waterings from an adjoining river. Polyanthuses are in good form, also the old and late-blooming blacks, now taking second place to the earlier whites and yellows, which seem to be so much more appreciated. These produce fine blooms and flower very early in the spring. The soil does not seem holding enough for Primroses, whether double or single, and in regard to these it is not possible to compete with the Irish or Scotch growers, who have suitable and moister climates. Amongst Sweet Williams the most favoured is the dark, broad-leaved kind; this is a very robust grower, and has foliage of the hue of Perilla, which makes it an effective winter and spring plant, but the flowers are poor. Good Sweet Williams now are grown, but the fungoid pest which attacks these favourite biennials has been very active during the year, and plants have largely suffered. Columbines, both of the common garden varieties, and the yellow chrysantha are well done; so also are Foxgloves, their fine leafage rendering them popular with dealers, although comparatively late bloomers. Delphiniums consist chiefly of the rich blue formosum, and there are blood-red and golden Wallflowers. Thrift consists chiefly of the old alpina, giving pretty tufts, and close by is a good breadth of Creeping Jenny, always so favoured as a window plant with town dwellers. Yellow Alyssum, Arabis albida, lucida, and lucida variegata are in abundance; and we noted Lad's Love in good stocky plants, Ragged Robin, and the spotted Pulmonarias; whilst in lesser quantities are the beautiful golden Valerian and Doronicum austriacum. There are, too, big breadths of yearling Hollyhocks, reputed good doubles, single Rockets, very strong; also Canterbury Bells, French Lavender, variegated Thyme, and last and least in height, Sedums, in small clumps of the golden tipped acre, already showing colour, and the bright green Lydium and the silvery glaucum. This list by no means exhausts the plants found here and awaiting a visit from the hawkers. A. D.

Dwarf Chrysanthemums.—I have grown for some years a number of dwarf Chrysanthemums, and I find them useful for decorative purposes. My plan is to take cuttings about the middle of July from plants growing in the open ground, putting three in a 3-inch pot, and placing them in a mild hotbed, which should be carefully shaded from the sun. The cuttings should be frequently damped with the syringe till rooted, which will be in about three weeks; they should then be gradually hardened off and removed to a cold frame. When the pots are filled with roots shift into 5-inch pots, a size in which they will make nice plants for vases indoors, or for side stages in the conservatory where plants grown in the ordinary way cannot be utilised. This season I have tried layering with good results, and in future I shall adopt that plan. A number of old stools should be planted out a good distance apart, in order to allow plenty of room for pegging down the shoots, which should be done towards the end of July, using good strong pegs for the purpose, and bringing the shoots within an inch or two of the ground. In a day or two the tips of the shoots will take an upward direction, and may then be layered in 3-inch pots, using a good rich soil; sprinkle with a fine-rosed pot night and morning, and in about three weeks they will be sufficiently rooted to allow of their being severed from the parent plant. Afterwards place them in a cold frame and shade them for a few days, gradually inuring them to sun and air. When they require it, shift onwards, as advised in the case of cuttings, over which layers have this advantage that they require less attention during the rooting process. Our plants grown in this way average a foot high; some have been disbudded to one flower, but the majority are carrying three moderate-sized blooms.—E. B. L.

Helleborus niger lacteus.—This is a very beautiful wild variety of H. niger. Years ago I got it by chance under the name of niger laxus; there is, however, nothing lax about it, and on account of the colour of its flowers I now call it lacteus; they are of good texture and roundish in outline; their colour is a beautiful creamy white, slightly flushed with rose, colours which contrast well with the large bright green eye. If kept under a hand-glass the flowers are slightly red, but if exposed in the open they take the same red shade as those of H. altifolius of English gardens. The principal value of this variety lies in the period at which it flowers, which is immediately after that of niger præcox (sinensis), and thus it fills up a gap between præcox and altifolius; it is just now in full flower here. N. altifolius of English gardens is, however, a very different plant from the type, which also flowers much later.—Max Leichtlin, *Baden-Baden*.

Chrysanthemums on north walls. — I lately saw in a small forecourt garden quite a good show of Chrysanthemums, where the amount of sun the plants got through the summer was less than I should have considered necessary to perfect their growth. They were planted against a north wall, and on the east and west were buildings sufficiently high to keep the sun from them. In spite of these apparently adverse conditions the show of bloom was very good, and they lasted longer in good condition than those in more open situations. This is one more proof of how well adapted the Chrysanthemum is for places where flowering plants generally would fail to perfect themselves.—Byfleet.

SHORT NOTES.—FLOWER.

Chrysanthemum Dr. Sharpe.—If Mr. Douglas (p. 517) will kindly refer to "The Chrysanthemum," 1st ed., p. 79, or 2nd ed., p. 100, he will admit that I am not, nor have I been in time past, unmindful of the history of this variety. Mr. Forsyth (now in Australia), struck with my having referred Dr. Sharpe to Chrysanthemum indicum of the *Botanical Magazine*, t. 327, years ago in The Garden, sent me the history as it stands in my book just named; but there remains the fact that no other Chrysanthemum now grown approaches the figure in question so exactly.—F. W. B.

Anemone japonica.—If "A. D." or anyone will read carefully what I wrote at p. 449 on Japan Windflowers, they will find that I speak of the white and rosy forms of this plant only so far as their European history in gardens is known. There is no reason why a plant raised in gardens as a hybrid should not be wild somewhere or other in the world, or a natural hybrid, or sport in its native wilds. Fortune did not introduce the white, but the purple A. japonica, but I still believe that a white A. japonica exists in China or in Japan.—Veronica.

Crocus bulbs.—Mr Douglas tells us (p. 518) that in the garden he believes Gladiolus bulbs grow downwards at the rate of an inch every three years. If this were true in Nature, some of the Gladioli at the Cape ought to be pretty deep down in the ground, but I imagine there are natural checks on their downward growth when wild, just as when under cultivation. Bulbs and other plants have, within certain limits, the power of adapting themselves to different soils and climates, and this, no doubt, accounts for our Croci growing upwards, while in other cases they go downwards. White Lilies always come to the surface here in a year or two after planting.—Veronica.

ABUSES OF FLOWERS.

Baron Bezecany, the director of the imperial theatres, Vienna, has prohibited the presentation of bouquets and other floral tributes to actresses on the stage. This practice, which has become more or less ridiculous throughout the theatrical world, seems to have degenerated in the Austrian capital into an intolerable nuisance. If a popular *prima donna* appeared in a new *rôle*, or re-appeared after a short absence, it was customary to throw on the stage immense bouquets, or to hand baskets of flowers and wreaths over the footlights, the donors of these emblems of admiration being usually purse-proud financiers. The reason given for this hard-and-fast suppression of the custom of throwing flowers over the footlights is that the performances at the imperial theatres have frequently been interrupted thereby. The director will not, it may be assumed, object to leaving nosegays and baskets of flowers at the stage door. The florists may be expected to make wry faces at what cannot but prove a serious check to the prosperity of their trade; but the persons who will feel perhaps most bitterly disappointed and aggrieved by the sensibly arbitrary action of Baron Bezecany will be the actresses. It remains to be seen whether the flower-throwing prohibition will spread to Russia, where the nuisance has long since attained colossal proportions. Indeed, full thirty years ago, it is said, the directors of the imperial theatres at St. Petersburg had a serious conference with Count Orloff as to the expediency of abolishing the offering of bouquets across the footlights. It was ascertained that in many instances the nosegays contained something else besides flowers—*billets doux* to wit—and, in some instances, very wealthy admirers of genius or beauty placed jewelled bracelets in the flower-basket, or enriched the bouquet-holders with diamonds. Count Orloff, however, did not by any means approve of the putting down of that which he thought to be a ridiculous, but harmless proceeding. "Let it alone," said the astute minister of police; "it is one of our safety-valves." He was quite right. The boiler of Russian despotism is kept at such very high pressure, that were it not for a few social "safety-valves," explosions might from time to time occur.

If we turn to the nations of the west, it will be found that the theatrical bouquet nuisance has been for a long time not only as flagrant as it has been in Austria and Russia, but has mainly lost that gracefulness which it once possessed, and has been made almost repulsive by the vulgarity which has been imported into the bouquet-flinging system. The unseemly spectacle has been witnessed not so very long ago at a London theatre of the nosegays offered to an actress on the stage being collected in a wheelbarrow and so removed to the side scenes; it is notorious, too, that artistes ambitious to take the citadel of popularity by storm, instead of waiting for the stronghold to capitulate to the *artistes'* genius and worth, have purchased on their own account the biggest of bouquets and have had them flung on the stage by hireling hands. It should, nevertheless, be understood that this throwing of bouquets to favourite female performers is not by any means a new thing. If we seek the origin of the practice, it will probably be found to be an Italian one, and of the remotest antiquity. Decoration with flowers, and the presentation of flowers, have been for many ages a conspicuous feature in Italian daily life. From the Italian opera the custom, at first a very tender and pretty one, spread slowly to the theatres dedicated to the performance of the British drama. Ere long it had ceased to be pretty; and did not escape the lash of the satirist. That the practice is carried to excess in our days is undeniable, and it would be unwise to expect its immediate decline, unless some London managers unanimously coalesced to discourage, and even to forbid it. Meanwhile, it may be pointed out that the florists have done very well by the largely additional demand for flowers caused by the bouquet mania, and this demand has led, of course, to a very extensive increase of employment among working men and women engaged in the rearing and the sale of flowers. The development of commerce in these beautiful productions has, within the last half-century, been simply astonishing. Fifty years ago, at a funeral in a country churchyard, a

few posies of Primroses or Violets used to be laid on the coffin of the deceased; at present, the bier of our dear brother or sister departed, if he or she have been rich or distinguished, is heaped high with wreaths or crosses of the very rarest flowers. In America the rage for flowers at funerals has been more violent than in England, and repeatedly has the American press denounced the floral craze, but scarcely with any practical effect. For half a dozen sensible people who are willing to forswear flowers at funerals, there are at least a hundred impulsive people who will not cease to send floral emblems of their love or their admiration for the dead to the house of mourning. Finally, the student of civilisation will remember that two generations ago only the festive boards of the great were adorned with flowers. From very few of the dinner-tables of those who enjoy even to a moderate extent the refinements of life are flowers absent now. These embellishments in all the cases which we have adduced have been carried to excess, there are too many flowers at funerals, too many bouquets thrown at the theatres, too many flowers and too much fernery at ostentatious dinners. The universal exercise of common sense would alone suffice to modify these excesses; but folly, frivolity, and the fashions are a very formidable trio, and against them common sense, backed even by literary and artistic satire, has always to tilt long, and often tilts in vain.—*Daily Telegraph.*

DRAINING LAWNS AND WALKS.

The rainfall this autumn has been such as, in the case of lawns and pleasure grounds, to show where any defect in the way of drainage exists; and, where work of this nature has to be done, there is no better time than the present for carrying it out. Here, as in other parts of the garden, the depth to which the drains should be cut must be regulated by the character of the land. On lawns where the soil is retentive, enough open material, such as clinkers, brick rubbish, or burnt clay, should be placed over the pipes in such quantity as to fill up to within 10 inches or 12 inches of the surface. By this means water will much more quickly find its way into the drains. The necessity for removing all stagnant water consequent upon badly-drained walks is equally pressing. It frequently happens that, however well such work has been done in the first instance, the drains get choked up in the course of time by the roots of trees. Where there are indications of any defects of this kind, they should at once be remedied, in all cases putting in tiles large enough to carry the water off as fast as it falls, even during the heaviest thunder showers. Any insufficiency in this respect entails a great deal of labour by the displacement of the gravel and the accumulation of soil and sediment upon the surface, after which a walk never looks well until the gravel is turned or some fresh material added to the top. For drains in paths the pipes should be always laid sufficiently deep to be out of the reach of the severest and most protracted frosts, for when unglazed pipes are used, if frozen with the moisture which they must have absorbed in them, they are certain to be destroyed. Nothing less than a depth of 12 inches or 14 inches is enough to keep them out of harm's way from this cause. It is very common, especially in small suburban gardens, to see the walks so badly made in the first instance, even when enough gravel has been used, as to render them soft and uncomfortable after any considerable amount of rain has fallen. This generally arises from the gravel being spread on them without care, rough and fine being indiscriminately mixed together. Where such a state of things exists, the best way is to begin at one end, and sift the whole over again, passing it first through a 1½-inch meshed riddle, and afterwards through a second of ¾-inch mesh, putting the large stones at the bottom immediately over the drains, the second size upon them, and the fine gravel on the surface. By this means one of the greatest comforts in a garden may be secured—an efficient path, through which the water can quickly penetrate, leaving the surface dry and pleasant to walk upon. An essential in all walk-making is to have a sufficient number of "eyes" or gratings to carry off the surface water. Where the ground is hilly these should be placed at short intervals apart, as, when the descent is quick, there is the most danger of the gravel being washed up during heavy rains. The formation of new walks, where required, should now be proceeded with, for at no time during the whole year can such work be carried out with greater advantage than at present, before the winter frosts set in. B.

White Daffodils.—I see no good reasen why the white varieties of Daffodils, wild in Europe, should not be very variable, as are their yellow prototypes, and if we are to include Narcissus pallidus præcox in the white section, then indeed, as Mr. Dod leads us to infer (p. 511), will the variations be well-nigh endless. But if we exclude N. pallidus præcox, N. variiformis, and one or two others of the sulphur-flowered group, we shall not get so far beyond Haworth's four white kinds after all. Of course, when we leave the purely wild plants and come to consider the garden seedlings, we at once find considerable additional variations. But, after all, it is of no practical use our wasting time in arguing this matter in print, since the best way of settlement will be for us all to agree to send bulbs to Chiswick next July and August, and let us decide on their differences and merits as grown side by side and under the same conditions. Mr. Barr, who knows more about white Daffodils than most of us, agrees to do this; so also does Miss Wemyss; and I trust that Mr. Wolley Dod will kindly send there at least a tithe of the many variations he has obtained. I hope also that Miss White and Mr. Englehcart, who seem to hold a little aloof from the Chiswick trial, will also agree to send bulbs there; and Mr. Hartland, of Cork, Mr. Poë, and other cultivators will doubtless also send bulbs. In this way we shall get a little more light on a much-vexed question. It seems pretty certain that an actual trial will be by far the best means of our settling disputed points as to these beautiful flowers and their variations, whether wild or cultivated.—F. W. B.

PREPARING FOR FROST.

Although the thermometer and the barometer are now used in many, even if not in most, good gardens, that particular and most useful combination of two thermometers, the one having a wet and the other a dry bulb—viz., the instrument known as a hygrometer—is by no means so constantly utilised as it deserves to be. The cost is only a few shillings, and by its aid it is possible to foretell the severity of frost with considerable accuracy. In the matter of frost, to be forewarned is to be forearmed. The way in which the hygrometer is of service is to ascertain the dew-point, and this, as Buchan tells us in his "Text-Book of Meteorology" (p. 96), "is of great practical importance, particularly to horticulturists, since it indicates the point near which the descent of the temperature of the air during the night will be arrested; for when the air has been cooled down by radiation to this point, dew is deposited and latent heat is given out. The amount of heat thus set free being great, the temperature of the air is immediately raised. But as the cooling by radiation proceeds, the air again falls to or slightly under the dew-point, dew is again deposited, heat liberated, and the temperature is again raised. The same process continues to be repeated, and thus the temperature of the air in contact with plants and other radiating surfaces may be considered as gently oscillating about the dew-point. For if it rises higher, the loss of heat by radiation speedily lowers it; and if it falls lower by ever so little, the liberation of heat as the vapour is condensed into dew speedily raises it. Thus, then, the dew-point determines the *minimum* temperature of the night. This suggests an important practical use of the hygrometer. If the dew-point be ascertained, the approach of low temperatures or of frost may be foreseen and provided against. Thus, suppose on a fine clear day, towards evening, that the dry-bulb thermometer stands at 50°, and the wet-bulbed one at 40°, the dew-point is practically 29°, and frost on the ground may be predicted with certainty, and no time ought to be lost in protecting such tender plants as may be exposed in the open air. If, on the other hand, with a sky quite as clear, the dry bulb was 50° and the wet one 47°, the dew point in this case being, say, 43°, no frost need be apprehended. The raising or depressing of the dew-point during the night by a change of wind is the only circumstance that can happen to interfere with predictions founded on the hygrometer. In the United States the weather bureau has of late years afforded valuable aid to cultivators by the general accuracy of their predictions, and the following table, by the use of which the probable severity of frost may be predicted from the two readings of the hygrometer, has been compiled by Lieut. Allen, an officer in the service to which reference is made above. By the intelligent use of a good hygrometer and this table, no gardener need be taken unawares by frost.

ALLEN'S HYGROMETRICAL TABLE.

Air temp.	0	1	2	3	4	5	6	7	8	9	10	11	12	13
30	30	27	24	21	17	13	7	−1	−11	−30

51	51	49	47	45	42	40	37	34	31	27	23	19	13	6
52	52	50	48	46	43	41	38	35	32	29	25	21	16	9
53	53	51	49	47	44	42	40	37	34	30	27	23	18	12
54	54	52	50	48	46	43	41	38	35	32	28	24	20	15
55	55	53	51	49	47	45	42	39	36	33	30	26	22	17
56	56	54	52	50	48	46	43	41	38	35	32	28	24	19
57	57	55	53	51	49	47	45	42	39	36	33	30	26	22
58	58	56	54	52	50	48	46	43	41	38	35	31	28	24
59	59	57	55	53	51	49	47	45	42	39	36	33	29	26
60	60	58	56	54	52	50	48	46	43	41	38	35	31	28
61	61	59	57	56	54	52	49	47	45	42	39	36	33	29
62	62	60	58	57	55	53	51	48	46	43	41	38	35	31
63	63	61	60	58	56	54	52	50	47	45	42	39	36	33
64	64	62	61	59	57	55	53	51	49	46	44	41	38	35

The manner of using the table above is as follows:—

Read the "wet" and "dry" bulb thermometers and subtract the reading of the wet bulb from that of the dry one. Find the reading of the dry bulb in the left hand (or air temperature) column of the table, opposite which in the column that is marked on the top with the figure which denotes the difference between the dry and wet bulb is to be found the dew-point or probable degree of frost to be expected.

Example.—Towards 5 o'clock the dry bulb reads 51°, the wet bulb reads 42°=difference 9°, so that the dew-point is 27°, this denoting at least 5° of frost as possible during the night.

F. W. B.

Ferns in small pots.—Where much decoration has to be done, some of the free-growing, hardier kinds of Ferns kept in small pots are very useful. By small pots I mean such as do not exceed 2 inches across. Such kinds as Pteris serrulata, the Maidenhair, Pteris cretica albo-lineata, P. scaberula, and others of a similar nature may be grown to nice little bushy specimens in pots of the smallest size. In furnishing jardinières and similar plant receptacles, I found this came in very handy, as they could be turned out of the pots and be worked in wherever there was a little space round the edge, thus giving a finished appearance.—J. C. B.

White variegated Adiantum macrophyllum.—A gardener at Montmorency has, it is stated, raised from seed a white variegated Adiantum macrophyllum. The effect of the variegation is said to be very striking.—H. P. B.

MARKET GARDEN NOTES.

Potting plants.—There is a general concensus of opinion among market growers in favour of potting plants firmly, the degree of firmness being, of course, varied according to the nature of the plant. There is more than one good reason in favour of firm potting, but that which has weight is the diminution of risk in watering. The closer the particles of soil are packed together the less room is there for water. Consequently there is less chance of a sufficient body of it lodging about the roots. Where many thousands of plants have to be watered and the work is done at high pressure, it is important that the soil should be as far as possible guaranteed against becoming soured through over-watering. With some market growers the season regulates the way in which the potting is done. Thus plants that are potted in the early portion of the year are made very firm about the roots, the firmness diminishing as the season advances, so that by the time the weather becomes warm and growth is rapid, the compost is not pressed in with the fingers; the pot is simply tapped sharply several times on the bench. The duller the weather and slower the growth, the greater necessity is there for taking precautions against over-watering. In late spring and during summer the soil dries out so quickly and root-action is so lively, that there is comparatively little danger of stagnant moisture remaining about the root. Another reason for rather loose potting at that time of year is the rapidity of growth that it favours. Plants may be grown in far less time to the requisite size when the roots can ramble freely among the compost than when they have comparatively to force themselves through it. Top growth is in exact proportion to root-production. This may be laid down as an axiom in the culture of pot plants. The plant grower who wants primarily solidity of tissue will at all times pot firmly, for a very rapid growth will not give this. It may not be out of place to remark that this is a detail much insisted upon by one of our best Chrysanthemum growers. He asserts that the solid, well-ripened wood that gives first-class blooms cannot come from loose potting. The market grower has two things to keep in mind, *i.e.*, quantity and quality. He must grow a plant well enough to take the popular fancy, but he has to make the most of his space, and this can only be done by inducing a rapid growth. Market culture under glass, especially that branch which relates to plants in pots, can only be made profitable when space is made the most of, and this is done by pushing the plants along as quickly as is compatible with their health. It would surprise many plant growers to know how short a space of time it takes to bring many things to a marketable size. It is no exaggeration to say that Fuchsias, Bouvardias, Cyclamens, Pelargoniums, &c., are grown to decorative size in half the time that it takes to do so in private gardens generally. As much food and water as they can take with houses specially designed to meet their wants, as well as unremitting attention, form the main elements of successful and rapid plant culture.

Solomon's Seal forced.—Passing through the Central Avenue on a gloomy day in last February, I was almost startled by the quite vernal freshness of some sprays of this hardy flower. Everything else in the market in the way of flowers unmistakably bore the impress of an abnormally cold, dark winter, but the Solomon's Seal looked as bright and pure in colour as if grown under a clearer sky. It seems strange that such a graceful-habited plant as this, and which apparently lends itself to hard forcing better than most things, should have remained so long in obscurity. I advise all who have not yet forced this plant to try it. Plants potted now will come in by the end of February.

Zonal Pelargoniums.—I have often thought that there is nothing in Covent Garden Market that has such a fresh, lively appearance in the early spring months as nicely grown, well-flowered plants of Vesuvius and other bright-flowered kinds. These are grown mostly in 5-inch pots, bearing about two trusses of well-developed blooms. One grower with whom I am acquainted grows many thousands of zonals for the London markets. At the present time his houses are filled with robust, healthy plants in all stages of development, from the newly-inserted cutting to bushy plants in 4½-inch pots. Through the winter these plants are gone over several times a week, and the blooms that are ready are cut for market, so that they afford a weekly revenue all through the dullest months of the year, and then the plants are sold. For plants in 4½-inch pots the ordinary market price is 4s. per doz. In this place all the watering is done with the hose, cold water from the outside being used, which seems to prove that water of the temperature of the house is not absolutely necessary, for the plants are remarkably healthy. Cuttings are taken all the year when they can be got, and in the case of zonal Pelargoniums this is absolutely necessary to keep up a large stock of saleable plants. For cutting in winter, no variety commands so much attention from market growers as the double scarlet E. V. Raspail, which, up to the present, seems to be the only double-flowering kind that possesses all the necessary requirements of a winter flowerer. It is remarkably free. As regards bloom production, it has a robust constitution, fairly dwarf habit, and the colour is just right. What is wanted is a white variety differing in no other respect than colour from this. We have a good many whites, but not one of them is sufficiently profitable. Every market grower has a different way of treating his plants for winter bloom; some grow them along from cuttings, others use older plants, and some plant them out for a month or two and lift and pot them early in August. One large grower in the home counties turns his plants out of their pots in July, shakes away some of the old soil, and re-pots in pots a little larger. I have no doubt that this is the best way, as old specimens of the double kinds flower more freely than young ones, and the repotting at that time gives an impetus to root action. The double kinds need rather more warmth than the singles. These latter will expand with 50° of warmth in winter, but the doubles want quite 5° more; 60° by day is not too much for them, but they must get plenty of air in mild weather. Only decided colours will do for market; intermediate tints will not do. There are many admirable pink kinds very free and good in all respects, but the public will not have them.

Late Chrysanthemums.—I fancy that the Christmas markets will this year be more bountifully supplied with Chrysanthemums than usual. A friend remarked the other day, "There will be plenty of Chrysanthemums at Christmas this year," and I think he is right, as from what I have seen and heard they are lasting longer in bloom this year than they do generally. It is probable that this is owing in a great measure to the fine sunny autumn, which induced many growers to keep their plants a fortnight longer in the open than usual. Moreover, the summer was cool, and many varieties showed buds late. I have a house full of a late white kind from which I expect to cut quite 7000 blooms. I thought that they would have been nearly all out by Christmas, but I see that I shall be cutting from them quite up to February. I am not sorry for this, as I think there is likely this year to be comparatively a glut of Chrysanthemum bloom at Christmas. My plants have had special treatment with a view to keeping them back, and are therefore no criterion as to the general condition of Chrysanthemums in the country. I believe, however, they are a fortnight later than in average seasons, and this seems to be the case in many places.

Red spider on Vines.—Painting hot-water pipes with sulphur to destroy red spider is a well-known remedy, but the way in which the operation is carried out in a market garden in the eastern counties would appear extremely hazardous to the major portion of Grape growers. When other means, such as syringing, fail, the pipes are coated with as thick a paste as can be laid on, and for several nights in succession the pipes are heated to their utmost capability. The fires are kept going all night, and the house gets so filled with the sulphurous fumes, as to render it impossible to remain in it for any time. In a house about 100 feet long as much as 42 lbs. of sulphur were used in the course of a single season. Few would probably think of using sulphur to this extent, but it is well to know that such a lavish employment of it is free from danger. The present appearance of a house of Alicantes that has been this year treated in this way is a proof that no harmful effects have followed. This house of Alicantes is one of the best in the country, the crop being uniformly heavy, the berries well coloured and highly finished. For years past this free employment of sulphur has been practised in the market garden in question, with results equally satisfactory both as regards the health of the Vines and the destruction of the spider. Red spider is such a fearful scourge and so difficult to deal with at times, that sure means for its destruction are welcome. J. C. B.

GARDEN FLORA.

PLATE 574.

THE CLUB-STEMMED DENDROBES.

(DENDROBIUM THYRSIFLORUM.*)

Our plate represents one of the most beautiful of a small group of drooping panicle-flowered Dendrobes from India. It may popularly be called the club-stemmed section of the genus, and contains four or five species only, the best known of these being D. densiflorum, a free-growing plant, of which D. thyrsiflorum may ultimately prove to be a white-petalled form. D. Farmeri, D. Palpebræ, D. Griffithianum, and even D. chrysotoxum (although the last has different-shaped bulbs) may all be grouped together here for convenience sake. All these species (if we except D. Palpebræ) are very variable from a cultivator's point of view; and even botanical authors have thought some of the geographical varieties worthy of specific names; hence we find the usual array of perplexing synonyms. All have club-shaped pseudo-bulbs, thin towards the base and much thickened towards the apex, and it is on this upper portion above the swollen part of the bulb that the leaves and their flowering panicles are produced. As well grown, their bulbs are more or less quadrangular in section, most so, perhaps, in D. Farmeri, and least so in the long and thin-bulbed variety of D. thyrsiflorum, which our artist has represented in the present illustration. In the case of D. chrysotoxum and its forms, the bulbs approach a more equal spindle shape or are fusiform, narrowing more or less abruptly, and the bulbs are fluted longitudinally. The arrangement of leafage and inflorescence, however, remains nearly the same.

With the exception of D. chrysotoxum, all the golden-flowered species in this group produce white-flowered forms, and one whitish variety of D. Farmeri has its blossoms suffused with warm, rosy colouring. Both Lindley and Reichenbach allude to another dwarf, yellow-petalled Dendrobium of this group, viz., D. Griffithi or D. Griffithianum, a plant somewhat resembling the rare D. bicolor or Palpebræ, but neither are by any means common plants in modern collections.

The accompanying table will show the nomenclature, colour, and prevailing distribution of this group at a glance, those usually considered

* Drawn in Mr. W. Soper's garden, 307, Clapham Road, May 4, 1886.

to be the typical species being printed in a larger type.

It is a matter of extreme regret that so little is really known as to the exact localities in which the species and varieties of Orchids are found. A type species may have a very wide distribution, but the variations of a species, which, as a rule, are more highly valued by the cultivator, are in the main confined to more or less restricted areas, these localities seldom being near the central or focus spot of the type, but more generally occurring at a tangent to the outer circle, or they represent the type at some one or more points at or near its margin. But there are reasons why the ordinary plant collector suppresses definite information as to the *locale* of the rarest or most marked variations from the typical species, and until the students of Orchids can obtain definite knowledge of this kind there is not much hope that work amongst Orchids of a really live and practical nature can be done. True, if they are introduced we can grow them and enjoy their beauty in our glasshouse gardens; but without knowing precisely how their distribution varies, we can never hope to know the physical or physiological reasons why they vary, as we know they really do. If the merely negative suppression of localities were the only difficulties, it would not matter much; but we have often been positively told that plants came from one place when they really come from somewhere else. Often the port of shipment is named as the habitat. For example, many of the Orchids mentioned in books and now lying in herbaria, as from Singapore, let us say, really were brought from Borneo, the Philippines, Java, Sumatra, or the main land of Johore, or even from Malacca, not to mention any one of the thousands of islets which lie within 500 miles of Singapore. Hence, when we come to even such a small group of four or five species like the present, we find any reliable statement of their precise geographical distribution quite out of our power. A few remarks may be devoted, however, to the characteristics of these plants as they are displayed in our gardens at home.

D. densiflorum.—This is a strong-growing plant, with stems 10 inches to 18 inches or more in length, and more or less thickened towards the apex where they are clothed with three to five broadly ovate, dark glossy green leaves. The dense racemes of orange and yellow blossoms depend from the upper nodes of the two or three-year-old bulbs, and each spike endures fresh for five or six days, but as all of them rarely open at the same time, it follows that the flowering season is prolonged from a fortnight to three weeks by irregular development of this kind. Specimens 4 feet across or even more, bearing from thirty to seventy spikes of flowers, were not uncommon in the old exhibition days, and even now are occasionally seen in collections. It generally flowers from March to June, sooner or later, according to the heat and aspect or light in which the plant has been grown. The flowers are deeper or paler in colour, and vary in size also according to cultural conditions. Of course, I admit that there are frequently initial variations between the imported individuals of this or any other species, but at the same time nutrition or good culture often adds much to the size and brilliancy, as also to the texture of all flowers. This is one of Nathaniel Wallich's species, and a figure is given (t. 140) in his Plants. Asiat. Rariores; more modern illustrations are those in Bot. Reg., t. 1828; Paxton's Mag. of Bot., vol. v., 121; and in "Flore des Serres," t. 1397. A strong-growing form of this species has been called D. Guiberti in Continental gardens, and it is figured in *L'Illustration Horticole*, series 3, t. 258; also in *Revue Horticole*, 1876, t. 431, and in M. Puydt's "Les Orchidées," t. 16.

Apart from the above yellow-flowered forms of the species, there are at least three white-petalled varieties, these being D. thyrsiflorum, D. Schroederi, and D. Walkerianum. Although distinct enough for garden culture, the botanist could only consider these as variations from the yellow blossomed type; the structure or anatomy is the same, but there has been some variation in the chemistry, although the chemists have not as yet told us why colour or aroma may vary in plants which physically seem precisely alike. The two last named variations are considered more beautiful than D. thyrsiflorum; they are certainly more rare, and, as a natural consequence, they fetch more in the market where "beauty" under the name of Orchids is sold to the highest bidder. In some cases we have seen a lovely soft, flesh tinting, a mere suffusion of delicate rose, so subtle as to be scarcely visible except in certain lights, on the crystalline segments of this thyrse-flowered Dendrobe, and this would seem to indicate a further struggle upward in the colour scale. The introduction of this fine plant has been the subject of controversy. The following is, I believe, a true statement of the matter. In 1855 or 1856, the Rev. C. Parish sent to Messrs. Hugh Low and Co., of Clapton, a Dendrobe, which appeared to be D. densiflorum, but which, as he said, had a white perianth and a shaggy, orange-yellow labellum. Mr. John Day obtained a plant of it, which flowered at Tottenham in 1866—that is to say, ten years or so after its first introduction—but it was not until July, 1869, that its portrait appeared in the *Botanical Magazine* (t. 5780), under the name of D. densiflorum var. albo-luteum. Then on April 6, 1870, Messrs. Veitch and Sons exhibited the plant before the floral committee of the Royal Horticultural Society, and were awarded a first-class certificate. There are thick and thin-bulbed varieties, the tall, thin-bulbed form with long spikes, as shown in our illustration, being generally preferred to the form with short, dense ones. It has been illustrated in *L'Illustration Horticole* (t. 207), and in the *Floral Magazine*, 2nd series, t. 449.

Schroeder's variety is a rather dwarf kind, and flowers in May, bearing delicate blush-tinted flowers, the lip being yellow and orange. It is a rare and valuable form, figured in the *Floral Magazine* (t. 502). Walker's variety of our plant would, however, appear to be the Anak of its race. I never saw it, but Mr. Williams says it produces pseudo-bulbs a yard high, the longest raceme on a well grown plant being 2 feet in length, and producing more than fifty individual flowers. It is figured in Warner's "Select Orchidaceous Plants," iii., t. 21.

As to culture, one need say but little, but there is a peculiarity about these Dendrobes I have not seen alluded to in books. This is anent their season of growth, which is more rapid and shorter than that of any others known to me. Soon after flowering the young growth appears, and at that time heat, moisture, and light can scarcely be too intense for their vigorous development; whereas, on the other hand, after the growth is made they enjoy a longer period of rest than most other members of the genus. These plants are not unfrequently placed in cool conservatories during their flowering season, after which they should be at once returned to a warm, close, light house before their growth appears, or it is apt to be checked and stunted, for that season at least. A good, vigorous plant of Dendrobium thyrsiflorum bearing ten to twenty or more spikes is so lovely when at its best, that one might almost be excused for apostacy from the flowers of the open air.

F. W. Burbidge.

WORK DONE IN WEEK ENDING DEC. 7.

December 1 to 4.

A week of dense fog has, as usually happens at this season, been followed by severe frost, the mercury on the mornings of the 2nd and 3rd falling as low as 18°—14° of frost—and with vegetation quite saturated with moisture. Broccoli, Lettuce, Endive, young Cabbage, and Celery will, it is feared, be injured. We have been busy putting Bracken protection over the Celery rows, as also over Lettuce and Cauliflower plants on south borders, and over the crowns of Broccoli just turning in; the large leaves have been bent. Globe Artichokes have been thickly surrounded with long stable litter, and Jerusalem Artichokes, which as yet are not dug up, have also had some litter spread over them, not for protection of the tubers, which is really unnecessary, but rather that we may be able to dig up supplies when wanted. Parsnips and Horse Radish we usually serve the same, but the frost came on us so suddenly, that we had no time to do the work, and now the ground is so hard that it would be labour in vain. As yet we have had no snow, and therefore the last three days of sharp frost have given us the desired opportunity of wheeling manure on to the various vacant plots of ground, and also we have been able to thickly cover early autumn-planted Strawberry plots with good manure, which is worked well up to the crowns of the plants, and thus it protects as well as manures. So long as other profitable work can be done, *i.e.*, work that will have to be done, and can be done just as well in severe weather as at any other time—pruning and nailing, and any other jobs that one cannot keep warm at are postponed in favour of more active labour, which, besides the foregoing, has been the clearing out of shrubbery clumps in pleasure-ground, and raking leaves off woodland walks. Work in the glass department has been the making of bedding plants in cold pits safe by surrounding the walls with Bracken or litter, as well as over the mats that cover the glass. Violas, Calceolarias, Leucophytons, Verbenas, Echeverias, and the like may remain covered for two or three weeks in such weather, and will take no harm, provided that when the frost is over the covering is left on for a couple of days or so, that the plants and soil that may have got frozen may thaw slowly. Sudden light, and particularly sunshine, before the frost is out of the frames is far more destructive than is a fortnight's frost. Pruned another vinery, and gave both Vines and house the usual cleaning. Tied Peach trees to trellises. Picked over plants. Cut down Chrysanthemums that had done flowering, and put in the first lot of cuttings. We strike them under hand-lights placed on the floor of the early Peach house,

the temperature of which ranges from 45° to 55° in the coldest weather. Though our Pine pits are well heated, an excess of fire-heat whilst the daylight is so short draws the plants, and also tends to cause premature shows, which, as a matter of course, make poor fruit, and to obviate these evils as well as to economise fuel, we cover the glass nightly with stout oiled canvas, that makes a difference to the temperature of the pits of from 8° to 10°. Apart from its being better for the plants, such covering is worthy of adoption on the ground of economy in fuel alone. Put more Seakale into forcing quarters, and placed Early Ashleaf Potatoes in boxes of leaf soil to root preparatory to planting in frames.

December 6 to 7.

The frost departed as suddenly as it came, which, if we could have foreseen, what an amount of labour of covering up might have been saved. However, it is not all labour lost, as the material is there, and partial uncovering is only requisite, such as opening out the Bracken immediately over the heads of Celery, and rolling up the litter tidily beside the pits and frames in readiness for the next occurrence of frost. Endive to blanch, and roots of herbs that are required for forcing we are now getting up as well as supplies of Parsnips and Horse Radish. Recommenced the pruning and nailing of Plums and Morello Cherries. Raspberries are being tied, the stools having been freed of all weakly, unripened canes, and those left shortened back to a height of 4 feet 6 inches. Peach borders are being trenched for early vegetables, as per last week's notes. Rolled walks. This work we always strive to do both after heavy rain and frost, and thus the gravel is kept firm and smooth. The ground is too wet for transplanting of shrubs, of which work we have a considerable amount on hand; hence it is that gravelling and walk-mending are now being done, that transplanting operations may go on without interruption as soon as ever weather conditions are favourable. Indoors the work of fruit-tree tying still goes on, Figs as well as Peaches now being in hand. Picked bad flowers off Chrysanthemums; cut down such as had done flowering, which gave more space to others yet in good flower. The flowers of Bouvardias and Carnations have damped off somewhat for want of a drier atmosphere, but, not having a suitable one at command, more heat has now been turned on the pit, and water will be more sparingly applied and the ventilation increased whenever the weather is mild and drying. Roman Hyacinths in flower have been brought out of heat and stood in a cool vinery; other Hyacinths and Tulips have been put in the forcing pit, and so has a third lot of Strawberry plants. Fruit-rooms and Grapes hanging on Vines have regular attention in respect of removing every trace of decay. Consequent on the sudden change to mildness from severe frost, both Apples and Pears are quite wet, and some few of the choicer varieties of the latter we are having wiped with a dry cloth, and as soon as the outside air is anything like drying, full ventilation will be given.

Hants.

HARDY FRUITS.

Planting this year, owing to the heavy falls of rain, has been delayed, and, much as many object to the performance of this work in December, the dry weather now prevailing will not only induce, but leave many people no other alternative than to go on with it. A wet late autumn tells unfavourably in many ways, for it prevents the nurseryman as well as the gardener from pushing on with his work. Trees lifted and planted in the wet never winter and start so well as if moved when the soil is in good working condition, and slender-rooted examples, owing to the low temperature of the ground, not unfrequently perish altogether. The trade, much as people complain of trade, seems overwhelmed with work; consequently late-comers must be late-served; but there is a way by which this difficulty may be avoided, or certainly reduced, and that is by establishing a small home nursery, and keeping it well stocked with trees for drawing from when weather and convenience favour planting. By a home nursery I do not mean a manufactory, as very few home-made trees are equal to the clean, healthy stock purchased from the leading nurserymen, but simply a well-cared-for spot, in which newly-bought stock can be grown and trained until wanted. Land, like trade, being slack, until even in these times a farm is to be let, every gardener should have all he requires for the asking; but should a difficulty arise—for these men are looked upon as suspicious characters when they begin to talk about old turf and soapy loams—they have only to explain that nurserymen's rents, very high, are paid by the purchasers of their trees, and, notwithstanding the fact that maidens at a cheap rate are perfect, disease not unfrequently follows the hard pruning back practised in nurseries. The nurseryman is in no way blamable so long as purchasers will have cut-backs; but I maintain that perfect trees can be formed without cutting back at all—that is, provided they are transferred to the home nursery when a year old, and, as a matter of course, before the maiden shoot is cut back to within three or four eyes of the union. The proper way, however, is pinching out the point of the leader when it has grown some 12 inches to 18 inches from the junction; side shoots are then formed, and the framework of a good tree is formed by the end of the first season from the bud. Some Rose nurserymen who exhibit allow maiden plants to throw a single shoot several feet in height for a single bloom, leaving their customers to cut back to the base buds, but being unripe and buried in crude sapwood, they never break, and the plants, transferred to poorer soil, perish. Others, who do not exhibit, pinch out the points when they have made a foot or two of growth, and secure bushy plants with four or five shoots of moderate strength, and well ripened by the end of the season. Fruit trees can be manipulated in the same way, and are infinitely superior to cut-backs, which not unfrequently make their *début* with a piece of dead wood rankling within a few inches of the union.

Orchard Planting

may still be pursued—that is, if the weather continues dry, open, and mild, and the land is in suitable condition. The old-fashioned mode of digging pits or water traps in Apple-sick orchards is not a good one, for no matter how carefully the compost may be prepared, the roots soon find their way to the solid subsoil, where, starved and poisoned by water teeming with decaying vegetable matter, they become inactive. The heads make little, if any, progress, a few feeble flower-buds instead of bright, healthy shoots are formed, the trees languish, canker and Lichen claim them for their own. Old orchards must, as a matter of necessity, be filled up, pruned, and renovated, but a young tree should never be planted on the spot from which an old one has been removed. The first operation in the renovation of old orchards is a clearance of all worn-out or useless sorts, thinning and cleansing of those retained. Then comes thorough draining, and finally planting, not immediately over the main drains, but where lateral drains will keep the roots free from stagnant water. The compost used in old orchards should consist largely of fresh loam, road-scrapings and parings from the sides, old lime rubble, and burnt earth or clay. All the old roots, prunings, and trimmings of the hedges, and as much more rough wood as can be obtained, should be used for burning the clay, and if all is not wanted for making up the planting compost, the surplus will be found the best of all top-dressings for the old trees.

Pruning.

When autumn planting is finished old trees should be judiciously pruned and thinned to throw the heads open to the influence of sun and air. If densely interlaced and matted together, as we too often see the branches, this work should be performed piecemeal—that is to say, the thinning of old, enfeebled trees should extend over a couple of years. The removal of very large branches should be avoided—certainly the first season, but small spray and crossing boughs should be cut out to inure the heads gradually to the light, and at the same time to form the largest possible external area of well-balanced fruit-bearing wood. By adopting this plan numerous dormant buds will be forced into activity, and young growths at the commencement of the second season will act as safety valves where the removal of extra large branches is decided upon.

Top-dressing.

Until quite recently the roots as well as the branches of old trees have been left to take care of themselves. Year after year has passed by, but nothing has been done to stimulate the roots or draw them to the surface. Draining alone has a wonderful influence on the growth of the trees, but something more is needed. All the refuse wood, as I have just stated, reduced to ashes and cast over the surface of Grass orchards soon tells; manure, the scourings from ditches, even the cake or "must" from the cider mill, thoroughly mixed and spread about, restore to the soil the salts and other elements so essential to free growth, and, as a matter of course, good fruit. If the whole surface of the orchard cannot be top-dressed in one season, a wide circle round each tree should receive a good supply of stimulating food, to be washed in by winter rains. Town-made manure, which not infrequently contains a little of everything, is excellent, and bone-dust is a host in itself; but, judging from the kind growth of trees in cottagers' pig-runs and the farmers' paddocks, animal manure is an excellent fertiliser. A Grass orchard is very pleasant to walk in, and convenient for gathering the fruit, but on no account should it be laid for a crop of hay, if grazing is practicable.

Cleansing.—As neglect, poverty, and Lichen generally go together, a word upon this head may be acceptable. The old Moss covered stems of trees in the first instance may be well scraped with a piece of hoop iron, when scrubbing with strong lime-water, brine, or soapsuds may follow. If more convenient, a quantity of fresh-slaked quicklime cast up into the branches on a damp day will answer equally well in the destruction of Moss and Lichen, and will help the roots after it has opened the pores of the bark to the influence of sun and air. Where American blight, the greatest pest in our orchards, has gained a firm hold, a pint of paraffin added to six gallons of strong soapsuds will be found a safe and certain remedy. This may be syringed over the parts affected, always, of course, when the trees and buds are dormant; but the most effectual and economical method is as follows. To this or any given quantity of the wash add as much stiff loam as will produce a thick paint; then, with a stiff brush, work it well into the haunts of the enemy. If well applied, one dressing may clear a tree, but every bug in old trees is not easily reached, and for this reason infested orchards should be looked over annually.

The Fruit Garden.

The principal work in this department now is pruning, nailing, and training. With the exception of Peaches and Nectarines, which will not require further attention until they are released from the walls in January, all other trees may be operated upon when the weather is suitable. Some fruit growers prune through all weathers, but by commencing early and taking advantage of every fine, mild day, exposure of the pith in frosty weather may be avoided. Moreover, the men who have to perform the work not only get on much faster, but do it better. With us bush fruits, also Currants against walls, are taken in hand first, and when finished they are well syringed with soapsuds, or dusted with quicklime to destroy Lichen and the larvæ of insects. Manure is then wheeled out in frosty weather, and although we do not believe in deep digging, it is lightly forked in at leisure. Raspberries come next, as early mulching is one of the main points in securing good crops of fine, juicy fruit. If the

formation of new plantations is contemplated and the planting of young canes was neglected in October, they may be put out now and well mulched with rotten manure to keep the roots moist and safe from frost. Raspberry plantations under good management last a number of years, but, like the Strawberry, they give the heaviest crops of the finest fruit when four or five years old. This method of rotation is very simple, as we only have to plant one or more rows every year always on fresh, deeply trenched ground, and destroy an equal number of the oldest stools. Few people care for many varieties, but rest satisfied with one or two good sorts which do well on their soil. With us Carter's Prolific on the five years' course is an especial favourite, as the fruit is extra fine and the flavour delicious. In low, damp situations subject to severe frosts, it is a good plan to defer topping the canes, or at least a portion of them, until the buds commence swelling in the spring. If Strawberries have not received their winter mulch, a good dressing of manure or rich compost should be placed between the rows at once, that is, provided they are free from weeds and the crowns of the plants are not frosted. Like the preceding, whose roots run along the surface, the beds should be kept clean by hand and hoe or smothered by heavy mulchings, but on no account should fork or spade be introduced amongst them.

Pears, Plums, and Cherries,

both on walls and open quarters, having at last lost all their leaves, may be pruned, nailed in, and washed. The first and last being so subject to green and black aphis the walls should be well scrubbed with brine during the time the branches are detached, or they may be syringed with soapsuds after they are nailed in. Where good soapsuds are plentiful, this washing may be repeated at short intervals throughout the winter, as it not only cleanses the wood and walls, but acts as an excellent manurial agent when it reaches the roots. Pears are not often attacked by aphis, but the oyster scale is often very troublesome, and, being the exact colour of the bark, sometimes does much mischief before its presence is detected. When badly infested, the main stems and branches should be well scrubbed with strong soap water and afterwards painted with a mixture of Gishurst compound and stiff loam, one pound of the first to a gallon of the second, to which half-a-pint of paraffin may be added when reduced with hot water to the consistency of thick paint. The tar mixture, half-a-pint of gas tar to a gallon of loam, as recommended for Vines, may also be used. Either of these will very soon cleanse the trees and leave the bark bright and free, when generous culture, including good mulching and copious watering in summer, will generally cause the trees to grow out of it. We have in this part of the country a very loathsome, slimy caterpillar called the slug worm, which attacks the foliage in August and September. If left alone it eats away the foliage and renders the fruit of little value. The best summer remedy is dusting with quicklime or syringing with lime water, but, prevention being better than cure, the scale paint with a little fresh lime added applied to the wood and walls in winter will destroy it most likely at one dressing. The month of December is perhaps the best time to apply insecticides to hardy fruit trees, as the sap at the present time is inactive, and the buds as well as the wood can be dressed without fear of injury. Many people attach great importance to the use of strong ingredients, but this is a mistake which often leads to mischief, and it is questionable if a well mixed solution of stiff clay, soot, and lime, with a very small piece of soft soap to make it work and adhere, would not prove a safe and certain destroyer of all scale to which fruit trees are subject.

Figs.

The weather up to the end of November having been so mild, Fig trees have not required covering, but 19° of frost on the morning of the 2nd reminds us that this precaution must no longer be delayed. We have accordingly placed a moderate layer of dry Fern in front of the trees, and may add more with a broad coping board above should unusually severe weather set in. When Fern cannot be obtained, a thatch of small Spruce or Yew boughs tucked in between the main branches and the wall, with their tips hanging downwards and overlapping each other, make an excellent covering not only for Figs, but also for Apricots in exposed situations. Some unnail their Fig trees, and, after tying the branches up in bundles, encase them in wheaten straw; but this is carrying protection to an extreme, as trees so treated become extremely tender, and frequently suffer after they are uncovered in the spring. Moreover, this snug covering forms a safe retreat for mice, which do irreparable mischief by barking the shoots during a long continuance of severe weather. In the south and western counties, also in South Wales, where trees attain a large size as standards, the covering of trees against walls is considered superfluous, if not positively, injurious. Next to covering the branches, it is well to prepare the trees by root-pruning early in the autumn, as the sap by this process is checked and the embryo Figs near the points of the shoots do not get too forward. It is needless to say a good mulch of dry leaves kept quiet by a covering of long litter is an important factor in low, damp gardens.

W. Coleman.

Eastnor Castle, Ledbury.

Fruit Garden.

THE PEAR CROP.

It is seldom we have to complain of having too many Pears, but this season has been an exception to the rule, and as a consequence the fruits individually are smaller than usual. Besides being abundant, too, the fruit is of exceptionally good quality, some sorts always previously sent to the kitchen being this season fit for dessert purposes. I am now alluding to fruit produced in our western counties, where the soil is in most instances of a moisture-holding, fertile character.

The earliest Pears we have is the Summer Doyenné, a small sort which rarely fails to crop heavily, but must be eaten fresh from the tree. At Rood Ashton, Wilts, it usually grows much larger than I have seen it elsewhere, and many handsome dishes of fruit I have gathered from it late in July or early in August. The Jargonelle is a delicious Pear, and the tree being a vigorous grower it is particularly well adapted for covering high walls or the gable ends of buildings. It forms an ugly pyramid, nor with us does it do well as a cordon. A fine standard may be formed by re-grafting a tall tree of any other variety with the Jargonelle. It is in season towards the end of August and early in September. Williams' Bon Chrétien nearly everybody is acquainted with. It has only one fault, viz, it keeps for a short time only after being gathered. It does well on walls of nearly all aspects, and succeeds equally well as a pyramid or as a standard. We prolong the season by gathering at different times, and by ripening the first in gentle heat. Beurré d'Amanlis, which forms a good succession to the Jargonelle, is also a favourite, and is of a very accommodating habit. It is free-growing, generally bears well, and is well adapted for any method of training or culture. With us its fruits are better from a pyramid than from a cordon against a south-west wall. Flemish Beauty is another excellent September Pear. It forms a good espalier and good average pyramid, and as a cordon usually yields moderately heavy crops of large, handsome fruits, which, if not left too long on the tree, are, when ripe, of excellent quality. Beurré Superfin is perhaps the least known of any yet mentioned, but it should be included in every collection. On the Quince it does well cordon-trained, but for espaliers and pyramids I prefer it on the Pear stock, no difficulty being experienced in growing fine, handsome and prolific trees. The fruits, which are of good size, are most delicious in flavour, and hereabouts ripen late in September and early in October. Fondante d'Automne ripens at much the same time, and is a most free-bearing serviceable variety. The best examples of this Pear I have yet seen were grown on wall trees in Kent, and a rich soil appears to suit it perfectly. We have quite a wealth of good October Pears to select from, but I would on no account omit Beurré Hardy. This variety also does well on heavy soils on the Pear stock, and forms handsome pyramids and espaliers. The best crops of this Pear that have come under my notice were growing in Derbyshire, the fruit being large, handsome, and extra good in quality. Beurré de Capiaumont, though of poor quality, forms a fine pyramid or standard, and rarely fails to bear well, but it is not good enough for wall culture. It ripens late in October, and sometimes keeps a month longer. Duchesse d'Orleans may well be included in large collections of Pears. We have a cordon of it on the Quince, and in this neighbourhood there is a fairly good espalier or horizontally trained tree on the Pear stock, and in both instances good crops of medium-sized fruit are usually obtained, the quality being very good. It is an October Pear, and keeps well into November. Jersey Gratioli is of good habit and bears well, but I am not an admirer of it, one cordon being the extent of our stock of it. Louise Bonne of Jersey is a well-known variety and a favourite in most gardens. We have good cordon, horizontally, and pyramidally-trained trees of it on both the Quince and Pear stocks, and all bear well. The fruit is usually of good size, handsome when ripe, and of a very distinct flavour, not, however, pleasing to all palates. This, again, unfortunately is another October Pear; so also is Marie Louise d'Uccle, but I would yet recommend it, especially where pyramids are in request. It is a sure bearer, quite distinct from Marie Louise, and very good to eat. Urbaniste appears to be of a very variable character. With us it is seldom so good as it has been this season. It forms a fine pyramid, and bears well.

Mid-season sorts include several extra good Pears—some of the very best, in fact. Beurré Bosc is not a high-class variety, but it is a free grower and heavy cropper, and if given a sunny wall, its quality is seldom found fault with. This season but little grittiness was discernible, the fruit being melting and quite delicious. All these remarks are equally applicable to Gansel's Bergamot, though the latter does not possess so good a constitution as Beurré Bosc. It ripens late in October or early in November, and does not keep long. Of all the 660 recognised distinct varieties, I fancy none would be found to equal Marie Louise, and none to surpass it in point of quality. It is, however, an uncertain bearer, trees of it growing side by side varying considerably. We have it against three differently situated walls and very rarely fail to secure a crop from some of them. Our finest fruit are from a sunny wall, but pyramids and standards give us quantities of medium-sized, deliciously flavoured fruit. By gathering at intervals and leaving some on the trees as long as it is safe to do so, a succession of fruit may be maintained from the middle of October to near the end of November, during which time this variety may safely be pitted against any other sort in season. Conseiller de la Cour ripens and is in season about the same time as the foregoing, and is frequently grown considerably larger in size. With us, on a south wall and on the Pear stock, it is never very large, but usually yields a good crop of fruits which, when ripe, are almost as buttery as those of Marie Louise. It also succeeds as a pyramid, cordon, or standard, and may well be more generally grown than it is. Pitmaston Duchess, also in season during the month of November is perhaps the largest Pear of good quality in cultivation. Mr. Garland, at Exeter, usually secures very fine examples of it, and in the neighbourhood of Bristol and Bath it is extensively and well grown, though at the Bath shows it is frequently and wrongly labelled Prince Imperial. It appears to be amenable to any kind of training, and where large fruits are prized it certainly ought

to be cultivated. Doyenné du Comice is in season about the same time or only a few days later than Marie Louise, and is nearly equal to it in point of quality. The very finest fruit of it I have yet seen were grown in the neighbourhood of Exeter; hereabouts it is smaller, has more colour, and is most melting and otherwise good. The Quince stock, whether the tree is cordon or horizontally trained, suits it best, and a friend has strong and profitable pyramids on the same stock. Nouveau Poiteau with us as a cordon on the Pear stock is mealy and worthless. It usually crops freely, and ripens early in November. Thompson's produces rather small fruit, which ripened early in November, and is of excellent quality. It is a moderately strong grower, and is best on the Pear stock, as, when worked on the Quince, the trees are apt to grow stunted and be of little service. Van Mons Léon Leclerc, a November Pear, I can speak highly of, as it possesses a good constitution and may be trained any fashion; it is a good bearer, the fruit sometimes attaining an extra large size, and is of excellent quality. I prefer it on the Pear stock. I have seen it trained over garden archways, where, when in full bearing, it presents a most imposing appearance. Huyshe's Prince Consort, though described as a large variety, only attains a medium size, but it is a sure bearer, and the fruits are frequently very serviceable at the end of November. We have a cordon trained against a sunny wall and on the Pear stock, and I have seen good pyramids of it. Huyshe's Princess of Wales if worked on the Pear stock forms a good pyramid, and from one tree we gathered two bushels of fruit. They are rather small, but the quality is excellent, and altogether I am much pleased with it. We commenced using it late in November, and it will be available nearly throughout this month. General Todleben, according to some authorities, is in season from December to February, but with us it is over by the end of November. In the midlands I have never tasted it in good condition, but hereabouts it is most delicious. Some of the fruits are not unlike Marie Louise in appearance, but there is no mistaking it when cut, the flesh having a distinct rosy tinge. We have a strong pyramid on the Pear stock, but for cordons or small horizontals I should prefer the Quince stock. Napoleon does not bear well here, but in other gardens I have had it good on both wall trees and pyramids, and always found it profitable. It is very distinct in appearance, and when fully ripe or late in November is very tender and juicy, bruising too easily for fruiterers to do any good with it. Beurré Clairgeau, a November Pear, I had almost omitted, is more remarkable for its size and attractive colouring than for any other quality it may possess. It is a sure bearer, but, as a rule, it ought to be included in the list of stewing Pears. Nor can I speak very highly of the quality of Duchesse d'Angoulême, which, with us, ripens during November. It is a robust yet free-bearing sort, and succeeds under any method of training, small pyramids on the Quince stock usually perfecting a heavy crop of large, extra heavy fruit, which, however, is usually very gritty and poor in flavour. Passe Colmar, a medium sized sort which ripens late in November, lasting sometimes till late in December, has long been a favourite of mine. To have it in perfection, it should have a sunny wall, though it crops well as a pyramid or standard. It is apt to produce large clusters of fruit, but these should be freely thinned out. Forelle, or the Trout Pear, is a small, but very handsome sort, of excellent and distinctly good quality. It is suitable for either pyramids or standards, crops heavily, and is in season during December and Janury. Beurré Bachelier is a capital grower, and is good on either Quince or Pear stocks and for any system of training. It is a good bearer, but should be freely thinned out, otherwise the size and quality are materially lessened. Large, well-grown fruits are usually buttery and sweet when ripe, in December. It is a noble Pear, and may well be given a good trial in most gardens. Winter Nelis is a small and quite distinct variety, but, although it forms a good pyramid, it is seldom first-rate from any but wall trees. With us it is in season during December, and double-grafted trees are found to give the largest fruit.

Late varieties are, unfortunately, comparatively few in number, and it is to this section that raisers of novelties should turn their attention. Chaumontel promises to be exceptionally good this season, but only from a wall tree, and those from a pyramid will be stewed as usual. It is a free-growing, heavy-cropping sort, the fruit being of good size, and is available during December and January. Large quantities of this variety are annually sent from Jersey, but the fruit is rarely so good as we have it. Beurré d'Aremberg is one of the heaviest croppers I am acquainted with, and is especially well adapted for pyramids. The fruits are of medium size, of fairly good quality, which may sometimes be improved by being subjected to a gentle heat. With us it is a good January Pear. Glou Morceau is simply invaluable. It forms a good standard or pyramid, but on heavy land the fruit cracks badly, and it is only on the wall trees that sound fruit is produced, the Pear stock being chosen. On shallow soils, however, the Quince stock is preferable. Our fruit, which we always gather late, commences to ripen in December and lasts till February, Josephine de Malines does not grow strongly here, but is a sure bearer, and the fruit is very good for several weeks early in the year. It is almost impossible to form a good pyramid, and I prefer a fan-shaped wall tree on the Pear stock. Bergamotte d'Esperen is a valuable late Pear; it may be grown either as a standard, pyramid, or espalier. It is a good bearer, and ripens during February and March. Easter Beurré seldom keeps good till Easter, but all the same it is one of the best very late sorts in cultivation. With us it is a failure in the open, the fruit being quite worthless, and it is the wall trees, cordon and horizontal, that we depend upon, and they do not often fail. I prefer Beurré Rance, this succeeding admirably either as a standard or pyramid, as well as against walls, keeps longer, and is of excellent quality. Ne Plus Meuris when grown against a wall is a sure bearer, requiring to be thinned out freely, or the fruit is small and all core; and thus treated it is of fairly good quality during February and March. Ollivier des Serres has been strongly recommended to me for the purpose of affording a late supply of good fruit, and is being given a trial. It is said to do well either as a pyramid or standard, but is of best quality from wall trees.

I find I have omitted two varieties marked in my list for commenting on, viz., Beurré Diel and Althorp Crassane. The former, owing to its very accommodating disposition, is included in almost every collection, but I cannot speak very highly of its quality. It is in season in November and early in December, and never fails to bear or to bloom freely. Althorp Crassane forms a grand pyramid and crops heavily. The fruit are rather small, and in point of quality are by no means to be despised. Season, November and December.

Stewing Pears are as much appreciated here as the dessert sorts, and one of the most profitable of these is the Vicar of Winkfield. This season it happens to be fit to eat, but as a rule it is best stewed. It forms a good pyramid or standard, and is a good cropper; in use at present time. Calebasse Grosse, which is a month earlier, is also a good cropper and is a capital stewing Pear. Black Worcester grown as a standard crops heavily. Its fruits are of good size and are fit for use any time during December, January, and February. Uvedale's St. Germain grows to an immense size, but ought not to occupy so much wall space as it does in various parts of the country, not being generally a heavy cropper. It keeps to April. Catillac, also keeping about the same time, is a more profitable sort and does well in the open. W. I. M.

Peach-growing out of doors.—Many seem to think that Peaches and Nectarines cannot be so successfully grown on open walls as they used to be thirty or forty years ago. I have grown good crops of Peaches out of doors in the Peak of Derbyshire, and for the past twenty-eight consecutive years I have never failed to secure good crops in West Cornwall. In some seasons they have certainly been better than in others, but I have never experienced an entire failure, though I have never protected them in the least, and I have gathered this year considerably more than the number said to have been grown at Ditton Park. Their quality, too, has been equal to, if not superior to, that of fruit grown under glass. Our first Peaches this year, Early Beatrice and Hale's American Early, were gathered on the 20th of July; our latest, Princess of Wales and Sea Eagle, on 15th October. The last I consider to be the best late Peach in cultivation. It is an excellent cropper, fine in flavour, large in size, and good in colour. Nectarines have done fairly well, but not so well during the past five or six years as formerly—a circumstance which I attribute to lack of sunshine and too much moisture. If Peach trees were pinched more and disbudded less, there would be, I think, fewer failures. I have seen many trees completely ruined by early and indiscriminate disbudding. Another important matter is periodically lifting the trees, as directed by Mr. Coleman—an operation which prevents rank succulent growth. I see nothing to prevent our growing Peaches on open walls quite as good as our forefathers. With the varieties now in cultivation, it should be by no means difficult to obtain good ripe fruit out of doors for at least three months in most seasons. —Sanguinea.

FRUIT TREES ON THEIR OWN ROOTS.

M. Jean Sisley, Monplaisir, Lyons, writes: "As The Garden has been the first to publish something about the advantage of fruit trees on their own roots, I send you herewith the translation of a letter on the subject I have just received from the celebrated Austrian horticulturist, Daniel Hovibruck, who is the president of the Austrian Horticultural Society of Vienna. I think it is our duty to endeavour to convert all agriculturists to the right way to produce the best, the most, and consequently the cheapest of all produce necessary to our wants."

M. Hovibruck writes to M. Sisley: "You ask me my opinion respecting the value of fruit trees on their own roots. I have grown thousands of them for many years, and now possess Peaches, Apricots, Cherries, and Prunes of twenty and twenty-five years old which are beautiful trees, producing yearly abundant crops of excellent quality, and a great deal more so than the same grafted. They are also more durable. This must also be the case with Apples and Pears."

Madresfield Court Grape cracking.—Mr. Castle says: "No doubt weight of crop is one step towards prevention of cracking." During these last four years I have grown on my Madresfield Court Vines two comparatively light crops and two rather heavy, and with the two heavy crops I have not experienced nearly so much cracking as with the light ones, although in each case they have coloured and finished off well. When I first took this Grape in hand I experienced no little vexation and anxiety through its cracking so badly during the ripening-off period. But this year I am glad to say I have had scarcely any crack at all, and I can only account for it in the following way: In the first place, I grow more foliage, by leaving one more leaf at the end of the bunch, making three in all. I have also paid greater attention to ventilation after colouring has commenced by way of avoiding as much as possible sudden rises of temperature in changeable weather. I think this has a great deal to do with it. And then from my experience, as stated above, I am inclined to give the Vines enough to do in the way of a crop. I think, by the way, that growers for markets now-a-days will be disposed to do this without being told. I believe with this variety there is something in having sufficient channels to carry off its luxuriant supplies of sap. I have taken over 30 lbs. per rod of good quality Grapes from mine this

season. Of course, to do this, every attention must be given at the roots in the way of liquid manure, &c. Mine receive adequate supplies in that way to the end of October. I omitted to water the Madresfields one season after the commencement of colouring, as I thought to prevent cracking, but I should not do that again. The cracking continued all the same, and red spider got ahead a great deal too much for my liking.—J. Hilling, in *Gardeners' Magazine.*

PRUNING DAMSONS.

The Damson is considered by many to be but little better than a wild fruit; consequently, when planted, no further attention is given it. That it is, however, a most valuable fruit few will deny, and that it is more profitable than many of the choicer Plums one would not need to go far to prove; its lateness alone entitles it to great consideration, and when we take into account the many culinary purposes for which it is used, I think we ought in return to give it the best of culture. I have myself proved that it will grow anywhere, and that it is tolerably fruitful even when planted in hedgerows! It can hardly, however, be expected that a tree with its roots in a dry bank can produce fruit equal to what it would do if planted in good soil. It succeeds well both in cultivated gardens and in orchards laid down with Grass. In the former half-standard trees should be employed, but in the latter 6 feet stems are not too high, to keep the heads clear of cattle that graze beneath them. The only way to keep orchards laid down with Grass fruitful is to graze them closely, and in winter feed young stock under the trees. Damsons in many parts are totally neglected as regards pruning. Under such circumstances the trees are thin; they push up a few strong shoots that eventually form the main limbs, and the centre of the tree soon gets full of dead twigs, starved by the gross shoots and smothered by their foliage. They bear heavy crops sometimes, but the fruit is not nearly so fine nor the crops so regular as that from pruned trees. I have no hesitation in saying that we cultivate no fruit which pays so well for timely and judicious pruning as the Damson. The best time for the annual pruning has now arrived, and therefore anyone sceptical as to the merits of pruned and unpruned trees can easily test the matter by pruning a few trees and leaving the rest to grow as they like. The way in which we proceed with standards is to form a rather spreading round head by shortening the top or erect-growing shoots more than those that spread out horizontally. The latter rarely grow too strongly, and just taking the tips off them, so as to induce every back bud to form a spur, is enough to ensure fruitfulness. The erect-growing branches will develop moderately strong shoots for several years after they have been planted, but if shortened to about half their length in winter, they will soon become so densely furnished with fruit-buds, that their load of fruit will be sufficient to check their superabundant energy. For dwarf-stemmed garden Damsons, we plant young maiden trees, and allow them to grow naturally for a year or two. The lower branches are then cleared away, and the tree formed into a sort of bush pyramid; every winter afterwards the strong shoots are cut in quite to half their length. Strong pruning-scissors or secateurs are the best implements for the purpose, and as the trees get large, a long-handled pruner can be employed. The difference between trees of the same kind pruned and unpruned is very great. On the former may be seen in the neighbourhood of Maidstone astonishing crops of the Farleigh Prolific. This kind is truly called the Cluster Damson, for its clusters of fruit are like unthinned bunches of Grapes, so tightly packed together are they—the result of continual stopping of the shoots. J. G.

Market Pears.—My information given in The Garden (p. 471) was supplied to me by the very man who grew, sent to market (Covent Garden), and realised the prices set forth. He has a large fruit garden in West Middlesex, Pears being his largest crop. He attends the market himself, and so his statement can be accepted as reliable. I know my informant to be a man of integrity.

Fairie's Lady's Slipper (Cypripedium Fairieanum)

But to perfectly understand the matter, some insight into the inner life of Covent Garden Market is necessary. There are, no doubt, "tricks of the trade" there. Thus I was informed a few days ago that a number of Marie Louise Pears was sent up to Covent Garden and the price returned was 3s. 6d. per bushel, there being a glut just then. They were bought by one of the salesmen, who, finding that they were scarcely ripe, housed them for ten or twelve days and then sold them at nearly five times the value returned to the grower. And there is no doubt that a grower in the habit of sending to the market, and being known there, fares much better than one who is unknown.—R. D.

ORCHIDS.

FAIRIE'S LADY'S SLIPPER AND ITS HYBRIDS.

This somewhat small-growing species was introduced to this country about the year 1855 or 1856, and flowered with Mr. Fairie, of Liverpool, in the autumn of 1857. It was tolerably plentiful in this country for some few years, but it may now be reckoned amongst the rarest and most valuable of the Slipper-worts. Its leaves are narrowly strap-shaped, arranged in a two-ranked fashion, from 3 inches to 5 inches in length, and of a uniform dull green colour. The scape is erect, furnished with a coat of short woolly hairs, and bears a single flower. The dorsal sepal is large and somewhat heart-shaped, greenish white, streaked and striped with dark green and rich purple; the lower sepal is smaller and less brilliantly coloured. The petals are deflexed and curved upwards towards the ends, resembling in shape the horns of a bison. In colour they are white, streaked and lined with green and bordered with purple. The lip or pouch is large, greenish brown, with purple reticulations. This plant is a native of Assam, probably the extreme north, so it thrives best in a cool house. This Lady's Slipper, being so thoroughly different in shape from that of any other known kind, has led to its use by the hybridiser in order to obtain new forms; but hitherto we have only met with two varieties which claim their parentage from it, *i.e.*, C. vexillarium and C. Arthurianum; both retain the deflexed petals peculiar to C. Fairieanum. C. vexillarium is the result of a cross between C. Fairieanum and C. barbatum. In the size and colour of its leaves it resembles the first named, but it has the reticulations of C. barbatum, although in a less marked degree. The peduncle is single-flowered. Upper sepal dull white suffused with purple, and veined with deep claret colour; lower sepal much smaller and duller in colour. Petals broad, deflexed, waved and hairy at the edges, where there are a few warts, but not curved upwards at the ends. In colour they are purplish, veined with green. Lip soft brown, tinged with green. It is a summer-bloomer, like C. barbatum. C. Arthurianum is the result of a cross between C. Fairieanum and C. insigne, both plain green-leaved species, and the offspring appears to be exactly intermediate. In size the flowers are about as large as those of C. insigne. Upper sepal yellowish green, dotted and spotted with deep crimson. Petals deflexed, wavy at the edges, suffused with purple and veined with crimson. Lip greenish yellow mottled with brown. It is an autumn-blooming plant. W. H. G.

Angræcum bilobum is one of the smallest species of a genus which contains some of the largest of cultivated Orchids, viz., A. eburneum, A. sesquipedale, &c. We have seen several widely different Angræcums named A. bilobum, but the true plant is well marked, and cannot be mistaken when once seen. It may now be seen in flower at Kew, the whole plant being about 3 inches high with distichous leaves; each leaf is half an inch

wide at the base, and widens gradually towards the apex, where it is 1 inch wide, and split into two rounded lobes; the texture is leathery and rather rigid; colour green above, pale brown below, and punctured over with black dots. The flowers are produced on a short decumbent spike, which springs from the base of the stem and bears three flowers, each 1 inch across, the sepals, petals, and lip being about equal in size, and they are ivory-white with fawn-coloured tips; the spur, which is straight and 4 inches long, is also fawn-coloured. A. bilobum is a native of Zanzibar, and was sent to Kew by Sir John Kirk, the British representative there, who, whilst engaged in important Government business, has also found time to look after the plants of that region, and has sent to England many beautiful garden plants, the best of them, in a purely garden sense, being perhaps the Zanzibar Balsam.

DECIDUOUS ORCHIDS.

Calanthes are always considered to be deciduous with annual stems or bulbs, and they certainly deserve to be cultivated by everyone who has a stove. I have tried for years to get them to flower with their foliage in a fresh and green state, and have never succeeded until this year, which I have done far beyond my expectations. I grow them in wire baskets about 8 inches in diameter, by 4 inches in depth, in a compost of fibrous peat, Sphagnum Moss, charcoal, and dried cow manure, placing four bulbs in each basket and suspending them in the stove about 2 feet from the glass, giving no water until they begin to throw out roots. When the latter get about an inch in length I commence to give water, increasing the quantity as they grow. When the roots reach the outside of the baskets I give a light sprinkling of Jensen's fish manure, which I repeat and increase in quantity every fortnight, giving at the same time an abundance of water until the flower-spikes begin to show. I then withhold gradually both manure and water, and remove the baskets to a cooler house and expose them to bright sunlight by degrees. They commenced to open their blooms in the first week of November with their foliage perfect, and they still are in flower with their foliage all that could be desired, each basket having eight and nine spikes about 2 feet in length, and thickly studded with flowers. They are arranged on a centre table of the stove, mixed with Poinsettia pulcherrima, and so arranged they look beautiful, requiring nothing to hide the baskets or pots, their own foliage doing all that is required. The varieties which I grow are Veitchi and vestita. I have also tried several baskets of Cattleya Trianæ with the above manure, and certainly they have made remarkable growths both as regards length of bulbs, size, and texture of leaf; but the leaves look to me rather transparent notwithstanding the fact that they hang close to the glass and are exposed to sunlight. I am anxiously looking for their blooms, which they are showing well. H. McC.

Bellevue.

Dendrobium profusum was described by Professor Reichenbach in 1884, when he received specimens of it from the Philippines, through Mr. Robelen. It is not a gorgeous-flowered Orchid, its chief interest residing in the large and curiously-formed spur, although the flowers are large enough to satisfy those whose admiration of Orchids depends mostly on bigness. The colour is the drawback in this case, being tawny yellow spattered with dust-like spots of purple. In habit this Dendrobe is similar to D. macrophyllum, but the pseudo-bulbs are thinner and rather shorter. The flowers are produced in short, terminal racemes on the ripened leafy growths, four flowers being borne on a growth in an example now in bloom in the collection at Kew, although as many as nine flowers are shown on dried specimens; each flower is over 1 inch across, and is of fleshy substance. The spur is 1 inch long, very thick for the size of the flower, and with a swollen end suggestive of a bird's toe. Although nothing more than what is termed a botanical curiosity, yet this Dendrobium is remarkable enough to find many admirers among those who like the uncommon and strangely-formed members of the Orchid family. Professor Reichenbach said it "would no doubt prove an elegant, chaste thing," but his taste for Orchids is not by any means of the common kind.

ORCHIDS AT THE DELL.

When we take into account the disastrous effects of the late fogs on Orchids about London, such a grand lot of plants in full flower as one finds at The Dell just now is truly a welcome sight. It is well known amongst Orchid growers that, at whatever time of the year one visits The Dell, there is always a treat in store for them. Taking cool-house kinds, we find a magnificent display of Odontoglossums, for which this place is justly celebrated. Some of the unique varieties, such as O. crispum Schroederianum, Schroeder's variety of O. Pescatorei, and an extremely delicately-tinted variety of O. Andersonianum, are now in full flower. There are also some remarkably strong and healthy spikes on some of the yellow forms of Odontoglossum. Among other cool Orchids in flower was the lovely Epidendrum xanthinum, whose superb yellow flowers, of indefinite duration, borne on long and slender spikes, are exceedingly bright and beautiful. Associated with this were also the lovely Oncidium incurvum, the curious Masdevallia macrura, the exquisite little M. Shuttleworthi, and many others—all either singular or beautiful. Cattleyas are represented by some really grand plants, and the same may be said of the Lælias, especially Dominiana, of which there are magnificent specimens, one plant of this Lælia bearing four spikes of lovely blossoms, fully expanded, contrasting strikingly with a grand variety of Cattleya Dowiana and a C. maxima of unusually good colour and form. This last-named plant, furnished as it is with six spikes, each of them bearing from four to six delicate flowers, is in itself quite a sight. The new Cattleya Bowringiana, which promises to be altogether a most valuable addition to late-flowering Orchids, is also in great beauty. Then the rare C. Mastersi and C. fausta bella, both recent acquisitions, the result of Mr. Seden's labours, are prominent features among home-raised varieties. In the same house was also quite a forest of spikes of Lælia anceps, which grows here with the utmost vigour. Several of these plants are white forms received last year, so that we shall soon be in a position to judge of their value as albinos. Masdevallia Chimæra and M. Shieldsiana, magnificent plants, are also in full beauty, as is also a charmingly-coloured form of Vanda cærulea, bearing two handsome spikes of sky-blue flowers. Among Cypripediums, we had the good fortune to see the hybrid C. vexillarium in bloom; also C. Fairieanum and a unique form of C. Harrisianum called H. superbum, surpassing in colour as well as in size anything previously seen; a fine form of C. Godefroyæ, belonging to the niveum and concolor section, is also in grand condition, its flowers being conspicuously spotted with magenta-purple; C. Dominii, with its peculiarly long-bearded and curiously-coloured flowers, I also saw; but the most beautiful by far of the many plants belonging to this popular section is undoubtedly the one named C. Schroederi. This beautiful Lady's Slipper, whose pale rose flowers are the largest of the Sedeni section, is certainly one of the best additions that have been made to the Selenipedium group. Its long, pendulous petals, which are twisted riband-like, and of a pale rose colour, marked with longitudinal deep rose veins, are particularly attractive and ornamental. It possesses also the dual advantage of being a robust grower and of flowering at various seasons of the year. As to the Vandas, Aerides, and Saccolabiums, their beauty at this time of the year lies chiefly in the vigour of their growth and the glossy, rich colour of their foliage, which here is perfection itself. Odontoglossum vexillarium is unanimously acknowledged to be one of the most beautiful of Orchids, but it is somewhat difficult to manage. Here, however, under *quasi* East Indian treatment, it appears to be in the best of health, a remark which also applies to the whole collection. S.

KITCHEN GARDEN.

DESICCATED POTATOES.

There exists in the neighbourhood of Belfast a manufactory for utilising Potatoes. The manufacturers, it appears, supply the army and navy largely with this prepared food for use abroad, and especially in hot climates, where it proves not only nutritive, but healthful, owing to its anti-scorbutic properties. For preserving or desiccating purposes, really good mealy kinds are essential—indeed the most profitable, as they contain the largest percentage of starchy matter. Previously in Ireland it was found that Regents and Champions furnished good proportions of dry, mealy solids after preparation, but the introduction of the disease-resisting Magnum Bonum has considerably affected the growth of the kinds just named, and this latter, unfortunately, yields far too large a proportion of water to render its conversion into prepared food profitable. Thus the manufacturers are anxious to introduce new varieties which may prove more suitable for their purpose. These kinds will be first submitted to the desiccating process, and if found satisfactory, stocks of them will be planted. The trade is an increasing one, and may be made more so if kinds of Potatoes can be found which will give solid matter in considerable proportions, and at the same time give good crops. It usually happens that the biggest croppers are kinds which give the greatest proportion of water in the composition of their tubers. Possibly, as with field roots, this result is inevitable. Still, it is hoped that some may be found which fairly fulfil the conditions required. The tubers are first cleaned thoroughly and then peeled, then steamed, and from thence transferred to a powerful press, which expresses all the water found in the tubers and leaves the deposit dry. This deposit somewhat resembles powdery or granulated tapioca, and in this state it is either pressed into paper packets or tins, and in this form is exported. When used, all that is needful is to moisten the Potato flour with water, and at once good mashed Potato is afforded. It may be thought odd that a manufactory of this kind should be found in a moist climate like that of Ireland, but it is possible that Potatoes are produced there at a much cheaper rate than here. Still, it might have been thought that our drier climate would have produced Potatoes having the largest degree of specific gravity. Germany excels us, but the tubers there are almost invariably small, and, where not otherwise employed, go to the ignoble purpose of making brandy and gin, the solids being employed as cattle food. It is stated that the introduction of this manufacture into Ireland has largely tended to improve the average culture of the farmers in the locality in which it is situated—a fact worth knowing, because it shows how materially the introduction of commercial enterprise into a country can socially, as well as pecuniarily, benefit a people. It is very satisfactory to learn that the Potato can be put to such desirable uses. A. D.

Rhubarb and Seakale.—These are looked for here about Christmas, also Chicory for salading; but as we have no Mushroom-house which could be used for forwarding them, I had to resort to the old hotbed—a system of forcing good enough when no better can be devised—yet one which always incurs a good deal of labour and watchfulness. Under these circumstances I made a pit with some bricks and mortar, and covered it with

a couple of old doors, hinged so as to open and shut properly. Into this 2-feet-deep bed I put 8 inches of soil, and then 20 rows of Seakale, giving it a thoroughly good watering. I then let down the doors, and covered them with about 8 inches of hay, leaving the contents to take care of themselves. I looked into this pit the other day, and found all doing well. This pit is heated by means of waste heat led into it from the other houses by means of earthenware pipes. Thus constructed, it forms an excellent place for forcing Seakale, Rhubarb, and Chicory for salading.—J. R., *Duncombe Park.*

THE READING POTATO EXPERIMENTS.

To the Editor of THE GARDEN.

SIR,—I am sorry to observe in the horticultural press that, in relation to recent Potato experiments, some reflections have been made in regard to the authorities at Kew. With Mr. Baker, F.R.S., of Kew, I have to-day visited the Reading collection. We have been vastly interested, and, I am allowed to say for both of us, instructed. Messrs. Sutton and myself are the persons most interested, and I beg to add we are grateful to the Kew authorities for unvarying attention and kindness, and we have nothing but appreciation to express in regard to that invaluable national institution.—Yours faithfully, CATHCART.

50, Portland Place, W.

TREES AND SHRUBS.

TREES NOT COMMONLY PLANTED.

JUDGING by the monotony with which almost every new garden is planted, one would think that there was not much variety among trees and shrubs, instead of the great number which is at the hand of every planter. One seldom sees a new garden planted now which includes any but the commonest trees and shrubs, except the work is done by one who knows trees, and has a desire to make them better known in the country. The following I have jotted down as being among those which are not so commonly planted as they might be.

Many of the Maples have handsome foliage, often large, sometimes remarkable for colour. Among the largest leaved are A. macrophyllum, a North American tree of free growth, which forms a broadly pyramidal head. The leaves are very large, deeply lobed, and in autumn, before falling, they acquire a rich brownish yellow tint. This tree forms a very handsome single specimen, and so situated the large foliage is very effective, added to which the racemes of yellowish flowers, which are borne so freely in the spring, form quite a prominent feature at that season. A. striatum or pennsylvanicum, called the Snake Bark Maple, is not a large growing tree, but in the case of healthy specimens the leaves are of considerable size, being heart-shaped at the base, and divided towards the apex into three nearly equal lobes. A prominent characteristic of this kind is the beautifully striped bark, and this, combined with its other attractive features, render it very desirable for planting as a single specimen on lawns of limited extent. Several other Acers have large foliage, especially when young, the most prominent in this respect being the Norway Maple (A. platanoides) and its varieties, with the different forms of the common Sycamore.

THE AILANTO (Ailantus glandulosus) is a beautiful tree, possessing quite a sub-tropical aspect. If the stems are cut back every year, it will push up stout shoots from the base; these reach a considerable height in one season. But when it is intended to form a tree, the main stem must of course be encouraged by cutting away all rival shoots. The Ailanto is of rapid growth, and though succeeding best in good soils, will thrive fairly well in light sandy spots, besides which the large pinnate leaves retain their freshness during unusually dry summers, and even in the smoke and dust of towns.

ARALIAS are represented by two or three kinds, one of which (A. Sieboldi) is far hardier than many suppose, and, at all events around London, will retain its large Fig-like leaves in all their freshness during most winters. The tough, leathery texture of its leaves renders them able to resist the storms of winter better than many other shrubs. There is a variegated form of this Aralia, but, though apparently nearly as hardy as the type, the white portion of the leaf is liable to be browned when fully exposed, for which reason it is essentially an indoor plant. A. spinosa is very dissimilar from the last-named, for it is a free-growing shrub reaching a height of a dozen feet, and, by pushing up shoots from the base, soon forms a mass or clump. The large triangular, much-divided leaves occupy considerable space, and for that reason it should, if possible, be planted as a single specimen. In early autumn some of the principal shoots are terminated by large, upright-branching panicles of bloom, which, though the individual flowers are but small, have collectively a very imposing appearance.

The various HICKORIES (Carya) are all characterised by fine pinnate foliage, which generally dies off more or less of a rich golden or yellowish brown hue. C. alba (the Shell-bark Hickory) has huge leaves, with, however, fewer leaflets than in the other kinds. It can also be distinguished by the manner in which the bark peels off in narrow strips. C. tomentosa, C. microcarpa, and C. oliviæformis are all very handsome, fine-foliaged trees.

THE CHESTNUT (Castanea vesca) has, when young and vigorous, noble foliage, and in a variety (prolifica) it is much larger than in the common kind and more glossy.

THE CATALPA, although so handsome, is planted much more extensively in the United States of America than in this country. C. syringæfolia, or bignonioides, forms a sturdy, stout-branched tree, furnished with large heart-shaped leaves, and about July or August it bears terminal branching panicles of flowers. The blooms are of a whitish colour, spotted more or less inside with yellow and purple. The variety speciosa is described as a taller and better grower, besides which the flowers are brighter, and expand two or three weeks earlier. It is also said to be hardier than the species. There is also another variety (aurea), in which the leaves are of a golden hue; not so pronounced, however, as in some other trees. These Catalpas, when young and kept to a single stem, produce fine bold, heart-shaped leaves, contrasting well with the light pinnate ones of the Ailantus.

DIMORPHANTHUS MANDSHURICUS is a bold-growing shrub, nearly allied to, if not the same as, Aralia spinosa.

THE KENTUCKY COFFEE TREE (Gymnocladus canadensis) is very dissimilar from any of the other subjects here noted. It is a stiff, erect-growing tree, with leaves on young plants as much as 1 yard long, and 2 feet in width. The leaves are doubly pinnate, and the leaflets of a peculiarly bluish green tint. The Gymnocladus forms a striking lawn specimen, as both the colour and the whole contour of the tree stamp it as something out of the common. When old enough it produces terminal racemes of white blossoms, which in their native country are succeeded by flat curved seed-pods, but in England they are rarely produced. It possesses deep penetrating roots, and on that account will succeed well in light sandy soils; indeed, it is very accommodating in this respect, provided the soil is thoroughly drained.

IDESIA POLYCARPA has only been known within the last twenty years; it is, therefore, quite a recent introduction, and is still far from common. It forms a stout, somewhat spreading growing tree, with large, heart-shaped leaves of a bright green tint. The leaf-stalks are crimson in colour. The greenish flowers are not showy, but the foliage is handsome. This Idesia is a native of Japan, and is fairly hardy in this country, though, even in the southern counties, it is liable to be injured during severe winters, but quickly recovers.

THE WALNUTS (Juglans), especially the North American kinds, have very handsome foliage. Both of them, J. nigra and J. cinerea, being for this reason alone well worthy of cultivation, added to which their timber is very valuable. The nuts, however, are by no means so palatable as those of our European Walnut. Koelreuteria paniculata is a very distinct low-growing tree with large pinnate leaves, to which the deeply divided leaflets impart an attractive feature. In autumn the foliage dies off a rich yellow colour. Its flowers are also worth consideration, as the spikes of rich yellow blossoms are borne about July, at which time flowering trees are scarce. The Tulip tree (Liriodendron tulipifera) has such handsome foliage that it must be herein mentioned, though the leaves do not attain the dimensions of several other trees. Apart from their peculiar shape, their distinct light glossy green colour is very noticeable. Magnolias include among their number some noble-leaved kinds, the largest of which is M. macrophylla, whose oblong-shaped leaves are sometimes a yard in length. Though the foliage is so grand, this Magnolia is not proportionately stout in growth; indeed it is rather weakly, and often needs support during its earlier stages. It is one of the worst of all to transplant, and will only thrive in a good, stiffish loam well drained. In sandy soils it will barely exist. From its huge leaves a sheltered spot should be chosen when planting. Another North American species, M. auriculata or Fraseri, in some characters resembles the last, but the leaves, though large, do not attain the same dimensions. Like M. macrophylla, it is rather particular in its requirements, and, generally speaking, it is not so valuable as M. tripetala (the Umbrella tree), which will thrive in light, gravelly soils. This species forms a free-growing tree with ascending branches, the large leaves being collected near the points of the shoots, and, from the ray-like manner of their arrangement, have obtained for this species the name of the Umbrella Magnolia; the flowers are white, and borne during the early part of the summer. All the Magnolias above mentioned are deciduous, but the one evergreen species that is hardy in this country (M. grandiflora) is so handsome from a foliage point of view alone, that it must be noted herein.

PAULOWNIA IMPERIALIS, a Japanese tree, when not in bloom bears a close resemblance to a Catalpa, being of the same stout, sparsely branching habit, and with huge heart-shaped leaves, but the flowers are very different. They are borne in large terminal panicles, and the individual blooms bear a great resemblance to a Foxglove, being of a purplish colour. Unfortunately, in this country, at all events, the blooms frequently drop before expansion, probably owing to the flower-buds being injured during the winter, as they occupy a very prominent position at that season.

THE POPLARS with fine foliage include the large heart-shaped-leaved cordata, a North American species, also known as P. candicans. It is rather a stiff-growing tree in habit, something like the Balsam Poplar, but the foliage is entirely different and retained till late in the season. Another kind with foliage something like the last is P. angulata, which is, however, of a deeper green than P. cordata. The distinguishing feature of this species is, however, the peculiarly angled shoots, from whence its name is derived. When young and vigorous, several other Poplars produce large leaves, but the above two are not equalled in this respect by any of the others. The different Oaks, especially the North American kinds, are strongly represented among fine-foliaged trees, as a proof of which I may mention the scarlet Oak (coccinea), the red Oak (rubra), the white Oak (alba), and its variety repanda, in which the leaves are partially drooping, and from this circumstance it wears a very singular aspect. The Chestnut-leaved Oak (Q. Prinus) and Q. nigra, with its peculiarly blunt-headed leaves, are a couple worthy of note. Q. Daimyo, a Japanese kind, has noble foliage, sometimes a foot or more in length, but the largest leaves on any of the Oaks is to be found sometimes in the case of Q. macrocarpa, rather a deeply divided leaf, dark green on the upper surface and whitish beneath. Another point worth considering in the case of these Oaks is that many of them change to a very bright colour in the autumn before the leaves fall.

The pinnate-leaved species of Rhus form either shrubs or low-growing trees of a very picturesque character, among them being the Stag's horn Sumach (R. typhina), whose peculiar inflorescence is such a prominent feature during the summer. Then there is the smooth Sumach (R. glabra) and the Japanese

R. Osbecki, with large leaves, the leaf-stalks between the pinnules being peculiarly winged. The largest leaves

Among the Limes (Tilia) is T. platyphylla, frequently regarded as a variety of the European Lime, while the American species itself—a much larger leaf than the common one—has also a variety (macrophylla) with leaves much superior to the type. The white-leaved Linden (alba) is particularly noticeable from the white undersides of the leaves, which, in the variety spectabilis, are very large. Besides this, it forms a handsome tree, less formal in character than the common Lime. T.

A FEW MORE EVERGREEN SHRUBS.

Pyracantha (Cratægus).—One of the oldest and best known wall plants in cultivation, and one of the most effective during the dull winter season when clothed with its bright coral-like berries. The yellow-berried variety is not so showy nor so often met with as the red one, still it is worth growing. Not the least of the merits possessed by these plants is their ability to thrive almost anywhere.

Kalmias.—K. latifolia is justly prized for its lovely flowers, which are produced freely in some localities, but not so in others, yet in places where it is found to succeed it is deserving of introduction into the most select company. K. angustifolia is also a desirable shrub.

Gaultherias.—G. procumbens is a useful little plant for a position next the Grass in the front of small beds of larger shrubs, and G. Shallon, which is likewise a dwarf-habited plant, can also be used with good effect in the front of stronger growing things.

Ericas.—Amongst plants of small growth there are few that combine such a lengthened succession of bloom with a pretty appearance as a good collection of hardy Heaths affords. In no way do they look better than in a bed by themselves, though they are well adapted for associating with other small-growing shrubs in front of larger things. To do justice to them they should have sandy peat to grow in, either wholly or added liberally to the natural soil, unless this happens to be of a character such as they require. The following are desirable kinds: Arborea, australis nana, rosea, carnea, cinerea alba, c. atropurpurea, c. carnea, mediterranea, m. hibernica, m. glauca, multiflora alba, m. rubra, Scoparia minima, tetralix alba, t. rubra, stricta, vulgaris alba, v. coccinea, v. Alporti, v. flore-pleno, v. Hammondi, v. rubra, v. rigida, v. tenella, v. Searlii, v. stricta, v. dumosa, vagans alba, v. rubra. To these should be added the Irish Heaths (Menziesias)—M. empetrifolia, M. polifolia alba, M. p. atropurpurea, and M. pumila.

Pernettyas.—Amongst shrubs of small growth there are few prettier things than several of the new varieties of P. mucronata, but they do not seem to succeed except in odd places. The milder parts of Ireland appear to suit them better than any part of England in which I have met with them. They would be most likely to succeed on the north-west coast of England where there is a copious rainfall.

Rhododendrons.—Little need be said about these unequalled shrubs, which combine foliage little inferior to that of the Laurel, with flowers of every shade of colour from pure white to the darkest purple, produced in such quantities as to almost hide the leaves. Their hardy nature, which enables them to bear our severest winters, and their ability to thrive almost anywhere where there is an absence of chalk in the soil, and enough moisture present to prevent their suffering in dry weather, collectively entitle them to the first place in evergreen flowering shrubs. The number of fine varieties is such, that in making a selection there is a difficulty in deciding what to leave out. However, amongst the following are most of the best sorts: Blandyanum, deep crimson; Bylsianum, white and crimson; Congestum roseum, light rose; Duchess of Edinburgh, crimson; Elfrida, rosy crimson; Erectum, rose colour; Fermosum elegans, pink spotted; Frederick Waterer, glowing crimson; Guido, crimson; Hendersoni, purplish crimson; John Walter, crimson;

Fertile branch of Libocedrus chilensis.

Fertile branch of Libocedrus tetragona.

Kate Waterer, rosy crimson, marked with yellow; Lady Lopes, light rose, dark markings; Lady Rolle, white and yellow; Leviathan, pinkish white; Lord John Russell, pale rose; Marion, shaded pink; Mirabile, deep rose; Mrs. Cameron, pink, orange spots; Mrs. John Walter, white centre, bright crimson edge; Neilsoni, rose; Nero, rosy purple, spotted; Purity, white; Lilian, rosy scarlet; Vandyke, rosy crimson; Alarm, white centre, scarlet edge; Atrosanguineum, deep red; Barclayanum, rose; Caractacus, purplish crimson; Celebrandum, dark purple-crimson; Charles Bagley, red; Concessum, rosy pink; Curricanum, rosy lilac; Fastuosum flore-pleno, mauve; Francis Dickson, deep scarlet; Hecter, crimson; Helen Waterer, pure white, crimson edge; H. H. Hunnewell, dark crimson; H. W. Sargeant, crimson; John Spencer, rose, pink margin; John Waterer, crimson; Joseph Whitworth, deep purple-lake, dark spots; Lady Clarement, scarlet, black blotches; Lady Eleanor Cathcart, rose, spotted with chocolate; Lady Frances Cressley, pink; Madame Mielan Carvalho, pure white; Michael Waterer, rosy scarlet; Mrs. Helford, salmon; Mrs. John Clutton, white; Mrs. Shuttleworth, scarlet, spotted; Mrs. Mendel, pink, centre yellow; Sherwoodianum, rose-lilac, spotted with lilac; Sigismund Rucker, magenta, spotted; Sir Thomas Sebright, purple, blotched with bronze; Sydney Herbert, crimson, spotted black; Old Port, plum colour; Meteor, crimson; Mrs. John Waterer, crimson; Princess Mary of Cambridge, rosy purple, centre white; Mrs. Harry Ingersell, pink, &c. The earliest of the above will come into flower after the danger from frosty mornings is past, the remainder later, so as to give a succession.

The plants named are not intended as an exhaustive list of all the evergreen shrubs that are worth growing, but they comprise the best and most distinct in appearance of the kinds grown for the beauty or interesting character of their flowers and foliage combined, and also such as are best deserving of cultivation simply as Evergreens. T. B.

THE INCENSE CEDARS.

(LIBOCEDRUS.)

Though there are but few of the Incense Cedars in British gardens, they are of wide geographical distribution, for one is a native of California, another of New Zealand, while the remaining two are found in the southern part of South America. They are all ornamental trees, with a good deal the aspect of a Thuja; indeed, the best known kind, Libocedrus decurrens, is frequently, though erroneously, met with under the name of Thuja gigantea, a totally different plant.

Libocedrus decurrens is a highly ornamental Conifer, and one that is perfectly hardy in England, which last remark cannot be applied to any other members of the genus. It is of a dense columnar habit of growth—at all events as seen in this country, but in California, where it attains a height of 120 feet to 140 feet and a diameter of 6 feet or 7 feet, it is said to become much more open in character, the branches being more spreading and widely scattered. Though its wood is valuable, the rate of growth is too slow to allow of it being grown for any purpose other than ornament, and from the limited spread of the branches it may safely be planted in positions where broader growing trees would be inadmissible. The colour of the foliage is a deep bright green, which is retained throughout the winter months without any of the bronzed appearance common to many Conifers. It succeeds best in a loamy soil that is well drained, fairly moist, for in dry, gravelly spots it is apt to lose many of the minor branchlets, especially near the bottom, and to acquire altogether a paler tinge. In California it is known as the Incense Cedar and the white Cedar, which latter name is in the Eastern States applied to the Cupressus thyeides, or Chamæcyparis sphæroidea, as it is often called. Libocedrus decurrens was at one time regarded as a tree that refused to strike root from cuttings, but such a theory has now been disproved, for cuttings will strike fairly well, though they take a considerable time. There is a peculiarity about them, and that is they generally form a large callos almost like a tuber, and in that state will remain for months unless they are lifted and the callos slightly wounded with a knife, when if the cuttings are re-inserted they soon root.

L. chilensis is a very distinct and handsome kind, but is unfortunately somewhat tender, except in unusually favoured spots in our southern or western counties. The severe winter we experienced half-a-dozen years ago either killed or seriously injured most of the specimens in the neighbourhood of London. In its young state it forms a very graceful plant of pyramidal outline, a prominent feature of which is a silvery line on the undersides of the small pointed leaves. The whole plant is of a peculiar bright glaucous green tint, and this, combined with the silvery markings of the foliage, arrest attention, even

when associatod with other Conifors, from tho indescribable hue that pervades it. This tree is a native of Chili, where it reaches a height of 50 feet to 60 feet, and there it is greatly valued as a timber tree. It was introduced into this country about forty years ago by Messrs. Low, of Clapton, but, owing to its being tender, a large specimen is rarely met with.

L. Donniana, a native of New Zealand, is essentially a greenhouse plant, for it is almost, if not quite, as tender as the various antipodean Araucarias, and, like them, it is valuable for conservatory decoration in a young state. I am acquainted with a specimen treated in this way now about 10 feet high, and it forms a perfect pyramid of bright green Fern-like branchlets which retain their brightness throughout the year. In some respects this species resembles L. chilensis, but is distinguished therefrom by the leaves being more closely set on the branches, by the absence of the silvery line on the undersides, and also by the entire foliage being of a richer and brighter green. In its native country it reaches a height of 80 feet to 100 feet.

L. tetragona.—This species inhabits a considerable tract of country in South America, from Valdivia to the Straits of Magellan. Under favourable conditions it forms a large tree of 100 feet or more in height, but in the extreme southern limits it is only met with in the shape of a scrubby bush, and in that state is by no means ornamental. It is greatly valued as a timber tree throughout Chili, the wood being characterised by extraordinary straightness of grain, besides which it is almost indestructible when exposed to the weather, and on that account it is greatly used for weather-boards. From the readiness with which it can be split, as well as its weather-resisting qualities, the wood of this tree is greatly used for shingles for roofing purposes, and the inner bark for caulking the seams of boats, where it will be kept in a wet condition, as so treated it is very durable. L. tetragona is known in Chili as the Alerse, or Alerze. As an ornamental tree in this country it does not take high rank, for it is rarely met with in a flourishing condition, and is besides often injured by our winters. A young specimen of this Conifer is characterised by a broadly pyramidal habit of growth, with horizontal branches ascending at their extremities, the branchlets being clothed with leaves about a quarter of an inch in length, arranged in a decussate manner, and bright green in colour. This Libocedrus was introduced in 1849 by Messrs. Veitch, through the agency of William Lobb. T.

Pruning Robinias.—Will someone inform me if Robinia inermis umbraculifera, or Mop-headed Acacia, will bear hard pruning, and, if so, the best time for doing it? I have two of these trees which I had about four years since from Woking, and planted one each side of a gateway on to a tennis lawn to form a green archway in summer, and, although old trees, they stood the moving well, and are now healthy, but somewhat weak and straggling in growth, and I find the branches snap off very easily in strong winds. May I venture to cut them into the old wood, and will they be likely to break strongly in the spring? They have never been cut since I planted them, and the heads are now from 4 feet to 5 feet in diameter.—W. F. B.

The common Holly.—We have seen such specimens of Holly that were valued more than any other tree in the grounds. Why is it not planted in our parks more extensively instead of in hedgerows, and as underwood only? Is it because its capabilities are not understood? If anyone who reads this has a fairly-shaped tree and will move it next May to a tolerably sheltered situation, providing a bit of good soil for it if the land be naturally poor, they will see what it will do in a year or two. Whatever trees are employed to form groups or single specimens, it must never be forgotten that they must be planted with that object, and not crowded together, or, if they have originally been planted thickly, early thinning must be attended to.

AMERICAN NOTES.

Productive Pear trees.—Marshall P. Wilder stated at a meeting of the Massachusetts Horticultural Society that Clapp's Favourite and the Boussock Pear were conspicuous among those which produced good crops and brought money. Clapp's must be picked by the 20th of August as far north as Boston to prevent rotting at the core. The Boussock, he said, makes a most elegant tree—in Belgium, where it originated, there are trees 60 feet high. He begins to pick the Pears on the 15th of August, and they become yellow, and are all of good quality. The Bartlett may be picked about the 1st of September. He predicted that the Anjou, which was introduced about fifty years ago, would become as popular as the Bartlett. Beurré Bosc is always good, but there are never so many in the market as are wanted.

Locations for orchards.—Having had some experience and observation of nursery and orchard trees, it seems pertinent to state the well-known fact that both nursery and orchard trees, as well as soft woods generally, make rapid and soft wood on rich, low, moist soils, such soft wood growth being continued late in the autumn, in consequence of the richness and moisture of the soil, thus making the immature or still growing shoots very susceptible to injury, and nursery trees to damage, by frost. Hence, although orchards on the lowest and therefore comparatively moist soils may escape damage and yield more fruit in dry seasons than high and dry orchards, the lowland Apples will not be as fine grained or of as good quality, nor will they keep as long as the same sorts of slender growth and smaller size from orchards on thin and high-lying lands. The same rule, in fact, holds with lowland fruit quality as of its wood quality. The growth being rapid in both fruit and wood, each is comparatively soft and more susceptible to damage by frost or bruising than the slower and firmer growth of wood, and smaller, finer grained fruit that is generally characteristic of upland orchards. Larger Apples, it is true, are produced on the richer and lower soils, but huge inferiority is not half so much a desideratum, particularly in winter Apples, as good eating quality, together with long keeping, neither of which may be expected to result, as a rule, from the rapid and tender growth of tree, and the soft texture, larger size, and comparative insipidity of fruit, produced on the relatively soft, tender wood of moist lowland Apple orchards. What seems to be necessary to successful growth of Apple trees and Apples is a soil deep and fine enough to hold sufficient moisture to supply the necessary water and other ingredients of sap, to make a moderate rate of growth and size of fruit—not too rapid nor too large to militate against good quality—situated high enough above the frosty valley.

Notes on the newer Pears.—Mr. Barry, chairman of the general fruit committee of the American Pomological Society, has furnished the following notes, the result of years of cultivation and testing on the grounds of the Mount Hope Nurseries at Rochester. The Reeder seems to rank with the Seckel in value for the amateur. The tree bears early, heavily, and regularly, and the fruit is handsome and uniform, being just of a size to eat conveniently from the hand. The skin generally is free from spots and defects. The flesh is juicy, melting, vinous, and the quality may be rated as best. It ripens the latter part of October and early in November, succeeding the Hardy, Sheldon, Superfin, and Seckel. In the nursery the tree is a slender grower, and in order to obtain good specimens, the nurseryman is obliged to double work it; hence it cannot be propagated profitably, and doubtless never will be disseminated as widely as its merits deserve. As the tree attains age, it droops somewhat and is highly ornamental, especially when loaded with fruit. It seems to be free from blight. After several years' trial, we think it has proved to be an important addition to the list of choice Pears, and although it is not large enough for market, it is entitled to a place in every garden, no matter how limited. Duhamel du Monceau is a fine winter Pear, and will be valued to succeed Winter Nelis. The fruit is medium-sized and of excellent quality. The tree is vigorous and yields well. As soon as this variety becomes better known, it will no doubt be grown quite largely by those who understand how to market winter Pears advantageously. Superfin, in our estimation, cannot be surpassed for flavour. The fruit is large and handsome, skin smooth and glossy, and flesh juicy, vinous, and rich. The tree grows well and bears a moderate crop. The fruit is too delicate to ship; hence it is an amateur's sort, but one of the best, and indispensable in an assortment. Souvenir du Congrès, when well grown, is a noble fruit, very showy and of fine quality. But it is such a poor grower that it must be top-grafted upon a strong-growing sort, and the trees thus worked have not always succeeded, although in several instances extraordinary specimens have been raised. We think if it is grafted on the right stock it may do well, but under the circumstances it is doubtful whether it will be much grown. The Rutter has done fairly well here, but we do not esteem it as they do in Pennsylvania, the Anjou in our opinion being superior, for this region, either for garden or orchard. The Fox Pears are straggling growers like the Winter Nelis. The fruit is valuable on account of its size, flavour, and late-keeping qualities, but poor growers do not take with the public nor with the nurserymen.—W. Falconer, in *Country Gentleman*

SOCIETIES.

ROYAL HORTICULTURAL.

December 7.

This, the last meeting of the year, was very smal compared with the large gatherings which have been witnessed during the past season. A few new plants and flowers were shown, and the following were awarded first-class certificates:—

Lælia anceps virginalis.—A chastely beautiful Orchid, and one of the choicest in cultivation. It is one of the several varieties of L. anceps, having white flowers, but differing slightly in shape and size. This virginalis variety has large flowers, broadish sepals and petals pure white, and a lip with scarcely any lines or colour upon it. A well-grown plant was shown by Mr. Philbrick, Oldfield, Bickley, and bore a tall two-flowered spike.

Narcissus monophyllus.—The now well-known and extremely lovely little white Algerian Hoop Petticoat Narcissus, which one would have thought had been certificated long ago. Mr. Ware, of Tottenham, showed several pots of it, each bearing numerous flowers, which at this season are specially welcome.

Chrysanthemum Carew Underwood.—A sport from the Japanese variety Baron Prailly, from which it differs only in colour, this being a chestnut-brown intermixed with a bright reddish brown. It is considered a good addition to the Japanese section. Shown by Mr. G. Stevens, St. John's Nursery, Putney.

Chrysanthemum Mrs. N. Davis.—A sport from the incurved variety Princess Teck. The flowers are of medium size, of good form, and of bright yellow. Shown by Mr. Mizen, Mitcham.

Cypripedium callosum.—A new species very similar to C. Lawrenceanum, having flowers almost as large and of the same colour, and with foliage strongly mottled in the same way. Shown by Mr. W. Bull, King's Road, Chelsea.

Among other plants of interest shown were the following: From Mr. Tautz, Studley House, Hammersmith, came the new Spathoglottis angustorum, with a tall spike of pinkish flowers, not so graceful or so bright as S. Fortunei. There were from the same garden three so-called hybrid varieties of Anthurium, named respectively Reine des Belges, Archiduc Joseph, and Tautzianum. All were hybrids from A. Andreanum, and similar to the older ferrierense, but scarcely distinct enough to merit different names. Mr. Partington, of Heaton House, Cheshunt, sent a specimen

from his collection of Odontoglossum crispum, about which we have heard a good deal lately. The plant was exceedingly well grown, and bore a spike a yard high and branched in the same way as O. Pescatorei usually does. The variety, however, as we suspected, was not first-rate, the flowers being small and "starry." The gardener quite deserved a cultural commendation. Mr. Bowring, Forest Farm, Windsor, sent a hybrid between Cypripedium villosum and C. insigne. It most nearly resembles C. insigne in the flowers, but in growth it has the appearance of C. villosum.

Among new Chrysanthemums, besides those certificated, was a pretty one from Mr. Smith, Caledonia Nursery, Guernsey. It was named Governor of Guernsey, and may be described as an incurved Japanese, if there is such a class. The flowers are bright yellow, and the florets do not lie in that form which characterises the pure florist's flower, but many would prefer it, and as a late variety it is invaluable. Another first-rate new late variety shown was Golden Ethel, otherwise named Mrs. H. J. Jones. It is a sport from the well-known white Japanese sort, Ethel, and possesses all the characteristic beauty of that sort, but instead of white it is a clear bright yellow. Mr. Reeves, Hadley, Barnet, showed a sport from Orange Beauty, but it is not a great beauty. Mr. Mansell's gardener (Mr. Peters), Guernsey, sent a fine spike of a new hybrid Nerine, the parentage of which is said to be N. corusca major and N. flexuosa. The progeny bears the features of both these Nerines, the flowers being as large as those of N. corusca, with the undulated sepals of flexuosa; the colour is an exquisite rose-pink. M. Hans Niemand sent a variegated Poinsettia, but no one seemed to see much beauty in it. The very beauty of a Poinsettia is the contrast of luxuriant leaves and brilliant scarlet bracts, and who wants a variegated sort? A very finely-flowered specimen of the Great Hellebore (Helleborus niger maximus), the finest hardy flower of the winter; also Primula obconica, to show how valuable it is in winter; and P. floribunda, the little bright yellow Indian Primrose, which seems to be a perpetual flowerer. Messrs. Cannell, of Swanley, made a brilliant display with cut Pelargoniums of the finest sorts for winter bloom. Of these the best were Mrs. Cannell, Kate Greenaway, Cato, Swanley Gem, Kentish Fire, Lady Reed, Queen of the Belgians, and Hyacinth. From Swanley also came a nice selection of Chinese Primulas. Mr. King, of Rowsham, also showed some bright new Primulas, one named Jubilee being particularly fine. Messrs. Hooper sent from their Twickenham nurseries a collection of winter-blooming Carnations, among them being such first-rate sorts as Chevalier, Irma, Jean Sisley, Mdlle. Carle (white), and Claudia.

The chief exhibits submitted to the fruit committee were three noble fruits of Smooth Cayenne Pine-apple, from Mr. Coomber, the gardener at The Hendre, Monmouth, and six similarly fine fruits of The Queen Pine-apple, from Mr. Harris, Singleton, Swansea. A few new Apples were shown, but none were remarkable.

Scientific committee.—The following were the chief subjects discussed:—

Veronica salicifolia.—Mr. Wilson exhibited sprays from this New Zealand species grown at Wisley, which had perfectly withstood a temperature of 15° in exposed situations. He described it as seeding itself very freely. Choisya ternata was, however, cut by the same degree of cold.

Jasminum odoratissimum.—A yellow species, exhibited by Mr. O'Brien, is said to be a native of Madeira, but being of an Indian type, it was suggested by him and corroborated by Mr. Maw, that it had been introduced there. He also exhibited flowers of Coryanthes speciosus var., from Major Lendy; Maxillaria cucullata, a Pleurothallis, suggested by Mr. Ridley to be near P. ophicephala.

Masdevallia with larvæ.—He also exhibited specimens of a species of this Orchid attacked by some Noctua.

Xiphion reticulatum, diseased.—Mr. Maw showed specimens, which were referred to Mr. Murray for examination and report.

Narcissus, photographs of.—Mr. Maw exhibited photographs of several species or varieties now believed to be scarce or extinct, taken in the Riviera fifteen years ago from wild plants. They were all of the Tazetta group. He also exhibited specimens of the following species: N. viridiflorus, very abundant south of Tangiers; S. elegans from the African side, and S. serotinus from the European side of the Strait; natural hybrids, like forms between N. elegans and N. viridiflorus, showing all gradations between the two; Pancratium humile, abundant south of Tangiers, with a remarkably elongated scape when fruiting; Gladiolus grandis, from near Gizon, in the Asturias; and Tapinanthes sp. from Morocco.

Parmelia esculenta.—Mr. Maw also showed specimens of this so-called "Manna," an edible Lichen obtained from the country about 100 miles south of Algiers. Mr. Maw exhibited leaves of Araucaria excelsa attacked by a form of mealy bug, which first appeared in consequence of the heat and moisture on board ship on reaching Bombay.

Early linen paper.—Professor Church exhibited specimens of the earliest known linen paper made in Europe. It was a portion of an episcopal register of 1273, from Auvergne; another, dated 1289, consisted of entries of revenues, in which some of the original rag could be detected. It consisted of six strands of warp and six of woof. The size used was entirely starch, which appeared to be from Wheat. The earliest authentic linen paper hitherto known is from a memorandum of the fourteenth century, now in the British Museum.

Variegated foliage.—Professor Church described some analyses he had made of Oak foliage taken from a tree at Kew Gardens, which bore one albino branch, about 20 feet from the ground. A full account will be found in the December number of the "Journal of the Chemical Society," 1886.

Scalade with Sclerotia.—Mr. W. G. Smith exhibited specimens in which large oval black bodies were attached to the stems. The fungus to which they belonged could not be determined from them in that condition. He also read a communication upon prehistoric Wheat, and exhibited several specimens of carbonised Wheat from Salisbury and elsewhere, to show the comparative sizes of these ancient Grasses and of average English Wheat; while those regarded as Romano-British appeared to be somewhat smaller, others were quite equal in size to living kinds, as also are those derived from the tombs of Thebes, in Egypt.

Fuchsia with petaliferous sepals.—Mr. Henslow exhibited a specimen of a semi-double Fuchsia remarkable for its thick red sepals bearing small dark purple petals at their very apex.

NATIONAL CHRYSANTHEMUM.

A meeting of the floral committee of this society was held at the Royal Aquarium, Westminster, on Wednesday last. There were comparatively few exhibits, and only one was considered worthy of a first-class certificate. This was a new variety named White Ceres, a sport from the blush-tinted Ceres. The flowers of the sport are very large and of snowy whiteness. It is a most valuable addition, inasmuch as it flowers so late, and being white, will be much appreciated at Christmas time. Among other varieties shown were the following: Carew Underwood, the same as certificated by the Royal Horticultural Society, shown by Mr. N. Davies, Camberwell. Syringa, a large Japanese sort, white, tinted with pink, from Mr. Bettisworth. King of Primroses, a bronzy yellow incurved variety; and Welcome, a bronze Japanese, both from Messrs. Cannell, Swanley. From Mr. Beckett, Elstree, came Prince Leopold, a bronze-tinted Japanese; Kyrle Bellew, a pretty, neat Pompon. Mr. Smith, of Guernsey, sent flowers of his new yellow incurved, named Governor of Guernsey, but was not considered distinct. Mr. Owen, Maidenhead, sent several new sorts, among them being Mr. Hobian, deep rose, Japanese; America, a fine single-flowered sort; Ivon and Citron, both of which the committee wish to see again. Mr. Bolas, Hopton, Warksworth, sent a sport from Bertier Rendatler; and from Mr. Churcher, Henfield, came a sport from Fulton, but of no merit.

A silver medal was awarded to Mr. C. Harman Payne for an album containing plates of Chrysanthemums, an interesting series collected from various sources, including the *Botanical Magazine*, The Garden, *Floral Magazine*, and other illustrated garden works, foreign and English, existing or defunct. Some of the plates are good, but the majority represent the old style of depicting florists' flowers—generally untruthful and often absurd.

National Auricula, Carnation, and Picotee Society.—The annual general meeting of this society was held at South Kensington on Tuesday last, at which Mr. H. J. Veitch presided. The president, vice-president, and committees were re-elected, with the addition of four new names on the committees. Mr. Hibberd was elected treasurer in place of Mr. H. A. Rolt, resigned. The secretary's report was read and adopted, but owing to continued illness, the treasurer was not able to place before the meeting his statement of accounts. The meeting also agreed to hold the exhibitions of 1877 under the auspices of the Royal Horticultural Society, if the usual arrangements could be made. It was agreed to hold the Auricula show on April 26, and the Carnation and Picotee show on July 26.

OBITUARY.

Mr. Edward Pohlmann, of Parkinson House, Parkinson Lane, Halifax, died on November 27, aged sixty-one. Mr. Pohlmann was an ardent admirer and cultivator of the Auricula. He was also well known as an exhibitor at both the southern and northern sections of the National Societies, at both of which he occupied a prominent place. He was a pianoforte maker; but he gave up that business and became a professional florist. As to Auriculas, he raised two dark selfs of the show class; one named Garibaldi he sent out himself, the other, Helen Lancaster, was sent out by Mr. Roydes, florist, Rochdale. At the time of his death he had a very promising lot of seedlings of show and alpine Auriculas from crosses of the leading varieties.

The late Mr. Charles Green.—I am grieved to see a notice in The Garden of the death of my old friend and most serviceable helper in many ways in my garden, Mr. Charles Green. All who read them will endorse the remarks made concerning him. But there is one thing which might be a little more noticed. Of all plant growers that I have ever known, Green seemed to me to individualise and love his flowers with an affection I have never seen equalled. As a proof of this I may mention that he gave to me as the reason of relinquishing his nursery at Reigate (he had this between his engagement with Mr. Wilson Saunders and Sir George Macleay) that he could not bear to part with the plants he had been tending for years. I remember his saying that to me in quite a broken-hearted sort of way, and as a nurseryman's business consists in passing things rapidly through his hands, Green soon had enough of it, and he was much more happy at Pendell Court. How successfully he managed that most splendid collection not a few can remember, but I put together these few remarks to emphasise the fact that he loved his flowers as most men love their own children.—H. E.

Names of plants.—*G. W. B.*—1, Maxillaria picta; 2, Odontoglossum Rossi; 3, Trichosma suavis; 4, Cymbidium, cannot determine the species by a single flower; send spike and leaf.—*N. P. WOODS & FORESTS.

CLASSIFYING TIMBER.

This is a duty which is continually confronting the forester, and perhaps more through the coming few months than at any other time of the year. It is, too, one of the details of his work which it is not easy to master without some actual experience and observation of the way in which it is done. Practice will be sure to vary a little in different districts according as the requirements of users differ; but there are general principles which may be deduced and which, as a whole, will apply in all places. Some, I know, do not attempt classification at all, and let good, bad, and indifferent go jumbled up together. This lack of attempt to reduce the various qualities of timber to anything like regular order will be very acceptable to the large buyer, as the whole lot will go at the "indifferent" price, and as the chances are that the proportion of first-class will be larger than that of the third, it is obvious he will get the corresponding advantage. When a felling is decided upon, I regard it as useless to trouble about any attempt at reducing it to classes until it is down and trimmed fit for removal—that is, of course, when the felling is carried out by the vendor. When this is done, the question will at once present itself, What really constitutes first-class timber? The answer is not altogether easy to give on paper. For one thing, the same qualities will not stand in the same relative positions for all classes of wood. A rough outline of the best qualities of timber, taken as a whole, may be made in the three words, length, straightness, and size, yet this definition is not enough. If we included freedom from all blemishes, viz., perfectly sound, we should cover the ground; but then in practice there is not one tree in a hundred which would come up to it. A tree may be of good length, yet full of heart-shakes; straight, yet largely composed of knots; of a good size, yet, which in some kinds is very often the case, so far past maturity as to be in a state of incipient, or it may be advanced, decay. What would be a good quality in an Oak is very likely to be a bad one in an Ash. As has been intimated, it is not so easy to describe in a few sentences what first-class timber really is.

Taking our common trees in the order in which they are generally spoken of, we at first will look a little at the Oak. This will serve to illustrate the fact that what may be essential to constitute a commercially first-class tree in one generation may in the succeeding one be of very minor importance, or perhaps actually a drawback. I refer to the use of Oak in shipbuilding. At the time this was so largely used in marine architecture, of course straight as well as crooked dimensions were in request, but a very considerable proportion of crooks was as essential as the straight pieces. Now, for the great majority of purposes, the absence of any appreciable bend in an Oak is much more desirable that its presence. There are, it is true even now, especially in wagon building and its allied trades, cases where a slight bend in the growth of a tree is an advantage, but this would probably not represent more than five per cent. of the Oak consumed in this country. To put it as concisely as possible: If an Oak lacks length, it must be perfectly sound and clear in the grain to be classed as a first-rate tree. If it is large and has gone greatly to limb, these must be removed and accounted for separately. Oaks which are comparatively knotty, so long as the knots are sound and not very large, are frequently rated as first-class timber, but this cannot be done unless they possess some compensating value, in the direction of length, straightness, and size. As a rule in classifying Oak, although the same price per foot may be realised, it is well, as much as possible, to keep trees which are very different in their characters separate. That is to say, long and relatively small-sized trees should not be thrown in with short and large butts. When a fall of timber is sold in bulk to a single individual, this would not be so necessary, as it will be enough to arrange that at the different prices separately; but when it has to be subdivided into smaller lots, it will generally repay a little extra attention if the trees are sorted in the way suggested, as different buyers have different requirements. When this is supplied in a particular lot, it is obvious that a better figure can be given than when a proportion of, to them, useless—because of another class—stuff is included with it. In classifying plantation-grown timber, doubt and difficulty are at their minimum, as there is always a certain amount of uniformity in character about closely-grown trees which is altogether absent in the case of field timber and that grown in the open forest. It is in dealing with these last-named descriptions that the forester has to have his wits about him to assess them at their proper worth. Taken all in-all, I think there is more judgment necessary in rightly arranging Oak in its different grades than with all the other kinds of wood commonly grown put together. With Elm, for instance, which next claims our attention, there does not seem to be nearly the same diversity, as, providing the trees are sound, it is really more a matter of size than anything else. Elm, of course, varies greatly in different districts, and for some purposes the wood of particular counties has to be sought for, but, on the whole, on any ordinary estate or district there are no very distinct lines to go upon in dividing first and second-rate timber, except, as I have said, the size. With Ash the case is different, as the ratio very often is an inverse one, and the smallest is the best. According to the present march of events, the forester is not likely to have his brains greatly racked in determining the respective worth of young and old Ash, if we except what is already in existence. With regard to such large Ash trees as we have, although it is too often the case that largeness is only another name for inferiority, it does not always follow, as I have again and again met with large Ash trees which, notwithstanding having lost the toughness which is so characteristic of the young wood, were perfectly sound and white. The appearance of the bark is little or no guide to this; at any rate, the healthy or uniform look it may have is no guarantee that the tree itself is good. The only test is to carefully examine the butt where it has been cut off, as also the top and any of the branches.

Beech and Sycamore, especially the Beech, are trees where size is of very little assistance in resolving its value. A large, sound Beech there can, of course, be no doubt about, but it very often turns out that large Beeches are not sound. When this unsoundness occurs in spots and blotches through the body of the tree, it requires careful attention to relegate it to its proper place. The worst part of it is that these external blemishes are but an imperfect index of what is contained within, and they may develop into a thoroughly inferior tree, or, on the other hand, be merely superficial, and the bulk of the tree be perfectly sound. Where there is room for much doubt, when possible, it is always well to have an average tree cross-cut through an unsound spot, and judge from the turn it takes whether unsoundness increases or decreases. It will depend a little on the nature of the industry for which it has to be used, but generally with small Beech, which is clear in the butt, but knotty throughout the upper portion, it is better to have it cut across where the knots commence and thus divide it into two qualities. Where firewood is in short supply it will often answer to burn the knotty part in preference to leaving it attached to the clean part of the tree.

Larch and the other Firs being tolerably uniform growers do not here call for any special remark. What classification there is needed, reckoning, of course, that the wood is sound, goes upon the lines of length and size, and really is about the simplest thing in this branch of the forester's business. With some it is the practice to make size the test of price—I mean to sell such trees or portions of trees as may quarter-girth a given size at so much per foot, whilst everything below this would go at a reduced figure. In selling Elm, for instance, this classification, though a rough one, would, in practice, answer fairly well, but such trees as the Oak, Ash, and Beech are notable exceptions, and attempting to work out values on such a basis would be not only useless, but dangerous. For these trees especially the judgment and not the rule will be the thing to employ, as size is only one item amongst many. It may occasionally be advantageous in classifying to place different kinds together. At first this may seem to be contradictory to what has been urged about sub-division, but, as a matter of fact, it is only pursuing the subject to its legitimate end, as two different kinds of timber may approximate very closely in value and in use, whilst trees of the same kinds may vary very widely.

D. J. Y.

HOW TIMBER IS VALUED.

Of the parties to this controversy I know nothing except through the pages of *Woods and Forests*, but from his confessions I really think that "Y.'s" simplicity is amusing. If he has no other grounds for the charge he has made than those he has hitherto given us, it would have been better never to have made it. As it stands at present it looks very like an attempt on "Y.'s" part to wreak his vengeance at being undersold upon someone or other. To argue back in the way he attempts to do would be a very interesting arithmetical exercise, were it not dangerous and likely to bring others into discredit. If "Y." has evidence that Larch from any given estate is felled and delivered at a stated price by the estate owner himself or his agent, if he could fix upon the actual cost of felling and transit, he would be in a position to say what the wood realised in the plantation. Where a third party intervenes such a line of argument proves nothing, and I am surprised that "Y." fails to recognise this. It certainly shows but little understanding of the exigencies of trade, and this is where the explanation lies. As to what prices timber actually sells at in North Yorkshire I have nothing to do, but with the admissibility of such a style of argument as "Y." uses I have, as it is one which is capable of being most unjustly turned against any selected individual. The falsity of the position is the assumption that every foot which passes through the hands of the middleman does so at a profit. Taking a year's transactions through, a merchant must make profit if he holds his ground, but he may not necessarily do so foot by foot as he sells. Take one of "Y.'s" own points; he says, "Larch has dropped here lately, and I quoted, &c." Now it is not usual for timber to be transported with telegraphic rapidity from the plantation to the market, especially when the distances are such as cost the sum for carriage which "Y." mentions. The timber in question may have been purchased months ago, and the merchant has had to dispose of it on what has been admitted to be a fallen market. Yet away we go, so much per foot delivered to the consumer, so much for felling and transit, plus profit, the balance to the vendor. A very facile way of reckoning, but a very unreliable one, nevertheless. It is perhaps not within the province of the forester to try and penetrate into the inner circle of a timber merchant's business, but to combat a specific line of reasoning it may become necessary. Besides, then, the unavoidable consequence of a lower market, for reasons not connected with the particular transaction, it may be expedient on the part of a seller to make a bargain at a figure that may leave him on the wrong side of the ledger. I do not say that this was done in the case "Y." cites, but it will further serve to show that there are numberless circumstances which intervene between the purchase of a lot of wood in the plantation and the subsequent disposal of it at the other end of the country, which make it impossible to arrive at a true conclusion as to what it was actually sold for in the first instance. Legitimate discussion is the very thing we want, but wild guesses upon grounds which are much more likely

to be wrong than right are to be deprecated—at least such is the opinion of

Another Forester.

THE AUSTRIAN AND CORSICAN PINES.*

Since the outbreak and general spread of the Larch disease in many wood-producing districts of the country, by which confidence in that valuable Conifer has been shaken, attention has been directed towards finding a substitute, alike rapid in growth, suitable for a variety of situations, of equal durability as a timber tree, and adapted to a similarly wide range of economical uses. The varieties of Conifers, distinct and widely different in their natures and habits, which form the subject of this paper have been successively brought under public notice as valuable trees for British culture, and worthy of extensive cultivation. Introduced at different dates, and consequently with a considerable difference of years' experience from which to judge of their respective merits as worthy successors to the fine old Larchwood of which the country could formerly boast, there can be no doubt that all three have proved to be well adapted for colture in Great Britain, and also suited to a variety of soils and situations. The two Pines now under consideration present individually distinct characteristics.

The Austrian Pine.—The distinguishing features of P. austriaca from those of Pinus Laricio are observed to be constant in the growing state, and when compared as timber in the sawn plank, there is a marked difference. The comparatively recent introduction of the Douglas Fir renders it more difficult to speak with certainty of its value as timber, seeing it has not yet been tested as a timber-yielding tree; and where specimens have been cut down, the rapidity of growth in early years prevents such cases of being fairly cited as any criterion of what the species may prove, when felled in a ripe state, with fully developed timber. Considering, then, the two Pines which form the subject of review, we notice first the Austrian Pine (Pinus austriaca). This Conifer is generally admitted to have been introduced into this country about the year 1835. Its native habitats are Lower Austria, Styria, Moravia, Carinthia, Transylvania, and the south of Europe generally. It is a most useful variety, whether shelter, timber, or ornament is the object mainly in view in planting. In its young state it is of rapid growth, acquiring in a few years a heavy rounded head, and, being rather weak-rooted, is apt to become "winded" in exposed situations in rich soil. This habit of forming a dense, heavy top when young is productive also of another evil, for such a mode of growth must engender the formation and encouragement of many side branches, and so detract from the value and bulk of wood in the trunk. As an ornamental Pine, Pinus austriaca is undoubtedly a great acquisition; its dark, rich green foliage, its dense head of massive contour, its strong side shoots, and its rapid rank growth all contribute to render it a tree of desirable habit for effective purposes; but we fear that when compared for economic purposes with the other two species referred to in this paper, it will be found deficient in quality, texture, and durability. The soil in which Pinus austriaca flourishes in its native habitats is a thin, cold, dry soil, of sandy or gravelly tendency; and in such situations it will thrive admirably, and succeed as a timber tree, much better than in rich alluvial deep soil, although more sheltered. In fact, it appears impatient of mild sheltered positions, preferring those apparently less suitable for the growth of timber. As already stated, it is not so well adapted for situations much exposed to heavy prevailing winds, being weak and shallow-rooted in its younger state, and at the same time densely clothed with close umbrageous foliage, which renders it not unfrequently what might be termed "top-heavy." In localities suitable for its development, and not exposed to heavy winds, Pinus austriaca will attain a greater height than the Scotch Fir (Pinus sylvestris), and is of equally, if not more rapid growth. The wood is inclined to coarseness, but is tough and firm in texture, rather knotty, but of more commercial value for country purposes than the timber of equal age of either Larch, generally, or the Scotch Fir. As compared with the Corsican Pine (Pinus Laricio), the growth of the Austrian Pine is not more rapid, and it is less suitable for exposed situations. Pinus austriaca, in habit and value, more nearly resembles Pinus Pallasiana, but both are inferior as wood to Pinus Laricio. The leaves of the Austrian Pine are easily distinguished from those of the Corsican by their being rather longer, and devoid of the twisted appearance which those of the latter present. As a tree to employ as a nurse in sheltered valleys it is invaluable, owing to its dense head, spreading arms, and rapid growth; and to be cut out when it has not attained full size, it is more valuable than the Scotch Fir, as it can be profitably used for country purposes at a younger age than almost any other Fir. Lamp-black and charcoal of excellent quality can be obtained from its branches, and the thinnings are, in its native country, much sought after by coopers and carpenters.

The Corsican Pine (P. Laricio) was first discovered in dense forest masses in Corsica, whence it was introduced into this country towards the end of the eighteenth century. It has since been found over several countries of Southern Europe, including Spain, Greece, and Italy, and it abounds on the mountain lands of Calabria. In these, its native habitats, it attains to a height of 140 feet, and forms a noble tree of bold, erect, open habit. The wood is extremely resinous, tough, and, although tending to coarseness, not so brittle as Scotch Fir or Austrian Pine of equal age, but is elastic and durable; under the tools of the carpenter it works smoothly and easily, and is much prized for many outdoor or constructive purposes. Felled when about seventy or eighty years old, the wood is found to be well matured, and of a whitish colour, and brown near the heart. In this country the Laricio has been extensively planted during recent years as a timber crop, and since the Larch failure, probably this Conifer, more than any other, has been substituted for it. It thrives in almost any soil where the Scotch Fir or Spruce succeeds, but will not attain its full development at the higher altitudes, preferring a rather good deep soil and sheltered situation in its younger stages; for, being of very rapid growth and early vigorous habit, like P. austriaca, it is apt to form a top rapidly, which the slower formation of roots cannot support during high gales of wind. In this aspect, however, it does not equal the Austrian Pine, and is materially assisted by its characteristic tendency to throw the vigour of its growth more into the trunk and terminal leader than to form a dense head or many heavy side branches. Another benefit accruing from this erect or fastigiate habit is the ultimately enhanced value of the timber, by its being less knotty and of better texture. In general appearance when young, the P. Laricio somewhat resembles the Scotch Fir of the old Strathspey indigenous type, but it is more open and longer between the tiers of branchlets. Its value as timber is not so marked when the tree is young, for thinnings of Laricio are found too soft and less durable than Larch, but when old it is reported to be remarkable for its toughness, and it is strongly impregnated with resinous sap. Numerous groups and specimens of the Laricio, 40 feet in height, exist in various parts of the country; and in Perthshire, at 600 feet elevation, in a loamy soil and gravelly subsoil, it proves itself equal to any indigenous Fir, resisting alike the gale and winter's storm, and rapidly shooting above contemporary trees of Scotch Fir, Larch, and austriaca. It may indeed be described as a tree consisting of the bole of Larch, with the lateral branchlets and foliage of Scotch Fir. One qualification of considerable importance possessed by the P. Laricio should not be overlooked—namely, its distastefulness in its young state to hares and rabbits. Without positively asserting that ground vermin will absolutely shun the young Laricio if mixed with other Conifers in a plantation, it may be safely asserted that they will nibble away everything else before they will touch it. An experiment to test this was made some years ago at Tortworth Court, in Gloucestershire, where Lord Ducie planted a young Laricio in the centre of a rabbit warren, and which, until the ground was quite covered with snow, the teeming population of the spot did not touch; and even then, when starving, and naturally less capricious in their bill of fare—after an attempt to consume the young needles of the buds—they abandoned the experiment and sought some less bitter and astringently resinous food. In like manner Pinus Laricio is less liable than any other Pine to suffer from the ravages of insects or such like enemies which infest and disfigure many of the coniferous family. Although we have said that the Laricio exhibits a preference for a deep, good soil, it thrives in almost any other description, if we except soft, spongy, and undrained marshy ground. Being of a deep tap rooted habit, in such a situation the spongioles of the main radicle get chilled and waterlogged, and hence the tree will not succeed. Throughout the country it has within the last thirty years been freely planted in all sorts of soils and elevations, and has been proved to be perfectly hardy, and altogether such a variety as ought to be more generally cultivated; for while it is a rapid grower and a handsome tapering tree, it is well calculated for planting in masses as a crop to produce not only quantity within a period of forty years, but quantity of heavy size, and timber of excellent quality. Although in its native country it is felled at about eighty years old, it may be profitably used at even thirty years. It may be seen luxuriating, and of considerable height, at Dolphinton, in Lanarkshire, at an altitude of 900 feet or 1000 feet above sea-level; and in many other counties in the north of Scotland, specimens of the P. Laricio show that it is suited to the climate of Scotland. From the long tap-root of this Pine, it is, unless frequently and regularly transplanted when young, somewhat difficult of removal, and when forming plantations small plants should be used, as they will ultimately succeed better than those that have had their tap-roots cut when young. Care is requisite to obtain the true Corsican Pine when desired for ultimate profit and for heavy timber purposes.

* Extracts from the Proceedings of the Scottish Arboricultural Society.

Walnut trees.—From the figures given by "Juglans," the trunk of the Walnut tree he wishes to dispose of contains from 35 feet to 40 feet. I take it that the 13 feet in length is up to where it commences to branch, that the quarter girth, after allowing for bark (taken at 6 feet 6 inches up the stem), would be 20 inches or 21 inches. This, leaving out fractions, would be 36 feet and 40 feet The branches are not taken into account. Unless these are considerable, "Juglans" will have found a good customer if he secures a £5 note.—D. J. V

Squirrels (p. 531).—Wherever there is an abundance of Hazel Nuts or seeds in Spruce or Fir cones the nimble little squirrel does not do much harm, but if food is scarce he is not particular in his foraging. I was at Straffan last summer, and noticed the young shoots of the Horse Chestnuts hanging brown and dead near the tree tops, and was told that this was owing to a squirrel having scooped out the pith. He steals Filberts and Walnuts wholesale if his woodland supplies fail, but he is such a pretty, sprightly little animal, that much is forgiven him.—Veronica.

Preservation of wood by lime.—I have for many years been in the habit of preparing home-grown timber of the inferior sorts of Fir—Scotch, Spruce, and Silver—by steeping it in a tank (that is, a hole dug in clay or peat, which was fairly watertight) in a saturated solution of lime. Its effect on the sapwood is so to harden it and fill the pores that it perfectly resists the attacks of the little wood-boring beetle, and makes it, in fact, equally as durable as the made wood. I have a mill which was lofted with Scotch Fir prepared in this way in 1850, and it is in perfect preservation. The timber is packed as closely as it will lie in the tank, water is let in, and unslaked lime is thrown on the top and well stirred about. There is no danger that the solution will not find its way to everything in the tank. I leave the wood in the solution from two to three months, by the end of which time an inch board will be fully permeated by it. Joists and beams would, of course, take a longer time for saturation; but in practice we find that the protection afforded by two to three months' steeping is sufficient if the scantlings are cut to the sizes at which they are to be used.—*Field.*

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

MODERN CHRYSANTHEMUMS.

THE great impetus that has been given to the cultivation of the Chrysanthemum since the introduction of the Japanese varieties of this useful and beautiful autumn-flowering plant needs no description from me. It is of the later developments of this flower that I would speak at present, when memories of the late shows or the glowing presence of some brilliant flower delight the mind or the eye. Is it generally understood by amateurs that the Japanese varieties are more easily and certainly grown and flowered than the older and well-known incurved varieties? Owing to the great height of some of the show varieties, such as Mdme. C. Audiguier, Boule d'Or, Comte de Germiny, and the like, amateurs too often think they must not try to grow Japanese Chrysanthemums; while the dwarfest and hardiest varieties are now to be found in this class. Madame C. Desgrange is well known as the earliest of white Chrysanthemums, and it is very dwarf in habit. G. Wermig, its yellow sport, is also very desirable, and should be sought after. Next on the list in earliness comes Margot, an exquisite pink and lemon variety, unequalled for abundance and beauty of bloom, lasting far into the season. Lady Selborne is almost as good a variety, but white in flower, taller in growth, and does not last as well. Bertier Rendatler, a tall-growing variety, and L'Or du Rhin, of a sturdy dwarf habit, are two yellows, with a touch of brown here and there, that grow and flower anywhere, and should be in every garden. Some of the latest additions are equally valuable, combining dwarfness and large-sized blooms. Val d'Andorre is a singularly fine rich red variety; and Fleur des Bois is so floriferous, that literally its flowers begin at the level of the pot. La Nymphe is a delightfully fresh-tinted lilac, of extra good and dwarf habit, but so well known there is no need to say more. Madame Henri Jacotot is a very free and early-flowering crimson-brown, of large size and good habit, but, save in the early sorts, I have not yet met with a dwarf white Japanese variety. True, there is one that should be grown by everybody—I mean Mdlle. Lacroix, for this has the peculiar advantage of continuing to push flowering shoots in a way that is most remarkable, so that a careful amateur may even have five series of blooms, one after the other. The beauty of this variety is (*me judice*) unrivalled; it may be grown like a big snowball, or you may have smaller flowers with a lemon centre and delicate lace-like petals drooping from it.

The Japanese varieties give the brightest colours in purple shades, and of these Mdme. de Sevin must rank first for habit and beauty in every way. This variety has been largely shown, but its beauty as a garden plant is even greater, and it deserves a place in every collection. This year Charles Hubert is so brilliant in red and gold, that one is tempted to forget that last year the dull and cold weather in autumn prevented anything beyond a scanty and imperfect bloom (in the north), while all the previous varieties succeeded; so, though good, it cannot be said to be as sure as those mentioned before.

It would be interesting to know the grounds on which that most useful of all red Chrysanthemums, Cullingfordi, has been placed among the reflexed varieties. No doubt when carefully disbudded for show blooms, a fully expanded cut flower is reflexed; but let it grow more naturally and the petals will curl and twist till a mass of flower on a branch attains a most truly "Japanese" effect, while Elaine, though classed as a Japanese, never shows any such characteristic, but remains reflexed at all times. Such are some of the experiences of a northern amateur.

E. H. WOODALL.

EVERGREENS FOR CHURCH DECORATION.

THE Evergreen that forms the prettiest wreath so that all its sides can be seen is the Ivy, short tufty pieces, which are often laden with berries, alone being used. I prefer the Ivy to anything else on account of the under sides of its leaves looking almost as well as the upper surface, and for a thick wreath it is well fitted; while for a slender one tree Box is the most graceful—decidedly more so than Cypress, Yew, or anything else of the same description that we have used. I am speaking, it must be recollected, of wreaths which are suspended in conspicuous situations where all their sides can be seen. Against a wall or surrounding a pillar I am not sure that other materials might not do as well, but I believe I am right in selecting the Evergreens mentioned for making a light festooning for open work. A very pretty festoon is also made out of some of the small-leaved Phillyreas; but perhaps the plants that furnish twigs from which the quickest lengths may be made, and that look well at the same time, are the Sweet Bay, Alaternus, and, finally, the Laurustinus. Portugal Laurel is more suited for a one-sided wreath, and common Laurel can only be used for that purpose, but we have also used Evergreen Oak, Yew, and Holly. The latter, if grown at all robustly, is rather stubborn and intractable, and its shoots require now and then to be cut almost through (or crippled, as we call it) to induce them to conform to the line required. Holly is also unpleasant to handle, so that, unless for special purposes, we prefer using something else; indeed, most Evergreens having plenty of small or medium-sized leaves answer very well; the larger leaved kinds get flabby too soon, the Aucuba being too large for most kinds of work, for which it would otherwise be adapted. Nothing is really neater than the Euonymus, plain green or golden; the common Daphne Laureola or pontica looks better in a growing state than when made into wreaths, its foliage being too much clustered at the points and the stem indifferently clothed—a remark which also applies to the larger-leaved Berberis; but B. Darwini when in flower makes a handsome wreath, and I have seen a very neat one made of Myrtle. The rather scarce Griselinia litoralis might be advantageously employed for this purpose could it only be obtained in abundance; and I have also found that the Majorca Box is thoroughly suitable, but I have never as yet seen any one Cotoneaster that could be recommended for the purpose. Various other plants besides common Evergreens may be formed into festooning. We have, when the season admitted of it, made many yards of Rhododendron festoons, securing the flower-heads with a few inches of stalk alone, the young growths on all kinds of Evergreens at the time precluding their being used with the flowers. About the same time the Deutzia gracilis forms an excellent festoon, followed later on by the double-flowered Deutzia, which, being in spikes about the length of one's arm, forms a festoon with the least trouble of anything, unless it be Fuchsias of the hardy class, which are also available, and look well. In fact, most flowers may be used that can be had in abundance, and in spikes rather than corymbs. Sprigs of Oak, with the dead leaves thickly adhering to them, also look well in winter, and can be worked into the same form and size as Evergreens. Beech, I dare say, would also answer; but I have not tried it. Now and then, however, we have used strings of berried plants, and one that works in as well as any with which I am acquainted, when assisted with Evergreens, is the Privet, with its clusters of jet-black berries. In like manner other berried plants, such as the Mountain Ash and all the Thorns, might help to make a good display.

Having a quantity of the twigs ready, which may be from 12 inches to 18 inches in length, a heap of them is laid on a table or bench, and with string that most people would call very small a loop is made, and fastened to some hook at or near the end of the table. One or two pieces of Evergreen are then held in the left hand, while, with the other, a sort of hitch knot is made round the Evergreens, some 2 inches or 3 inches from their points, which we shall say is the beginning. Evergreen twigs are added near the butt ends of those already placed, and, the string being carried down in the midst of them, is made to form another hitch knot round both the tips of the new shoots and the butts of the others, a process which is continued on until a convenient length has been made, which may be about 10 feet or 12 feet. For convenience, however, the string is seldom more than 6 feet long; otherwise it is liable to get in the way, and, being very small, is easily knotted. Care, of course, must be taken not to confine any more of the leaves than can be helped; and a little practice will enable anyone to judge how much of the tip of each shoot should be left beyond the first tie, the shoots being fastened at each end, and a rather more secure knot being made at the end of all, to prevent it coming undone when moved, as these festoons are, where amateur decorators have their handling, sometimes subject to rough treatment, which, however, they usually bear without injury. When taken to the place where they are to be hung up, they can be joined together without the joint being detected, by merely tying the strings at each end, taking care that the direction of the foliage is continuous if the decoration is to be carried round the room, or in one direction. It can be looped up at any place required; and, the string forming it being very slender, it can either be suspended to a tack or tent-hook, or the festoon can be twisted round a pillar; or, if hung in front of the upright mullion of a church window, will hang down in its place without much trouble. If against a picture or looking-glass frame, it is equally available. In fact, wreaths of this kind may be made to do service in various ways where no nails are to be driven. I have even known the weight of such festoons borne by an ordinary pin, forced into some penetrable portion of the moulding, without being seen; while the indented work that frequently surmounts the moulded work of a screen, or other portions of church architecture, will frequently admit of a common cork being fixed between the notches, which makes a most excellent support, while, in many places, a small tent-hook may be inserted in the recesses of a moulding, or in other places where it can do no harm—indeed, it is not bad practice in public rooms, that are frequently decorated, to fix a series of hooks or staples, which prevent further damage from nails.

In carrying wreaths round pillars, I may mention that it is better to have two or more such wreaths than one, the inclination being less, and, I think, the effect better. I have seen as many as four such wreaths twined round a very stout pillar, a string being tied tightly round the capital just above the narrow moulding so as to keep them up, the wreaths commencing there and terminating in a similar way at the bottom. A thick wreath is then bound round both top and bottom, and it much enlivens the beauty of the spiral wreaths if they consist of two different kinds of Evergreens—say one of them Cypress, and the other of a larger-leaved plant, such as Sweet Bay or Alaternus, or, if need be, Holly. I would hardly recommend that more than two kinds be used, unless there are three wreaths, which cannot be worked in so well, but, if need be, they might be of different kinds. G.

Beautifying odd corners.—The real taste and skill of a person is more generally brought

out in the odd corners of a place than in elaborate efforts, and the more the odd corners are utilised for special features the more interesting the place becomes when a person's whole strength is laid out upon one elaborate effort. When that is seen, the whole has been passed under review; but special features, such as a group of striking trees or shrubs or creepers, a cluster of Roses or Pæonies or Ferns, may be dropped in anywhere. Often by brushing up the waste corners of a place, and placing some special little feature there, the tone and character of the place is completely changed. A shady corner, planted with Ferns and hardy Cyclamens, instantly becomes attractive. And dozens of similar, but separate, ideas might be carried out at a trifling expense, so that everywhere something of interest would be cropping up. Tea Roses, Carnations, Musk, Honeysuckle, Jasmines, Snowdrops, Daffodils, Primroses, and Anemones are all suggestive in their way. Bits of rockwork might crop out in appropriate situations. In short, the idea only requires to be thought out to secure many exceedingly interesting combinations.—E. H.

NOTES OF THE WEEK.

Acacia platyptera.—This is at once one of the earliest and one of the most showy of Acacias. It makes a handsome pot plant, and is at present very gay in the large temperate house at Kew, where some years back many species could be seen in flower during the winter and spring months.

Gomphia decora.—This handsome Brazilian shrub is now very conspicuous at Kew. It is a plant of robust habit with alternate, shining deep green leaves and large panicles of brilliant deep yellow flowers, and as it continues blooming from the present time up to early spring, its value may easily be estimated.

The Bottle-brush Flower (Callistemon lineare).—The brilliant scarlet blooms of this fine old plant are now to be seen in the temperate house at Kew, its appearance reminding one of the days when this and its near allies, together with the Banksias, Dryandras, and numerous other fine Australian plants filled the large conservatory near the entrance gate.

Salvia leucantha.—Although this is by no means so showy a plant as S. Pitcheri, it is, nevertheless, a welcome addition to flowering plants at this particular season. It is an abundant bloomer, its long spikes of lavender-coloured flowers being very effective in the greenhouses at Kew at the present time.

The first Daffodil.—I send you the first blooms of the season of Narcissus pallidus præcox, opened under glass on December 10. You can still perceive the rich May perfume, which was very powerful and agreeable on Saturday; the flowers were gathered on Friday. I daresay it will interest some of your readers to know that this beautiful Daffodil can be flowered under glass so early.—P. Barr.

Jasminum angulare.—This is a very free-flowering and graceful species, obtained from the Cape by a Cambridge lady, and sent to the Botanic Garden there. It is grown on a rafter in one of the greenhouses, where it succeeds well. A good figure of it will be found in the *Botanical Magazine* for March of this year. To the greenhouse species it is a grand acquisition. Its blossoms are very sweet-scented.

White Daffodils.—The intended trial at Chiswick has been alluded to so many times lately, that I must beg to be allowed a word of explanation. Chiswick was first named as being a central and, if one may call it so, non political meeting ground for the contending varieties; but the objection was raised that the soil there was not suitable for this special class, and that unless seen when grown under the most favourable conditions, a proper judgment could not be formed as to individual and distinctive merits. It was then suggested that a similar trial might be made under Mr. Burbidge's care in Dublin, and also elsewhere in any suitable position; but the difficulty in carrying this out was the fact that many of the questioned varieties which it was wished to prove were still scarce, and that their owners would not care to part with many of these, three bulbs at least being required wherever possible to ensure sufficient means of comparison. More than one of those present promised to send collections to Chiswick when the time came, and in July I began to write to remind them of their promises, and also to ask others to join. The first answer I received was from one whose acquiescence was specially desirable, and in this letter the writer declined. I had other letters written and ready to send off when I was taken ill suddenly, and unable at the time to do anything further in the matter or to hand it over to others. Afterwards I had to give up the hope of getting the trial carried out this season. I can only hope that the delay may be of use in getting together a more complete collection next year, with the heartier co-operation of all in any way interested in these beautiful flowers.—C. R. Scrase-Dickins, *Hon. Sec. Narcissus Committee.*

Centropogon Lucyanus.—This is a most valuable plant for winter-flowering in a cool stove or warm greenhouse, treated either as a shrubby plant in a pot, or as a basket plant suspended from the roof. In the latter case young plants should be struck from cuttings every season. The flowers are long and tubular, soft rosy carmine in colour, and produced in great profusion upon short lateral branches. We recently saw it in the aquatic house at Kew.

Anemone Fannini.—We stated some time ago that we had good reasons for believing this grand African Windflower would prove hardy in England, and it is therefore interesting to find that some young plants which were planted in a border out of doors at Kew have not been injured in the slightest by the severe frost experienced on several nights last week, even quite young leaves having withstood the trial, which on one night was severe enough, 17° of frost having been registered near the border where these Anemones are planted.

Chrysanthemums Meg Merrilies and Grandiflorum.—I send you a few blooms of these two excellent varieties of Chrysanthemum to show their beauty at this season. I have grown other sorts, but no yellow or white seems to equal these two. The plants from which the flowers were cut were grown in 12-inch pots and stopped once, not disbudded at all. They were watered with liquid manure, and otherwise treated as if for producing exhibition blooms. The plants were lovely before we began to cut the flowers from them.—J. Doughty, *Angley Park Gardens, Cranbrook.*

*** Excellent flowers.—Ed.

Winter flowers.—The following plants were in bloom here up to the 29th of November in a high exposed situation, viz.:—

Pansy	Cactus Dahlia, in very sheltered positions
Yellow Sultan	Tagetes pumila
Marigolds of all kinds	Lithospermum
Scabious	Chrysanthemum segetum and coronarium
Marguerites, yellow and white	Anemone japonica
Primroses of various colours	Schizostylis
Auricula	Coreopsis
Pentstemon	Indian Pink
Large-flowered Pyrethrum	Michaelmas Daisy
Carnations	Tritoma
Violets	Evening Primrose
Iceland Poppy	Godetia
Phlox Drummondi	Lupines
Potentilla	Catananche cærulea
Gaillardia	Roses
Cornflower	Mignonette
Blue Agathea	Sweet Pea
Jessamine, yellow and white	Nasturtium
St. John's-wort	Tropæolum canariense
Arctotis	

—M. Lane, *Dangstein, near Petersfield, Hants.*

Ipomæa Horsfalliæ var. Lady Briggs.—This new variety of the well-known I. Horsfalliæ may be described as being smaller in leaf, in flower, a more profuse bloomer, and altogether as pretty as the original, if indeed it does not surpass it in some respects. One may see both the type and the variety growing side by side on the rafters of the Bromeliad house at Kew, and may therefore judge of the merits of the newer kind. We think it so beautiful, that we intend to make a coloured illustration of it for The Garden. Can anything in the way of flowers be more lovely at this season than the bright carmine flowers of the Ipomæa? The elegance of the plant when growing freely up a pillar or rafter is most pleasing, yet you may not find it grown in more than one in twenty private gardens, and yet people are continually asking for a good winter-flowering stove climber. This Ipomæa and the new Bornean Jasmine (Jasminum gracillimum) are plants which anyone can grow in a stove, and can be obtained cheaply.

Royal Horticultural Society.—The latest Journal of the Royal Horticultural Society contains a report of the Primula conference and exhibition, and also a very comprehensive list of species and varieties of Primula, compiled by Mr. Dewar, of Kew. This list alone makes the Journal valuable to cultivators. A report of the conference on "Orchid nomenclature," held at Liverpool in June last, is also given, but it does not appear to possess much practical value. We hope that the other publications announced will soon be forthcoming.

Clematis Davidiana.—This rare and interesting species was introduced some years ago to the Jardin des Plantes at Paris. It belongs to a small section which does not climb, and which has flowers very much resembling those of a Hyacinth. It is allied to C. tubulosa, but differs from it exceedingly in appearance, and is without the woody stems of that species, being strictly herbaceous in habit. The stems grow about 4 feet high, and have long internodes; the leaves are large and handsome, with elliptical or obovate leaflets, cuneate at the base. The flowers are very numerous, and in dense fascicles in the axils of the leaves; they are of a delicate blue colour, about 1½ inches across, and very sweetly scented. The dried leaves, too, are very fragrant. It is a native of China, and in the Cambridge Botanic Garden flowers from July to the end of September.

Erythronium Nuttallianum and Dens canis sibiricum.—Allow me to make a few observations on these Dog's-tooth Violets. E. Nuttallianum, although it has not sufficient character to distinguish it botanically from americanum, is nevertheless distinct as a garden plant. The leaves are plain green, never mottled, and the segments of the flower are narrower, longer, and not blunt-pointed. It also bears two or three flowers sometimes, and is altogether a more elegant plant than americanum; besides, it does not require particular soil. E. Denscanis sibiricum and japonicum are stated to be inferior to the type. I do not know the Japanese variety, but sibiricum is much better than the type; the flowers are twice as large and better coloured. It can scarcely be known in English gardens, as it was introduced only three years ago by Dr. Regel.—Max Leichtlin, *Baden-Baden.*

Billbergia vittata.—The collection of Bromeliaceous plants at Kew, which some time ago was augmented by the celebrated collection formed by the late Professor Morren at Liege, attracts interest during this dull season, as many are in flower. Some of these bear inconspicuous flowers, but the majority are really grand, vieing with even the Orchid flowers in the adjoining house. Perhaps the queen of the great genus Billbergia is B. vittata, known also in gardens as B. splendens. This is now in bloom in the Victoria Water Lily house. One fine plant of it carries three or four long spikes drooping from the top of the tall, vasiform crown of leaves. The flowers are a bright purple, while in contrast to these are numerous large membranous bracts of a rich carmine-red colour, which adorn the whole length of the spike. The plant is, therefore, very showy, and the leaves being variegated by silvery transverse bands, it is beautiful even when out of bloom. The healthy look of all the Bromeliads at Kew is remarkable, indicating that their present quarters are more suitable to them than the comparatively dry atmosphere of the Palm house, where they were previously grown.

Cheshunt Hybrid Rose.—Nothing that anyone can say will ever lower this Rose in my estimation. Is "T. W. G." (p. 516) right in classing it as a Hybrid Perpetual? At p. 454 I said it was "generally classed as a Tea-scented variety," and so I find it to be in Messrs. Veitch's catalogue, and also in other good lists, but I am unable to find it anywhere amongst Hybrid Perpetuals.—J. Muir, *Margam.*

Indoor Garden.

ACHIMENES IN BASKETS.

Achimenes seldom now-a-days receive that amount of cultural attention which was at one time so freely accorded them. They came originally from Central America, but the varieties which have been obtained in this country by means of cross-breeding far surpass the species in beauty. Achimenes have long, slender, catkin-like tubers or corms, by the division of which they may be propagated, as well as by cuttings made of the tops. They love heat, shade, and moisture during the growing season, but when the flowers begin to expand, if desirable, they may be gradually inured to withstand the temperature of a somewhat cool, but close greenhouse. The soil in which we have found them to thrive best is a mixture of peat, leaf-mould, well-decomposed manure, and sand in about equal parts, with the addition of a little loam; the drainage must, of course, always be kept open and free. In order to maintain a succession of these beautiful flowers, a few of the scaly tubers should be planted monthly, from about the beginning of February until the end of April or beginning of May. When required for hanging baskets, several varieties of different colours, judiciously mixed in each basket, produce the finest effect when in flower, but for pot culture we prefer the colours kept separate; therefore, each variety should be grown by itself. Achimenes, however, produce the best effect in suspended baskets, but, in order to get them to display their flowers to the greatest advantage, the baskets, after being properly filled and planted, should be placed bottom upwards; the plants will push through the soil and grow erect. As they advance in growth, the stronger kinds will be benefited by having their points pinched off at once—an operation which tends to make the plants more massive through the production of laterals. Owing to the check thus received, too, the weaker-growing kinds are enabled to keep on a more equal footing with the more vigorous growers. When the plants show signs of flowering, the baskets may be hung up in their proper places; their bottoms will be well furnished, and the gentle curve upwards which the shoots are sure to take serves to bring the blooms more plainly into view.

When not treated as basket plants, Achimenes are usually grown in shallow pans, by which means a greater display is obtained than in pots. Treated either as pot or pan plants, they should not, however, be placed in their flowering positions when first started into growth; on the contrary, when some 2 inches or 3 inches high, they should be transplanted, selecting for removal such as appear to be about equal in vigour; otherwise, if strong and weak plants are taken indiscriminately, when they come into flower they are apt to have a patched and ragged appearance. Achimenes being deciduous will, soon after the flowers are over, cast their leaves, and their stems will decay. During this stage the supply of water must be gradually diminished until the time comes when they are quite dormant; then the supply should entirely cease, and the pans or baskets should be removed to a dry, cool place for the winter, whence they can be brought forward as required in the following spring.

The following selection comprises some of the very best varieties, and represents a good variation in the way of colour. Admiration—deep rose; eye, white. Argus—deep plum-colour, spotted with carmine; eye, orange. Ambrose Verschaffelt—white, flaked with orange and purple. Diadem—magenta and crimson; eye, yellow. Edmund Bossier—white and purple, flaked with orange. Eclipse—orange-red, spotted with carmine. Firefly—reddish carmine; eye, golden. Grandis—deep violet, shaded with carmine. Harry Williams—bright cerise and mauve, spotted maroon; eye, yellow. Hoffgartner Mastrana—purple, spotted crimson. Longiflora major—large, pure blue. Longiflora alba—pure white. Leopard—magenta-rose, spotted throat. Loveliness—rich magenta and crimson; eye, golden yellow. Margaretta—pure white. Mauve Queen—large, pure mauve. Meteor—crimson-scarlet; eye, yellow. Madame A. Verschaffelt, white, veined with purple. Pulchella—blue with violet centre. Purpurea elegans—deep purplish claret; throat, orange. Rollissoni—large, blue, with light spotted throat. Stella—clear magenta; eye, orange-yellow, dotted with carmine. Unique—rosy-pink; eye, deep yellow, spotted with crimson. Vivicans—carmine; eye, crimson. Williamsi—brilliant scarlet; throat, orange-yellow.

W. H. G.

Achimenes in a hanging basket. Engraved for The Garden from a photograph.

Luculia gratissima.—In the York Nurseries this grand old plant has been blooming freely in small pots for some time past, and I am glad to see in The Garden (p. 534) an account of a plant of Luculia bearing 100 heads of bloom. The writer is, however, wrong when he says that the blooms last several days in water. They take no water up; consequently they fade in a few hours. I have cut hundreds of blooms in my time, and have found this to be the case. The only way to save them is to put them overhead in water after they have been exposed in a room for a few hours; in this way they may be kept a little longer than they otherwise would be. Our old plant here is in great beauty; the blooms on it were counted on December 1, and they numbered 480 heads, open and opening. We once had 672 heads of bloom on it. But it has been considerably reduced of late, as it overgrew everything near it. It was planted in a small border, 15 inches wide, thirty-five years ago, and it has never been disturbed since. It is top-dressed every season, and is given a little weak guano water when making its growth. — William Culverwell, *Thorpe Perrow, Bedale.*

Azalea Deutsch Perle.—This is one of the best Azaleas for forcing with which I have yet met. Its flowers are a beautiful clear white, semi-double, with petals so finely rounded that they make a good substitute for those of Gardenias. It is a free-flowering variety, and if very gently forced, may be had in bloom at Christmas. A well-shaped young plant of this Azalea covered

with bloom makes a grand table plant. After blooming, we kept our plants growing on in gentle heat, and during the autumn they were set out of doors in a shaded position for a couple of months. They were moved under glass again early in October, when the most forward of them were placed in a very gentle heat, and are now in bloom. Anyone wanting really good white flowers at Christmas should make a note of this variety, which certainly forces easier into bloom early than many of the older white varieties. In the case of Azaleas, double or semi-double flowers are best, as they are more lasting than single ones. For decorative purposes where it is desirable to have large heads of bloom on plants in as small pots as possible, this variety is very useful, and if the drainage is kept perfect and the soil never allowed to get dry, it is surprising what fine plants of it may be grown in 6-inch pots.—J. G. H.

CAMELLIA FLOWERS.

Double Camellias, that used to be looked upon as second to no flower for use in a cut state, have somewhat lost favour, especially the higher coloured ones. Yet, nevertheless, the beauty and adaptability of the flowers of this matchless Evergreen for use in floral arrangements of all kinds are such as to ever maintain it in the front rank. Not the least of the merits which the plant possesses is its adaptability to widely different treatment. It is well known to be able to live out of doors, and pass uninjured through severe winters in many parts of England, yet, except for the mere novelty of the thing, or to gratify an inclination sometimes evinced to do that with some particular plant which can be much better and easier done with others, Camellias are not likely to be much used for growing in the open air; so treated they bloom late in spring, when the flowers are least wanted and short-lived, besides their being liable to suffer from the frosts that occur at that season. So far as outdoor cultivation is concerned, it may be safely said that Camellias will never be used to an extent worth naming. In a cold house, that is, where there is no means of giving them artificial heat, Camellias thrive well and flower profusely, especially when planted out in a well prepared bed and allowed sufficient room. But under such conditions they bloom late, not coming in until much of the time during which their flowers are most required is past, in addition to which the blooms do not last more than half the time that they are capable of doing in the winter when the sun has little power, and whilst there is no disposition in the plants to begin making growth. When the plants are kept constantly in a house of this description where no means exist of excluding frost, if grown in pots it is necessary that they should be plunged, otherwise when standing above the surface the soil gets frozen through causing it to expand in a way that is sure to break the pots; when in tubs or boxes this will not occur, but the expansion of the frozen soil crushes the roots; consequently even when they are grown in tubs or boxes plunging becomes necessary. Those who have had ever so little to do with Camellias will not require to be told that the most usual way of treating them is to subject the plants to a moderate amount of fire-heat, with a moist atmosphere and shade for a time after they have done blooming until the buds are set and have attained more or less size, after which heat is discontinued until the winter comes round, when as much is applied as will keep them at something like an ordinary greenhouse temperature. Oftener than otherwise the plants are located at this season with various other things that require greenhouse warmth, and to which all are alike subjected.

Simple as the treatment is, and comparatively little the judgment required to regulate the setting and development of the flower-buds, so as to have the plants in bloom at any given time when they may be wanted, it often happens that when the time they are required approaches, it is found that the flowers will be late, and then heat is used with the intention of hastening on their opening. When this is done, unless care is taken not to raise the temperature more than that of a warm greenhouse—say, about 45° in the night, with a little more by day—and to see that the atmosphere is never allowed to get dry, it is all but certain that some of the buds will fall off without opening. The danger of this happening when heat is used to push on the flowering of these plants after once they have been subjected to cold treatment after the buds were set is known to those who have had much experience with them; still there is nothing more common than to see this mishap occur. If, in place of thus attempting to push them on after they have had a season of cool treatment that has reduced them to a dormant state, the heat they were submitted to whilst making growth and setting their buds had been long enough continued so as to sufficiently develop the buds to enable them to open at the time the flowers were wanted, there would be no occasion for a subsequent application of heat, and the premature dropping of the unopened flowers would not take place, the buds simply keeping on swelling until they opened. It is the stoppage that takes place consequent on the heat being cut off for a time that brings about a condition in the plants that does not admit of their being afterwards hurried. But it requires a certain amount of forethought and experience to thus regulate the length of time the plants are kept in heat after the buds are set, so as to have them in flower at any particular time, as, if the heat is kept on too long, they will bloom sooner than required. Instances in proof of this are by no means rare where plants that have flowered early have been kept too long in a warm house, the result being the too rapid development of the buds and premature opening of the flowers.

One of the first cases that I recollect seeing of this kind was soon after I went to reside in the neighbourhood of Manchester, where a person I knew who grew fruit and flowers for sale had some half-dozen plants of the old double white variety that, after flowering, were placed in heat in the usual way. The intention was to keep them in warmth long enough to get the buds sufficiently up in size, so that the flowers would open considerably earlier than they had done the season previous; but the heat was kept on too long, and the flowers all at once, about the beginning of August, began to show colour. The plants were then turned out of doors in a cool, shady place; but this had no effect, as they were in full bloom in a few weeks. Camellia blooms were then in winter-time worth very much more than they are now, and the owner lamented much at what he looked on as the loss of his crop of flowers; yet he did not come out of the mishap so badly. There happened to be a wedding in a nobleman's family in the locality, and white Camellias were to be the principal flowers used; none were to be met with about London; the prematurely-flowered plants were heard of in the quarter where the flowers were wanted, and the owner did not miss the chance of making a good price out of them, some six or eight dozen being supplied at 7s. per flower. But times are changed; now the great London growers of Camellias would be glad to get that much a dozen, even at Christmas, or the time when the flowers above named were wanted—about the end of August.

There is no difficulty in having Camellia flowers for nine or ten months out of the twelve, or, possibly, all the year round, provided the stock of plants is sufficient and there is the requisite knowledge and means of regulating the growth, setting the buds, and forwarding them so as to bring them in at the time required. Messrs. Cuthbert, of Southgate, who are amongst the most successful growers of these flowers, and who, I believe, are always the earliest in the market, now have them constantly from the end of July to the end of May. They have a very large stock, most of which is planted out, consequent on which the plants that occupy any particular house do not admit of being brought into flower in succession in the way that can be done when they are grown in pots or tubs, and are, therefore, movable. But they have a number of houses devoted to Camellias alone, and the time when the plants occupying each house come in is regulated by the early or later time of growth, and the length of time the heat is kept on after the buds are set. It is in this way, and only this way, that the time of flowering can be satisfactorily determined by the use of fire-heat. Attempting to push on the opening of the flowers by the application of fire-heat late in autumn, or in winter, is doing the work at the wrong end.

T. B.

The first Chrysanthemum.—Is Dr. Sharpe the first Chrysanthemum? Being much interested in this question, started by Mr. Burbidge, and further commented on by Mr. Douglas, who, writing of the late Mr. John Salter's seedlings, says, "I fancy Dr. Sharpe was not one of them," I have carefully looked through the last five catalogues issued, previous to his retirement, by Mr. Salter, 1865—1869, inclusive, which I have bound and kept in memory of my correspondence with him, and visits to his nursery. The first place where the name Dr. Sharpe occurs is at page 15 in the catalogue for spring, 1868, where it is amongst the "Second Section—Large Flowers," the "First Section" being the novelties of the year. The name Sharpe is there repeated within brackets, as being the name of the raiser, presumably. In no case has this name been inserted amongst the novelties sent out by Mr. Salter. In the *Gardeners' Chronicle* of Nov. 21, 1868, it is one of those described as the most striking varieties then in bloom in Mr. Salter's nursery.—J. T. Poë, *Riverston*.

Isolepis gracilis as a wall plant.—"J. G. H.'s" note on the usefulness of this plant as a fringe to a plant stage (p. 512) induces me to strongly recommend it as a wall-clother for a moist plant stove or fernery. Planted in small recesses on a cork-covered or other wall in a little maiden loam, or loam and leaf mould, it will quickly establish itself, and cover the entire surface with roots and its Grass, or, rather, Rush-like leaves. The firmer it can be made at starting, and the more liberally it is watered afterwards the more luxuriantly it will grow and the denser will be its verdure. Under such conditions, too, the leaves will grow to an abnormal length, and the effect is most beautiful, either by itself or intermixed with the more slender Maiden-hair Ferns or delicately variegated Fittonias. The Isolepis should be looked over once a month or so, and the faded leaves, which will be found underneath the others, should be pulled or dressed off. This, with copious watering, is positively all the attention needed to keep an Isolepis-clothed wall charmingly fresh and verdant for years. The plant enjoys heat, though it also thrives well in the greenhouse, window garden, or sitting-room. The finest plant ever seen by the writer was over 2 feet across. It was placed on a small plant stand nearly a yard high, and its long drooping leaves almost reached the ground. This plant had never once suffered for lack of water, and had been in a shady window in a sitting-room for years. I do not remember ever seeing the leaves

so long and slender, unless in the case of plants grown in a stove temperature. The Isolepis is rather a dangerous plant to use for decorative purposes; if employed to depend from a vase or basket its leaves must be kept dry, for no sooner are they wetted along their entire length than each thread-like leaf becomes a syphon or capillary tube, and these will very speedily empty the vase or bucket of water on to the table, or over the furniture or carpet.—Hortus.

NEW CHRYSANTHEMUMS OF 1886.

Although large numbers of new Chrysanthemums have at different times been introduced, never until the early part of this year has so large an influx taken place. A few years back it was the custom to receive about a score of new Japanese varieties from the Continent, with the occasional addition of an incurved sport, or perhaps two; but recently we have had novelties from America, Japan, and France. It may be roughly estimated that there are at the present time not less than 1500 different kinds of Chrysanthemums in commerce, and how far this state of things is beneficial or otherwise to the grower it is, of course, difficult to say, especially when looked at in a broad sense. The thirst for novelties continues, and the united efforts of raisers do not apparently assuage it.

Having been present at both of the exhibitions held at the Aquarium under the auspices of our National Society, and having attended all the meetings of its floral committee, I have had ample opportunity of closely scrutinising many of these new flowers. In addition to that, visits to several private collections, local exhibitions, and other establishments in which Chrysanthemums are grown enable me to give some little account of such new forms as seem to promise well for the future. I leave the task of describing the new incurves to others; at least fifteen of the new Japanese sorts arrested my attention in a very striking way, and they are as follows:—

Mons. Wm. Holmes.—An early-flowering hybrid (Japanese) with reflexed florets of dark crimson; shaded velvety brown, and having a golden reverse; very striking.

Miss Stevens.—A large well-formed flower raised by Mr. Stevens, of Putney, of a soft mauve or lilac colour.

Mdlle. Paule Dutour.—A very large flower; light rose, creamy white centre.

Wm. Clark.—A semi-early bloomer; salmon-red and gold; most attractive.

Charlotte Montcarrier.—A beautiful large-sized rosy flower with drooping florets.

Carew Underwood.—A sport from Baronne de Prailly; in all respects similar to the parent but in colour, which seems to approach a rosy chestnut-brown.

A. Vilatte des Prugnes.—An early-flowering variety; violet and rose, suffused with salmon.

Buttercup.—A fine bright yellow, drooping-petalled flower; raised by Mr. Alfred Salter.

Phœbus.—Another fair-sized yellow flower with long spreading florets.

Edouard Audiguier.—Very deep-coloured velvety purple-violet with a distinct silver reverse; a large flower and a great acquisition.

La Triomphante.—A French-raised, full, compactly-built variety when opening; it becomes rather loose with age; the florets are broad and flat; colour rose, on a white ground.

Roi des Japonais.—Immense flower; deep orange-red with golden tips.

Moonlight.—A fine large white variety of transatlantic origin.

Mrs. H. J. Jones.—A yellow counterpart of Ethel.

Mr. Ralph Brocklebank.—A sport from Meg Merrilies with clear yellow flowers; form resembles the type.

There are several others in the Japanese class that may eventually prove to be desirable sorts, but I hardly care to recommend them, as they were in several cases past their best, or not in a good state, on account of their immature condition when seen. I merely, therefore, mention these by name: Souvenir d'Angèle Amiel, Mdme. Marie Clos, L'Auréole, Dr. Crévaux, Blanc Précoce, Vierge Japonaise. We must consequently wait another season to see how these will turn out.

Amongst large Anemone-flowered kinds attention may justly be drawn to—

Cincinnati.—One of the old type; colour clear rose; size rather above the average.

Citrinus.—Another of the same class; colour dull buff-yellow, curious but choice.

La Marguerite.—A beautiful companion to such flowers as Fleur de Marie; this novelty is a self-coloured variety, bright violet, and exquisitely built.

Jeanne Marty.—A Japanese Anemone with drooping guard florets white and lilac.

Mdme. Ghys.—A hybrid Anemone with lengthy horizontal guard florets; self, lilac.

Among the new Pompons I particularly admired—

Alice Butcher.—A sport from the well-known Lyon, and of similar shape; colour deep orange.

Mdlle. Elise Dordan.—A perfect little gem; the flowers are quite globular, of good size, and the colour delicate light lilac deepening to mauve.

Wm. Bealby.—A pretty bloom; colour soft mauve and cream; good size.

Precocite.—Somewhat large, and of a fine dark crimson.

C. H. P.

CINERARIAS AND CALCEOLARIAS.

Cinerarias we expect to make a brave show in the greenhouse during the four months beginning with the new year. They should be grown in pots ranging in size from 5 inches in diameter to 8½ inches. Those in small pots are intended to flower early; those in the larger pots are expected to flower in April; at least, they are at their best about the middle of that month. It is needless to dwell upon the advance which has been made in recent years in the quality of the flowers of the Cineraria, and also in the habit of the plants. Mr. James, of Farnham Royal, has made both classes of plants a speciality. He has bestowed infinite pains upon them, and the results are well known. Six or eight years ago it was hinted that perfection had been reached. The old species C. cruenta was brought forward as a novelty, but it seems to have retired again into the background. Fine hybridised seedling forms now hold the high position which they undoubtedly merit. Propagated plants and seedlings may be grown and flowered equally well if their culture is understood. The time to propagate them is in May or early in June, whether they are to be raised from seeds or from cuttings. Let us suppose that we are about to increase the stock of some choice variety. We cut the plant down as soon as the flowering period is over, and from the base of the old stems young growths are produced. These may be removed as soon as ready, with a portion of roots attached to them, and be potted in small pots, using light, sandy soil, but by the time most of these offsets are got ready, the weather will be warm and bright, a state of things which the Cineraria dislikes. The best position for the plants would therefore be under handlights or frames on the north side of a low wall or fence. The lights should be kept rather close until fresh roots are formed, but when that has taken place, admit a small portion of air, gradually increasing it until it is safe to remove the lights altogether. In summer and early in autumn the lights may remain off the plants both night and day. Gentle showers have a beneficial effect on them, but heavy thunderstorms they cannot bear, and therefore from these they should be protected by the lights.

Seeds may be sown in May, June, or July, or in all three months to produce a succession of bloom, and the seedling plants should be treated exactly the same as those propagated from cuttings. Neither the seedlings nor the propagated plants make such rapid growth at first as they do subsequently, when they have been placed in larger pots and in good compost. Good loam is essential for the production of the finest specimen plants. To four parts of loam, add one of leaf-mould, one of decayed manure, and some sharp sand. Turfy loam is best, as it is of an open texture, owing to the decayed herbage which it contains. We had our plants out in frames until October this year, when they were taken into a span-roofed house, and since that time their growth has been most remarkable. Now that we have arrived at mid-winter, or nearly so, they require rather more attention than heretofore in order to keep them in good health; for, once allow them to get into a bad condition, and they take long to recover lost ground; moreover, they cannot be made good. Cinerarias are not nearly so hardy as Calceolarias. A degree of frost that would not touch the latter would put the former past remedy. The temperature may fall during severe frost to 35°; but if maintained between that and 40°, the plants will do admirably. All our plants have now been placed in their flowering pots, and they must be kept steadily growing during winter. This they will do in the minimum temperature just indicated. In mild weather, the lowest temperature will, however, probably be nearer 50° than 40° without artificial heat. Cinerarias must never be allowed to get over-dry at the roots. A state of dryness that would suit a specimen Pelargonium would be disastrous if applied to a Cineraria.

Ample ventilation is required even in winter, but precautions must be taken not to expose the plants to high winds, which would be sure to damage the leaves. Two parasites are troublesome at this season, but both of them can be kept at a distance provided prompt remedies are applied. Green-fly does most injury if undisturbed, but it can be easily destroyed by fumigating with tobacco smoke, or, what is better still, let the house containing the plants be fumigated once in three or four weeks, because prevention is better than cure. In order to obtain a good large specimen, the centre of the plant must be pinched out when a few inches high. It will soon start into growth, but in the meantime the large leaves will have increased in size and closed in over the centre. They should therefore be tied out to allow of light and air to reach the young growths. Another important point is that of keeping the plants close to the glass at mid-winter; the leaves should if possible be within 6 inches or 12 inches of it, but they would be injured if they came into contact with it.

Calceolarias require treatment very similar to that just described, and they are not more difficult to manage. Their seeds, I may mention, are very minute, and require great care in handling. The surface soil in the pot or pan in which they are to be sown must be finely sifted and made quite level. Sow the seeds carefully and merely sprinkle some sand thinly over them. The small plants when up are very fragile at first; a dash of water carelessly applied might wash them out of the pots, but when they have once passed through the initial stages they speedily increase in size, and but for green-fly, which is even more partial to the leaves of this plant than it is to those of the Cineraria, they would soon form handsome specimens. It may, however, easily be kept off if precautions are taken to fumigate at intervals of three or four weeks. Pinching, tying, watering, and other cultural details are the same as in the case of the Cineraria. J. Douglas.

Roman Hyacinths.—These early flowering bulbs come in at a time when flowers of any kind, and particularly white ones, are very valuable. They may be had in bloom quite early in autumn, but I find them to be most useful in December and January, as they do away with the necessity for hurrying the large-flowered Hyacinths into bloom, and all who have had much to do with the forcing of these know that it is in hurrying them that so many are spoiled. Give them time to develop gently, and even small bulbs will flower better than the largest if pushed on too rapidly. Not the least of the good qualities of the early white Roman Hyacinth is the facility with which it may be moved out of its pots, pans, or boxes for making up indoor decorations. When required for this purpose the bulbs should be grown in very fine loose soil or in Cocoa fibre, as the whole of the roots may then be shaken clear without breakage, and if inserted in damp Moss the flowers will last as long, or even longer than if they had been left in their pots; the slight root-disturbance to which they have been subjected gives just check suffi-

cient to lengthen the following period. About Christmas-time, when indoor decorations are the rule, a few pots or boxes of these useful bulbs are welcome for making up Moss banks on mantelpieces, window-sills, &c.; with ordinary care they last for a considerable time in bloom.—J. G., *Hants.*

Worthless plants.—Among these I would reckon Dahlia imperialis, not because of its being single, but owing to its unwieldy height. In such a house as the Palm house of Kew it is all very well, but in private establishments it is not worth house room in a moderately warm stove, even where such a structure 20 feet high is available. It is too exacting in time and space for the harvest of beauty it yields under the most favourable circumstances; whereas as commonly met with it is the one gaunt skeleton at the feast of beauty that should be exorcised forthwith.—Hortus.

Tacsonia exoniensis.—This deserves all that has been said in its praise by "R. D."; indeed, it is perhaps the best climber in cultivation for large cool houses. Three years last spring I put two small plants of it in a large old show house, with the view of covering the back wall and roof—a space altogether about 50 feet by 30 feet. The space is now completely filled, and it is a question if the plants would not in the time have covered an area twice the size of that named. They are growing in nothing but loam—the top spit from a pasture well chopped to pieces. In pruning we do very little spurring; we only remove from time to time the longest shoots, leaving the shorter growths hanging from wire and rafter, and all through the summer both wall and roof are literally a mass of bloom. Bare stems and branches are quickly covered by selecting a strong growth and twining it round the old wood. On the stage underneath are Coleus, Fuchsias, and Francoas. The branches of the Tacsonia droop down, and, meeting the tall, feathery spikes of the Francoa, produce a pretty effect. I have once before called attention to the merits of Francoa appendiculata, and must again recommend it, as it does not appear to be so generally known as it should be. It is a useful plant for the summer decoration of the show house, and a plant which almost anyone can grow. It is very nearly hardy, and thrives well under the treatment given to herbaceous Calceolarias. Where the stock is short, the plants should be shaken out of their pots and divided. This should be done directly after flowering. The principal lot, however, should be established and in their flowering pots by the end of September. The last-named not only flowers more freely, but last longer in bloom than younger spring-shifted plants. They do well in a mixture of loam two parts, and leaf-soil one part, and, beyond a little weak manure water when in flower, they do not require any feeding.—E. B.

SHORT NOTES.—INDOOR.

The blue Marguerite.—This old-fashioned plant is useful where cut flowers are required, for, with a little management, it can be had in bloom all the year round, and, if planted in the open ground in the spring, it will yield blooms throughout the summer. At the same time we grow a quantity of it in pots, treating them much the same as Chrysanthemums. This plant (Agathea cælestis) was, many years ago, plentiful in most gardens, but lately it appears to have become scarce. Cuttings of it strike in a very short time, and they are seldom troubled with insect pests. It is a native of the Cape of Good Hope, and, like most plants from that region, needs the protection of a greenhouse in winter.—H. P.

Best Chrysanthemums.—I may state that the list which I gave (p. 483) was compiled when looking over the stands of flowers exhibited at the Royal Aquarium. The catalogue of the National Chrysanthemum Society is, no doubt, correct, but Emily Dale and Golden Queen were represented by flowers so different in character on comparing them, that I felt justified in putting them both in my list. They were distinct enough in character, as I saw them, to be shown in the same stand without fear of disqualification, but in the hands of some growers incurved Chrysanthemums appear to be considerably altered in development. At the Royal Aquarium the judges passed as a large-flowered Anemone variety one that in the National Chrysanthemum Society's catalogue is classed among the Japanese Anemone-flowered. I am quite sure that the catalogue was prepared with great care, but the best informed among us cannot lay claim to absolute infallibility.—R. D.

AMERICAN NOTES.

Phacelia campanularia.—I grew and flowered this little gem for some years before it was distributed by the trade. In general appearance it much resembles the common P. Whitlavia (usually known as Whitlavia grandiflora), but it is less robust and a good deal more miffy. The flowers are very freely produced, and of the most intense gentian-blue (Sereno Watson says violet purple). It seeds quite freely, and I find that where I had planted it out early, and the seeds ripened and dropped upon the ground, a second crop has come up and the plants have been in bloom since the middle of September. I do not think that this brilliant little Californian will become a very popular plant, on account of its uncertain growth.

Salvia Greigi.—This is a pretty rosy carmine-flowered Texan perennial, and well worthy of cultivation in our gardens for its pretty flowers, small rosemary-scented leaves, and neat, bushy habit. It is nearly, but not quite, hardy. It blooms the first year from seed, and, like S. farinosa, Gaura Lindheimeri, Conoclinium pinnatifidum, and several other desirable Texan perennials, has a great drought-resisting character. It is now (Oct. 26) in a soil dry as dust, and after a killing frost (4° with wind) is as bright and cheerful as the great Tritomas near it, and without the least appearance of injury from cold or drought.

Callirhoe linearilobа.—A few years ago Dr. Edward Palmer, the eminent botanical collector, gathered herbarium specimens and seeds of this beautiful perennial plant in Texas. He gave me the seeds. From them I raised a quantity of plants which grew well, and flowered and ripened seeds the first year. The general habit of the plant somewhat resembles that of our old favourite C. involucrata, but it is less straggling and much more branching and tufted, and the leaves are more finely divided. The flowers are lilac-purple, shaded with white in the centre. They measure 1½ inches to 2 inches across, and are produced on long stalks from the axils of the trailing branches. The root is tuberous. It is an extremely free and continuous-blooming plant, prefers a sunny place, and is well suited for rockwork or the front of a mixed flower border. Although it has survived several winters with me, I cannot recommend it as being perfectly hardy; either mulch it well or keep it in a cold frame over winter.

Eucharidium Breweri.—A beautiful, rosy purple, free blooming Californian annual, about a foot high. It was first offered by the trade last year, but I had seeds of it from California, and grew it several years ago. For border decoration it is a deserving little plant, and lasts in bloom a long time. It likes a warm, dryish, sunny spot to grow in. Some botanists wish to refer it to the genus Clarkia.

Haplocarpha Leichtlini.—This pretty little African plant has given me a good deal of pleasure this year. I sowed the seeds in March in the greenhouse; they germinated readily, and afforded me nice-sized plants, which I set out in the border in May. These began blooming in June; have been continuously in flower ever since, and are now (October 26) in as full and perfect bloom as they had been during any of the previous months. The plants are stemless and form rosettes of dandelion-shaped leaves some 7 inches to 10 inches long, glossy green above, and thickly lined with white, closely pressed, silky down beneath. The flowers are from 2 inches to 3 inches across, golden yellow, backed with purplish brown, showy, and borne singly on scapes from 10 inches to 13 inches high. They open wide in the sunshine, but shut up at night in dull weather. It seeds freely. The recent severe drought did not seem to hurt it much. It is a perennial, but I do not think hardy enough to survive our winters unprotected. I should think it is about as hardy as biennial Stocks. While it is a very interesting and pretty plant, and well worthy of cultivation as a garden flower, it has not the showy appearance of a Marigold, Gaillardia, or Coreopsis.—W. Falconer, in *Country Gentleman.*

Flower Garden.

GLADIOLUS CULTURE.

Nothing is to be gained by ignoring difficulties in regard to the Gladiolus. No wise general will ever undervalue the difficulties of his position, for he knows it may be fatal to him; and if he calculates on bringing all his soldiers into action when he knows some regiments to be tainted with disloyalty, he will probably rue his over-confidence. So when we plant our Gladioli let us not calculate on getting a good spike of bloom from them all; some will go off, and, notwithstanding all that has been said about degeneration, I still adhere to my opinion, strengthened by what scientific men (of which I do not pretend to be one) have written on the subject. I do not call it degeneration, because, as I have often said, that is a collective term, and would imply that the whole race has gone off in vigour; thus we are sometimes asked whether the Ribston has not degenerated, not meaning whether the trees in my garden are weakly, but whether the whole of those now propagated have not lost their vigour owing to the length of time this Apple has been in cultivation. If this be the true meaning, then degeneration is a misnomer; for although one bulb of a variety may die off, others are as vigorous as ever, and spawn obtained even from such bulbs is as healthy as ever; moreover, degeneration belongs to things a long time in existence, and, as I have already stated, a bulb of one of the newest varieties went as badly diseased as any I have ever seen.

I have now finished the clearing off of my bulbs, and I never recollect having taken up so fine a lot, especially from that part of my garden where the soil is stiff in character, and I contend that a good stiff, but not wet-soddened, soil is the best for them. My eyes were opened on this subject when I saw the soil in which Mr. Dobree grew his bulbs at Wellington, and further conversation with him and Mr. Burrell deepened the conviction that those who advocate light soils are wrong. They may succeed, but they have a better chance of doing so when in stiffer soil; but, after all, it is the harvesting of the bulbs that is the great point, and they who can obtain the highest amount of sunshine in the autumn and the lowest quantity of rain during September and October are the most likely to succeed, and this is why I believe that the Scotch growers will find it very difficult to keep on, unless they import largely from France every year. The moister climate favours them in their earlier stages, and they look fresh and vigorous, but as blooming time comes on they have to be much shaded, and then comes the process of drying off the bulbs, and a Scotch autumn, with its greater amount of rain and absence of sun, is sadly against them. "W. I. M." asks why I think the climate of Cambridge better for harvesting the bulbs than that of Langport or Clonmel. Just for this reason, that there is less rain in the two autumn months of September and October than there is in any other locality in the kingdom. I take from Symond's "British Rainfall" the amount of rain in the following places:—

	Rainfall in Sept. and Oct.		Year.
Cambridge	2·58	..	20·56
Clonmel	4·71	..	43·77
Gourock	6·93	..	40·97
Langport	5·74	..	45·76

In the three latter cases no observations have been made, but I have taken the nearest point to them where the rainfall is recorded; besides this, there is no part of England where there is a greater amount of sunshine. Is it not, then, clear that with so low a rainfall in those months there must be a better chance of ripening the bulbs? The time for lifting the bulbs must depend on circumstances, of course; but I was very glad this year that I had finished mine by the end of October, for we had 4 inches of rain in the first part of November, and the ground became completely soddened, and the taking up and clearing off would have been a much more unpleasant and odious task; but I met yesterday (Dec. 9) Mr.

Burrell, and he told me that he had not yet finished taking up his; there had been, he said, some sharp frosts, and he had covered them, although he hardly thought it to be necessary.

Some of one's experiences with them are certainly curious. I had a bed of them about twelve years ago, where my Roses now are, and every year since bulbs are continually making their appearance. I this year took up a clump of Titania which must all have come from one bulb; there were four good-sized bulbs and some smaller ones. Does not this, someone would say, point to the advisability of leaving them in the ground, as some have advocated, it seems, to do so? But yet when I have attempted it, as I have done more than once, the result has been disastrous, and I have lost most of the bulbs. I find that these bulbs go a long way down, and although the new corm is formed on the top of the old one, yet it gets deeper instead of shallower. With regard to the comparative excellence of French and English bulbs, I have believed generally that the experience which Mr. Douglas details was correct; but my brother-in-law, who is a good grower, assures me that he has as fine spikes from his own saved bulbs as from French bulbs; while Mr. Burrell says that he has even grown them three years from the imported bulbs, and that these are quite as good and vigorous as the imported bulbs. It may have been that, as I have said, the growing of them in light soil, with a good deal of decayed vegetable matter in it, has helped on the disease, through which the bulbs have been weakened, and that, grown on stiffer soil, they would succeed better. Let me give one year's experience. I planted a number of imported bulbs in the lower part of my garden, where the soil is stiff, and I had not one diseased bulb; they also lifted in fine condition. I planted amongst others three bulbs of Shakespeare, which I cut in two before planting. These six halves produced six bulbs, which, a month after lifting, weighed 1 lb. 6 ozs., and measured 10½ inches round. There is clearly, then, no deterioration here, and I shall be anxious to see what the result is next year. I do not like to calculate too much on it, for I remember a good many years ago I lifted some large bulbs of Madame Desportes, which the following year all perished, so I must wait patiently.

I may have somewhat to say by-and-by about new varieties, but in the meantime I would refer all who wish to grow them to the lists recently given. I shall be only too glad to find that what has been written about them may induce some to try them. Years ago, when they were much dearer than now, it was a hazardous thing to attempt them; but now, when they can be had at such a small cost, people ought not to be deterred from growing them. And of all the autumnal flowers that we have, there is not one which is so grand and good for indoor decoration as the Gladiolus; while the manner in which it keeps opening in water when cut gives it an additional value. DELTA.

White Everlasting Pea.—In reference to the subject of this lovely Pea coming true from seed, I wish to state that I collected seeds from a plant of the white variety in a garden where there was not any plant of the pink form, and that the result from these seeds was that out of a number of plants I had but two which produced white blooms, all the others proving to be the ordinary pink variety. Did "J. G., Hants," see the half-dozen plants in bloom which he purchased as white ones? He does not state (p. 518) if they bloomed last year and were white, and this year turned into pink blooms. May they not have been seedlings from a white Pea and sent out as white, but not proved to be so?—J. T. Poë, *Riverston.*

WHITE ALSTRŒMERIA PELEGRINA.

This lovely flower, though generally considered a greenhouse or frame plant, may be successfully grown and flowered in the open air in favourable places. The engraving shows a clump as it grew and flowered early last August in a sheltered, sunny place in a garden on light soil in a southern county, where, for its only protection, it has a sprinkling of dry Fern over the ground in winter. This good plant deserves a choice position, alike from its delicate and distinguished beauty of flower, and from its neat, dwarf habit. It is less than a foot in height, and, unlike its taller brethren, is well clothed with foliage.

Alstrœmeria Pelegrina alba. Engraved for The Garden from a photograph.

Plant shelters.—Many years ago I visited a garden where mud banks had been hollowed out so as to make caves to shelter plants. A short time back, acting on this idea, and having a quantity of mould got by digging out a pond, I made a long mound, and at the north side of this let in pieces of sandstone, so as to make back, sides, and top, and brought the soil so as to cover them. I then planted among known hardy Ferns, such as Hypolepis millefolium and Adiantum pedatum, two caves of Adiantum cuneatum; the shelter and warmth of the covering earth have made these resist the frosts of the last two winters and of the present one. I mean to carry out the plan on a larger scale, and believe that Primula obconica, which was not much cut in the open last winter, and possibly P. floribunda, may be grown out of doors by this means. I have some shelters which I believe to be new, and which promise well; when these have been proved a little longer I propose to send you a note on them; meantime, I may say that a common wicker hen-coop with Bracken worked round it makes a good portable shelter.—George F. Wilson, *Heatherbank, Weybridge Heath.*

OPEN-AIR CHRYSANTHEMUMS.

For the information of "J. R." (p. 536), I append the names of twenty-four varieties of Chrysanthemums suitable for growing out of doors. I also add a few hints upon their cultivation. In growing Chrysanthemums purely for outdoor decoration, a great advantage is gained if they can be planted at the foot of a wall, which affords great protection during early frosts or excessive rains. Satisfactory results cannot always be obtained when the plants, of necessity, have to be grown purely in the open. In shrubberies or herbaceous borders, for instance, they are often spoiled by frost just at a time when the flowers are expanding. In such positions early-flowering sorts only should be grown; but where a wall exists (almost any aspect will do) a charming effect may be had. With such help, a much larger show of bloom and more varieties can with safety be grown; I also add a list of sorts suitable for wall decoration; for this purpose single varieties have a charming appearance, blooming, as they do, so profusely. Nor do they suffer so much from excessive rains as incurved or reflexed varieties. Moreover, the singles, being thin in the florets, dry much quicker after rain than the double sorts. Pompons do well on walls, particularly where these are high, say from 6 feet to 10 feet. Pompons being, as a rule, dwarf in habit, are very suitable for training under their taller neighbours, particularly the Japanese. Thus, by a proper method of training, the wall may be clothed from top to bottom with both foliage and flowers.

For open borders young plants are the best. Many plant in such positions old plants which have the year previously flowered in pots. These are not so good as young plants, inasmuch as they take up more space. Nor are they likely to flower so early as properly prepared plants. In preparing suitable plants to plant out early in May or when sharp frosts are not likely to occur to damage them, the cultivator must be guided somewhat by the locality in which he resides. Cuttings should be inserted any time during February either singly in small pots or several in 3-inch or 4-inch pots placed in a cool house under hand-lights, or in a partly spent hotbed. As soon as roots are formed, the point should be pinched out of each plant, to induce it to throw out branches. Where struck in single pots, pot off into larger pots; or where several are in a pot, place them singly in small pots, return them to the frame for a few days until established, then set them on a shelf close to the glass in a cool house where they will get sufficient light and air to make a stocky growth. When the side branches have grown about 4 inches, remove the points again; after this no more stopping will be required. As the pots fill with roots, replace them in larger pots till 5-inch ones are reached. Early in April they will be better in a cold frame, giving them plenty of air to prevent them from becoming drawn; take the lights off on all favour

able occasions. The soil used for potting need not be very rich; a compost consisting of two parts loam, one part of the materials of a spent Mushroom bed, a good sprinkling of leaf-soil and sharp sand will suit them perfectly. Pot firmly to induce short-jointed growth. Plant out in the borders at the time stated, adding to the soil some well rotted manure; tread the soil firmly about the roots; if the weather is dry give a good soaking of water, repeating this several times during the summer. Attach the branches neatly to a centre stake to prevent them from being blown about by strong winds; from this time onwards allow all branches to grow as they will, and should the weather be favourable, capital heads of bloom will be the result.

For wall decoration the treatment differs somewhat from the foregoing. Old plants having previously flowered in pots are best adapted for walls, as in that case a greater number of shoots spring direct from the base of the stool, thus furnishing the wall entirely from the bottom. Planting may be performed at the end of March or early in April, as circumstances admit. Should the soil be of a poor description, freely add some manure, and, in addition to this, place around the roots some loam and horse manure, first shaking the greater part of the old soil from the plants. A distance of 3 feet should be allowed between each plant of the tall-growing varieties, and between each of these place one Pompon, which will cover the bottom part of the wall. Tread the soil firmly about the roots, which if at all dry should be thoroughly soaked. If the plants were of good size the previous year they will start into growth with many shoots; select four of the strongest on each plant, removing all the others, except in the case of the Pompons, which may be allowed to have six or eight growths. When the branches are long enough spread them out thinly, and fasten them to the wall with shreds and nails, continually securing them as growth proceeds. Do not top the branches when the first break takes place; select two of the strongest shoots on each original stem, or more if space will allow, as some kinds, owing to their larger foliage, require more room in which to develop than others do, and remove the other shoots. From 4 inches to 6 inches apart is a suitable distance to train the branches. In the case of Pompons many more stems may be allowed to remain, as they have smaller leaves, and do not require so much space. Some of these may be trained across the stems of the taller varieties, bending them to the right and the left, according to the space to be covered. Should the summer be hot and dry, the plants should have copious supplies of water at the roots, as the bricks absorb a large amount of moisture. Neglect of this causes a loss of foliage. Liquid manure applied once or twice a week will be of much service in assisting growth, and after a hot day the plants will be much benefited by a thorough washing overhead with the syringe. This keeps the foliage clean and healthy. If the cultivator wishes to have a few larger blooms, those flower-buds which form about the middle or end of August must be retained, removing the growth shoots from as many as it is desired to have larger blooms. One or two on each plant of this sort will suffice, but where a profusion of flower (and this is most desirable for wall decoration) is the object aimed at, all the stems which break at this time from the main branches should be allowed to remain, which will in time perfect blossoms on each shoot. In giving the list for border growth, I have not enumerated any of the ordinary summer-flowering kinds, as I imagine "J. R." means the regular varieties of Chrysanthemums. Where a less number is required the first-named kinds in both lists will be found suitable.

Twenty-four varieties for borders—

Soeur Melanie	George Glenny
Madame Desgrange	George Gordon
Lady Selborne	Simon Delaux
James Salter	Elaine
Mrs. G. Rundle	Bouquet Fait
Mrs. Dixon	Margot
Golden Beverley	Fleur Parfait
White Beverley	La Frisure
Madame Bertie Rendatler	The Cossack
Emperor of China	White Trevenna
Early Red Dragon	Annie Salter
Beauté des Jardins	Refulgence

Thirty varieties for walls—

Japanese.	Black Douglas
Peter the Great	Aigle d'Or
Dr. Macary	Adèle Prisette
Grandiflorum	*Incurved.*
Bouquet Fait	White Venus
Elaine	Golden Empress
Fair Maid of Guernsey	Mrs. G. Rundle
Simon Delaux	Refulgence
Père Delaux	Jardin des Plantes
Reflexed.	Princess of Wales
King of Crimsons	*Singles.*
George Stevens	Patience
Golden Christine	Oscar Wilde
Mrs. Forsyth	White Perfection
Pompons.	Helianthus
President	Mrs. Langtry
Soeur Melanie	Miss Lulu Martin

NOTES.

Home-grown fruits.—I quite agree with Mr. Coleman (see p. 533) that the best motto for the possessors of old orchards is *Festine lente*—"hasten slowly," or, as we sometimes put it, "slow and sure." One part of Mr. Coleman's article ought to be printed in letters of gold and strewn broadcast by all landowners. Here it is: "To all who own or rent an orchard I still say, prune and cleanse, drain, subsoil, and top-dress. Cut down old and graft inferior sorts, and your ancient Moss-clad plantations will yet pay their way. Do not rest at the attainment of this point, but supplement your old by planting young orchards on deep suitable soils resting on the hillsides, well above the line of fog and frost. Avoid endless variety, but plant in duplicate the best sorts for market or vintage purposes, especially those sorts which do well in your immediate localities." Occupiers may do much for themselves, but proprietors should also assist their tenants in all permanent improvements of this kind. Some landowners already do, or have done, so with the best results. Take, for example, the bulb-growing, early vegetable, and flower culture in the Scilly Islands as originated and fostered by Mr. Dorrien-Smith. Last May I passed through Normandy and part of Brittany on my way to Paris. The old orchards there are as poor as any in England to-day, but there are miles and miles of newly-planted trees, not in low, damp places as of old, but high and dry on the warm hillsides near the farms, villages, or towns. I see on p. 553 that an experienced American pomologist points out the advantages of moderately high and dry sites for orchards, even in the sunny United States of America; but one of the most valuable notes I have lately seen is that anent fruit trees on their own roots from M. Jean Sisley, of Lyons. Grafting, as we all know, is convenient for the nurseryman, but it has never yet been shown that properly-managed fruit trees on their own roots would not be best for the market grower or producer of fruit for home consumption. The extra time we should have to wait for a crop would be more than compensated by the permanent health and fruitfulness of the plantations—in a word, the most profitable fertility-line may yet be obtained by cultivation instead of by grafting. Every fruit grower should test for himself a few trees on their own roots, even if he holds on to grafted trees, as one prefers an old and well-tried friend to a new one. Of course, grafting is convenient, and often most expedient, but we have yet to be assured that fruit trees on their own roots may not, all things considered, be the best. I heard a long discussion on profitable land culture only yesterday, and it resolved itself into two things, viz., fertile brains and cultivation by machinery.

Surplus fruit.—Of course, there are two sides to every question, and my old friend Quibbler, to whom I showed the above note, asks me, "What is the good of growing fruit when that we do grow already is sometimes not worth marketing? Only last year in Kent," he says, "the Plums lay rotting under the trees, and some growers who gathered their fruit crops and sent them to Covent Garden were money out of pocket, as the fruit itself did not realise enough to pay cost of carriage and marketing dues." I read something of the same kind myself, so that I have no doubt that my friend is right, but this only proves that not only must our growers learn to cultivate fruit of the finest quality only (*i.e.*, no second or third-rate produce), but they must also study the marketing question in all its practical details. If market agents form "rings" to keep prices down below a just limit, then the fruit growers generally must combine in self-defence. But above all, is it necessary in dealing with perishable products to prevent any one market becoming overstocked? and to this end the fruit growers must work the wires, and also be prepared to candy or preserve their fruits if they cannot obtain a fair and remunerative price in market for them. Then, if the markets are glutted on any one day, good fruit need neither be wasted nor sold under its fair value. Let the fruit growers of any one district contribute towards a fruit-preserving factory, or a cider mill, or drying machinery for quick-ripening or non-keeping Apples, if such be grown. In a word, a combination of brains and machinery must be made by fruit producers. Shall it be said that a handful of middlemen and commission agents in any one, or in twenty markets, is more than a match for ten times, or a hundred times, their number of fruit growers? Is it possible for injustice on the part of salesmen to linger on in the face of a combination of growers who simply claim their rights? If it is possible for America to send us Apples at a profit, surely it is possible to grow them profitably at home. Fruit growers must combine to get justice from the landowners, the railway companies, and the market agents with whom they trade.

The Tree Tomato.—I remember seeing this plant in fruit in the great temperate house at Kew ten or fifteen years ago. It is not a Tomato in the strict sense of the word, but reminds one more forcibly of some of the innumerable varieties of Egg Plants, or Aubergines, met with everywhere in the Tropics, and especially in the gardens of the Chinese. In habit the plant forms a sort of sub-shrubby bush, 4 feet to 6 feet high or more, its general appearance being somewhat like that of a Brugmansia, but its fruits are golden yellow in colour, and about the size of a Bantam fowl's egg. In warm countries it fruits freely, and its pulpy fruits have been used as a substitute for Apricots in compôtes and other confectionery. Before using them it is necessary to remove the skin of the seeds, and if the pulp is then too acid, it may be improved by steeping it in boiling water for a short time. Its Latin name is, or was, Cyphomandra betacea, and the plant is such a sturdy and vigorous grower, that it might be readily naturalised in waste places in hot countries, just as has already been the case with the Capsicums or varieties of Chili pepper, and also the Tomato. Like the true Tomato, its seeds grow readily, and soon attain to a fruiting state. There are several varieties, some dwarf, others taller, and there is some slight variation in the size, shape, and colours of the fruit, so that if once this plant becomes generally cultivated there is some likelihood of its becoming much improved. I have several times observed the fruits in Covent Garden under the wrongly-applied name of "Granadilla," a name

which of right belongs to the produce of some of the large edible-fruited Passion Flowers of South America.

Ipomœa Horsfalliæ.—Instead of our calling this fine old plant the East Indian, it ought, as I believe, to be called the West Indian Morning Glory. Of course, I am well aware that if reference be made to the gardening or botanical dictionaries, you will there find it set down vaguely as East Indian, and the date of its introduction given as 1833. This plant serves as an admirable illustration of the loose way in which habitats have been recorded in times past. A plant, native or wild in one colony, is admired and taken to another one, or to India, as in this instance, and then when introduced to Europe from Indian gardens it is put down as an Indian plant. There are scores of instances of this having been done in perfectly good faith, but on an insufficiency of knowledge. As Alphonse Karr tells us, "a savan proper prefers error to ignorance, and on no account will he tell us frankly that he does not know." Mrs. Horsfall's beautiful Ipomœa is in reality a native of Jamaica, and my evidence of this fact is the "Annual Report of the Public Gardens and Plantations" of that colony for 1886. On page 18 we are informed "a bank near the director's residence has been converted into a small rockery for the growth of Jamaica hill Ferns and other similar plants; a trellis at the back of this hiding an unsightly roof is intended for the cultivation of some of our native tuberous Ipomœas. It is curious to note that one of these, though so long known in England under cultivation, has only lately been determined as belonging to our native flora. I refer to the beautiful Ipomœa Horsfalliæ; besides this there are several others interesting on account of the profusion and variety of colour of their flowers" As an evergreen stove climber, this plant and its white-flowered reversion, I. Thompsoni, deserve a place in all good gardens. Perhaps Mr. D. Morris, of Kew, or Mr. J. Hart, now acting director in Jamaica, will kindly tell us under what conditions this fine species luxuriates when at home in the west.

Bulbs from abroad.—I fancy I see signs of a radical change in the bulb supply to our English gardens; the cloud is already much bigger than any one man's hand, and the shower promises to be a rich and varied one. Originally our extraneous bulb supply came from two sources, viz., from the Francis le Veans, whom Parkinson describes as "the honestest root gatherer who ever came over to us," that is to say, from Holland, and from Italy and the Levant, through the more enterprising of our Italian warehousemen. Now-a-days, Italy and Holland must look to their laurels, for our own colonies bid fair to take up the bulb trade in earnest, and in a few years' time I question much if the glasshouse culture of any but the very rarest of bulbs for sale will be profitable. So long as private growers or amateur gardeners like to grow bulbs at great expense for their beauty, well and good; they may as well pay for lovely flowers as for pictures, old china, or many other things. But it is not everyone who, like the late Earl Dudley, can afford to pay £500 per annum for the sake of enjoying the beauty of a pair of unique Sevres vases, for which he paid £10,000. Whenever we come to consider our bulb supplies from an economic point of view, then we shall find that it is cheaper to grow all our bulbs in the open air by making our colonies the sources of supply. Jamaica has taken the initiative in this direction, and will soon send us Amaryllis, Gladiolus, and other bulbs by the thousand. Already I see that bulbs of Amaryllis, named as well as seedlings, are offered from Jamaica, and, from the official report of the Public Gardens and Plantations (1886) of that enterprising colony, I see that Gladiolus and Tuberose culture is also likely to be a commercial success there. Transit rates by steamer direct are now so low that even the most remote of British colonies have a chance of contributing to our markets here at home. If ever free trade is abandoned, or a prohibitive duty is placed on foreign produce, we shall then, for the first time, find how really valuable and serviceable our colonies may become. One thing is already clear, viz., that bulbs of all kinds may be grown in our colonies, since they afford us all sorts of climate, and as land and labour are cheaper there, the innovation is likely to be a success in all ways.

Late Chrysanthemums.—These flowers are at all times lovely and serviceable, but from the florist's point of view they are infinitely more valuable during or after Christmas week than at any other previous time. Just now, such sorts as Ethel, Princess of Teck, M. Astorg, and Fleur de Marie are at their best, and I yesterday saw plants of Fair Maid of Guernsey which had been cut down to the pot-tops in May last, and the plants were very bushy, and their flower-heads very numerous, although the individual blooms were not large. Meg Merrilies, Thunberg, Roseum Superbum, and Etoile du Midi are also good, distinct, late kinds, and for profusion of blossoming and long endurance in a fresh state, St. Michael, a yellow-flowered Pompon, is admirable. Cullingfordi has been, and yet is, rich and good in its own way, and we have two or three seedlings which are much admired, although only half-double-flowered kinds. The best is a delicate rose, shading to white in the centre, yielding nice clusters of flowers for cutting. One good point possessed by seedlings is their dwarf and bush-producing character, and they seldom fail to retain their lower leaves quite perfectly. According to the New York papers, the Chrysanthemum is becoming as much appreciated in America as it is here, and some very fine seedlings have appeared there this season. Mr. John Thorpe is, and has been, at the bottom of Chrysanthemum culture and improvement in America, and recently exhibited a plant nine months old from a cutting bearing 1200 flowers. A friend of mine writing from Oporto tells me Chrysanthemums do well there and seed freely, owing to the florets being fertilised by a drone bee-looking insect, and he has already reared a few good kinds.

Bulb growth.—A gardening friend writes to me as follows on the question as to how bulbs manage to descend deeper year by year as some of them assuredly manage to do: "That statement of yours the other day that a line of Crocus planted 5 inches deep had in such a short time come up to the surface rather startled me, being quite contrary to my experience. Now and then Croci do come to the surface hereabouts, but it is always at the instigation of hungry pheasants, and never of their own accord. I know quite well how seedling Croci select a special depth at which to form their first bulb; the radicle descends to a convenient or suitable point, and then enlarges, and various species select different depths. Some form close to the seed, some go down an inch, others 2 inches or 3 inches, and some as much as 6 inches, but how established bulbs manage to descend is rather a mystery; that they do so is certain. I have thought that it happens in this way: the mass of roots in a measure eat up some of the soil below, they penetrate it in many directions, and when these roots decay there is a shrinking of the soil together or downwards, with the result that the bulbs drop, or are borne down into the cavity by the weight of the soil above. Worm-casts will account for some of it; the process is necessarily slow; were it otherwise they would quickly disappear altogether. This theory is defective, however, as it fails to show how some kinds go down faster than others. I should imagine that they would go down more quickly in soils rich in humus than in those composed almost entirely of sand; and it may be that there would be almost as much tendency to come up in the latter case as to go down."

Tulip bulbs.—These bulbs, as most practical growers are aware, descend by means of what are called "droppers," and often fail to bloom while this process is going on, as sometimes happens, for several years. These droppers are figured by my friend in his letter, and seem to be roots a little thicker than ordinary, on the sides of which buds, or bulblets, are produced in a manner as mysteriously as are the bulblets of the Bath Window Onion, called in Latin Ornithogalum longibracteatum. These roots drop down into the soil deeper than the tuft of ordinary root fibres, but are not so thick and marked in appearance as are the ephemeral roots on Crocuses, &c, as alluded to by Mr. Maw and Mr. W. Dod. Perhaps some Tulip grower will enlighten us further as to the nature of these droppers, the object of which seems to be twofold, viz: firstly, to increase the individual; and secondly, to ensure to the bulblets produced the best position as to depth in the soil, so as to favour their after development. "Galanthus (Snowdrops)," continues my informant, "go down in a similar manner, but not often." I have myself observed the fiddle-shaped bulbs of Bluebells and Snowdrops, as though they were effecting a change of level in the soil, but whether downwards or upwards I could not now say. Again, while Lilium candidum and L. pyrenaicum always come to the surface and usually flower better in such position, it is notorious that L. chalcedonicum may be established for many years and no appreciable difference in level be observed. My friend acknowledges that he is puzzled as to how the seedling Bluebells get down so rapidly, even below a gravel path; but he believes they, like the Crocuses above alluded to, drop down the radicle, which is sensitive enough to thicken itself into a bulb instinctively at the proper level. The going down, or *vice versâ*, is not merely mechanical; and, as my friend observes, we must allow the existence of an instinct in plants analogous at least to that in animals. Another friend tells me that his Crocuses in one garden came to the surface, while in his present garden they descend. The whole question is so full of interest, that it is well worth careful investigation.

Light and Lilies.—Some of the American cities are now lighted by electric lamps fixed up on high towers, and a gentleman residing at Davenport, Iowa, whose garden is near one of these towers, writes that his Lilies—Water Lilies we presume he means, as he mentions that they ordinarily close their petals at sundown—now again unfold a few minutes after the electric lights are lighted. We are also informed that the foliage of the trees in the city of Detroit was more luxuriant this summer wherever the electric light had illumined them at night. Without further evidence, one could scarcely assert that trees are really benefited permanently by the electric light as above described, since luxuriant foliage is not always a sure sign of permanent well-being. The more light plants are inured to, the less do their leaves become, as

a general rule, with all due respect to the gentleman of Detroit, who seems to believe the contrary. I remember when the late Dr. W. Siemens read a paper on the effects of the electric light on certain flowers, he mentioned that Tulips expanded at once under its influence, but, as someone pointed out, Tulips, Crocuses, and many other flowers will expand in a room under gas, or candle, or fire light, and that heat is as much a factor as is light in their doing so. Anemones are more sensitive to light, and will close if placed in a dark closet even in a warm room. VERONICA.

TREES AND SHRUBS.

PHOTINIA SERRULATA.

ALTHOUGH this noble Evergreen was introduced from Japan about the beginning of this century, I question if it is so well known as its congener, Raphiolepis ovata, sent home by the late Mr. J. G. Veitch some twenty-five years ago. To the rising generation of gardeners, who see Japanese shrubs and Conifers braving the breeze in every good garden throughout the kingdom, this may appear a little strange, but when it is borne in mind that the female Aucuba was at one time treated as a greenhouse, if not a stove, plant, shyness on the part of early planters is in no way surprising. As a wall shrub, Magnolia grandiflora, especially the Exmouth variety, stands unrivalled, and justly so, for, taken at all points, it is, perhaps, the most noble shrub ever introduced; but we want variety, and a worthy companion will be found in the Photinia, at one time called Cratægus glabra. Loudon, in the "Arboretum," describes it as an evergreen shrub, or low tree, growing from 12 to 15 feet in height, and states that the largest and oldest plants in Britain were growing at White Knights in 1835, and had then attained the maximum height. Fifty years, including the memorable 1860 and 1861, having rolled by since those measurements were taken, it might be interesting to learn through the pages of THE GARDEN how those fine shrubs have fared, and if they still weather the storm. Although I have not seen White Knights, the soil and climate are, I believe, rather above the average, certainly much better than ours, and here a remarkably fine tree, quite 20 feet in height, passed through the winter of 1860 unscathed. This tree, planted against the south side of the rectory, and unfortunately beyond the range of my care, some few years later had reached the gable, and the lateral growths presumptuously shaded the study windows. Aware of the fact that this was an exceptionally fine specimen, I strongly advised the rector to prune back the breast-wood, but the rare Photinia had grown into disfavour, and, greatly to my regret and the annoyance of the patron, I discovered, when too late, that it had been grubbed up and destroyed. Yet another tree, a standard on a dry rocky bank in the castle grounds, exposed to the north and east, had made a very fine specimen, but 31° of frost following a cold, wet summer were too much for it, and, although it did not die, I was obliged to cut it down nearly to the ground. It is still alive, and makes strong growths every year. For the information of planters unacquainted with this shrub, I may state that the large leaves are oblong, acute, serrulated; buds very large, red; flowers white, April and May. The young shoots and leaves are a rich red throughout the season, and the decaying leaves die off a deep maroon or mahogany colour. It is easily propagated by means of layers, and takes freely when budded on the white Thorn or Quince.

Exclusive of the leathery-leaved Raphiolepis ovata, there are three more varieties, P. integrifolia, P. dubia, and P. arbutifolia, no doubt equally hardy and worthy of cultivation wherever a wall can be found for their accommodation. These I have not planted at Eastnor, but a large bush of P. integrifolia grew freely in a peat bed for a number of years, and appeared perfectly hardy without the protection of a wall at Lyons, in the county Kildare, Ireland. Photinia serrulata grows well on our stiff calcareous loam; but were I making special preparations for a plant, I should give it a liberal supply of turf from the old red sandstone, burnt earth, and a taste of peat to start in. W. COLEMAN.

Eastnor Castle, Ledbury.

HOLLY BERRIES.

THESE have almost wholly disappeared in this part of East Anglia during the first week in December. At no time a full crop, they are now, writing in general terms on the 8th inst., wholly cleared. It is, however, a singular and fortunate circumstance that a few plants here and there, and occasionally whole groups and hedgerows, escape the ravages of the birds, and hence those that can hardly enjoy their Christmastide without the ruddy glow of Holly berries mostly find a few to gratify their sentiment and add a special glow of brightness to their decorations. But, judging from the wholesale clearances about here, it is feared that Holly berries will be scarce this Christmas, and those responsible for furnishing them abundantly for home or church decorations had better lay in stores of any left as quickly as possible.

Fortunately, Holly berries will keep on the boughs for several weeks after the latter are cut if the boughs are placed in a shady place in the open, or, better still, in a covered shed or cellar. In the open air the branches laden with berries are still exposed to the risk of being ruthlessly and rapidly cleared by the birds. The latter are quick to discern their legitimate food, and prompt to devour it after it is cut. We hear a good deal of red rags and bulls being enraged by their sight or close proximity; but hungry birds become yet more excited over Holly berries, ripe, rich, mellow, and of fascinating brilliancy. The wood or shrubbery, all still and apparently tenantless before, is at once filled with eager, restless life, intent only on devouring every speck of coral as rapidly as possible. And no one who has not watched the rapidity of the process of clearing Hollies could credit the devouring capacity of the birds. Holly berries are by no means small, but the number devoured, after making liberal allowance for the slips between Holly trees and bird crops, is incredible. The berries, in fact, seem to exert a sort of intoxicating or maddening effect. The more the birds eat, the hungrier and more excited they seem to become. Under the spell of this feast of coral they seem conscious of but one object—the red berries; inspired with but one purpose—the clearing of them off as quickly as possible. In the pursuit of this latter purpose great waste ensues, the ground being frequently strewed over with coral. To a large extent they seem to lose their sense of fear, and to become blind to danger. Hence they not seldom wildly dash against each other in their short, swift, straight flights for the berries; and so absorbed are they in their feasting and gorging, that they may often be netted or shot down almost unawares. Birds on the clearance of Hollies bent assuredly have no care for the morrow. Hence berries almost sufficient for a winter's supply are often devoured or destroyed in a few days.

This season the Holly berries are taken and most of the Haws left. This is a reversal of the usual order of proceeding. But no doubt the haw harvest is at hand. It is, however, a curious fact that when the time of the birds for any particular feast or food, such as the berries of the Mountain Ash, the haws or the Holly, passes by for any considerable period, they seldom clear them off afterwards. I have noted this fact again and again in regard to Hollies. Unless the berries are eaten by Christmas they are seldom eaten at all, and never cleared off in that wholesale manner as they have been during the past week. It is also a curious fact in the economy of bird diet and life that isolated specimens of berry-bearing plants are nearly always spared. I have often examined those rejected ones, to determine the causes of their being left out in the cold. At times the reasons have been obvious enough, in inferior berries as to size, ripeness, and colour; but in other cases no reasons could be found. But it is as fortunate for the decorator as for the propagator, that even in the seasons when the berry clearances are the most general and complete, while the many are taken a few are left. D. T. F.

Desfontainea spinosa.—This dwarf evergreen shrub is not so generally used in the decoration of pleasure grounds as it should be. Few shrubs are more attractive than the Desfontainea, with its orange-scarlet, tube-shaped flowers glittering in the autumn sun. This year it was much later in flowering than usual, and was a very pleasing object during the early part of November. Some entertain an idea that this shrub is not hardy; this may be the case in some localities, but here it has stood the test of twenty winters unscarred. It has not, moreover, had the best of treatment, nor has it been favoured with the best of aspects. In the grounds at Wray Castle, situated on the Lancashire side of Windermere, there is a large plant of Desfontainea that has stood in its present position for thirty years. A well drained position, sheltered, if possible, from north and east winds, suits it best, and it likes some bog mixed with the natural soil in which it is planted.—W. B., *Windermere.*

GARDEN FLORA.

PLATE 575.

MYOSOTIDIUM NOBILE.

(THE ANTARCTIC FORGET-ME-NOT.*)

THE well-grown examples of this choice Borage-wort which were exhibited in flower by Mr. Loder, of Floore, Weedon, at a meeting of the Royal Horticultural Society on April 13 of this year, were exceptionally interesting to those who knew of the existence of the plant, who knew also that it was a reputed bad grower in England, and that it had been grown and flowered by Mr. Watson, of St. Albans, in 1858. This grower also sent his plants for the inspection of the society, and they are reported to have attracted much attention at the time. The stock of the plant was sold to Mr. Standish, but, so far as we can learn, it did not flower again, and finally it disappeared from English collections. Three or four years ago a fresh lot of seeds was procured, and from these several of our correspondents succeeded in raising plants which flowered for the first time this year. Mr. Loder has, however, been most successful with this plant, and we have to thank him for the information given below with respect to the treatment best adapted to the requirements of the Myosotidium in English gardens. Many of our readers will feel disappointed that this plant has not proved hardy with us, for it is in the rock garden only that a plant of this kind is seen to the best advantage. Considered as an indoor plant, it cannot be called really useful, and, according to Mr. Loder, a period of warm house treatment, or at all events protection from frost, is essential to its safety. Probably, however, in the south of England and Ireland it may prove to be hardy.

M. nobile is the only species of the genus, and was first described under this name in the *Botanical Magazine* in 1859, although it had been described by Sir Joseph Hooker the year previous in a contemporary as a species of Cynoglossum, to which Myositidium is very nearly allied. It has a thick prostrate root-stock, from which arise the large, broadly, heart-shaped, succulent, shining green leaves, the petioles of which are thick, grooved, and from 6 inches to 9 inches long. The flowers are borne on an

* Drawn from a plant in Mr. E. G. Loder's garden, Floore, Weedon, April 17, 1886.

erect, stem-like scape, which springs from the apex of the prostrate stem and rises to the height of 1 foot or 1½ feet; it is leafy all the way up, and is terminated by a loose corymb of primrose-shaped flowers. The colour of these is exactly that of the favourite Forget-me-not (Myosotis dissitiflora), but, as in this, the shade of blue varies, either through varied conditions of growth or seminal changes; consequently there is a difference between the colour shown in Mr. Loder's plants and that figured and described in the *Botanical Magazine*. The flowers last about a week, and are succeeded by rather large four-winged fruits, which, however, did not contain good seeds in the plants we saw. After flowering, the plants should be kept in a cool and light position in a frame, and be liberally watered in dry weather. We have yet to learn whether this plant continues to grow and produce flowers after the first time, but the probabilities are that it will be a true perennial. It is a native of the Chatham Islands, a small group in the Pacific, lying 400 miles east of New Zealand.

M. nobile has generally been considered, says Mr. Loder, to be a difficult plant to grow and flower. It has, however, done very well here with very ordinary treatment. The seeds, which were sown in 1884, soon came up, and the young plants grew rapidly. They were kept in a cold frame and protected from frost by mats. In March, 1885, they were potted on, and were kept in an intermediate house for a month or six weeks, and were then again moved back to a cool frame. Some of the plants came into flower in March, 1886, and were exhibited at a meeting of the Royal Horticultural Society on April 13, 1886. The plants require plenty of air, and should be well syringed in warm weather and shaded from the midday sun in summer. Green-fly is fatal to them; the plants must be kept absolutely clean.

WORK DONE IN WEEK ENDING DEC. 14.

December 8 to 14.

During the entire week the weather has been an almost continuous succession of wind or rain-storms, and progress with open air work has been of a very minute description. Digging, planting, pruning, and the like have been quite at a stand-still, and, beyond a little cleaning up of the wreckage, dead sticks, and boughs, no other open-air work, in the strict sense of that term, has been done. We have a considerable extent of walks and roads to keep in order, and with this work, as weather permitted, our hands have the whole week been engaged—opening the drains, cleaning out the fall pits, and re-gravelling such parts as needed that attention. After gravelling, the roads are repeatedly rolled with a heavy, self-ballasting water-roller that is drawn by horse power, and thus the gravel is at once consolidated. This labour is about as profitable as any I have ever had aught to do with. The rolling at this time of year whilst all is so soft makes the roads so hard in the weed-growing time, that even if weeds do make an appearance, a week of hot, dry weather settles them for the remainder of the summer. When rain has prevented our doing the before-mentioned work, having a quantity of shrub planting in prospect—our time has been fully occupied preparing labels and pointing stakes for them, as well as making a supply of labels for renewal of any that are getting obliterated, especially those in the herbaceous plant borders, a section of plants that are known well to but a very few (myself amongst the number), but about which increased interest and inquiries make us anxious to have them all correctly labelled. The principal work in the houses has been the continuation of training Peaches, Nectarines, and Figs, and pruning and cleaning all vineries soon as the fruit is cut. It is to this annual thorough cleansing of both vines, glass, woodwork, and walls that we owe our comparative freedom from insect pests in the summer-time. All Grapes that we have space for in the Grape room have been cut, and Alicante, Gros Colmar, and Muscat of Alexandria would be better cut had we space, but till that is available the temperature of the vineries will be kept as equable as possible—between 45° and 50°—and the atmosphere as dry as the outside air will admit of, and the Grapes will be examined twice a week to remove decayed berries. Lady Downes will be the better if left on the Vines for another month or more, but care will be requisite that the temperature does not get too high to prevent the Vines going to rest, that stage having already been nearly reached, as the rapid fall of the leaves indicate. At the present time Primulas, Cyclamens, and double-flowered Pelargoniums are amongst the best of our flowering plants, and the additional warmth that we have given them during the last three weeks has wonderfully improved them, and there has been no damping off of flowers; mixed with Maiden-hair Ferns in vases and baskets in the hall and staircase of the mansion, they are highly prized, as are also the mixtures of Calanthes, Poinsettias, and Palms for the same positions. Chrysanthemums are fast fading; the season has been a long one, and such creatures of change are we that we can view their end without regret, though, no doubt, anticipations of future glorious displays of them have something to do with our being able so complacently to witness their ending, and we have been high busy during the week making provision for this said display by inserting cuttings of all the kinds that it is intended to grow—at least, so far as cuttings could be got, for some few have not yet thrown up suckers, and these plants we have put in slight warmth—early Peach house—to induce them to throw up cuttings. As plants come into flower in the forcing pit we take them out, and put them in as cool a house as our judgment warrants, and others take their place in the pits. The last of the Roman Hyacinths have now been put in, and a few more crowns of Lily of the Valley, and clumps of Christmas Roses, and large clumps of Snowdrops, which we dig up in the park, and that force very well, provided the ball of earth is kept intact. A small batch of Seakale we put into forcing quarters weekly, and a root or two of Rhubarb fortnightly. Asparagus we do not begin to force till the new year, for till the days begin to lengthen, when at least the points may get greened, the flavour is very insipid.

Hants.

FRUITS UNDER GLASS.

Peaches and Nectarines.

The buds upon early varieties, started in November, will now be swelling freely, and some will soon show the colour of the petals. When this stage is reached a little more warmth may be given by day and the minimum raised to 50°, or, in very mild weather, to 55°, always with a circulation of air. Nothing, however, will be gained by distressing the trees through the early season of their growth; therefore, should frost, or, worse still, cold, dark, stormy weather set in, the figures contained in my last paper may still be adhered to. I always make a point of starting my Peaches at a very low temperature, as I find the flowers open strong and perfect when, the energies of the trees having been husbanded, not only by the absence of sharp fire-heat, but also by a continuous circulation of air, they set freely, and make up for lost time under a high temperature which debilitated trees cannot stand. Let the syringe be plied on bright sunny mornings, and again about mid-day, but avoid a wet, sloppy state of the house, for, much as Peaches revel in moisture when in full growth, they resent it through long cold nights and dark dull days in December and January. Moisture, it is unnecessary to say, must be present, but this can always be secured, not in chilling showers, but by the judicious use of fermenting leaves placed upon the borders, and renovated from time to time as the genial warmth declines. If the borders were in a proper growing state when the house was closed, a further supply of water may now be necessary; but this is a matter which a stranger cannot presume to regulate, as so much depends upon the surroundings, the nature of the compost, the depth of soil, and the amount of drainage. One thing, however, is certain: they must never feel the want of water, for if once allowed to get dry, all the finest buds will drop when the flowers ought to be opening. Therefore, provided they are well drained, as all Peach borders should be, a liberal supply of water, at a temperature of 70°, will certainly do them no harm, and they will then stand until the flowering period is over. If Strawberries are brought on with early Peaches, the plants should be dipped in sulphur-water to free them from the remains of spider or mildew before they are introduced; and all Peach houses, whether they contain other plants or not, should be fumigated once or twice to secure freedom from fly during the time the trees are in flower.

Succession houses intended for closing about the first week in January must still have plenty of air and more or less water to secure a thoroughly moist condition of the soil before the trees are excited. Some Peach growers, under the impression that they start better, leave the trees untied until the buds are well on the move, but it is difficult to realise the advantage, as many of them get injured and the process of training is more tedious. Moreover, the work in all forcing gardens increases rapidly after the turn of the year, and for this reason alone delays should be avoided. Although there may not be any perceptible increase in the length of the days, the month of January is often bright and frosty, and the time for these precocious trees making a start being nearer, a somewhat higher maximum temperature from the first may be indulged in. The syringe, too, under such conditions may be more freely, if not more frequently, used, but in all other respects rules laid down for starting the early house must be closely adhered to.

Late houses in which the trees are thoroughly at rest cannot be too freely ventilated. Pruning, cleaning, and tying in these is generally reserved for wet or inclement days, but on no account should cleansing or painting where still practised be put off until the buds begin to swell. If these late structures must be used for storage purposes the winter occupants should be of the hardiest nature and not likely to be injured by a few degrees of frost, as it is bad policy to light fires over-night to shield the plants from possible danger the following morning.

Cherries.

It is yet early enough to start these, but where fruit is wanted early in May preparations for closing should now be complete. Being highly excitable even in the open air in mild winters, the houses cannot be too freely ventilated not only during the time the trees are resting, but also after they are started. Fire-heat is of course necessary at times, but, aided by fermenting leaves placed on the borders, the minimum of 40° and a maximum of 50° can frequently be maintained without it, and these temperatures being quite sufficient to swell the buds, the successful forcer's greatest care will be the avoidance of an excess until after the fruit is stoned. Like Peaches and all stone-fruit trees, Cherries require liberal supplies of water throughout the growing season, and, although they do not often cast their buds, the want of this element through the resting period tells unfavourably when the fruit is setting. Water, therefore, especially where the houses have not been stripped and exposed to autumnal rains, should be freely administered as often as may be considered necessary to the maintenance of a thorough growing condition from the fall of the leaf onwards. When the buds are fairly on the move the syringe may be plied twice a day, and external conditions being unfavourable to a rise to 50° with plenty of air, a gentle circulation on the pipes from daylight until noon will help

them forward without taxing the trees. Much, however, depends on the state of the weather and the amount of light at command, for, as I have just observed, the Cherry is excitable and precocious, and must be coaxed forward on the give-and-take principle always at a low temperature with plenty of air.

Succession houses, where they exist, may remain uncovered so long as the weather continues mild, but the roof-lights by this time should be painted and ready for placing in position on the approach of frost or falls of snow. When covered in, cleansing and tying can be proceeded with at leisure, and the trees being so subject to green and brown aphis, particular attention should be paid to washing the old wood and spurs with strong soap water. The latter, especially on old trees, in course of time become crowded, and require thinning with a fine-bladed knife, not only to facilitate thorough cleansing, but also to throw strength into the buds from which fruit is expected. If the trees were neither renovated nor top-dressed in the autumn, all old mulching should be removed as soon as tying in is finished, and replaced with good friable loam or rotten manure; but unless there are signs of decided weakness, animal manure should be withheld until after the fruit is set and swelling freely. These remarks apply to trees established in internal borders and trained on trellises precisely the same as Peaches; consequently, having a more extended root-run, stimulants must be more sparingly used than when they are cramped up in pots or boxes. When grown in this way, the proper time to pot and top-dress is immediately after they have completed their growth and before the leaves fall. They then get thoroughly established in the fresh compost, and, being exceedingly floriferous, will stand heavy mulchings at the outset. Space being limited and variety pleasing, this is perhaps the best, certainly the only mode of growing a selection of Cherries. Gardeners, whose main point is quantity combined with quality, frequently, I may say generally, confine themselves to two or three good sorts, like May Duke, Black Circassian, and Elton, with perhaps a tree of Bigarreau Napoleon for winding up the forcing season or exhibition. If enthusiasts, they may greatly extend the supply of house Cherries by potting up a quantity of the finest late dessert varieties. Indeed, in our variable climate, especially in wooded districts, bird-proof houses offer the only facility for ripening and keeping them until they attain their full flavour. Glass alone will secure the flowers from frost, but damp—the greatest enemy—may decimate or ruin the crop where fire-heat is not provided. A flow-and-return pipe attached to a slow combustion boiler, fed by a few cinders, will do good service for a few weeks when the trees are in flower, and again occasionally to expel moisture when the fruit is ripe. Handsome floriferous pyramids can be obtained from any good nursery, and now is the time to pot them. Pots with perforated sides answer best, as they can be watered freely; but they should be plunged up to the rims in the borders, and heavily mulched through the summer. A houseful of Cherries in flower is a most charming picture, and the thought that time will transform these fragrant blossoms into a harvest of luscious Bigarreaus greatly enhances its value. The best compost for Cherries is a free calcareous loam, burnt clay, or lime rubble, and a liberal sprinkling of bone dust. This should be used rather on the dry side, and firmly rammed home with the potting-stick. A moderate watering to settle it about the roots will finish the operation, when plunging must immediately follow. A good crop of fruit being the main object, an abundance of air must be given night and day until the buds burst into flower.

Plums.

These and the preceding require precisely similar treatment throughout the early stages of their growth; indeed, many fruit growers use the same compost, and not unfrequently bring the two on together. Such being the case, it is hardly necessary to repeat my remarks, at least for the present, as some weeks, if not months, will pass before the early ripening of the Cherries will render their separation advisable. Where a separate house or compartment can be devoted to each from the first this arrangement is desirable, as trees can then be planted out in the borders, whilst others in perforated pots will not sustain a check from disturbance when the fruit requires support from young rootlets creeping into the plunging material. For very early forcing suitable varieties established in pots perhaps answer best, as the trees are then portable, and, being rather excitable, require full exposure to the elements soon after the fruit is gathered. If pot culture is impracticable, the roof lights should be movable. Golden Drop and other choice late sorts which, like the Bigarreau Cherries, come on gradually with the season, not only require constant protection from heavy rain, but derive great benefit from a dry, brisk, artificial warmth when the fruit is ripening. Moreover, a thoroughly dry atmosphere is the main factor after the fruit is ripe, as damp and mould are the greatest destroyers in Plum and Cherry houses. Plums, it must be understood, will not be hurried; therefore those who would have them early must make a judicious selection, get them thoroughly established, and start early. De Montfort and Denniston's Superb are the best old Plums I have met with for very early forcing, and if I now wanted quality I should confine myself to these two and fill a house with them. Rivers' Czar and Sultan have a good name, and may be worth forcing. Of mid-season sorts we have an abundance, but nothing can surpass Kirke's, Jefferson, McLaughlin's, Oullin's Golden, and the old Green Gages. For the late house Coe's Golden Drop is a host in itself, but variety being charming, Blue Impératrice, Late Rivers, and a tree or two of Grand Duke may be added.

The Grape Room.

If this important structure, not unfrequently used for Pears which give off a great deal of moisture, has not been put in order, no time should be lost, as the latest Grapes in another fortnight will be fit for bottling. The first step should be thorough cleansing and washing the walls with a solution of quicklime and sulphur; then the bottles, or other vessels, may be filled with soft water and placed in the racks to drain and get dry externally before the Grapes are introduced. A cool dry atmosphere being so essential to the preservation of the fruit, the windows and ventilators should be opened on fine mornings, and brisk fires made to dry the walls and expel moisture. By fires it must be understood that a slow combustion boiler placed outside, with a flow and return pipe running along one side of the room, is the proper mode of heating, as smoke and dust are then avoided, and an equable temperature of 40° to 45° can be maintained in all weathers. By firing on fine days, and keeping the room close and cool through the night and on wet days, it will be fit for the Grapes by the first week in January, when, all the leaves being off the Vines, cutting and storing may be commenced and finished in a few hours. Each bunch should be cut with all the wood that can be spared, in order that the stalks may pass deeply into the water, and still allow the bunches to hang clear of the bottles. When detached, the berries should neither be rubbed nor disturbed in transit, neither must the ends of the growths or laterals be shortened, for if this is done the dry atmosphere of the room will rob them of a great deal of moisture, and imperfectly ripened bunches will soon shrivel. When all the bunches are arranged it may be necessary to open the apex ventilators and warm the pipes for a few days to expel moisture, but the less fire-heat the better the Grapes will keep, provided 40° to 45° can be maintained, and mould does not get into the largest bunches. The person who cuts the Grapes, it must be understood, should remove every doubtful berry, as one that is faulty soon destroys many, and it will be necessary to look them over once a week throughout the season. Newly cut Grapes, or the wood to which the bunches are attached, take up a good quantity of water at first, but when the bottles have been filled up once, or perhaps twice, the waste is trifling. Still, a close watch should be kept upon them, as the most perfect berries soon shrivel if the ends of the shoots are allowed to become dry. Some put a small piece of charcoal in the water to keep it sweet, but this is unnecessary, as I have bottled Grapes with and without it, and the result, the fruit being ripe, in each case has been satisfactory.

Eastnor Castle, Ledbury. W. Coleman.

Fruit Garden.

BOARD FENCING FOR GARDEN WALLS.

One of the impressions conveyed by the sight of an ordinary fruit and vegetable garden when of considerable extent is, that the high, substantial walls with which it is usually enclosed have formed much the largest item in the cost of its formation, and that too often, either from the unsuitable character of the soil or climate, or other causes, the value of the fruit produced by the trees that occupy such walls, if reckoned, would fall short of giving an adequate return in the shape of interest on the money sunk in building them. In times past there was much to say in favour of the brick walls in question. A garden requires a fence of some kind, in addition to which shelter is needed for early Peas, Lettuces, and numbers of other things that can be had earlier from a cosy border protected from cutting north and east winds. Those entrusted with the formation of old gardens might have used living fences, such as Yew, Holly, or plants of a similar character; and much on the score of appearance might be urged in favour of them, but then, as there ever must be, there is the objection to garden fences of this kind that the roots of the fence interfere with whatever crops have to be grown near them. Glass was then too dear to admit of much in the way of fruit being grown under it, except Grapes and Pines, and these in limited quantities. Peaches and other choice fruits could be grown in quantity on open walls; therefore brick, or occasionally stone, walls were looked upon as the best to adopt. Wood might have been used, but wood was then dear, and the means of converting it and preserving the more perishable kinds were not then in existence. Now, matters are different; timber was never so cheap as at the present day, and the best of all materials for rendering it durable—gas tar—costs little beyond the trifling expense of applying it. As is known to those who have used this tar, its preservative properties are such that it is a question if deal of inferior character will not last as long when coated with it as wood which is of better quality. For instance, I know cases where ordinary Spruce boards 1 inch in thickness have stood exposed to the weather for forty years before they were so far decayed as to be unserviceable. Swedish flooring boards, planed and ready for use, are now selling in London at the river side for from 7s. 6d. to 8s. per 100 feet square. For the purpose under notice, it is needless to say that planing is useless, the boards being as good in every way just as they come from the saw. As a matter of course, the posts required to support these wooden walls would need repairing before the boards were worn out; yet that would not involve any great cost. It is more than likely that iron uprights, sufficiently stayed and let into concrete footings, would be best, taking cost and durability into account. Now, when malleable iron is only about £4 10s. per ton, cast-iron supports for a fence—say 10 feet high—should be had at a cheap rate.

With ordinary garden walls, as with other things that people have been accustomed to, it often happens that everything in the way of an innovation is wrong; but board-fencing, only somewhat lower than that which I suggest as a substitute for brick garden walls, is common enough, and the comparatively little cost which the use of boards, even with iron supports would entail can scarcely fail to be worth considering. Gas-tar has one advantage, and that is, aphides do not like it. One of my Peach trees, the branches of which are partly trained against a wall and partly against a board-fence that has been tarred for the last two years, has been much troubled with black aphides, which, despite repeated dressings every summer, have again appeared, yet they have been almost wholly confined to the branches that are against the wall. They seem to have no relish for the shoots against the boards, though it is over seven years since they were last tarred.

It is not likely that wood will supersede brick walls for enclosing gardens. When well built, there is an air of durability about such walls that wood does not possess, and the eye has got accustomed to brick walls to an extent that makes them appear the fittest for enclosing a fruit and vegetable garden; and when people are engaged in this kind of work, there is often a disposition to adopt that which has all along been looked on as the right thing. Yet it is possible to pay too dear for appearances, especially at the present day, when expenses connected with gardens are in many case perforce more closely looked into than in times past. T. B.

LIFTING THE ROOTS OF VINES.

Some places are so favourably situated for Grape growing, that the position or condition of the roots seems to give no trouble. These, however, are exceptional cases, as by far the larger number of good Grape growers know the importance and the necessity of keeping sight of the roots, which can only be done by occasionally lifting them, and, doing as Bacon suggested in one of his admirable essays, placing new soil about them. The Vine revels in fresh turfy loam. If it gets so much out of condition as to be incapable of producing a perfect bunch of Grapes, lift the roots out of the sour, close mass of earth and lay them in a newly-made bed of chopped turf, and the whole character of foliage and produce will be changed. The chopped turf should be taken from an old meadow or pasture, and if of a non-calcareous nature, lime in some form should be added. Lime may be used in Vine borders in the form of fragments of old plaster, or mortar from the débris of old buildings. Yard manure should be very sparingly used, except as mulchings in summer, but bones in all forms are valuable; artificial manures, such as nitrate of soda, guano, and the manures manufactured by Thomson, Clay, Amies, and other makers have, when used with judgment, produced beneficial results. Very many of the borders made for Vines are ruined by too much yard manure being used when the borders are made. As the fibre in the soil decays the earth settles down, and the manure when used abundantly clogs up the pores of the soil and renders it unwholesome, and the roots decay in it, and shanking in some form ensues. In the renovation of a border in which the roots of the Vines are in a bad condition, care must be exercised.

Autumn is the best time to do the work. Begin it by opening a trench from 3 feet to 4 feet wide, according to the width of the border along the front, cutting away everything found there; and remove all bodily down to the concrete or drainage. Then begin in the trench, and with steel forks gradually fork down the soil, liberating the roots as carefully as possible, laying them back on the border or on one side, as is most convenient, covering them with mats to shelter and protect them till the work is completed, and they can again be made comfortable. When the whole of the soil has been taken away, examine and renew, or repair the drainage, if required, and then fill in with fresh turfy loam, treading it a little to give the requisite firmness; after pruning the roots, to remove damaged or unhealthy parts, lay them out straight in the border from 6 inches to 9 inches deep. Long, naked roots, if there are any, may be notched with the knife at intervals, to induce the formation of young fibres. Mulch with leaves and litter to keep off cold rains, and to keep the roots at an equable condition as to temperature and moisture. If the border is more than 12 feet wide, it need not all be filled in at once. Do half, and fill in the remainder in a couple of years' time. Only a light crop of fruit should be taken the year after replanting; and a young shoot here and there should be encouraged to break away, so that the Vine rods may be renewed as well as the roots. E. H.

WATERING INSIDE VINE BORDERS.

The value of an unlimited supply of water for Vines, the roots of which are confined to the interior of the house, is well illustrated in the case of a vinery in the garden of Sir J. W. Ellis at Byfleet. When Mr. Bisset, the gardener, planted the Vines several years ago, he had no means of giving them an ample supply of moisture, and when I saw them about two years since, both wood and berries were small, although the Vines looked healthy. I saw them again last season, and was surprised at the difference in their appearance, which is due to frequent floodings which they received during the growing season, an unlimited supply of water being now at command. I believe that there is no greater mistake than making Vine borders exclusively in the house, where an ample supply of water cannot be had. I would sooner have a poor border outside than a rich one inside and deficient in moisture. However well you may feed Vines, the good store of nutriment is of no avail without fluid to render it sufficiently soluble for their use. In all market gardens where the roots of Vines are inside, provision is made for thoroughly drenching the soil at frequent intervals. I know a Vine grower who grows late Grapes remarkably well. He makes a practice of forking over the surface once a fortnight, and this is immediately followed by a drenching of water. Under this treatment the berries swell up and colour well. In the greater portion of the gardens in this country it unfortunately happens that sufficient water cannot easily be had. It is impossible to give enough in the ordinary way of watering; it must be given through a hose, and this can only be done by means of pressure from the outside. I once had charge of a tolerably large garden where one man could water every flower-bed in the course of about three hours. Taps were fixed here and there on which a hose was screwed, and it was pleasant to see the cool spray falling on the plants which had passed through a parching day. In a nursery on the Continent it required the daily labour of a man and a lad from 6 a.m. to 9 p.m. and a horse water-cart to fill the tanks in the glass-houses. The owner at length resolved to make other arrangements. A tank and suitable machinery were fixed, and the result was that one strong lad filled the whole of the tanks, as well as a great many tubs sunk in the ground in the course of an hour. I am sure that the outlay thus involved was covered in the course of one summer. Nothing fatigues a workman more than daily dragging about big water-pots, which, by the way, are often so large as to defeat the end they are intended to effect, and frequently all that can be given in this way is as but as a drop in the ocean compared with what is needful.

J. Cornhill.

Blenheim Oranges.—The Blenheim Oranges sent us by Mr. Coleman last week, and alluded to in his article in the first page of the paper, were specimens such as we rarely see in London, very handsome, and of a splendid colour. Apple growers would do well to consider Mr. Coleman's remarks about them; and we think nurserymen and others who send out new Apples so often, wholly inferior to the Blenheim in its cooking or eating qualities (in its season), would also do well to consider whether it would not be better to call attention to the culture and perfecting of our fine native fruits like this than to raising kinds which merely happen to have a showy appearance or some other quality quite secondary to that of flavour.

THE GOOSEBERRY.

This, to many, is the best of all fruits, and one, according to my estimation, far too much neglected in even good gardens. It is not only the cottager's friend, but at the same time fit for any nobleman's table. The culture of the Gooseberry, unlike that of the Vine, entails little or no expense; after being carefully planted, all it needs is good attention in the way of an annual top-dressing of rotten manure, and pruning, or, I might say, proper thinning out of useless wood. Pruning has been very much altered of late years; now, in most cases, the bushes are merely thinned; all misplaced and cross branches are cut away, and as much fruit-bearing wood left as is consistent with the strength of the plant. The thinning of the wood is no doubt good practice when quantity of fruit is required and where it is used in a green state, but if fine large well-flavoured berries are the desideratum, the bushes ought to be kept quite open in the centre, and the main branches should stand quite apart from each other, thus allowing the admission of plenty of air and sunshine to impart flavour, which is so much valued in a Gooseberry. Another point where handsome fruit is desired is to thin the fruit well. This is rarely attended to, but are not Peaches, &c., thinned? then why not the Gooseberry? This thinning process is all the more necessary in the case of bushes of pendent habit, which in many seasons are so weighted down with fruit, that it is utterly spoiled by lying on the ground. As to their after cultivation, the spade ought under no circumstances to be used. Early in the season apply a top-dressing of good rotten manure, thus causing the fibrous roots to find their way to the surface, and thus invigorating the plant. Check all weed growth by means of the hoe, and there will be no necessity whatever to have recourse to digging in any form either with spade or fork.

The following is a list of select sorts, viz.: Early Sulphur—an early variety of medium size, very hairy, bright yellow. Aston Hepburn—a small, early variety, dark greenish yellow. Keepsake—large, early, whitish green. Mount Pleasant—large, midseason, greenish yellow. Broom Girl—large, early, greenish yellow, very fine flavour. Topgallant—very large, midseason, whitish green. Monarch—very large, late, whitish green. Gretna Green—very large, early, very dark green, of exquisite flavour. Green Globe—large, early, pale green, flavour very good. Sir J. B. Warren—very large, late, red, quality very fine. Roaring Lion—large, late, pale red. Lancashire Lad—large, midseason, red, very hairy. Hedgehog—medium, late, pale red. Langley Green—medium size, midseason, light green, very hairy, of excellent flavour. Porcupine—small, midseason, white, very hairy, exquisite flavour. Over All—small, late, deep red, very hairy, keeps well. Green Gage—medium, early, dull green, good flavour. Starling, large red, early, smooth, first-rate quality. W. P. T.

Apple Braddick's Nonpareil.—With us the invaluable Cox's Orange Pippin seldom keeps good later than December, and at the present time many of its fruits, although apparently fit for the table, are discoloured inwardly. In Braddick's Nonpareil we have an excellent succession, and this comparatively little grown, though well-known, sort ought to be given a trial in every fruit garden.

It is not a strong grower, the shoots being more slender than those of the majority of varieties. We have it in bush form, and this method of training would appear to best suit it. Heavy crops are never obtained from it, but a failure is very rare. The fruits are of medium size, rather flat in shape, and some of them are well coloured. On the whole, it is not a showy variety, but the quality never fails to satisfy us. It is fit for eating early in December, and keeps two months or longer if there is no run on it.—W. I.

APPLE-TREE HEDGES.

In gardens near the seacoast, hedges of any kind have a value that dwellers in sheltered inland valleys can hardly realise, and many are the materials, both live and dead, used in the formation of both these wind-screens; for although frost is not so intense as inland, the withering effects of violent gales, that at times threaten to tear the crops out of the soil, have to be guarded against, and therefore hedges of Escallonia macrantha, Tamarisk, Euonymus, Laurustinus, and other plants that luxuriate near the coast are in great request, while good high walls answer a double purpose. Walls, however, although they check the onward sweep of the blast, do not provide a perfect shelter for the inmates of the gardens enclosed, as the force of the wind is only altered in its course, and it dashes down on the other side with such fury, that trees subjected to it suffer more than others that stood right out in the open. The only way to effectually screen any garden that suffers from violent gales is to make the occupants perform a part of the duty themselves, by converting them into fruit or flower hedges, as the case may be. Thus all sorts of things are planted in lines, and securely fastened to stout galvanised wire fixed to posts, just like rows of Raspberries, and it is surprising how many things do equally well in continuous lines. Nothing, for instance, makes better hedges in the fruit garden than the Apple, and in growing it in this way one gets rid of the old drawback to espaliers so common in all old gardens, viz., the means of supporting them, for if trained on stakes the latter soon rotted and had to be replaced, and the ties were always getting out of order. If wire trellises were employed they were expensive, to begin with, and were always a source of trouble when the tree reached full size. But Apple-tree hedges require neither stakes nor trellises, and but little tying. What is needed is to plant very much closer than what used to be the rule in the case of the old horizontal-branched espalier, and to simply tie the points of the shoots of one tree to those of its neighbour.

By following up the simple plan of cutting off the foreright shoots in summer and letting the others extend in the desired direction, an impenetrable hedge is soon formed, and no other plan produces larger returns in the shape of fruit compared with the space occupied than these do. The fruit, too, is of the finest quality, fully exposed to the sun and air, but perfectly safe as regards being blown off by wind, for after violent gales, when the tall trees have been nearly stripped of their fruit, not a single sound fruit has been blown off the hedge trees. Some may say what about the cost of planting? Well, at the price at which Apple trees are now sold in quantity, the cost of the trees need not deter anyone from planting. One-year-old maiden trees are best for any sort of planting, except when one is in a hurry to get fruit, which is not always the case; if a start is made in time to allow of successional trees coming into bearing before others are worn out, there is no reason why one might not plant the stocks in lines about 2 feet apart where the hedge is desired, and graft them the following year. They can then be headed down to any desired height, and will soon form a well furnished hedge.

Hedges may also be formed by planting cuttings, or rather branches, some kinds of Apples rooting very freely, provided good sized branches are used; little ones of the current year's growth are useless. Directly the leaves fall, many kinds of Apples will show a disposition to form roots similar to what occurs in the case of Vines when the atmosphere is too much charged with moisture. These incipient roots are most noticeable around the old hard knots and spurs; these therefore we select and cut off, so as to allow of their being planted at least a foot or 18 inches deep, and the majority of them root freely. The old French Crab is an example of a useful late-keeping Apple that increases readily in this way. I have also many others on their own roots. Some sorts strike as freely as Willows in this way; those with clear shining bark are not good subjects on which to experiment on. Those who fail in striking Apples from cuttings do so, as a rule, from using too young wood.

Raising Apple trees from cuttings may not be advantageous to all, but in forming Apple hedges when we find sorts that root freely from cuttings we use them, economy being an essential point, especially in the case of those who live by gardening as a profession. A hedge cannot be formed without a goodly number of trees, and the cheaper they can be produced the better. J. G.

SALEABLE FRUIT.

Although we hear on all sides that our markets and shops are overstocked with fruit, flowers, and vegetables, it is not denied that the best of everything finds a ready sale at good prices. Some of the shrewdest among us are profiting by this knowledge, and now turn attention to the cultivation of a better class of products, quality rather than quantity giving the best returns. Some there are who cannot be prevailed upon to act so judiciously, and yet these are the first to grumble at the bad times. Every time I pass a good fruiterer's shop, where American Apples are usually most conspicuous, I credit the Yankees with superior judgment, and believe them to be better business men than we are. If the average English farmer has a lot of Apples to sell, it never occurs to him to select only the best, and thereby secure a remunerative price, but all, good and bad alike, must go together. The consequence is low prices are given, less money being returned than if only the best had been sold and the rest thrown away. Many do not even take the trouble to keep the sorts separate. This season, a friend of mine bought an orchard of Apples, the owner to gather the fruit. When sent for all were found to be mixed together, the lot being thereby literally spoilt for home sales, as but few purchasers would go a second time for a basket of Apples that included culinary, dessert, and cider varieties. They were sent to the nearest large market town and were sold by auction. Another favourite trick, when baskets or sieves of fruit are sent to market, is to put all the best on the top and the rubbish underneath, but this very shallow species of deception really deceives no one at all acquainted with the "tricks of the trade." No matter how many Apples are grown in this country, unless we act more sensibly and honestly, the American Apples will always be bought up most readily. A dealer knows when he has purchased a barrel of Baldwins, Newtowns, or other popular sorts, that the contents, as a whole, are nearly, or quite, what they are represented to be. No rubbish is found; all are well selected fruit, fit for any purpose. It cannot be too often repeated that rubbish is not wanted in any market, and not only should Apples be well selected, but all other kinds of fruits and flowers also should be carefully assorted. Two inferior Pears would materially affect the price of ten fine fruit with which they were associated, and it is just the same with Grapes, Peaches, and Nectarines. Send only the best, and this not only simplifies the work of selling them, but also prevents dishonest salesmen having an excuse for condemning the consignment. W. I. M.

Apple Peasgood's Nonsuch.—This is altogether a most desirable variety, good alike for home or market purposes. As a show fruit it is unequalled, and, being fit for either culinary or dessert purposes, it is sure to sell readily. Some of the finest fruits I have seen of it were exhibited at the first Exeter Apple fair—the produce of quite a small pyramid. This summer I noticed in the Castle gardens, Sherborne, a pyramid of it which was well cropped with very fine handsome fruit. It also does well as a cordon, and, being of a vigorous, yet fruitful habit, I have no doubt it will become a popular orchard variety. The quality is good, but, as a rule, the fruits are too large for dessert purposes. I should therefore class it as a handsome culinary variety, in season from November to January.—W. I.

Outdoor Grapes.—As regards "Veronica's" observations about outdoor Grapes, we think this quotation from *The Field* may be useful: "We have asked two of the most experienced gardeners we know what they think of Grape-growing in the open air—Mr. Robert Marnock, who has perhaps seen as many of the gardens of England of the better class during the past fifty years as anyone, and Canon Ellacombe, well known in the west country. Neither of these gentlemen can point to any successful examples of culture, and they quite agree in thinking it hopeless to get any good results."

Two worthless Grapes.—I have formed a poor opinion of the value of both Alnwick Seedling and Gros Maroc. Alnwick Seedling first bothered most cultivators on account of its non-setting propensity, and then when this had been overcome somewhat it turned out that it had never been worth the trouble taken with it. Passing the hand lightly and frequently over the bunches when in bloom is a sure method of effecting a good set, and since this or any other plan of fertilising the blooms has been adopted, good-sized, handsome bunches have been common enough. As before stated, no difficulty is experienced in colouring the berries as "black as Sloes," but in October or much earlier, if ripened for the August shows, the berries commence to shrivel, and at no time is the quality anything but second-rate. It certainly possesses a good constitution and is very prolific; but why grow a Grape that no good judge would eat? Gros Maroc has been more highly eulogised than Alnwick Seedling, and perhaps I am treading on dangerous ground when I assert that it is altogether over-rated. At first our experience with it was that nothing would induce the young Vine to make any real progress, and the rods we have fruited have both been either grafted or inarched on a Black Hamburgh stock. We have it in both a Hamburgh house and a late vinery, the former being slightly warmed in order to ripen the fruit in July, and the latter given sufficient heat to ripen Muscats, Alicantes, and other varieties about the middle or end of September. Now, if the Gros Maroc would be of good quality under any circumstances, surely we should have had it good in one house, if not in both. On the Hamburgh stock we found it to be exceptionally vigorous—much too gross, in fact. It was moderately fruitful, and ripened a few days later than the Hamburghs. The size of the berries was satisfactory enough, and the colour equally so, but who would eat its fruit if a very middling sample of Black Hamburgh was available? I would even prefer Alnwick Seedling to Maroc; of the two it is certainly a better keeper. It sells readily, I admit, though I am not yet prepared to recommend market growers to cultivate it largely. I certainly would caution private growers who market no fruit against planting either Maroc or Alnwick Seedling.—W. I. M.

SHORT NOTE.—FRUIT.

The best fruit preserves are made by boiling down the juice without any addition till it thickens. The natural gum and sugar present in most fruits only needs concentration to form either syrup or jelly, but the practice has been so long to use sugar for a more rapid process at the expense of flavour, that the earlier and better method is all but forgotten. The first confections and conserves of fruit ever known were made in this manner, in the rich valleys of Persia and Northern India, a process doubtless learned from Dates, Grapes, Figs and Nectarines curing themselves on the bough in favourable seasons, drying in their own sugar crystallising

round the stem. The Grape juice thickening on the side of the wine press in the sun would teach some one more intelligent than his fellows to try evaporating the juice on slabs of stone, and the honey so made was delicious enough to fix the process in favour.—*Vick's Magazine.*

WHITE DAFFODILS.

THE accompanying outline engraving was intended to illustrate a note which appeared in THE GARDEN two or three weeks ago. The flowers are examples of the variableness of wild white Daffodils collected in the same spot on the Pyrenees. It is found that such characters as the relative length and breadth of the perianth segments and the crown remain constant in the increase from the same bulb, and at a time when those who studied the Narcissus founded distinct species on such characters, the three flowers here figured would each have claimed a different botanical name. The slight variations in form are, however, so many, and the forms pass into one another so gradually, that no modern botanist would think of separating them. There are two or three fields and orchards in England in which white Daffodils have become naturalised, and grow mixed with the common form of wild N. pseudo-Narcissus, with which they appear to have crossed. In these fields it would be difficult to count the number of varieties of shade and shape which these white Daffodils have assumed.

In reply to the note of "F. W. B." on p. 543, I by no means propose to increase the number of Haworth's names for wild white Daffodils. My contention is that, as far as our present knowledge goes, the one name N. moschatus is wide enough to include them all. I consider N. pallidus præcox, variable as it is, to have well-marked characters, and to be separated by a long gap from the high mountain form N. moschatus. N. variiformis, though perhaps not so well defined, and probably connecting N. nobilis of Redouté and N. muticus of Gay, amongst which I found it growing on the Pyrenees, is in none of its forms white, and does not come near N. moschatus. The many varieties of N. moschatus to which I referred are chiefly from meadows or orchards in England, where N. moschatus has become naturalised together with N. pseudo-Narcissus (type). These I have in mixed lots in my garden, and not yet sorted and arranged; but when I have completed that work, and wish any of them to receive the honour of being named by the Royal Horticultural Society, I will send them to the gardens at Chiswick for that purpose.

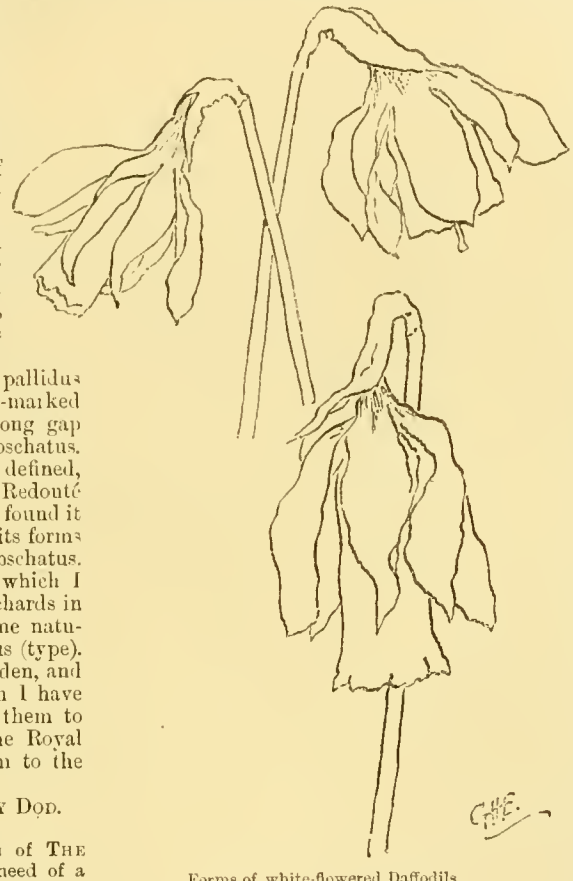
C. WOLLEY DOD.

The Kniphofias.—In recent numbers of THE GARDEN there have been references to the need of a revision of this genus. The results of my observations are somewhat different from those of some of your readers with respect to time of flowering. With us K. Macowani has always been first followed closely by K. corallina and K. caulescens. Afterwards come K. Rooperi and K. Burchelli, sorts apparently identical. Following these are K. glaucescens, K. grandis, K. Uvaria grandiflora, K. mutabilis, K. nobilis, and K. Saundersi; again, between these last two I can see no difference. Last come K. media Macowani and K. carnosa. K. carnosa and K. Leichtlini are evidently one and the same thing. That K. corallina is a seedling of K. Macowani is clear, inasmuch as seedlings from K. corallina have all proved to be K. Macowani. I have seed of media-Macowani which I intend to sow, and will, I hope, see how far they will revert to the type. That K. Rooperi, so named with us, is identical with K. Burchelli, is evident in every way, and in one particular decidedly, viz., that of producing underground stolons, which, I believe, none of the others do, except, perhaps, K. sarmentosa, which I have not seen.—T. D. HATFIELD, *Passaic.*

Books.

A BOOK FOR LITTLE GARDENERS.*

ALLOW me to direct attention to a work, the very backbone of which is gardening for children, and even children's parents of the wisest might learn something from its well-pictured pages, if they should care to do so. The work to which I allude is "Mary's Meadow" (containing also "Letters from a Little Garden"), by the late Mrs. J. H. Ewing, a friend of the late Rev. Mr. Ellacombe and of Canon Ellacombe, of Bitton. "Mary's Meadow" relates how a little girl tried to make a pretty bit of meadow still prettier by planting flowers in it, instead of making it poorer by rooting the flowers out of it, as so many people now do. A good deal of information anent Parkinson's delightful old gardening book, called the "Paradisus," published in 1629, is woven into the story, and there is an allusion to



Forms of white-flowered Daffodils.

another, but more modern classic, viz., "The Tour Round my Garden," of Alphonse Karr. Now, this little volume, yclept "Mary's Meadow," first appeared in the numbers of "Aunt Judy's Magazine" from November, 1883, to March, 1884. It was the last serial story which Mrs. Ewing lived to write, and Miss H. K. F. Gatty (her sister) tells us in the preface that she believes "the subject of it arose from the fact that in 1883 she went to live at the Villa Ponente, at Taunton, where she had" (after much travelling about) "a settled home with a garden, and was thus enabled to revert to the practical culture of flowers, which had been one of the favourite pursuits of her girlhood." The game of the earthly paradise was received with great delight by the readers of the story; one family of children adopted the word "Mary-meadowing" to describe the work which they did towards beautifying hedges and bare places, and Mrs. Ewing received many letters of enquiry about the various plants mentioned in her tale. These she answered in the correspondence columns of the magazine, and in July, 1884, it was suggested that a "Parkinson Society" should be formed, the objects of which were "to search out and cultivate old garden flowers which had become scarce, to exchange seeds and plants, to plant waste places with hardy flowers, to circulate books on gardening among the members, and, further, to try and prevent the extermination of rare wild flowers, as well as of garden treasures." It may interest many little gardeners to know that this society, with Prof. Oliver, F.R.S., of Kew, as its president, is still in existence, and anyone can procure a copy of its rules by sending a stamped addressed envelope to Miss Alice Sargent, 7, Belsize Grove, N.W.

I think it is Charles Dudley Warner, in "My Summer in a Garden," who says that "what a man needs most in gardening is a cast-iron back with a hinge in it," and, he further adds, that the highest consolations of philosophy are also of great assistance in the undertaking. But with the children this is not so. They, at any rate, are delighted in grubbing up weeds and in planting and watering their pet flowers, and this little work is, as I believe, one of the best, even if not the best—that is while most practical, most amusing also—of all the works on gardening known to me.

Mrs. Ewing, although devoted to the dear old-fashioned flowers and their countless associations, is nevertheless just to the better phases of "bedding out," and "takes some little credit," as she observes, for her moderation. In a word, she was so far-sighted as to see that fashion-waves "come and go—ebb and flow" over our gardens, just as they do on the pebbly shore. Thus in speaking of her own garden, then gay with dear, old-fashioned blossoms, she says there is no doubt whatever that the good lady who shall coddle it after her will be quite as fond of her flowers and her garden as she herself. On page 77 two portraits are pleasantly sketched, the originals of which were and are well known to most of the readers of THE GARDEN. The annals of fashion must always be full of funny stories. I know two of the best amateur gardeners of the day; they are father and son. The father lives and gardens still (he sent me a specimen Lily lately by parcel post), and is making good way between ninety and a hundred years of age. What we call old-fashioned flowers were the pets of his youth. About the time when ribbon bordering came in he changed his residence, and in the garden where he had cultivated countless kinds of perennials his son reigned in his stead. The horticultural taste proved hereditary, but in the younger man it took the impress of the fashion of his day. Away went the "herbaceous plants" on to the rubbish heap, and the borders were soon gay with Pelargoniums and kaleidoscopic with Calceolarias. But "the whirligig of time brings in revenges," and perhaps a real love for flowers could never in the nature of things have been fully satisfied by the dozen or by the score; so it came to pass that the garden is once more herbaceous, and as such far-famed. The father . . . has told me, chuckling, of many a penitential pilgrimage to the rubbish heap, if haply fragments could be found of the herbaceous treasures which had been so rashly cast away. Doubtless there were many restorations. Abandoned "bedding material" soon perishes, but uprooted clumps of "herbaceous plants" linger long in shady corners, and will sometimes flower pathetically on the heap where they have been thrown to rot.

* "Mary's Meadow," and "Letters from my Little Garden." By Mrs. J. H. Ewing. Illustrated by Gordon Browne. Pp. 96. London, S. P. C. K. 1886.

Apropos of this last remark, I was once looking at some exquisite sketches of hardy flowers, and after I had admired the pictures as showing an enlightened phase of flower gardening, their owner remarked, "No, sir; you are wroug. These pictures were made in an old rubbish belt surrounding the flower-garden proper, and these results of beautiful flowers among the Grass were not at all intentional; they are the outcome of prunings and parings which the gardeners in 'tidying-up' had thrown away to die."

Mrs. Ewing was a gardener who believed that "good rules were good tools," and so in her "Letter 3." she gives a few of what she calls rough-and-ready ones which may be introduced here without any apology :—

Hardy flowers in hedges and ditches are partly fed, and are also covered from cold and heat, winds and drought, by fallen leaves and refuse. Hardy flowers in gardens have all this tidied away from them, and, being left somewhat hungry and naked in proportion, are all the better for an occasional top-dressing and mulching, especially in autumn.

Again—

Concentrated strength means large blooms.

You cannot grow everything; grow what suits your soil and climate, and the best of these as well as you can.

North borders are safest in winter. They are free from the dangerous alternations of sunshine and frost.

Very little (protection) will keep Jack Frost out, if he has not already been in, either in the garden or in the house.

In drought one good soaking with tepid water is worth six sprinklings.

Flowers, like human beings, are to some extent creatures of habit; they get used to many things which they cannot at all abide once in a way.

Those parts of a plant which are not accustomed to exposure are those which suffer from it.

All these are good tools, and all the better ones because in the book they are clearly and fully explained by the authoress, who, as she tells us, reserves "a sneaking credulity in reference to lucky fingers," or rather a belief that some people have a strange power or tact in dealing with plants, as others have in the control and coaxing of animals. This belief is very much more common in Ireland than in England. I once complained because a pet plant did not flourish. "Ah!" said the gardener, "how can ye expect it to flourish? Sure, didn't Pat Connor plant it, and doesn't everybody know that he hasn't a 'lucky fist,' at all at all?"

The more one looks over this little book the more enchanting does it become. Glints of sunshine, and tender sympathy for the garden at all times and seasons, show themselves on nearly every page. Here is a morsel on the feeling of perennial youth which life in a good garden in some sort brings :—

If ever we do taste anything of the vital hopeful rapture, the elastic delight of the old man of a fairy tale, who leaves his cares, his crutches, and his chimney corner to go forth again amongst the young, it is when the winter is ended and the spring is come. Some people may feel this rising of the sap of life within them more than others, but there are probably very few persons whom the first mild airs, and bursting buds, and pushing flower-crowns do not intoxicate with a sort of triumphant pleasure.

Especially eloquent does Mrs. Ewing become when she speaks of little gardens.

It is such little gardens which have kept for us the blue Primrose, the highly fragrant summer Roses (including Rose de Meaux, and the red and copper Brier), countless beautiful varieties of Daffodowndillies, and the whole host of hardy flowers, which are now returning, like the Chippendale chairs, from the village to the hall.

"All is fine that is fit," is a text from which she preaches eloquently. Even the bedding system comes in for a good word, and she points out what lovely "Whistlerian" effects from shades of the same colour might have been produced instead of the lurid contrasts which helped to lower it in public esteem. Besides the fitness of gardening to the garden, there is, as she explains, its fitness to the owner's taste, and also to his means and leisure. Lastly, if there is but little of taste, and time, and money to spare, surely nothing can be more satisfying than a gardenful of such flowers "as our Englyshe ayre will permitt to be noursed up." Bear in mind these counsels: make a wise selection of hardy plants; grow only good sorts, and of these choose what suits your soil and climate. Give them space and good feeding. Feed them as well as you can from the top. Disturb the roots as little as possible, and constantly cut your flowers. Then you may expect your flowers to be, as they will be, "fine as well as fit." F. W. Burbidge.

Kitchen Garden.

CELERY AND LEEK SHOWS.

These are by no means confined to the counties of Lancashire and Yorkshire, several being annually held still farther south, notably about Nottingham. Anything which an intelligent cottager or mechanic takes seriously in hand is sure to be eventually brought to perfection. Having had good opportunities of contrasting the productions of cottagers' gardens in both the southern and midland counties, I can safely assert that the latter as specialists are simply unapproachable by either their southern or western contemporaries. As was pointed out in The Garden (p. 527), there is a good and a bad side to these friendly rivalries, and, as far as the final proceedings are concerned, I am of opinion the competitors derive more harm than good from them. It may be of interest to note that some of the very finest Celery I have ever seen or heard of was never inside a trench, nor was it earthed up in any way. The plants are put out on deeply dug, very heavily manured land, and assisted by abundance of sewage water mulchings, and perhaps a sprinkling of soot or salt, they grow surprisingly strong. A soon as the outer leaves attempt to assume their natural, that is to say, a horizontal position, they are lightly tied up, the blanching being eventually accomplished by paper wrappings. I have seen Celery fully 4 feet high carefully wrapped up in various folds of paper, only the tips of the leaves, as in moulding up, getting any amount of light. When ready for the show no grub or worm-eaten stalks have of necessity to be removed, but all are beautifully clean and white, and worth three times the number of ordinarily grown sticks. I am convinced that the Wortley Celery Collars were a step in the proper direction, only they were not large enough, and something of the kind may yet become popular. The bad side of these Celery shows is, that they are usually held at public-houses, and to make matters worse the proceedings are made to extend over three days, the middle or show day being on a Sunday, and this in the suburbs of such an important town as Nottingham. On Saturday the exhibits are brought and arranged; on Sunday they are on view, and on Monday the exhibition is broken up and the prizes distributed; so that altogether the exhibitor, and perhaps some of his friends, spend the best part of three days in or about a public-house. Surely this state of affairs might easily be remedied. Any hobby the cottager may have in connection with his garden ought to be encouraged, but it is also advisable to guard against these finishing up in a public-house. W. I.

Hardy Cabbage Lettuces.—A good supply of salading is never more welcome than at Christmas, and, whatever other material may be at hand, Lettuces of some kind are indispensable. There are many good winter Lettuces, but none that give so sure a supply as the small hardy sorts of the Cabbage kinds, such as the hardy Hammersmith or All the Year Round. If these are sown thinly on a border with a good steep slope, to ensure thorough drainage, in August, a good supply of nice little hearts will now be obtainable. Moderately good soil is better than that which is over-rich, as a luxuriant growth is against hardiness, and if very gross they are sure to suffer from frost. In gardens in which there are glass pits vacant, it is a good plan to make sure of the most forward by transplanting them therein. Those who rely on open-air produce must guard against exceptionally severe visitations of frost by placing some kind of covering over the Lettuce bed, or at least a portion of it. Inverted flower-pots serve the double purpose of blanching and protecting at the same time, but for covering I have never found anything to surpass the dead tops of Asparagus, or the dry fronds of Bracken secured by means of Pea sticks laid over them, as rough gales soon displace them. Coverings of this kind admit air, and thus prevent decay, which is encouraged by coverings of a denser character.—J. G., *Hants.*

KITCHEN GARDEN NOTES.

Forcing Asparagus.—In some years Asparagus roots force more freely than in others; and, judging from the way in which the roots are growing now, forcing will be an easy matter this winter. For some years past we have cut the first of our forced produce in November, but as all outdoor vegetables have been plentiful this autumn, our Asparagus was not put in very early; the first, therefore, is only ready for cutting now, but although open air vegetables may be ever so plentiful, Asparagus will be none the less acceptable, being king of vegetables from now until June. All who can force it to have it on the table in December, January, or in any of the spring months may rest assured that their work will meet with approval. It is pretty well known now that roots cannot be forced profitably until they are five or six years old, but after that they are always good so long as they remain strong and healthy. In lifting them for forcing, they should not be broken any more than can be helped, and they should be put into their forcing quarters before they have time to dry up in any way. Some prefer white Asparagus, others green. Where white is most valued, growth must be made in a dark place. A good hotbed with a frame on the top is a good place to produce Asparagus of this sort. A layer of soil should be spread over the surface; on this lay the roots close together, and cover them over with some kind of light soil until the crowns are out of sight; water them with water heated to 90°, and await results. As soon as the heads begin to appear, cover the lights over with a coating of hay, straw, or some old mats to exclude light, and the heads will soon assume a very pale colour. To grow green Asparagus the same system may be followed, only do not use the covering on the top of the glass. The roots may also be put into the bed of a Melon or Cucumber pit where a bottom heat of 80° or so can be maintained. Here a little soil is put under them and over them, as in the frame, and they require more water, as the situation is drier than a damp hotbed. The heads should be cut as soon as they are 8 inches or 10 inches in length, and the very small growths which may not be strong enough for use should be cut off as they appear, as they only rob the stronger ones. Strong, healthy roots will produce dish after dish for three weeks or so, and although the roots are of little use afterwards, the abundance of the produce now will pay handsomely for all the expense incurred in raising the roots.

Mushrooms in sheds.—We are now cutting Mushrooms from several beds in sheds, and they are excellent; but as we are now in the dead of winter, and the weather very trying for them, I would advise that the hay or straw which covers the surface of the bed be changed once or twice a week, and the new covering should always be dry and upwards of 1 foot in thickness. The covering

which is taken off will be moist, and it may be shaken out and dried before being used again. Should any of the surfaces of the beds be dry, water them well with water heated to 95°; but as the smooth surface does not take in the water readily, it should be watered four or five times over, at intervals of five minutes or more. This watering will make beds which are ceasing to bear begin anew and produce a second crop, in many cases almost as good as the first; and should any bed become so dry before bearing as to check this occurring at the proper time, a good watering will generally cause the spawn to move rapidly, and the Mushrooms to appear at once.

Forcing Rhubarb.—In many gardens Rhubarb roots are too numerous, as three parts of the produce go to waste. In early summer Rhubarb is generally a "drug in the market;" but it is not so now, and all who have surplus roots ought to force them, as being the most profitable way in which to utilise them. If any old casks or boxes are turned upside down over the crowns, and the whole surrounded with 4 ft. or 5 ft. of fermenting material, the produce will be fit for use in three weeks. At one time we placed a cask upside down over a Rhubarb crown with the view of forcing it, but no means were provided for the escape of the steam and the root was killed. Since then we have always been careful to allow a little ventilation on the top of whatever covered our forced Rhubarb, and all who force vegetables must observe this.

Large *v.* Button Mushrooms.—Cooks will always have their way, and when they ask for Button Mushrooms they must be supplied; but, in my opinion, the plan of using small quarter-grown Mushrooms in preference to those more fully developed is a great mistake. The little round knobs may be convenient for some dishes, but the question of flavour should be considered. Those Filbert-like Mushrooms generally termed "Buttons" are almost flavourless, but if allowed to remain for a few days longer, until they measure 3 inches or 4 inches across, and are thick and fresh, they are simply delicious, and no more like the insipid Buttons than a Turnip is like a Pine-Apple. I know some good judges of Mushrooms who always help themselves to the largest when the dish is handed round. The flavour of fully-developed specimens cannot be surpassed. Let your readers put this matter to a practical test, and they need not tell me what their verdict will be.

December sown Peas.—As a rule, Peas sown in autumn are put in during November, but December is an equally good month in which to sow them. Those put in about Christmas succeed admirably as a rule, and the sowing of early Peas should be very general at this time. They will not be through the ground until about the end of January, nor will they be very tall by March, but they will be robust and ready to grow away freely in April, and here rests the secret of their success. The ground in which they are sown should be rich and well exposed to the sun. Narrow drills answer best at this season, and the seed should be sown a little thicker than in summer; but, apart from this, their sowing now may be done in the same way as at other times.

Digging and trenching are too seldom done in winter, and the habit of digging over the ground a few hours before sowing or planting is too common. Winter weather, especially frosty weather, helps the soil wonderfully, but neither wind nor anything else can penetrate far down when the surface is like a road, and if the full benefits arising from frost-pulverisation are to be secured, the surface should be made as porous as possible. Trenching and rough digging are the best means of effecting this; therefore all vacant vegetable quarters should be turned up to the weather at once.

Early Radishes.—These are the most easily grown of all early vegetables. A gentle hotbed is the best place for them. A bed 2 feet in height will suit them; soil to the depth of 4 inches or 5 inches should be put on the top of this, or inside a frame furnished with a glass light, and here they will grow freely and at once. The soil is in best condition for them when very poor, as a rich soil at this season only causes them to make a superabundance of foliage and very small or no bulbs. It is almost impossible to have the soil too firm, as they do not bulb freely in light material, and a firm, poor soil is undoubtedly the best for Radishes during any of the winter months, more particularly where they are confined and apt to be drawn up, as they always are in frames.

Green Mint.—Where a quantity of the shoots were cut in August or September with their leaves on and dried they will now be much valued in the kitchen; but green Mint is acceptable at all times, and it is not a difficult matter to have a supply of it in winter, as if the roots are lifted and put into pots or boxes with a little soil over them, and then placed in a temperature of 70°, young shoots will soon appear, and they will push up rapidly until quantities of them may be cut frequently.

Chicory.—This is the midwinter friend of all who are deficient of Lettuces and Endive, as it can be forced into full leaf in a very short time, and it is excellent for filling the salad bowl. The roots are like those of miniature Parsnips, and they should be dug up and potted in tens or twelves in 8-inch and 10-inch pots. They should then be placed in bottom-heat and in a dark place, and the young leaves, which will soon appear in abundance, will be as delicate as the centre of a well-blanched Lettuce. Where there is no dark place in which to force them, another flower-pot the same size as that in which the roots are potted should be inverted over the crowns.

Kidney Beans in pots.—The present is a good time for sowing these for fruiting in February or March. As a rule it takes from ten to twelve weeks for them to come into bearing after sowing at this season of the year, and wherever there is space and heat to accommodate a few, they should be put in, as open-air vegetables generally become scarce in February and March, and kidney Beans then are much valued. Osborn's variety, which was such a favourite at one time for forcing, has been supplanted by Cooling's Ne Plus Ultra, which is equally dwarf in growth, more prolific, and has longer pods. It is also quite as early. The best of all ways of sowing dwarf Beans at the present time is to fill a number of 3 inch pots half full of good soil; put eight or ten Beans into each, and fill up with more soil; then place them in a temperature of 65° or 70°. They do not require much water until the young plants are in leaf, and as soon as the pots are well filled with roots and the plants are 5 inches high, they should be transferred to larger pots. Each lot may be re-potted into a 6-inch pot, or three lots may be put into a 9 inch pot. They enjoy moderately rich soil, and they should be kept near the glass and fully in the light. J. Muir.

Margam.

Potatoes.—It would, I think, be useful to obtain before planting time a list of the varieties of the Potato specially adapted to different soils and situations, for it is true of this vegetable, as of others, that different conditions have a great deal to do with successful culture. I find that Myatt's Ashleaf, Covent Garden, Magnum Bonum, and Red-skin Flour-ball in their respective seasons cannot be beaten in our light soil. We also grow a few of the Beauty of Hebron to succeed the Ashleaf for early digging, and this is certainly a first-class Potato. It is not, however (except in cropping qualities), equal to Covent Garden. This last I look upon as about the very best mid-season Potato in cultivation; there are certainly varieties that crop more heavily, but for the table it cannot well be surpassed. Magnum Bonum turns out well with us. It is good alike in size, shape, numbers, and flavour, and has nothing of the closeness that is sometimes a characteristic pertaining to it on heavy soils. This is one of the Potatoes that vary wonderfully in different soils. I have tasted samples (true) from heavy and from light ground, and found that it could not be recognised as the same variety. Red-skin Flour-ball is the best keeper we have; it thoroughly bears out its name, and is a very heavy cropper. Of other varieties that have been tried from time to time I may mention Schoolmaster, Bedfont Prolific, Woodstock Kidney, White Elephant, Cosmopolitan, Idaho, and Reading Hero. Of these Schoolmaster and White Elephant are the best, but they are not likely to oust the varieties first named by me. Cosmopolitan and Idaho are failures, and Reading Hero is not equal to Flour-ball.—E. B.

AMERICAN TOMATOES.

Are these in any way superior to those raised in this country? I have tried nearly all of them, including Cardinal, Acme, Beauty, Livingstone's Perfection, and the Yellow Trophy, and can confidently assert that we have better kinds of English origin than any of them. The Yellow Trophy is simply worthless; no one would eat such a flavourless sort if any other were forthcoming. All the other sorts named possess the qualifications enumerated by Mr. T. D. Hatfield (p. 527), but solidity I hold to be objectionable. We like Tomatoes to be of medium size, thin-skinned to a certain extent, perfectly shaped, and prolific, but they ought not to be too solid—this implying seeds few and solid core to be in the ascendant. The pulpy matter surrounding the seeds is really the best portion of the fruit—at least, such I believe to be the case—and this is not very plentiful in the majority of the American sorts. In addition to those above named, I have grown Pennsylvania Chief, Mayflower, Vick's Criterion, and King Humbert, all being sent me at different times in packets from America. They were more or less prolific, according to the treatment given, though not remarkably prolific; while in flavour they were inferior to Carter's Perfection and the Dwarf Orangefield, and not superior in any way to Hackwood Park, Dedham Favourite, Reading Perfection, or Hathaway's Excelsior. The latter was, I believe, the first American introduction to this country, and this excellent variety was one of the progenitors of a new race of English-raised Tomatoes. Trophy, the red form, also an American, has done me good service as an exhibition variety in times past, but it required extra good treatment to bring it to perfection, and unless the blooms were particularly well fertilised and selected, the fruits were liable to be both very ugly and very solid. Trophy, or its synonym, Stamfordian, is now fast going out of cultivation, and its place is being taken by one of the Perfections that have cropped up. The new Mikado I have not tried, and the description given will not tempt me to grow it.

W. Iggulden.

PLANTING OUT *v.* POT CULTURE.

There are, as is well known, many plants that bloom in winter and spring that are greatly benefited by putting them out in the open ground during the summer months. One of the greatest advantages conferred by this system is that it enables a comparatively inexperienced person to succeed in the growth of a plant which he would have a difficulty in bringing to perfection by pot culture. Berry-bearing Solanums, Bouvardias, and Arum Lilies are instances in point; it requires a considerable amount of care and much labour to grow such plants into strong, well developed specimens with their roots confined in pots all through the growing season. True, we have resources in the shape of concentrated manures, but judicious, timely feeding is often, through pressure of work, neglected. Perhaps no cultivated plant feels want of nutriment more acutely than the Chrysanthemum. It is naturally a gross feeder, and the naked condition of so many plants that one sees in private gardens is due to absence of food at some period of growth. I was looking some time since at a collection of Chrysanthemums, and I could not help coming to the conclusion that the grower had given himself

much pains to little purpose. The plants bore individually about a dozen blooms of fair quality, but they were defoliated half-way up the stems. There are doubtless good reasons for growing Chrysanthemums in pots, and it is probable that fine exhibition flowers cannot well be obtained in any other way. But the Chrysanthemum grower who needs good specimens bearing an abundance of well-developed blooms and clothed with healthy green foliage down to the soil may certainly go to work in an easier way than by keeping his plants in pots all through the growing season. Of all flowering plants with which I am acquainted, the Chrysanthemum bears transplanting best. With ordinary care, plants taken up from the open ground when the buds are beginning to burst will show no signs of removal. Few who have written on Chrysanthemum culture appear to have given the planting-out system much attention. In the course of time I, however, venture to predict that for all ordinary purposes it will be the system generally followed.

Last spring I planted out about 300 of a late white Chrysanthemum. They remained in the open ground until housing time, and were then carefully lifted and planted again in a light house. I shall begin cutting from them at Christmas, and through January they will yield about 7000 blooms of fair average quality. Taking the cultural expenses into calculation, I am sure that they will pay me much better than if they had been grown in pots, in which, moreover, they would not have made such good specimens. The old stools were very weakly; they were taken up from the open ground late in autumn, and many of the shoots through overcrowding were blanched. They were wintered in a cold frame, and it was late in spring before they were ready for propagation. At that time there was not one cutting on them that a Chrysanthemum grower would like to have used. They were pulled to pieces and were planted out late in April 6 in. apart. Some of the suckers were very spindly and had very few roots. I had no great hopes of their doing much good, but by the end of the autumn they developed into bushes 4 feet high, each carrying after disbudding on an average three dozen blooms. All the attention they had when growing was an occasional soaking, and in very hot weather a sprinkling overhead.

Just to illustrate how indifferent the Chrysanthemum is to root-disturbance, I may mention that, as the plants got too thick, one-half of them were transplanted when about 2 feet high. The weather at the time was very dry, accompanied by an unusually parching wind. I should not have voluntarily chosen such a time for moving them, but I was afraid of their spoiling. A few stakes were put in with cross pieces tied to them, on which canvas was laid to keep off the hot sun. Twice a day they were syringed. In the course of a fortnight they needed no further care, and not a leaf discoloured. A friend came in one day and was surprised to be told that plants so large had been moved without sustaining a check. There seems indeed to be no danger attending the lifting of Chrysanthemums at any period of their growth.

The good results of planting out are certainly most marked in the case of plants of a gross-growing character, and which have to attain considerable dimensions before they have much decorative worth. Arum Lilies, Habrothamnuses, and Abutilons are instances in point. The two last-mentioned are comparatively of but little value in a small state. It is only when they come into tolerably large pots they give an idea of their worth. Only those who are utterly regardless of labour and time would think of growing these in pots through the summer. Put into a rich bit of ground and given a mulch of manure, they will make good growth, with the aid only of an occasional soaking with water. With respect to Arum Lilies, everyone knows what planting out does for them. Cyclamens can be grown much more easily planted out in a frame for the summer than kept in pots, and many would get good plants in this way who cannot get on with them under pot culture. I have grown Cyclamens as large as a small Cabbage in this way, the roots being so numerous that I could hardly get them into an 8-inch pot. I could never get them so good wholly under pot culture, and they required only about one-tenth the labour to grow them.

Most readers of The Garden have seen the Belgian-grown Azaleas that annually come in such quantities to this country and noted the amplitude of their foliage and generally robust appearance. It is a free root-run in congenial soil that gives this, and experience has proved that we can grow them equally well in this country by the same method. It is as well to mention that planting out Azaleas for the summer is a common practice in Belgium. Even quite large specimens are treated in this way—if not every year, now and then—which gives them renewed vigour. The difference in the appearance between plants that

The Dove Orchid (Peristeria elata).

have been in the open ground and those that have been grown along in the ordinary way is great enough to warrant the practice. Passing once through Van Houtte's nursery at Ghent, I was shown two lots of large Azaleas, one of which had been planted out; the other had been grown in pots. The difference between the two was so great as to make one wonder that Azaleas should ever be kept in pots all through the summer. Cape Heaths are amongst the most unlikely things one would think of treating in this manner, but it is a rather common practice to grow them thus in some parts of the Continent. I have seen the free-growing, soft-wooded kinds brought to good-sized specimens in a short time in this way.

Coming to fine-leaved plants, there is no comparison between those that get an unlimited amount of food and such as have the roots confined in pots. Ficuses, the coloured Dracænas, and some other things are largely and successfully cultivated in this way in Germany. The finest lot of India-rubber plants and Dracæna terminalis I ever saw was planted out in span-roofed frames on a bed of fermenting material in spring, to be lifted carefully and potted in September. One advantage of this way of growing them is that one can get large plants in small pots, as, when taken up, the greater portion of the soil can be worked away from the roots, which are crammed into pots just large enough to contain them. With ordinary care they soon strike root again, and are then equal to root-bound plants. Very good crops of Strawberries may be had from plants that have been grown liberally in the open ground, and are taken up and potted in October, keeping them in frames until wanted for forcing. This plan will not do, however, for early work; for this purpose the plants must be well established in their pots by the end of the autumn. For late crops it answers admirably. I have gathered much fine fruit in this way with comparatively little trouble. Whether planting out or pot culture is the better plan entirely depends upon the purpose to which the plants are to be put. Plants that have to be subjected to anything like a forcing temperature should get no check of any kind, and they cannot have the pots too full of active fibres at the beginning of the winter. If Azaleas are required to be in bloom at the beginning of the year, they must be pot-bound when placed in warmth; and all kinds of plants that have to bear rough treatment should be similarly circumstanced. For this reason market growers do not favour planting out, as their customers soon complain if the plants do not "stand well." There is the check that a plant experiences when brought to market, which, added to a change of atmospheric conditions and more or less unskilful treatment, soon takes the life out of it, unless the vital forces are at a high point. A newly-potted plant at the dull season of the year needs more judgment in watering than the average window gardener possesses, and one overdose of water will suffice to ruin a plant in that condition. The moral to be drawn from this is that planting out is a useful auxiliary to, but cannot entirely supersede, pot culture.

J. Cornhill.

Orchids.

THE DOVE ORCHID.

(PERISTERIA ELATA.)

From time to time various Orchids have been placed in this genus, but all are now removed from it to the nearly allied family Acineta. The plant in question is a vigorous grower; the pseudo-bulbs are ovate, pale green, and bear from three to five large, prominently ribbed leaves, which attain a height of 4 feet or more. The flower-stem is erect, longer than the leaves, rising from the base of the growths, and bears flowers on about one-third of its length. The e are somewhat globose, thick, and waxy in texture, delicately fragrant, and creamy white in colour, more or less freckled with lilac. The resemblance of the column of the flower to a little dove with expanded wings led its first discoverers to name it El Spirito Santo, or the Holy Ghost plant. To flower it satisfactorily it requires strong heat and abundance of moisture, both as regards its roots and in the atmosphere during the growing season; but after the growth is mature, water should be entirely withheld and the temperature reduced. It is a native of Central America.

W. H. G.

Winter Orchids. — Amongst the numerous Orchids now in flower at Kew, the following are well worthy of notice by those who wish to keep their plant houses attractive at this time of year. Amongst those content with cool treatment may be noted numerous forms of Lycaste Skinneri, the large wax-like flowers of which are so beautiful; Odontoglossum crispum and O. Rossi majus, species now largely used for button-holes. Oncidiums are represented by the small-flowered, yet elegant, O. cheirophorum, O. aureum, and O. Jonesi-

anum, the lovely coloured flowers of which appear to be highly appreciated, judging by the quantity of them now in the market. Lady's Slippers are also now in great beauty, and the length of time during which their flowers endure should commend them to all lovers of Orchids; the most noticeable of these are Cypripedium insigne, in masses; C. calurum, C. Roezli, C. porphyreum, and the chaste C. Spicerianum, the large white upper sepal of which is in some forms slightly flushed with violet, and peculiarly attractive. Amongst Lælias, the Mexican L. autumnalis, L. anceps, and its variety, Barkeriana, are well represented. Of scarlet-flowered Orchids, there are fine examples of Sophronitis grandiflora, the curious Ornithidium Sophronitis and the rosy red Mesospinidium vulcanicum. Amongst blue flowers is the lovely Vanda cærulea and Zygopetalum Mackayi; the white Masdevallia tovarensis is flowering most profusely; whilst M. ignea and M. Chelsoni are likewise in good condition. Calanthes have evidently felt the ill effects of the late fogs. Some other Orchids are flowering out of season, notably a fine example of Saccolabium Blumei majus, Dendrobium formosum giganteum, and Miltonia Moreliana. Fine specimens of the Madagascar Angræcums—eburneum and eburneum virens—bear numerous spikes of inverted white flowers, whilst the West African Ansellia africana, with its greenish flowers, richly banded with chocolate-brown, is well represented.

EASTERN ORCHID CLIMATES.

The information gathered as to the conditions influencing the growth of Orchids is almost entirely due to experiments made by gardeners. In a few cases, to be sure, a new species or variety is collected by some one who gives full details of the climate in which he has found the plant, but only rarely. You consult some standard authority, and are tantalised by being informed that your species is a native of India, or a part of India, as Assam or Burmah, which are spoken of as though they were climatological hen-coops. In the latter country, the surveys which will soon be instituted will undoubtedly give greater elevations than have hitherto been quoted, but even in the portions long since known, the elevations vary from the sea to 6000 feet above it. Take Assam, again, and we have places such as Gowhatty, 134 feet above the sea, and the Upper Phoongan-Boom, 15,474 feet above it. So, again, with Munneepoor, Jerce-Ghat is only 131 feet above the sea, while Kewho peak is 8202 feet above it. Similar elevations occur in Arracan, Cossyah, Chittageng, Sylhet, Nepaul, Neilgherries, Ceylon, Java, Darjeeling, the Himalayan regions, and even on many portions of the western Ghauts, and yet when speaking of the home of an Orchid, all that is deemed necessary is to say "India;" and all there is to do is to place it in the East India house. Now, let us look for a moment at a few of these East India climates, and see if it be likely that plants from there can all possibly flourish, or even exist, under one set of conditions. They do not flourish, nor can they. It is singular enough that Orchids from the western hemisphere have to some extent been divided into tropical, intermediate and cool, a division requiring a very great deal of revision, no doubt, while those from India are almost all regarded as tropical. How untrue it all is, I hope the following table of elevations and temperatures will show:—

	Elevation, feet.	Jan. temp. Fah.	July temp. Fah.	Lat.
Calcutta	....	70°	86°	....
Assam	134	60	82	27 N.
Munneepoor	2500	58	79	24 N.
Chota-Nagpoor	2010	62	77	....
Cossyah	4200	53	72	....
Nainee-tal	6200	42	69	....
Darjeeling	7000	40	64	....
Simla	8000	40	80?	....
Kotagherry	6100	66	70	11 N.
Ootacamund	8000	55	61	11 N.

Now, here is a range of climates which embrace all the varieties of Orchid house temperatures, and Vandas and Aerides, Saccolabiums and Dendrobes are found, in the shape of one species or another, in nearly all of them; yet in our very best places everything goes into the "Orchid house," or into the "Vanda house," or the "Dendrobe house." I do not know anything which would be of more use to Orchid growers than a conspectus of the popular species of each country, with the elevations at which each is found, and the amount and season of the rainfall. Who will compile it?—James MacPherson, in *Country Gentleman*.

Lælia albida bella.—This form produces much larger flowers than those of the original L. albida, and the colour is also richer and more intense. The sepals and petals are creamy white and waxy in texture, tipped with rose or rosy lilac. The lip, which is yellow, is deep orange in the throat; whilst the middle lobe is broadly margined with rich magenta. It is a charming Mexican Orchid, suitable for block culture. We recently saw it in the Marks Tey Nursery.

Lælia præstans.—This beautiful dwarf-growing Brazilian Lælia is now flowering in profusion in Messrs. Horsman's Marks Tey Nursery, Colchester. It is a charming plant for block culture in a cool house. It somewhat resembles Cattleya marginata, but is a much better growing plant, and, as regards its blooms, it is abundantly distinct. The short, stem-like pseudo-bulbs produce a single-flowered spike, the flowers being from 3 inches to 4 inches across. The sepals and petals are deep rose. The lip, which is broadly margined with deep velvety purple, has a yellow throat. It is an extremely beautiful Orchid for blooming at Christmas.

Lælia anceps.—Amongst hundreds of spikes of this fine old Mexican Orchid, now bearing flowers and buds in the Marks Tey Nursery, Colchester, there are some very beautiful forms, especially the variety Percivaliana, numerous plants of which are carrying about a dozen spikes. The sepals and petals are about the same shade of rosy lilac as the normal form, but the lip is more beautiful; it is much broader in front, and the colour is deep purplish magenta, suffused with mauve, streaked with lines of deep purple, and crested with yellow. The rare variety coccinea has extremely rich, dark-coloured flowers. Many other forms are also in great beauty just now, especially L. anceps atre-rubens.

Aganisia cærulea.—This is a charming little Orchid, the flower of which measures 1½ inches across, and resembles in shape somewhat a gigantic bloom of Calanthe masuca; the exterior of the sepals and petals are about the same blue as that of Vanda cærulea; interiorly they are slightly paler; the lip is reddish brown. A specimen has been sent to us by Mr. W. Holland Linwood, Mossley Hill, Liverpool, who says: "It is evident that the plant will prove easy to grow in a warm, damp atmosphere, and from its peculiar colour should prove a valuable acquisition to our gardens."

Dendrobium nobile.—I send you a flowering bulb of Dendrobium nobile to show you how beautiful the blooms are at this dull season of the year. I find if the plants are grown in an ordinary greenhouse through the summer months up till about the middle of October, and then put in a temperature of about 60°, they will be in flower by Christmas. The Cypripediums have been grown in just the same way; they are in good health and full of flower.—George Jupp, *Brantridge Park, Balcombe*.

*** The Dendrobium represents an excellent variety, and is flowering upon this season's growth, with the leaves still fresh upon it. The Cypripediums are ordinary forms of C. insigne and venustum. —Ed.

Angræcum bilobum.—The plant referred to under this name in The Garden (p. 549) is, I presume, the variety known as A. bilobum Kirki, a much smaller plant than Lindley's A. bilobum, figured in the *Botanical Register*, 1841, t. 45. Of this plant, which is a native of West Africa, some fine examples existed in the Kew collection upwards of twenty years ago. The leaves are intensely green on the upper side, and deeply notched at the apex. The spike is decumbent, and bears from nine to twelve flowers, some 2 inches across; the colour is creamy white and the lip has a long slender spur at its base. This species blooms during the autumn and winter months, and lasts in perfection a considerable time. It was by no means uncommon a few years back in collections of Orchids, but it seems to have been pushed on one side by the more recently introduced and showier kinds.—X. Z.

A grand new Orchid.—One of the finest new Orchids that have appeared in London for a long time was sold at Stevens' Rooms on Thursday last. It is named Catasetum Bungeroti, and is, without doubt, the finest of the genus. In growth it strongly resembles the other species, the bulbs being spindle-shaped, terminated by a tuft of ribbed leaves. The flower-spike, which is produced from the base of the bulb, is borne almost horizontally. The blossoms measure about 4 inches across, and the whole flower is waxy white flushed with green. The shape of the flower is different from that of most other Orchids, but the labellum resembles that of Angræcum eburneum in shape, except that in the centre there is a deep cavity formed by the spur, and which is coloured with bright orange-red. Six flowers were borne on the spike of the specimen in bloom, and were a great attraction to orchidists. Three plants were sold; the largest fetched 50 guineas, the other two 32 guineas and 20 guineas. The plants came, we believe, from M. Linden, of Ghent. Another high-priced Orchid was also sold on Thursday. This was a finely-flowered specimen of Odontoglossum crispum Stevensi, which fetched 80 guineas. It is a very handsome variety, the large, bold flowers being white, heavily blotched with chestnut-brown. Dendrobium nobile nobilius, a small plant with two leads, fetched 12½ guineas, and Cœlogyne cristata alba was sold for 10½ guineas.

WILD FORMS OF TUBEROUS SOLANUMS.*

The well marked distinct species of tuber-bearing Solanum are five in number, and are all natives of America, viz.:—

1. Solanum tuberosum, including numerous subspecies and varieties; 2, S. Commersoni; 3, S. cardiophyllum; 4, S. Jamesi; 5, S. oxycarpum.

The Potato of cultivation originated from the first. I will say a few words about the others and then return to this one, S. tuberosum.

2. S. Commersoni is a native of Uruguay, Buenos Ayres, and the Argentine territory, in rocky, arid situations at a low level. It is a dwarfer plant than tuberosum, with small, oblong, obtuse, subequal leaflets and larger flowers, with a corolla always pale lilac, and deeply cleft. It has been cultivated successfully in France, but is probably too sub-tropical in its climatic needs to be adapted for our own country.

3. S. cardiophyllum is more like some of the tuberosum forms in general habit, but the corolla is different in structure. It is a native of the highlands of Central Mexico at an elevation of 8000 feet to 9000 feet above the sea level. It was cultivated many years ago in the Chiswick Gardens, but is not in this country now, and no record seems to have been left about the shape, size, and quality of its tubers.

4. S. Jamesi is a northern type, being a native of the mountains of Colorado, New Mexico, and Arizona. It is very different from the cultivated Potato in size and habit, much dwarfer, with oblong acute sub-equal leaflets, and small pale flowers with a deeply cut corolla. It has been grown at Kew and many other places in England. The tubers are very palatable, but I have never seen them larger than marbles.

5. S. oxycarpum.—Of this I have never seen even dried specimens, and know it only from a drawing. It is like Jamesi in general habit, and differs very much from all the others in its fruit, which is oblong and sharp-pointed, hence its name. It is a native of Central Mexico, and the flowers and tubers have never been described.

Tuberosum, using the name so as to include under it all the tuberous-rooted Solanums with short deltoid segments of the corolla, extends down the western side of the American continent, from the Rocky

* A paper read at the Tercentenary Conference, December 2, 1886, by J. G. Baker, F.R.S.

Mountains in latitude 30° north, to the Chonos Archipelago, off the coast of Patagonia, in latitute 45° south, so that it is spread over a latitudinal range of 75°. Within this area we get no less than sixteen forms, so far different from one another that they have been named by some one or other botanical writer as distinct species. They are not, however, species in any comprehensive sense. They all coincide in the general characters of tuber, leaf, inflorescence, flower and fruit; tuberosum, therefore, is one of those polymorphic vegetable types of which we have examples in the Old World in Rosa canina, Rubus fructicosus, Narcissus pseudo-Narcissus, and Nephrodium Filix-mas. The case is very similar to what we have in England in the genus Rubus. Chamæmorus, Idæus, and saxatilis are well marked, definitely bounded, and clearly characterised types. In the tuberous Solanums, Commersoni, cardiophyllum, Jamesi, and oxycarpum are the distinct types, and tuberosum, like Rubus fruticosus, a comprehensive species in the sense of Bentham and Hooker, a group of closely allied species in the sense of Dunal and Babington. The extreme forms look very different from one another when they are placed side by side, but if the whole series is taken there is no very decided gap to be found in any one character, but between the extreme types we get gradual intermediate stages of gradation. In the present case the principal differences between the sixteen forms lie in the robustness of growth and hairiness of the whole plant, the shape and number of the leaflets, the absence or presence of little leaflets intercalated on the leaf axis between the big ones; the shape of the calyx and segments, and the colour of the corolla. Although the Potato has been cultivated in Europe for 300 years, in point of fact we know extremely little that is trustworthy about the alterations that may be produced in these characters by change of climate and soil. On the present occasion I will enumerate them geographically, referring those interested in the matter for botanical details to a paper which I published in vol. xx. of the *Journal of the Linnean Society* (pp. 489–507), with six plates.

Chili.—The Chilian types are Maglia, etuberosum, Bridgesi, and Fernandezianum. We have had Maglia at Kew since 1862. It differs from etuberosum by its fewer leaflets, intercalated little leaflets absent or scarcely present, hispid peduncle, and white flowers. It is abundant on the coast near Valparaiso. A closely allied form was found by Darwin in the Chonos Archipelago. Etuberosum is very little different from the cultivated Potato in leaf and flower. When it was first described it was said to have no tubers at all, but in a plant I saw last summer, grown at the Edinburgh Botanic Garden under the name, tubers were present. Fernandezianum comes from the island of Juan Fernandez. It looks very like the ordinary cultivated Potato. Bridgesi is a high Andine form with numerous narrow leaflets and obtuse calyx segments.

Andes of Peru, Ecuador, Bolivia, and Columbia.—In Peru a plant is widely spread which quite agrees with the common cultivated Potato. This I will therefore call eu-tuberosum, as I think it best to keep the name tuberosum for the whole group, and have a separate name for each of the distinguishable forms. The drawing of it which I now exhibit was made from a plant gathered by Matthews on the rocky hills of Amancaes, near Lima. Whether this eu-tuberosum is really native in Peru I am not able to say with certainty, but I should think this is most likely. The other named Andine forms are Mandoni, immite, columbianum, and valenzuelæ, none of which have been seen alive in Europe.

Mexico.—The Mexican types are verrucosum, suaveolens, stoloniferum, demissum, utile, and squamulosum. Verrucosum was cultivated for several years on a large scale near Geneva, but was not able to compete with eu-tuberosum, and was abandoned. Suaveolens was once grown at Kew, but we have not got it now. Demissum was described by Lindley from specimens grown at Chiswick. Of stoloniferum I have seen plants grown at Leipsic. Squamulosum and utile I know from descriptions alone.

Rocky Mountains.—Here we get Fendleri, the most northern of the tuberosum varieties. It is much dwarfer and weaker than eu-tuberosum, with three to seven thin, ovate, sub-acute leaflets, intercalated leaflets few or none, and few-flowered cymes. What is the economic value of its tubers still remains to be tested.

I take the names as I find them in the botanical books. I do not mean to say that I can undertake to identify sixteen sub-species and varieties. Taking eu-tuberosum as the type, Maglia and Fendleri, the two geographical extremes, look to me to recede from it most. All that I know about their characters and localities I have given in the paper to which I have already referred. I wish much that some one would monograph these tuberous Solanums in the same thorough way that Mr. George Maw has just monographed the Crocuses. We do not even know clearly whether eu-tuberosum, the common cultivated esculent so freely displayed on the tables in front of us, be really an original type, or a form produced by the agency of man; and in investigating the relations to it of the other fifteen tuberosum forms, there is scope for the labour of a lifetime. I leave to those who are better qualified than myself the task of thinking out what are the practical deductions to be drawn from these facts.—*Gardeners' Chronicle.*

Garden Destroyers.

INSECTS ON FRUIT TREES.

All fruit trees infested with insects in summer will be sure to retain many of them throughout the winter, as although some of them may fall off with the leaves, those on the wood are not so easily detached, and in spring begin their depredations anew. Thrips and greenfly are foliage pests, but scale and American blight cling to the wood, and it is these two that ought to be exterminated in the winter-time when the foliage is off the branches. Scale and American blight are not easily destroyed. Frost and severe weather have no effect on them, and, as a rule, they increase in numbers spring after spring until the tree suffers greatly in health. Those who know the advantages of keeping their trees free from insects will be only too glad to adopt any measure which will act either as a prevention or a cure. Of all the insecticides we have tried for killing American blight and scale we have found none to equal petroleum. No fruit-tree insect can survive a good dose of it properly applied. American blight is absolutely consumed by it, and scale drops off in quantities. The best way of using petroleum is to add one pint of it to six gallons of hot water, and a piece of washing soda about the size of an egg; stir it all well up, and then syringe the trees with it. In applying it, many are inclined to syringe it as forcibly as they can, but that is useless, as hard syringing will never kill insects, while a great deal of the mixture is lost in the operation. If it is syringed gently, just to moisten the branches, it is equally, or indeed more, effective than when applied with force. In the case of wall trees, it may be syringed on them in such a way as to moisten the wall and damp the joints between the stones or bricks, as many insects lurk in such spots. The petroleum may be allowed to remain on the trees five minutes; it should then be syringed off with water heated to 90°. One dressing of this kind is quite sufficient to clean the worst affected trees, and with such a simple remedy at hand no one ought to allow their trees to be infested with insects of any kind.

Cambrian.

SQUIRRELS.

I observe that "G." omits Strawberries in his list of fruits devoured by squirrels; but for many years in our gardens they have done far more mischief among these than amongst Cherries, Apricots, or Peaches. Next to Filberts and Nuts, Strawberries seem to be their favourite fruit, and they climb our Cherry-clothed walls in their way to these, and mostly leave the Cherries alone. A couple of squirrels among the Strawberries are something to shudder over and dream about. They cut the entire truss over as if with sharp seissors, even in many cases where there is no ripe fruit, as if in very wantonness, and thus destroy many quarts in a single night, and once they find Strawberries nothing but prompt destruction will arrest their ravages. It is impossible to net fruit, for I have seen them cut their way through double or treble nets with a dog at their heels as rapidly as if slashed with a sharp knife. In regard to nut-storing, &c., the wisdom and provident provision of the squirrel have been greatly exaggerated; for where squirrels abound they destroy all the nuts months before there are any kernels worth storing. Hardly are the nuts fairly formed when they are devoured, the major portion of the soft shell and its spongy contents being cleared off, while the kernel is a mere rudimentary speck in the centre of the mass. The squirrels are too wise to store these nuts in embryo, and too impatient to wait till they are fit for storing, as a rule, though some of the more sage squirrels do make goodly stores of prime nuts when they come upon them.

Mice and rats, however, are more diligent in transporting and storing supplies when they find them, but, with a short-sighted fatuity that defeats its purpose, they heap up choice food, offal, and excrements in such heterogenous mixtures, as to hasten decomposition and render the contents of their granaries too offensive for the unsavoury palates of such rodents. Such modes of storing, of which most horticulturists have had all too many examples, seem to reveal a fault in the instinct of these destructive rodents. For it can hardly be that they steal and carry away our choice Nuts, seeds, and fruits for sheer love of mischief, and without reference to the abundant supply of their own future wants. And yet their storing is so filthy and faulty, that their stores speedily become uneatable, or are transformed into loathsome masses of corruption even more useless to the thieves than to the losers of the stolen property.

Hortus.

QUESTIONS.

5535.—**Nigritella angustifolia.**—Can any reader inform me where a little Orchid called Nigritella angustifolia is to be obtained?—J. H.

5536.—**Daisies on lawns.**—Will some one kindly tell me the best way of getting rid of Daisies on a lawn?—R. L. Allman.

5537.—**Spent Hops for potting.**—Can any reader inform me if refuse Hops can be used, or if it is advisable to put them to any use in a garden, more especially for pot plants?—C. Edwards.

SHORT NOTES—VARIOUS.

Lilac-like Privet (*F. W. Y.*).—You probably mean the Chinese Privet (Ligustrum sinense).

Double seedling Primulas (*J. Cruickshank*).—Fine flowers of a pretty variety, but not superior to the best sorts of double Chinese Primulas sent out a few years ago.

White Cineraria (*T Stratton*).—The flowers represent a really fine, pure white Cineraria, the petals being of good shape and substance. It will undoubtedly be an acquisition, being dwarf and early.

Lathyrus Drummondi.—As I judge, from notes in The Garden, that some of its readers have not been able to procure this pretty and uncommon red-flowered Pea, I shall be very pleased to send some seeds of it to any of your readers who either failed to raise it before, or who wish to grow a very effective hardy border plant. I can send the seeds now on receipt of stamped addressed envelopes.—J. T. Poë, *Riverston, Nenagh.*

Diseased Eucharis.—I have sent a Eucharis bulb which, I am afraid, is attacked by the Eucharis mite. I should like to know if the mite is the cause of the mischief. The plants appeared to be in good health till within the last week or two.—R. J. W., *The Hermitage, The Park, Nottingham.*

The Eucharis bulb sent is undoubtedly infested with the bulb mite (Rhizoglyphus echinops), remedies for which have been recently given in the columns of The Garden.

Auricula shows.—As this seems to be the usual time for making show fixtures, I would like to make a suggestion to our Scotch friends. There is a considerable number of Auricula growers north of the Tweed, and I think a very creditable show might be got up if the matter is promptly taken in hand. I would suggest Edinburgh as the best centre for holding it, and Wednesday or Thursday, May 11 and 12, as the best dates. I will undertake to send from thirty to fifty plants—not necessarily for competition.—W. Stratton, *Annfield, Broughty Ferry.*

Names of plants.—*H. Rondebosch.*—1, Eriocephalus racemosus; 2, Osyris abyssinica; 3, Indigofera cytisoides; 4 not recognised; 5, Gerbera asplenifolia; 6, Osteospermum moniliferum; 7, Lobostemon fruticosus; 8, Hermannia sp.; 9, Amphithalea multiflora; 10, Gnidia pinifolia; 11, Belmontia cordata; 12, Rhus sp. We should be glad to get good seeds of these plants, and all others named for this correspondent.——*J. W. R.*—Specimens of Epidendrum insufficient; send more details and better examples.

Names of fruits.—*C. C.*—2, Doyenné du Comice 14, Beurré de Jonghe; 9, not recognised; 4, Winter Nelis. ——*J. A. W.*—Your Pear is Beurré Diel. —— *Rogler.*—Pear Vicar of Winkfield.——*Stella.*—Yellow Pear is Broompark green, Vicar of Winkfield.

WOODS & FORESTS.

HOW TIMBER IS VALUED.

As "Y." withdraws (p. 531) one of the statements to which I objected, viz., that relating to a lot of Larch from this estate, which he alleged had been delivered in South Yorkshire for less than 1s. 1d. per foot, although he ignores my denial of the other, I do not see it is incumbent upon me to notice further his remarks. But to gratify his curiosity I may say that for the last lot of Larch, which I sold a few weeks ago, I got 9d. per foot in the wood. For the one previous to that in the same place, but not quite such a big average, I obtained 8d. per foot. These lots will contain about 8000 feet each of Larch, and are not selected trees, but a clearance of the woods. The cost of removal to the station, which is, of course, borne by the buyer, will be from 1¾d. to 2d. per foot. The trees are measured up to 4 to 5 inches diameter at the small end, and only quarter of an inch allowed off the girth for bark, excepting in a few of the largest trees, when half an inch is deducted. We allow 2½ per cent. discount on all our sales, which are cash transactions.

I am still unable to test "Y.'s" figures as to the cost of removal by rail, for although he professes to deal closely with "details," and invites me to follow him, yet he neglects to say to what station in the wide district of South Yorkshire this Scarborough (not Helmsley) timber was delivered! The cost of removal by road from the wood to the station is here between ¾d. and 3d. per foot, or rather less than what "Y." states in his first article.

"Y." also says (p. 531) that the "Larch growers in North Yorkshire depend largely for their market on South Yorkshire." Now, I can only speak authoritatively for the estate with which I am connected, and so far from what "Y." states being the case, the opposite is more in accordance with the facts. Only a very small proportion of our Larch is taken to South Yorkshire; nine-tenths of it goes north into the Cleveland district and county of Durham.—THE FORESTER ON THE DUNCOMBE ESTATE.

—— Before "Another Forester" indulged in remarks upon other people's "amusing simplicity" he would have done well just to have re-perused his own remarks before committing them to print, and tried to regard his own assumptions of wisdom with a grave face. His little lecture about the fluctuation of prices, a subject familiar to any butcher's boy, he delivers as if the things he writes about had never occurred to anyone before, and all his arguments are based upon that assumption. This is what I call simplicity pure and simple. As it is probable that "Another Forester's" sale transactions are much fewer and smaller than our own, unless they are amongst the largest in England, readers may be left to judge whether he or I know our business best. As to the subject under discussion, the price of Larch and its valuation in certain districts, I have only to say that I may be a trifle under or above in the carriage rates by road or rail and such like costs, but I am certain that what was left out of the shilling after these were paid was the price the vendor received, for there was no change in prices in the interval between the forester's and the merchant's sales, and the latter did not sell without a profit. There is no "wild guessing" in the matter at all, and "Another Forester's" wild surmises in that direction are therefore quite irrelevant. But the "reckoning-back" process is not my only ground of calculation. Some of the foresters in the localities referred to by me state both the number of trees and feet for sale, and in a sale that happened about a year ago I learned the exact amount of money the lots realised, and had only to reckon the average price per foot or ton straight off. It is no one's business, of course, as to what his neighbour sells at, but when one reads these long rigmaroles about the difficulties of valuing and knows at the same time what is actually going on, one is apt to lose patience. There is more Larch to be sold where the last came from, and which will probably soon be set out, so I may be able to give you further and more exact particulars by-and-by.—Y.

GATHERING AND STORING TREE SEEDS.

THE best seeds are of course produced by fully fertile, healthy, vigorous trees growing not too close together in a favourable soil and situation. Very young trees usually furnish a large proportion of barren seed, while very old or weakly trees yield seeds which are not only difficult to keep, but also produce weak plants. Seeds ought to be collected only when they are ripe; such as are not fully ripe when taken off the tree do not possess the germinative faculty in the same degree as ripe seeds, and, moreover, lose that faculty much sooner. The ripe fruits of some species hang on the trees for a considerable time, and such one need be in no hurry to harvest; but there are other species, the majority of the seeds of which, with or without the rest of the fruit, are shed as soon as, or soon after, ripening. Among these are several kinds of deciduous Oaks, Silver Firs, Birch, &c. The collection of such seeds evidently admits of no delay. Rainy weather ought, whenever possible, to be avoided for the collection of seeds, especially of such as are small; but this prohibition, as a matter of course, does not extend to such seeds as are to be sown at once, or, which comes to the same thing, as cannot under any circumstances be preserved.

Hand-gathering from the trees is the most costly method, but is the only one applicable in the case of small or light fruit, such, for example, as Elms, Maples, Ash, &c., or of small light seeds that escape from the ripe fruit still hanging on the tree, as those of the Deodar, Silver Fir, Birch, &c. The seed-collector must climb to the crown of the tree, with or without the help of a ladder, as he can best manage, and with a sack slung over his shoulder. What he cannot reach directly with his hand he must draw to within arm's length of himself by means of a hook attached to the end of a light, but strong sapling of sufficient length. Branches and branchlets break off less easily when drawn upwards than if pulled downwards; hence it is always advisable for the collector to climb up to the highest point he can attain and begin by plucking off the fruit hanging at the summit of the tree. Gathering seeds or fruits from the ground after they have fallen from the trees is economical, and applies especially to large, heavy fruit which fall more or less perpendicularly, and which do not break up and allow the enclosed seed or seeds to disperse. To facilitate the fall of the seed or fruit, the branches of the trees may be shaken.

When trees marked to fall within a year or so are chosen as the seed-bearers, it may be found inconvenient or impossible to fell the trees as soon as the fruit ripens. On account of the nature and small size of the fruit and seed, shaking the trees and picking the seeds from the ground may also be inapplicable, while hand-picking would be unnecessarily expensive, since there is no reason for sparing the fruit-bearing branchlets and twigs of such trees. The fruit may then be broken off singly or in bunches with the aid of a strong hook forming a sharp angle of about 30° firmly attached to one end of a long sapling. The inside edge of the hook should be sharp and serrated and slightly curved inwards. The hook should be passed over the fruit-bearing branchlet or twig at the point at which it is to be broken off, and jerked downwards; or, if that does not suffice, it should be twisted round once or twice, by which means the branchlet or twig, as the case may be, will be firmly caught in it and a single jerk will then suffice to cut the former through. Where small wood has no value, and there is no objection to thinning out the crowns of the trees, branchlets of a certain thickness may be cut off with a bill-hook, and the fruit then hand-plucked from them. Some trees produce bunches of fruit, the common stalk of which dries up at maturity and early disarticulates from the rest of the branchlet.

In the case of seeds having a thick and fibrous covering the rind must be torn off with the aid of special shears, and in the case of seeds included in a capsule or pod, or between scales, the quickest method, when practicable, is the application of heat, under the action of which the valves of the capsules or pods and the scales of cones open out or disarticulate, and allow the enclosed seeds to escape. In many cases simple exposure to the sun suffices; in others, however, a higher and more sustained temperature is required in order to bring about the full expansion of the seed vessel.

With seeds having leafy appendages, the wholesale removal of the appendages, except one by one with the hand, is not always possible without injury to the germinative power of the seeds; but whenever practicable, it should be effected. If the seed is hard or tough, friction, more or less rough, suffices to detach these appendages. When this is the case, a very expeditious method is to nearly, but not quite, fill a large stout sack with the seed, and to thresh these or work them violently backwards and forwards, according to the toughness of the seed, until the appendages are detached or crushed, when they can be easily separated by the ordinary process of winnowing.

The seeds of many trees have to be plucked before they are quite dry, in order to prevent their being disseminated and scattered far and wide. Other kinds of seeds contain a great deal of moisture even when they fall off naturally. Such seeds should be spread out not more than from 2 inches to 3 inches high in a dry, airy, sunny place, and turned over with a rake twice or thrice daily for a period varying with the kind of seed and the dryness and temperature of the weather. After this they should be piled up higher, the raking being continued as before, but being limited to only once a day. This latter process should go on until the seeds are sufficiently dry. Experience alone can tell when this is the case. It is needless to say that in cold weather the seeds should be removed under shelter while dew is being deposited. As regards seeds that are moist even when they are shed naturally, this drying is really the completion of the ripening process. W.

LIME AS A WOOD-PRESERVER.

A NOTE upon this subject in a recent number of the *Field* has interest as to the possibility of using lime extensively in preserving the more porous of our common wood, such as the Scotch and Spruce Firs. With any of the processes now in use there is really nothing to be done, as they can only reach large masses of wood, such as railway balks and sleepers, on account of the expensive plant which has to be laid down. If anything practical is to result in the direction of chemically preserving our common timber, it must be from an exceedingly simple and cheap process, one in which the apparatus can be constructed on the spot without skilled labour and from materials at hand. The *modus operandi* of the lime process is simplicity itself, and the materials are everywhere at hand. The only point is to be satisfied as to its efficacy. In the mind of the writer referred to this seems to be satisfactorily established, and he quotes an instance of having preserved some Scotch Fir in this way, and then using it in a mill-loft. This occurred in 1850, and the timber is still in a perfect state. If we had any data as to the length of time the Scotch Fir would have lasted under similar conditions if it had not been preserved, this evidence would have been very conclusive. As it is, it shows that Scotch Fir, so preserved, is as good after a lapse of nearly forty years as it was when put there. In weighing the merits and demerits of the system, an important question is the behaviour of the impregnated wood when exposed to the wet. To anyone looking at the subject from this point of view, it would seem natural that, by exposure to rain, in course of time the preserving substance would be gradually washed out by the same agency it was, in the first instance, soaked or washed into it. It is quite possible there are some readers of these pages who can answer this question from their own experience; if so, their evidence will be valuable. If lime-impregnated wood will withstand the action of the weather, then it opens up a new use for wood which has hitherto been at a great discount in anything like permanent structures. If Scotch or Spruce Fir boards, for instance, can be used for weather-boarding with a reasonable expecta-

tion that they will last for forty or fifty years, the introduction of the lime-preserving process will be a boon. As the length of timber taken up in charging the wood with the solution depends on the size or thickness of the scantling, the time occupied in preparing weather-board of an inch or less in thickness would be relatively very short. Before storing away the boards or scantlings in the pit or tank, it is obvious that it is very necessary that they should be cut into the exact form required for use, and in the operation of stacking in the pit should be so laid as to give the least possible chance of being bent out of shape or of warping. Joists or beams would occupy a longer time in getting thoroughly saturated, but this would be of little moment, as they would not be liable to get out of shape, and a few months can generally be afforded in getting material ready. If there are good grounds for believing it to answer for outdoor as well as indoor purposes, there is no reason why fence posts and rails should not be treated. Given a large water-tight tank or pond and a good supply of lime, which, when the quantity to be done is enough could often be burnt upon the place, there is nothing to be done but stack away the wood and supply the lime as wanted. There is just this about it, that arrangements will be necessary to empty the tank or pond preparatory to placing the timber in it, and also for filling it up with water when the wood is ready. A little ingenuity will, however, overcome this, as there are few places where some existing water supply cannot be diverted temporarily to serve such an end. It would not, I take it, do to allow a stream of water to run through the tank or pond, unless there were a series of reservoirs, as the waste of lime would be so great and the solution would never be at rest.

D. J. Y.

THE DOUGLAS FIR.

Abies Douglasi is now a well-known tree, and probably the most popular of the many excellent introductions of its original and ill fated discoverer, whose name it bears. The first appearance of the Douglas Fir in Great Britain, says Mr. Hutchison, was about the year 1827, when it was raised from the seeds of cones brought by Douglas from the banks of the Columbia River, where it abounds in immense tracts, covering the lofty hill-sides, and appearing near the summits of the Rocky Mountains no larger than a mere bush, and gradually increasing in its proportions until in the valleys and at the foot of the mountain ranges it attains a height of 200 feet, with a straight noble stem fully 10 feet in diameter. It is common also in California, and in Mexico a variety of smaller growth, and with longer leaves of a deeper green colour, is found. In Scotland this Fir has proved perfectly hardy, of very rapid growth, a most graceful tree for ornamental or park purposes, and a valuable timber producer. It has been planted in every conceivable soil and situation, and adapts itself to almost any description, provided the drainage of the subsoil be porous, so that it does not become "water-logged." It thrives at any elevation, and the only drawback is its tendency to lose its leading shoot in early spring, or liability to have it broken over by any bird alighting upon its sap-surcharged stem. This is, however, in a great measure only of secondary importance, for the rapidity with which the Douglas Fir repairs the damage is amazing; and we do not think, unless in very exposed open situations, where it is liable to receive the full force of the west and south winds, which are so prevalent in Scotland, that this tendency should be any detriment to its cultivation. There are many other important qualifications, superior to both the Laricio and austriaca, which the Douglas Fir possesses, and which will, we think, tend ultimately to its being preferred by planters generally. While we can hardly point to a single specimen of either of the two former-named Pines of 50 feet or 60 feet in height in this country, we have instances of the Douglas in many places throughout the country of fully that size. At Dropmore, where one of the original seedlings is luxuriating in a naturally poor soil, this noble tree has already attained an altitude of over 100 feet! In many other situations, both in England and Ireland, we find it, not certainly of the great height of the famous Dropmore tree, but of large tree dimensions, and in all kinds of soil, from sandy light porous earth to deep heavy loam and clayey subsoil. Many instances might be cited showing the adaptability of Abies Douglasi to all sorts of soils and situations in Scotland. The tree at Baith, near Kirkcaldy, in Fife, planted by Douglas himself, is now a grand specimen, and grows within the influence of the sea-breeze, though in a somewhat sheltered site; and inland, on poor soil at Dolphinton, Lanarkshire, at nearly 1000 feet above sea-level, it is thriving in quantities. When young the bark of the Douglas Fir is covered with numerous small blisters surcharged with highly aromatic and resinous sap, and breaking one of these, in passing through amongst a group of plants, quite perfumes the air, around. As the tree grows older, the bark becomes dry, and of a greyish and rough appearance, quite different from the younger stages of its growth. The wood is reported to be very durable, tough, elastic, beautifully grained, and susceptible of a high polish. No doubt the utility and beauty of the fibre of the wood in old specimen sections point it out as suited for either constructive or decorative purposes; and the beauty, symmetry, and gracefully branching habit of the dark green-clad branches and side shoots, combined with its rapidity of growth, render it equally well adapted in the live state for either ornament or profitable planting.

SEASONABLE WORK.

When the weather is dry and open, seeds of most hard-wood trees may be sown in the nursery, choosing a piece of well-worked pulverised soil for the purpose. Young seedlings of Elm, Oak, Ash, Sycamore, &c., may be transplanted from the seedling beds into nursery lines, and cuttings of all deciduous trees should now be put in.

As the different plots of ground are cleared of young trees, lose no time in having the ground dug into rough ridges, which will not only keep it dry, but also expose it to the influence of frost, which will renovate and prepare it for the next crop. In places where the soil is of a poor, thin nature, take advantage of frosty weather to cart and apply a dressing of good loam, in order to improve it. Turn over compost and manure heaps, so that they may be ready when wanted.

Gather cones of the Larch and Pine tribe, which, as a rule, are generally ripe at this season. The cones of the following species are, however, improved and ripened thoroughly after severe frost, which has the effect of changing them from a green to a yellowish brick colour, namely, the Scotch, Austrian and Corsican Pines, Pinus romana, P. contorta, P. Pallasiana, P. muricata, P. Pinaster, P. Hamiltoni, P. Pinea, P. Pumilio, P. pyrenaica, &c. The cones of P. romana, though of a large size, are always hid among its dense foliage, so that a person may pass the tree and never observe them, except by searching for them. The seeds may be extracted from the cones during weather that is unsuitable for outdoor work, and kept in a dry place till wanted in spring. In collecting Larch cones it is a matter of importance to gather only such as are produced by fine, well-developed, healthy trees, and any small cones less than medium size should be rejected, as the seeds of such are small, and produce inferior plants.

As the buds of the Hawthorn expand at an early time of the year, no time should be lost in finishing the formation of new Quick hedges, and filling up blanks where necessary, before the buds begin to swell. Finish planting ornamental hedges as soon as possible; any of the following list of plants are suitable for such a purpose, and may be used according to taste: Holly, Yew, Berberis Darwini, Cotoneaster Simonsi, C. buxifolia, Evergreen Privet, Portugal Laurel, common Laurel, Laurustinus, common Box, Arbor-vitæ, Sweet Bay, and Sweet Brier.

In woodland work, take advantage of mild, open weather to push forward planting operations as vigorously as is consistent with the proper execution of the work. All dry, warm soils should be planted in autumn, but stiff argillaceous soil and deep peat bog which retains an excess of moisture had better not be planted till spring. On such situations Black Italian Poplar, Goat Willow, Huntingdon Willow, Bedford Willow, Alder, and Birch may be planted with success, and as there is always a demand for this class of timber, it soon turns into money. I have sold Alder at 20s. per ton—the purchaser undertaking delivery from the plantations himself—the size of the timber being not less than 6 inches in diameter at the small end of the tree. Birch at 12s. 6d. per ton for all shapes and sizes, from branches of half an inch in diameter up to any size. Such being the case, I think proprietors of waste bogs, that produce nothing but Heather and Bog Myrtle, should have them drained and planted at once, and in doing so they would only be consulting their own interest and that of their family.

In addition to the hard-wood trees named above, and in cases where it is desirable to get up cover, the following Conifers may be introduced with the most good results, namely, Scotch and Austrian Pines, Pinus Pinaster, P. Pallasiana, P. Pinea, P. excelsa, P. Cembra, the Norway, Douglas, Black American, and Oriental Spruces, Chamæcyparis of kinds, Cupressus Lawsoniana, Thuja gigantea, and Sequoia sempervirens. These are a few of the hardiest, but the list is by no means exhausted of trees which we have found to thrive on peat bog. In planting these trees my practice has always been to mix a small quantity of soil with the bog at the time of planting.

One of the principal occupations of this month will be the felling of heavy timber when hands can be spared, and in doing so use the cross-cut saw in preference to the hatchet, which will not only prevent unnecessary waste of timber, but also give the timber a better and more marketable appearance when put up for sale.

Continue the thinning of young plantations, and allow plenty of room for the development of the trees in early life, which will be in their favour in after years. In the case of Fir plantations, collect a quantity of branches in an open place in the vicinity of the wood to be left as a trap for the Pine beetle and Pine weevil, which will begin to breed among them in April, and, as soon as they are observed to commence their sub-cortical burrows, the whole should be burned up, which is a wholesale way of getting rid of these pests. As the woods and covert, in most cases, will now have to be shot through, all drains and ditches should be examined, and such as are in want of scouring or repairs of any kind can now be done without disturbing the game. Gather leaves from roads and walks, and store them up to rot for future use. Newly planted ornamental trees and shrubs should be properly fenced and tied, to prevent wind-waving; likewise a good mulching round the roots will be beneficial. In the case of newly planted half-hardy trees, protection should be provided for such in a time of hard frost—a few branches stuck in round the plants will often prove invaluable in severe weather.

J. B. W.

Abies Nordmanniana.—If Abies nobilis is the best of the new Californian Silver Firs, this is undoubtedly the finest of the European or Asiatic species. It is likely at no distant date to supplant the common Silver Fir for ordinary planting, the timber being of better quality, and as it starts later in growth it is less apt to be injured by late frosts. Its growth is rapid and symmetrical, and the foliage of a bright grassy green, which has a very cheerful effect in mid-winter. The colour of this tree varies at different hours of the day; the leaves, which in sunshine spread out and show the green upper surface, curve upwards when the sun is off them, and show the silvery lining.

Acer platanoides Schwedleri.—The merits of this Maple are, I consider, over-estimated. Its peculiar characteristic, viz., its colour, should be as constant as possible; whereas, in this case the bronzy hue of its new leaves lasts only for a very short time. It usually makes its growth in the spring very rapidly. When the leaves first unfold their colour is deepest and brightest, but this quickly passes away, and they gradually acquire a dusky, unpleasant brown hue, and finally a dirty green, and, besides, the leaves are rarely perfect, often having broken edges, a peculiarity for which I can scarcely account. I think we are often much too prone to neglect old friends for new ones.—S.

No. 788. SATURDAY, Dec. 25, 1886. Vol. XXX.

"This is an Art
Which does mend Nature: change it rather; but
THE ART ITSELF IS NATURE."—*Shakespeare.*

BOARDED GARDEN WALLS.

HAVING had some little experience both as regards the erection and utility of wooden walls, I can endorse all that "T. B." (p. 568) has said in their favour. Where money is plentiful and every part of a domain must be in keeping, by all means build substantial brick walls, and do not forget to cope them well; but where cash is scarce, or where the owner is unwilling to be convinced that the light will pay for the candle, no one need despair, as the finest Peaches and Pears can be grown upon timber fences. My first experience of walls made of deal boards carries me back a little over thirty years to a delightful spot made highly interesting, and I should think, profitable, by Mr. Niven, of the Garden Farm, Drumcondra, near Dublin. Foreign timber at that time being much dearer than it is now, that highly intelligent horticulturist set up stout sawn Oak posts and rails and nailed thin deal boards against them, making when finished most excellent walls about 6 feet in height. Fruit trees of all kinds did well, but what struck me most was the collection of young Vines which Mr. Niven grew against them, just such canes as any Grape grower would be delighted to have for stocking his vineries. These Vines, to the best of my recollection, were struck from eyes on open-air hotbeds, and planted out the following spring on slightly raised banks, resting at the foot of walls facing full south. The canes were the thickness of one's smallest finger; short-jointed, bright as gold, and models of what first-rate Vines for planting should be.

Convinced in my own mind that warm resinous timber was an excellent as well as a cheap substitute for brick, an opportunity a few years later enabled me to put Mr. Niven's system into practice at Eastnor. The walls here built of brick and flued, upon which Peach growing had been indifferently carried out, were not more than 9 feet in height; consequently the knife as well as the spade came into use soon after the trees got into bearing. Strongly opposed to restrictive training, I made up my mind to add a cubit or two to their height, but finding these old hollow foundations would collapse under an additional weight of bricks, I took off the coping and raised the wall with 11-inch deals, one on each side set on edge and well spiked to blocks to keep them in position. In this way I have made an excellent Peach wall over 12 feet in height, and when I state that I think of adding another deal, your readers may conclude that my crops of fruit are satisfactory. From a south wall I turned my attention to an old limestone boundary wall, well capped or coped with Ivy, but too cold, although facing full west, for Plums to ripen well upon it. Brick facing was suggested, but for certain reasons I decided upon using rough, unplaned red deal boards three-quarters of an inch thick, which I can buy in Gloucester at 8*s.* 6*d.* per 100 feet. Home-grown Oak was used for light posts and rails; an 11-inch deal forms the cap and a very important part of the structure, and my first twenty yards of almost useless limestone now ripens good Peaches and Nectarines with this advantage, that any given variety is about two weeks later on the west than it is on the south aspect. For training purposes these boarded walls are admirable, and where large numbers of young trees are grown in nurseries surely these shelters would soon pay for themselves, as a man would nail in half-a-dozen trees whilst fixing the stakes and crosspieces on the old, I may say present, cumbrous system.

Again, in these days and within a week's steam of Canada, what grand cordon Apples and Pears might be grown upon them. Indeed, so satisfied am I with the plan, that I now have another 60 yards run of stone wall in hand, also facing the west, specially for Peaches. "T. B." suggests iron posts, but the rails must be of wood, and I question if good Oak would not be the best for posts also. Then, again, he recommends gas tar, but, excellent as this material is, it must be used with care, otherwise mischief may follow, and few, I think, would care to look upon walls of this sombre colour. There are, of course, exceptions to every rule, but in the majority of old places we find the warm lichen-grey or warm brick-red colours prevailing, and it has always been my practice to make new work blend with the old, by the use of colours with lime and oil or Russian tallow for the foundation. Lime in itself is an excellent wood-preserver, and when good linseed-oil is added, Venetian red, red lead, soot, and other materials for giving tone and colour may be added. This I have always used, and although my first deals are resting on their edges, apparently they are as sound as when first put up more than ten years ago. This is not, however, the best position for timber that is exposed to the weather, neither is it the most convenient for fixing new fences. The first thing to determine is the height, and when the skeleton framework has been securely fixed, the boards should be nailed on in a vertical position. Narrow boards, say 9 inches in width, answer better than wide ones. The ends should not touch the soil, and a broad, throated or undergrooved cap-board, 1½ in. thick and 11 in. wide, should always complete the structure. W. COLEMAN.

Eastnor Castle, Ledbury.

Snowdrops.—When the wind suddenly veered round to the south-west on the shortest day, and the snow vanished from the flower borders, the one thing which caught my attention was the sudden growth of the Snowdrops. They are now almost an inch above ground, and the sight of their soft grey leaves is most cheering. The popular French name of Pierce Neige is quite justified by the habit Snowdrops have of growing at a low temperature, and especially when the ground above them is covered with snow. After all, there is often, and always in the best of popular names, a deep-laid truth or meaning. Not only does the Snowdrop grow rapidly under the snow, but the converse of this is true also, as anyone who has tried to force Snowdrops in artificial heat will tell us is a fact, all of which simply points an old moral, and shows us somewhat of the varied idiosyncrasies of plant life in the garden. I think it was the sight of Mr. Alfred Parson's Salon picture of "The First Frost" to-day which set me thinking of the waning year. Like all good art, it is simple and true. It is only an old Horse Chestnut tree with uncropped, drooping boughs hanging over the reedy margin of a lake or pool; but a slender, fur-clad figure in black walking over the carpet of its ruddy brown fallen leaves tells the tale. So also in the garden all art should be true and simple, for a garden worth the name contains far more than the mere beauty-worshipper or the economist can express for us. It contains, indeed, a world of sympathies peculiarly its own. Now-a-days it is not uncommon to find our best artists interested in gardening and expressing therein some of their finest thoughts. Art effected by the spade may be as precious, even if not as endurable, as that of the chisel, or the brush, or the pen. A garden supplies food to our minds throughout all our varying moods and phases of feeling; it gives us Laurel wreaths or Cypress boughs for the old who precede us, as well as bridal garlands for the young who remain. Above all, do I object to the popular notion that a garden, because flowerless, is necessarily uninteresting. A good garden is full of buried hopes and glorious resurrections; of swelling bulbs and rooting seeds of a thousand kinds; it is, indeed, the birthplace of miracles, which would be even more wonderful if less common, or if we had the power of seeing and of understanding the full and true value of simple things.—F. W. B.

SMALL GARDENS.

THERE is no doubt whatever that small gardens, when planted and attended to with intelligent care, yield more real pleasure even than many large ones. A few weeks ago I visited that of Mr. P. H. Rooke at Weybridge, and certainly no garden of equal size has ever afforded me so much interest as this did. It was designed and planted by himself; it contains a few glasshouses, a fernery, and an arboretum, in which are some fine Conifers and flowering shrubs, bordered by herbaceous plants, Bamboos, Arundos, and similar vegetation, the whole forming a pleasing combination of tree, shrub, and flower life. Amongst other matter I noticed a fine example of Magnolia grandiflora, about 16 feet high and 10 feet across, the branches of which sweeped the ground. Taxodium sempervirens and variegated Hollies formed distinct features. Penetrating the arboretum by means of small winding paths, we found some grand masses of hardy Ferns, such as Scolopendrium vulgare and its varieties, crispum, crispum lætum, cristatum, and others; Cystopteris montana, a mass of fronds a yard or more across; Polystichum aculeatum plumosum, Lastrea Mapplebecki, Polypodium vulgare trichomaneoides, several very rare varieties of Athyrium Filix-fœmina, all large and well-grown specimens. Each plant of the Scolopendriums if taken up would fill an ordinary wheelbarrow. Emerging from this shady hardy fernery, we find clumps or belts of trees flanked by herbaceous plants, and in a delightful dell were massive specimens of some of the very rarest of hardy Ferns —Mr. Rooke's special favourites. These grew through an undergrowth of Ivy, which set them off to excellent advantage. Beyond this lies the rock garden, in which are many fine examples of rock plants—all beautiful and some rare. Amongst others which I noticed doing well were Androsace sarmentosa, Saxifraga oppositifolia, Meconopsis simplicifolia, Arnebia echioides (the Prophet flower), Polygala Chamæbuxus var. purpurea, Cistus crispus, C. formosus and C. algarvensis. Associated with these were perfect carpets of Acæna Novæ-Zelandiæ, Omphalodes verna, Hypericum reptans, Alyssum alpestre, Pelygonum vaccinifolium, Thymus thuriferus, Arenaria montana, Erysimum alpestre, and Helianthemum tomentosum. Some of these were from 1 foot to 3 feet across. Ramondia pyrenaica was growing here nicely, as were also Lithospermum petræum, L. prostratum, Erica Maweana, and many others. Gentiana verna was really good—better in fact than one is accustomed to see it in the south of England. Another feature to which Mr. Rooke drew my attention was a large bed of Vincas; with these, though highly interesting, Mr. Rooke wished to plant something to break the monotony and to give colour at different seasons of the year. He therefore inserted 4-inch pipes 2 feet long in an upright position, and filled them to the top with good loam. In these were planted double Whin, Genista hispanica, and various species of Cistus. These have now grown into large bushes, and hang down over the sides of the pipes sufficiently to conceal them, an arrangement excellent as regards effect, especially when the various shrubs are in blossom. Another matter to which Mr. Rooke pointed with evident interest was some large tubs or barrel ends, that is, a barrel sawn in two. In these were grown Cypripedium spectabile, C. Calceolus, Orchis foliosa, Montbretia Pottsi, &c. The tubs are furnished with handles, and when the plants are in flower they are carried

to wherever they may be wanted, either indoors or out. When the flowering season is over they are again removed to their winter quarters, plunged in ashes, and well top-dressed with manure. The plants have now been in the tubs for many years, and better examples of good growth could not be desired. R. P. Y.

NOTES OF THE WEEK.

Stephanophysum Baikiei.—This useful West African plant for winter decoration does not find so much favour as it deserves, because it is not serviceable in a cut state. It is a shrubby plant, with opposite, somewhat square branches, and roundish, lance-shaped, dark green leaves. The flowers, which are borne in large terminal panicles, are tubular, scarlet in colour, and upwards of 2 inches in length. This plant should be grown from cuttings struck every spring. It comes from low districts bordering on the river Niger.

Catasetum Bungerothi.—This new Catasetum is now flowering for the first time in this country with Mr. F. G. Tautz, Studley House, Shepherds Bush. It is at once the largest and most interesting representative of this singular genus. Its large, thick, fleshy, ivory-white flowers have just a tinge of green pervading the sepals and petals; the lip is ivory-white, cordate in front, with a deep, round cavity at the base lined with orange-yellow. The individual blooms measure upwards of 4 inches across.

Ruellia Herbsti.—We have recently seen this fine old plant in bloom in several suburban gardens, and few plants are more beautiful, chaste, or bright than it is in a cool stove in mid-winter. It is somewhat shrubby, the branches bearing on their summits large heads of rosy purple, tubular blossoms of peculiar shape. The leaves are deep green on the upper surface, ornamented on each side of the midrib with a conspicuous feathery white border, the under part being red. Like the majority of Acanthads, this forms a more handsome plant when young from cuttings struck annually than when older, and these young plants, moreover, produce the greatest quantity and the finest flowers. It was figured in the *Botanical Magazine* under the name of Dipteracanthus Herbsti. Its native country is unknown.

Dendrobium Dearei.—Some time ago one of your correspondents noted how long this fine Orchid remains in bloom. If I remember rightly, it was stated that for sixteen weeks the blooms had remained fresh. I have now a plant of this Dendrobe in flower, and two of the spikes on it opened in the second week in July last, now over five months ago, and it was only within the last week that they began to show signs of fading. Flowers of such purity, substance, and endurance are most valuable, and a striking contrast to the fleeting beauty of some of the evergreen Dendrobiums.—J. T. Pcë, *Riverston*.

The great Christmas Rose.—If there is one flower more than another to which the title of "December's Glory" might rightly be applied it is the Christmas Rose (Helleborus niger), and most especially is it applicable to that form well named maximus, and sometimes called the Scotch variety. The flowers are produced in twos or threes on stout, erect stems, fully 8 inches long; they are 4 inches across at least, and, rising well above the soil, in addition to the natural protection afforded by the autumnal leaves lying on the surface of the ground, the broad expanded cups of lovely whiteness remain unsullied by even a speck of the closely adjacent soil. I ought to mention that the flowers do not all expand at one time, but follow each other in rotation. The foot-stalk is of a lovely marbled pink colour, which colour, by the way, expands in gradually softening tints over the entire upper portion of the sepals, giving to the flower, as viewed externally, a charmingly delicate roseate hue that is never met with in the old species. Added to the colour and magnitude of the flowers, we have equally distinct characteristics as regards foliage. The leaves are double or treble the size of the old species, supported on long, stout foot-stalks, and remarkable for the broad, deflexed character of the lobes—so distinct, in fact, is the plant in every way, that I have no hesitation in saying, were it a new introduction, it would receive at the hands of our descriptive botanists a distinct specific title, and none could be more appropriate than Helleborus maximus, omitting the niger altogether. When pure and unsullied there is no more lovely flower for the decoration of the hair than this Christmas Rose, and not one in a ball-room would ever suspect its humble origin. Though I have written thus enthusiastically about this variety, I do not for one moment wish to disparage the old species itself, or its narrow-leaved form; though blooming a little later it still comes, and comes naturally, at a time when it has scarcely a rival. It is one of the few legitimate December-flowering plants that are able to stand all sorts of weather.—G.

New plants at Ghent.—At the last monthly meeting of the Horticultural Society of Ghent (held on the 15th inst.) certificates of merit were awarded to the following: To M. A. D'Haene for Calanthe Veitchi rosea alba; to M. Louis Van Houtte for Cypripedium Leeanum and the variety superbum; to M. Jules Hye for Cypripedium caudatum roseum splendens, C. politum and C. Lawrencianum, fine variety; to MM. Boelens frères for Odontoglossum Alexandræ album, and Dracæna fragrans aurea lineata from M. Louis Desmet-Duvivier. Cultural certificates were awarded for Tillandsia tessellata from Madame Ve. Van Acker-Maenhout, Cycas circinalis from M. B. Spae, and Restrepia antennifera from M. Jules Hye. Honourable mentions were accorded to M. Jules Hye for Cypripedium tonsum, and C. sylhetense from M. Jules Hye, and Cycas sinensis from M. Spae-Vander Meulen.

Calanthes.—These beautiful deciduous Orchids may now be seen in perfection at The Dell, Egham. The varieties grown are Veitchi, a very deep rose strain, the finest we have seen; vestita rubra and vestita oculata, two charming kinds—these in all cases have developed some extra fine spikes, on which there are on an average from thirty to forty flowers. Success, says Mr. Ballantine, is mainly due to giving the plants extra heat from the time when the spikes begin to show themselves until they are in full bloom and keeping them much drier than usual; very little water is given during the flowering time; the flowers expand much brighter and larger when kept dry. C. ignea oculata gigantea, a noble variety, was also flowering in the same house. Its flowers are large, creamy white, double the size of those of the ordinary vestita with a rich ignea eye. This Calanthe has been flowering since the beginning of July—over six months; surely a Calanthe of this duration and with its fine flowers must be an acquisition, and when better known largely grown.

Christmas Roses.—These are now attracting attention, for the niger forms are in full bloom, and later on we shall have many fine hybrids in bloom. These crosses are generally between Helleborus abchasicus and H. guttatus, and also between H. orientalis and H. niger. Of the types, perhaps, H. niger maximus is the best. It grows 2 feet in height, and has large white flowers 4 inches or 5 inches in diameter, but requires, as do all the varieties, to be well established before it is seen to advantage. There is also a small variety of H. niger (H. n. minor), but it is scarcely worth growing, excepting in large collections. H. orientalis is a good kind, with pale rose-coloured flowers. The leaves are deciduous and appear with the flowers, and are much divided. H. abchasicus has green flowers, with pale yellow anthers, and requires a well-drained soil and a sunny situation. H. atrorubens has purplish flowers, and does not bloom until late in March; whereas the other kinds are generally in perfection by February. H. purpurascens resembles a dwarf form of the preceding, and does not attain the height of more than 6 inches or 8 inches. The blooms are purple (as also are the stems) with white stamens, and they measure about 1½ inches across. An interesting winter garden may be made with the different species and hybrids of Christmas Roses alone, but we must bear in mind that we cannot see them in perfection except when permanently established, and I should say that they require at least two years to become so. I hope that these Christmas Roses (blooming as they do when there is nothing else) may have more attention paid to them, particularly as they force well, in addition to their other good qualities.—O.

The public gardens of the world.—The last report of the Montreal Horticultural Society contains a list of the chief public gardens of the world. This list (see pp. 594-5), which we have revised, will no doubt be useful to many of our readers. The report states that a classification of the countries of the world, according to the number of gardens they support, would give the following:—

Germany	36
Italy	23
France	22
Russia	16
Austro-Hungary	14
Great Britain and Ireland	15
Hindostan	7
Scandinavia	8
West Indies	6
Belgium and the United States	5 each.
Australia and Holland	4 ,,
Cape of Good Hope, Portugal and Switzerland	3 ,,
Denmark, Roumania and Spain	2 ,,
Algeria, Brazil, Canada, Canary Islands, Caracas, Ceylon, Chili, China, Cochin China, Ecuador, Egypt, Greece, Guatemala, Guiana, Island of Reunion, Japan, Java, Malta, Mauritius, Natal, New Zealand, Peru, Philippine Islands, Servia, Siberia, and Tasmania	1 ,,

It will be also interesting to see, from the following classification, how far each of the nations of the world is responsible for these gardens:—

England and Colonies	42
Germany	36
France and Colonies	27
Italy	23
Russia and Siberia	17
Austro-Hungary	14
Scandinavia	8
Belgium, Holland and Colonies, Spain and Colonies, United States	5 each.
Portugal, Switzerland	3 ,,
Denmark, Roumania	2 ,,
Brazil, Chili, Ecuador, Egypt, Greece, Guatemala, Japan, Peru, Servia	1 ,,
Total	206

The Veronica which I showed before the floral committee at South Kensington on the 7th inst. excited some interest owing to the flowers and foliage having stood 17° of frost. I was asked to get the correct name of it, as the one I had it under, V. salicifolia, was disputed. A spray was therefore sent to Kew to Mr. Baker, and he has kindly named it, saying that it will not pass muster for a form of V. parviflora, but considers it to be V. ligustrifolia of Allan Cunningham.—George F. Wilson, *Heatherbank, Weybridge Heath*.

Cutting off green leaves.—It is a mistake to cut off the top of any plant as long as it has any vitality in it. In the case of bulbs and tubers, if I am compelled to lift them before the tops are quite dead, I always leave the tops full length, for I am convinced that the leaf-sap goes into the bulb and strengthens it; in fact, one has only to compare the size and weight of bulbs lifted early in autumn and those left as late as possible, to be convinced that it is the descending sap that aids the growth of the bulb, for it swells but slowly while in full leaf growth.—J. G. H.

Japan Anemones.—As a contribution to the Japanese Anemone discussion, I wish to say that I think the Japan Anemone must have been known in England before 1845. Some relations of mine of an old Devonshire family have a set of crewel-worked curtains, said to be more than 100 years old. Upon them are worked all sorts of flowers, some highly conventional, others true to Nature. Among the latter is what can only be a Japanese Anemone, the red kind; leaves, shape of flowers, stamens, and growth are all like it. As William III. landed at Torbay, might not some of his Dutch followers have introduced it, as the Dutch knew Japan before that time?—A. J. C., *Twyford, Berks*.

Camellia Sasanqua (*S., Guernsey*).—All three specimens represent varieties of C. Sasanqua, an uncommon plant in this country. The white is less rare than the pink. We have not before seen the variety with white flowers tinged with rose.

A NEW ORLEANS GARDEN.

About gardening in New Orleans, and about our own garden in particular, I am sorry to say there is not much to record. Ground being very cheap here, all the best residences, the majority of which are wooden, are built upon large "lots," measuring each from 80 feet to 125 feet in front by 160 feet to 250 feet in depth, and in some cases much more. This arrangement allows free ventilation and sunlight, and sufficient space for town gardening where people choose to take advantage of it. There have been but few attempts, however, at artistic effect; on the contrary, the grounds are planted in the most desultory manner, the main effect being apparently to get as much into them as possible. Notwithstanding, the general effect of these "wild gardens" is decidedly pleasing, and, in consequence, New Orleans has a wide-spread reputation for beauty, in addition to the quaint picturesqueness of the French quarter, about which so much has been said. As our winters are generally short and mild, and the atmosphere quite moist, vegetation is strong and rapid in its progress, so that in two or three years new dwelling-houses, which are never more than two stories high, become imbedded in dense verdant thickets, which, but for the saw and shears, would soon crowd these structures not only out of sight, but occasion speedy ruin and decay.

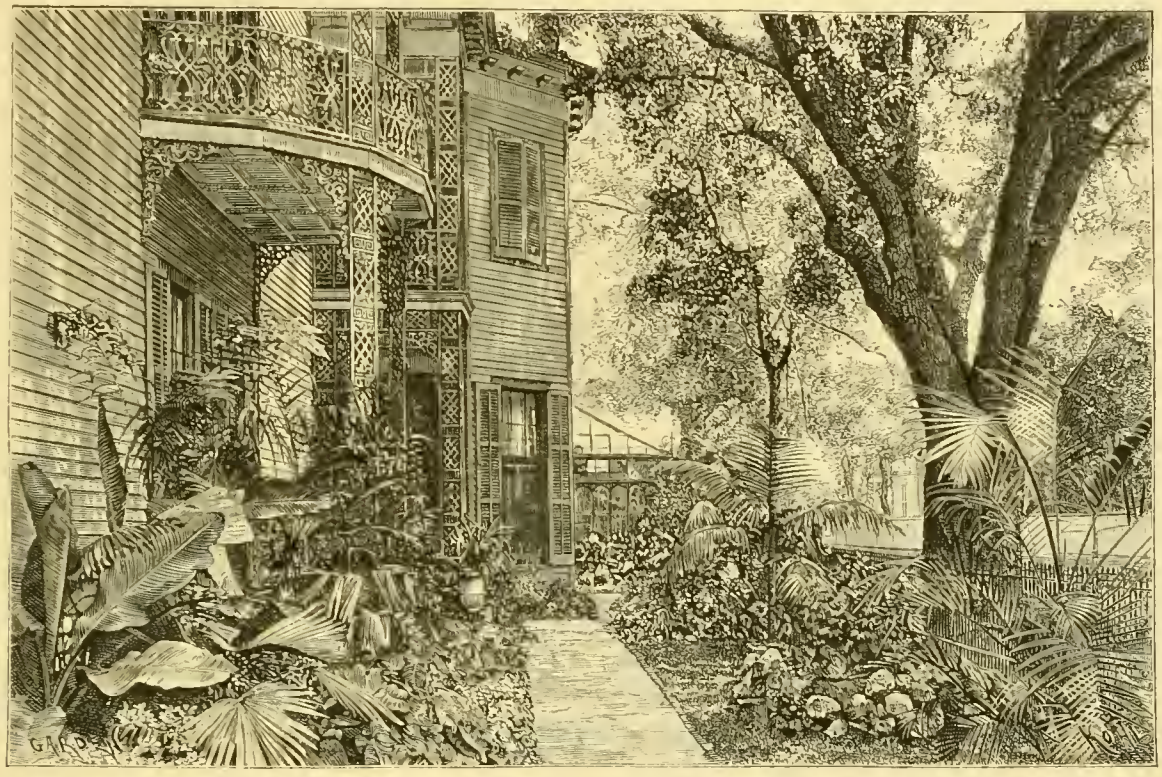
Our shade trees are for the most part natives, such as Oak (several species), Cypress, Elm, Catalpa, Sweet Gum (Liquidambar)—probably the most beautiful of all—Plane, Hackberry, Magnolia grandiflora, Pine, Cottonwood, &c.; to which may be added, of foreign introduction, Tallow Tree (Stillingia sebifera), Privet (Ligustrum japonicum), Pride of India, or China (Melia Azedarach), Japan Varnish (Sterculia platanifolia), and Ailantus. For ornament the Orange tree is in general use, especially the bitter species, which is not only somewhat hardier than the edible Orange, but holds undisturbed possession of its beautiful fruit from one season to another. In addition to Oranges we have Palms, of which there are three indigenous species, and about as many more from abroad which are equally hardy; also Pittosporums, Magnolia fuscata, Oleander (pink, crimson, purple, lilac, and white-flowered), Sweet Olive, Smoke Tree, Laurustinus, Chinese Azalea, Bottle-brush, Castor-oil, Camellia, Crape Myrtle (Lagerstroemia—crimson, rose, lilac, and white-flowered), the prince of all flowering trees; Cape Jessamine (Gardenia florida), Pomegranate, Yucca, Cycas revoluta, Banana, Bamboo, Poinsettia, Agave, Acalypha, Alocasia, and others too numerous to mention.

In regard to my own garden, after several years of unsatisfactory work, I laid it out upon what is sometimes called the French system, *i.e.*, in circles and in portions of circles, and it has proved to be quite a success. It has no walks, the result being a long, unbroken sward,* which, besides its intrinsic beauty, deepens the perspective, and adds very greatly to the effectiveness of the water, rockery, and tree plantation in the rear.

For flowering plants we rely mainly upon Roses, more especially Teas, all of which flourish in the open air without protection, and the display of colour which they produce in March, April, and May is truly magnificent. Even now and until Christmas an abundance of blooms may be cut for house and table decoration. Besides Roses, Cannas—of which Ehemanni is by far the best—Crinums, Hydrangeas, Chinese Hibiscus, Lantanas, Abutilons, Plumbagos, Chrysanthemums, and a host of others with which readers of The Garden are familiar adorn the borders. For bedding purposes we rely principally upon Pansies, Anemones, Phloxes, Gladioli, and Hyacinths for early spring; Portulacas, Pelargoniums, Petunias, Torenias, Salvias, Asters, Balsams, and Coleuses for summer; and Chrysanthemums, Dahlias, Zinnias, &c., for autumn and early winter. At present (Nov. 20) the garden is all ablaze with Roses, Zinnias, Alternantheras, Acalyphas, Poinsettias, Chrysanthemums, Acacia corymbosa, perennial Ipomæas, Antigonums, annual Thunbergias, Manettias, &c. For covering trellises and verandahs, we make another large draft upon Roses, such as Maréchal Niel, Solfaterre, Lamarque, Queen Henrietta, Gloire de Dijon, Ophirie, and Perle des Jardins; but in addition to these much use is made of Rhynchospermum jasminoides, Solanum jasminoides, Wistarias, Bignonias, Clematises, Antigonums, Honeysuckles, Ipomæas, and Aristolochia elegans. The seed of the Aristolochia was received by Mrs. Richardson some years ago without any name, and has been extensively cultivated ever since. It requires but little protection in winter, and when killed to the ground shoots up again early in spring.

In our pond, which is cemented, we grow several species of Nymphæa, of which devoniensis and rubra are probably the most satisfactory; also Nelumbiums (speciosum and luteum), Pontederia crassipes, Limnocharis Humboldti, Pistia, and Trapa. The last, in consequence of its very rapid development, has to be cleared out every few weeks. Last season we succeeded in flowering the Victoria regia without artificial heat, the young plant having been started in the propagating house, and transplanted early in June.

For some years past I have been endeavouring to acclimatise some of the sub-tropical Palms which grow at considerable altitudes in their native countries, and thought that I had succeeded in adding quite a number to our old list until



View in Dr. Richardson's garden, New Orleans. Engraved for The Garden from a photograph.

* Our best lawns consist of Bermuda Grass (Cynodon Dactylon?), which forms a beautiful turf, but unfortunately loses its leaves by the first frost. Has its seed ever been discovered?

last winter, when the extreme cold which we experienced wrecked all my hopes. Only one genus (Sabal) is indigenous to this locality, and of this we have two species, Adansoni and serrulata; to this may be added S. Palmetta and Pritchardia filifera, which belong to the same latitude, the former in Carolina and the latter in California. Two species of Chamærops, excelsa and Fortunei, and Phœnix dactylifera were naturalised long ago, and of late years Cocos australis has also been found to be quite hardy. To these I had added Phœnix tenuis, sylvestris, reclinata, canariensis, spinosa and rupicola, Sabal Blackburniana, Jubea spectabilis, Corypha australis, Latania borbonica, Kentia Belmoreana, and Rhapis flabelliformis, and by means of such protection as was afforded by stuffing Spanish Moss (Tillandsia usneoides), which hangs in such profusion from our forest trees, between the petioles so as to envelop the crown, all went well for some time. Phœnix reclinata and canariensis and Latania borbonica had already attained considerable size, the former furnished with a trunk 5 feet high by 2½ feet in diameter, and the latter with one 3 feet by 12 inches—the admiration of every passer-by. Many of our neighbours, profiting as they supposed by our successful experiment, made similar plantations upon a smaller scale, and therefore the part of New Orleans in which we reside had begun to assume quite a tropical appearance. But, alas! for all our joys and hopes, on the 8th of January, 1886, there came from the far-off Rockies in the north-west a "blizzard," which carried death and destruction not only to all delicate and half-hardy vegetation, but also destroyed many of our indigenous trees and shrubs, and even extended its ravages into countries ten or twelve degrees south of us, destroying some large plantations of Coffee trees on the east coast of Guatemala. The thermometer registered 12° Fahr., and the ground remained frozen for a week—a circumstance which had not happened along this coast before for more than sixty years. It was not until the weather became warm that we began to realise our losses, and, in some cases, not until the following spring. Suffice it to say, there now survive one Phœnix canariensis, two large Sabal Palmetta, two Chamærops, one Cocos australis, one Jubea spectabilis, and several small Sabal Adansoni and serrulata. Although greatly discouraged, yet, hoping that we may not live to experience such another visitation of northern weather, we have inaugurated another similar experiment. I ought to say, in praise of the Sabals, Chamærops, Cocos, and Jubea, that they stood the severe trial without any protection whatever.

The length to which my remarks have already run forbids even the enumeration of other plants which succumbed to this terrible frost. The death of four-fifths of all the Orange trees in this neighbourhood was, of course, the greatest loss, both on account of their economic and decorative value. T. G. Richardson, M.D.

NOTES.

Flowers of December.—Up to the second week in December we could have made sure of plenty of outdoor Chrysanthemums and other flowers, and even yet with hoary Garrya leaves, each shoot tipped with its soft grey tassels, Smilax sprays, and the berries of the Spindle Tree (Euonymus europæus), the fruit and flowers of Arbutus, purple Ivy leaves (Hedera atro-purpurea), Christmas Roses and the scarlet, red, crimson, orange, and pale yellow berries of various Hollies, there need be no lack of freshness and colour for the biggest of flower vases, if necessary. But, fond as I am of praising the open-air garden, I must for once frankly confess that, like a snail, I must pull in my horns, and retire to the indoor garden for flower-colour and flower-fragrance at this season. It is after all this winter of our discontent in the frost-bound flower garden which gives to the genial hothouses their main charm at this season, and also makes us welcome with a delight all the more keen and enjoyable the first warm, genial days of a budding and flowery spring. As it is, most of our flowers for the next month or six weeks—that is, until the advent of the Snowdrop—will have to be supplied from under a glass roof. Here and there Christmas Roses, Violets in frames, Schizostylis, and Iris stylosa may be had of course, but this cold snap has been pretty general, and has practically cut off the outdoor supplies. Even from Nice and Cannes come the news that flowers are scarce and dear, so that we may console ourselves and feel grateful for a glasshouse variety of climates in which well-nigh all things are possible. I see the pale amber buds of the Japan Allspice (Chimonanthus) here and there on the walls, and 12° of frost—the mercury having gone down to 20° on the index—have not robbed these of their delicious odour, suggestive of a spicy day in spring.

White Daffodils.—The difficulty of dealing with, distinguishing, and naming the distinct varieties of such a polymorphic species as Narcissus pseudo-Narcissus assuredly is need not here be enlarged upon, since to all who have grown Daffodils in quantity it is self-evident; hence I was delighted to read on p. 571 what our friend Mr. Wolley Dod writes as follows on this matter: "I by no means propose to increase the number of Haworth's names for wild white Daffodils. My contention is that, as far as our present knowledge goes, the one name N. moschatus is wide enough to include them all." Of course, if Mr. Dod means to add English varietal names to the Latin binominal N. moschatus, such as N. moschatus var. William Goldring, or N. moschatus var. Colleen Bawn, for example, I agree with him; otherwise of course I do not. Even as now used, N. moschatus means or is applied in gardens and bulb lists to two very distinct and different white Daffodils, viz, to the large white, sulphur-crowned N. moschatus as grown in Holland, and to the much smaller and whiter little Swan's Neck, as found wild on the Pyrenees, and as figured in The Garden (p. 571). I never suggested that Mr. Dod or any other cultivator should send bulbs of white Daffodils to the Chiswick Garden and trial grounds of the Royal Horticultural Society for the purpose of their being named. Bulbs sent there under names or numbers will be grown side by side, and the main object is to note accurately first of all whether they really differ from each other—say, for example, as much as the N. moschatus of the Pyrenees differs from the two forms of N. moschatus as figured in the *Botanical Magazine* (t. 924 and t. 1300). After we have decided for certain that we have some dozen or two of varieties worthy of popular names, it will be time enough to decide amongst ourselves what they are to be called. Let all who send bulbs be enrolled on the Chiswick white Daffodil trial committee, and then let such committee settle as to the names, while those who do not send bulbs should be excluded from the committee.

The Strawberry tree.—There are two Strawberry trees, but what I call the true Strawberry tree is Arbutus Unedo, while the Indian, or Nepaulese, Strawberry tree (Benthamia fragifera) is different, and a far rarer shrub or small tree in our gardens. Both are barely hardy, and so are apt to become injured or even cut down to the ground level during exceptionally hard winters. Wherever the Arbutus grows well it is of all shrubs one of the most pleasing during the winter season. It is evergreen, and when old its trunk and main branches are of a beautiful reddish brown tint, quite different from that of the stems of anything else, although in colour a little resembling the Californian Redwood (Taxodium sempervirens). During November and December the Arbutus is at its best—a rare gain—and when its clusters of waxy white Erica, or Clethra-like, flowers are contrasted with its rich red, Strawberry-like fruitage, it is a sight worth seeing. Years ago I saw it in fruit for the first time in the cemetery at Brompton, but it is in Devon and Cornwall, in the Isle of Man, or in Wicklow, or, better still, at Killarney, where it is most luxuriantly at home, and most ornamental. There is a tradition that salmon is never eaten in perfection unless cooked as pulled fresh from the water, on the glowing embers of an Arbutus wood fire. Is it not in that enjoyable little book called "A Little Tour in Ireland," by Canon Hole (when an Oxford undergraduate), that I have seen a sketch of the cooking process as above alluded to? and have I not myself reason to feel grateful to the genius of John Leech for that same illustration, seeing that the memory of it once suggested to me a mode of cooking some delicious, but nameless, fish I once caught off an island in the Eastern Seas, where cook-pots were *non est?* Nothing eatable was there indeed but the fish and the fire, and with good appetites a rich banquet was made of such scanty fare. As I write, some rich, Grape-like clusters of Arbutus fruits are before me amongst their own glistening leaves in a China bowl. They have all the deep rich, rough ruddiness of the old Black Prince Strawberry at its best, and but few other of our hardy fruits surpass them for indoor ornaments or for church decoration at this season.

The first Chrysanthemum.—If we take the direct evidence of the plate in the *Botanical Magazine*, t. 327, we may consider it as the first large-flowered Chrysanthemum that ever flowered in English gardens. Whether it is identical with the seedling raised by Mr. Harding in 1864-5, when he was gardener to Dr. Sharpe, of Tunbridge Wells, must remain a matter of individual opinion, but I believe it to be the same, and so do other observers who remember that the drawing was made from a plant that would scarcely be so well grown in the year 1795 as is possible with us to-day. So far as I know, Mr. Burbidge never has said that it is the same, but has merely drawn attention to the resemblance of the modern variety, Dr. Sharpe, to the *Botanical Magazine* illustration of what is therein figured as C. indicum, but which is really, according to modern lights, C. sinense. In "The Chrysanthemum," p. 100 (2nd edition), I find the following account of this variety: "Dr. Sharpe (Ref.), raised in 1864-5 by Mr. G. Harding, then gardener to Dr. Sharpe, of Tunbridge Wells, who is said to have crossed Madame Poggi with Golden Queen of England. Result: Seven seeds, all grew, yielding Dr. Sharpe, Mrs. Sharpe, and five worthless varieties. The plants were sold to Mr. Forsyth, then of Stoke Newington, who named and distributed them. It has quilled florets of crimson-purple or rich maroon, backs of florets (and quills) silvery rose, fine colour, early, and of good dwarf habit. Dr. Sharpe seems of all modern varieties to approach most nearly to the plate in the *Botanical Magazine*, t. 327, which represents the first large-flowered Chrysanthemum which bloomed in England." After all this is the point, for out of the 2000 to 3000 Chrysanthemums grown to-day in English and French gardens I am not aware that any one resembles this figure so closely as does Dr.

Sharpe. That Mr. Harding did really raise it is, with me, a foregone conclusion, but it is an old trick of Dame Nature to go back or revert to a former type or variety when seeds are sown in hope of an improvement. Sometimes she fixes on a point in the middle distance, so to speak, as in Mr. Poë's (p. 563) seedlings from the white Everlasting Pea, which so often persisted in bearing pink or rosy flowers.

Outdoor Grapes.—When the barking of a watch dog is rewarded with brick-bats instead of bones, he is perhaps wise in his generation if he curls himself up in his kennel and goes to sleep comfortably; but, of course, he seldom does this unless the brickbats actually hit him, which they very seldom do. Neither does the quotation from *The Field* (p. 570) quite apply to what I wrote in The Garden (p. 539). I have all respect for Mr. Robert Marnock's opinion, but I submit that "gardens of the better class" are not quite the places in which to look for outdoor Grapes. In such gardens there are, as a rule, good Grape houses, and I have never yet said that outdoor Grapes are better than hothouse ones. My own experience may not be quite so extended as that of Mr. Marnock, but I have seen good open-air Grapes in English gardens, and especially on cottage walls. Allow me now to ask in these pages of anyone who has seen useful crops of outdoor Grapes in England that they will tell us where and how they were grown, and how the fruit was utilised. That vineyards formerly existed in England which yielded fairly good wine is perhaps beside the point; the question being whether such success is now possible, or, if possible, acceptable to more modern, and perhaps more fastidious palates. Was not Lee's Vineyard Nursery at Hammersmith once a Vine field? and was not the wine there made sold to the wayfarer in a thatched-roof office above the cellar or wine store? Even in a green state I think the Grape preferable to the Gooseberry for jelly or confections. It is not quite fair, however, to put questions of this kind either for or against, but to avoid prejudice let the question be put in a manner quite neutral. I do not think the open-air Vine likely to be so profitable as many other hardier fruits, but under the most favourable natural conditions I have no doubt that fairly good Grapes may be grown in Southern England.

Plant shelters.—I think it is in Mrs. Bridges' "A Lady's Travels Round the World" that we are told that the Japanese gardeners had no greenhouses when she was there, but that their tenderest plants were sheltered in pits, tanks, or caves dug into the earth and exposed fully to the sun. These sunken pits could, of course, be easily covered over with frames of oiled paper or branches of coniferous trees during actual frost. What most surprised Mrs. Bridges, however, was the extreme facility and apparent carelessness with which the Japanese gardeners and nurserymen dug up their finest Camellias, when in bloom, for the decoration of their temples or dwellings. They did this with as much security from actual damage apparently as in the case of our own employment of Rhododendrons for the floral exhibitions in April or May. I think there can be no doubt that the introduction of glass-houses to our gardens has not, on the whole, been an unmixed advantage, since before their introduction many protective plans for protecting and sheltering tender plants were in vogue which are now unused. There can be no doubt that caves as cut into dry banks of earth, or as formed by turves or rough stones, are extremely useful for sheltering half-hardy things. A broad coping on a wall, or even the leafy branch of an Evergreen tree laid over a plant during frost, often bridges over the difference between life and death; while the same may be said of a forkful of dry leaves or a shovelful of dry ashes or sand. Delicate bulbs and other plants may often be preserved by keeping them dry; and Mr. Ewbank's suggestion as to the Willesden paper for the covering of things of this kind when at rest will enable us to enjoy the beauty of many things previously thought ungrowable in the open air. Veronica.

Rose Garden.

PROTECTING TEA ROSES.

The winter has come in with a rush at last, and to the tune of from 15° to 20° of frost. True, the cold has not lasted long, the thermometer rushing up from 12° to 50° within a few days. These short frosts seldom work such severe havoc as those that last longer—or see-saw—upon or among such plants as Tea Roses with pertinaceous persistency; still they are far too much of a cold thing for the well-being of Tea Roses if any such were caught all unfurnished—that is, unprotected. Neither do these stinging frosts reveal the evils they inflict on the instant; on the contrary, plants often look as if they had passed through severe frosts with impunity, and not till the sap tries to rush through their branchlets in the spring is the fact revealed that their substance has been ruptured into mere masses of dead tissue, impermeable to fluids and incapable of revival into new life. Early protection is the obvious lesson taught by these early December frosts, but with Tea and other Roses blooming through November such lessons are apt to be forgotten. But it is far better to clothe autumnal or winter beauty with a handful of Fern fronds any time in November than run the serious risk of sudden frost-bites through leaving tender Roses unprotected too late in the season. But better late than never, and those who may not yet have protected their Teas should not lose a moment in doing so.

It would be a grievous error to reason that because the plants had passed through one severe frost with impunity that others would not cripple them; for this impunity is more apparent than real, as we have already seen; and, besides, frost never hardens tender plants; on the contrary, each freezing leaves them the more susceptible of injury for the next, and so on in succession until such plants as Tea Roses finally succumb to frosts that would hardly have injured them in the least had they been duly and carefully shielded from previous chills—not that overcoddling is desirable, though it is safer far than excessive exposure.

One gets almost ashamed to repeat such advice to infinity as to leave the top intact when applying protection. The latter not seldom proves the most potent of all protection, and, being posted at the point of danger, is the more efficient on that account; and yet not a few cultivators, to save time and husband sap in the spring, prune their Teas before protecting them. No practice could be more dangerous, for early pruning fosters early spring growths and it is these first fruits of the first fitful, genial days of spring that invariably fall victims to the late frosts.

D. T. F.

The Everlasting Rose.—Ought we not rather to write Everlasting Roses, for are there not many more varieties than ordinary folk dream of? In an old garden the other day I found four distinct deep crimson kinds, one with a peculiar smell like that of a fruit shop, and this plant had grown—so I was told—for full fifty years where I saw it; still it was in perfect health. There were several forms of pink and rose-coloured kinds also, but in no case was there a name for any of them. More recently in another garden I saw a large round bed of the common pink Monthly in full flower in this present month of December. This bed consists of bushes fully 4 feet high, which have grown into each other. They get next to no pruning, except perhaps now and then a rough going over with the hedge shears. The owner of the place told me that this bed was just as I saw it twenty years ago. In the same garden are huge bushes 6 feet high and fully as wide of a light crimson-coloured sort, and also of a deep red-coloured kind which is new to me. Some time ago I also came across a big bush of a large-spined, big-leaved sort, with very full rosy crimson blossoms with a paler reflex and a sweet scent. This had no name, and had occupied the position in which I saw it so long, that the oldest inhabitant and the garden records failed to establish anything whatever as to its history. Again, I found a very beautiful nameless variety growing only 1 foot or so high, and bearing in profusion most brilliant crimson blossoms. The only white sort I know is Duchére, a plant of moderate growth, bearing flowers that open badly. There are hundreds of gardens up and down the country in which any of these China Roses would be quite at home, and as permanent subjects they have no equals. What we want, however, is to gather all the kinds together, and get acquainted with them. In a French list before me I find no fewer than twenty-six kinds enumerated, including the green-flowered one. Does this list of twenty-six include, I wonder, all the known kinds, or are these twenty-six distinct? Who will tell us something about these old favourites, that will enable us to distinguish them—to know, in fact, the one from the other?—T. S., *Newry*.

SOME TEA ROSES OF 1886.

I give below the results of our tests of the new French Roses grown in our trial grounds in the past season. We carefully noted all the characteristics shown by the plants—of which we had several thousands—with a view to being able to furnish an accurate description of each from personal observation. Of course, one season's trial is not conclusive, and after another year's trial we may find some worthy Rose or Roses other than those we mention, but the following is the result of our experience with them up to date:—

Claudius Levet.—A moderately vigorous grower, with dense short growths. Colour, a carmine-rose with a peach centre. This variety produces quantities of buds, but its greatest charm is in the open state. Buds on young plants were somewhat disappointing, but as the plant grew and became established, the open flowers were grand, and warrant us in recommending the variety. In colour it is not unlike Mdme. Watteville, but differs from it in having shorter petals and a larger and more double flower.

Comtesse de Frigneuse.—In colour, charming; in freedom of bloom, second to none, with finely-coloured foliage. Buds not unlike those of Niphetos in form, being long and of good size. Colour, a charming canary-yellow, with a softer shade on inside of petals. We are so well pleased with this variety, that we are growing it by the thousand. We find it to force finely, and its buds are eagerly sought after. A beautiful Rose for bedding purposes, and a good winter bloomer.

Edmond de Biauzat.—A strong, vigorous-growing Rose, with fine leathery foliage and erect shoots. The petals are very thick in texture, but rather short. Colour, peach, tinged with salmon and pink. We shall have to test it further before recommending it.

Marquis Vivens.—Carmine-rose, centre shaded bright yellow, delicate and beautiful in its colouring. Not unlike Madame Cusin in colour, but with buds similar in shape to those of Safrano. This variety, from its freedom of bloom and exquisite colouring, is destined to be used extensively by florists for forcing. To the amateur it will be welcome in the bud state for cutting from, but as an open flower it cannot be considered a success. The more we see of this Rose the better we like it.

Flavian Budillian.—Vigorous in growth, with fine, healthy foliage. Colour, soft tender rose, with brighter shading at times. Cannot speak definitely of this variety; will require further trial to determine its standing.

Sussane Blanchet.—Colour of outer petals a clear flesh white with deep flesh centre. Perfection itself in colour, and charmingly beautiful. In shape similar to certain varieties of the old Provence Rose; outer petals very large and broad, with short inner petals. Of delightful fragrance. We think highly of this beautiful Rose, and if it continues to preserve the same charming colours and unique form, it will undoubtedly be in great demand. Foliage large, erect in growth; beautiful.

Souvenir Victor Hugo.—Bright China Rose, with copper-yellow centre; ends of petals suffused with carmine. A charmingly beautiful combination of colouring, and each colour blends nicely with the other. This variety will take rank with the best, and is a Rose of decided merit. It is not improbable that it will prove useful for forcing. The evident relationship to Comtesse de la Barthle assures us a free bloomer, and in size and length of bud it is the equal of the best Teas. Of merit. —E. G. Hill, in *American Florist*.

OWN-ROOT ROSES.

"T. W. G." (p. 516) states "that the suckers from the base of the plants make their appearance in July just as the flowers are about to open; consequently, if the suckers are left alone, the flowers seem to stand still and never attain their greatest possible beauty, or, if the suckers are sacrificed to the flowers, the plant is damaged for the next season." The first may happen to some extent, if by greatest possible beauty is meant the highest perfection and largest size for showing, but hardly otherwise, and, besides, the suckers start in June, not July, provided the shoots of the previous season are pegged down, as they ought to be, either the previous autumn or very early in the spring. So treated, I have not found the suckers at the base of the shoots or springing from the root-stocks to practically or sensibly so lessen the supplies of food to the flowering shoots as to cause the blooms on the latter to stand still. On the contrary, suckers and flowers run fairly well abreast, and the latter develop in such numbers and to such perfection as to make own-root Roses by far the most useful for decorative effects in the garden, and for cutting for all purposes, except showing for prizes. Should, however, the suckers of any particular variety, or in any exceptional case, manifest any tendency to an excess of vigour, such may be simply checked in two ways without any damage to the plant for the next season. They may be pegged down to the level of the flowering branches, and this bending from the vertical to the horizontal checks their vigour for a considerable time. A still simpler and better method is to stop the strongest suckers at three or, at the most, six eyes from their base. The one strong shoot will then break into three or more, and as the season advances, and all danger from any excess of vigour has been grown out of the plants, the shoots from the suckers may be thinned down to such numbers as sufficient space can be found for. One more very important point must be noted here. "T. W. G." writes, "In the case of worked plants, these strong growths from the base of the plant do not appear until the flowers are expanded, and hence never interfere with the others." My experience would say that, as a rule, these strong shoots do not appear at all on worked plants. Of course, there are exceptions, but they are so rare, that very few attempts to renew worked plants, through a regular succession of strong shoots equivalent in regularity of development or in recuperative force to suckers, have proved successful.

Neither have I found the difference in time in the appearance of base shoots from worked plants and that of suckers anything like so marked as that indicated by "T. W. G." Possibly, however, this rosarian will be able to throw further light on the wide disparity of time in the appearance of suckers and base shoots on worked plants, for the subject is one of vast practical importance, as well as of the highest physiological interest. It also seems almost a physical impossibility that the few roots of the Brier and an inch or two of its root-stock should have the power of holding back the Roses worked upon it for a month or a fortnight. Nay, the power claimed is even more marvellous than this, for it is an elective choice between Rose shoots of different character, viz., the blooming and growing ones, the former keeping time or never getting in advance on own-root Roses, the latter being made through the magic of the Brier stocks to lag behind them. If Brier stocks can do this, then indeed we may readily grant that nothing is impossible to them, not even the making of Rose roots to bloom instead of their tops. D. T. F.

New Rose Comte de Paris.—The Journal of the Tuscany Royal Horticultural Society (Florence) publishes a plate of a new Hybrid Perpetual Rose distributed under this name. It is described as superlatively good; the flowers are large and of a bright red, shading to velvety purple; the stalks are strong, so that the blooms are seen to advantage. The blooms, when open are, on account of the regularity of the petals, excellent; while, in the bud state, they are invaluable for cutting. Altogether "it is a plant that no Rose lover would be without." The name is not well chosen, as there is a Rose already in gardens under the title of Comte de Paris.

Roses for a small garden.—Twelve dwarf plants may consist of three Gloire de Dijon and one each of Cheshunt Hybrid, Abel Carrière, A. K. Williams, Baroness Rothschild, Captain Christy, Charles Lefebvre, Duke of Edinburgh, Victor Verdier, and Prince Camille de Rohan. For walls I should recommend Gloire de Dijon, Aimée Vibert, Belle Lyonnaise, Bouquet d'Or, Devoniensis, and Jules Margottin. In this selection of eighteen plants, I have suggested planting four Gloire de Dijon, for the reason that it is, without doubt, by far the best outdoor Rose grown, and will produce during the season more satisfactory blooms for cutting than any other Rose—which, to my mind, is the chief object. Devoniensis is a more beautiful flower, especially in the bud state, but then the proportion of bloom is about one to six. Aimée Vibert, with its vigorous growth and beautiful foliage, clad in summer with a canopy of snow-white blossoms, is very beautiful, but still not to be compared in usefulness to Gloire de Dijon, which from May until November yields blooms of excellent quality, shape, and perfume. As regards stocks, have them on the common Brier and plant low, so that they may form "own roots."—J. K.

Sunless propagating houses—One of the relics of the past is assuming considerable importance in connection with many Rose-growing establishments, says the *American Florist*, and to the north-side houses may be attributed no small amount of blame for the degeneracy in the vital energies of the Rose. Let us for a moment reflect on the *modus operandi* in vogue in many places. Cuttings of Roses are taken from plants grown in the full blaze of the sun and in a temperature productive of fine growth, and are supposed to be full of life and vigour. The next step is to remove them to a sunless house with top temperature in the forties. This lowering of temperature and avoidance of sunshine is considered essential by some of the leading lights in the Rose-growing world. Reflection will show at once the unnaturalness of the whole operation. The change is so sudden, that a check is given to the future plant's action, and granulation is retarded instead of accelerated, and consequently we have that sickly, watery look so prevalent in establishments where this method is practised. Better by far plant your cuttings on a bed with full southern exposure, using light paper shading in the middle of the day, when the sun is hottest, and that for only a limited time after the cuttings are inserted. Experience will prove and common sense will endorse this method as against the practice so commonly employed. Every observing man will see at once the desirability of securing the beneficent rays of the sun to not only preserve, but help along the cutting after granulation has commenced. If we all practised the saucer-and-sun method in rooting our Roses it would be far better with the Rose, especially our forcing varieties. I know I am treading on the toes of many who profess to know all about Rose propagation, but I am prepared to back old Sol and common sense against all the theories in the world.

Flower Garden.

TULIP BULB "DROPPERS."

As a grower of the Tulip in its florist varieties, and for many years a raiser of it from seed, I have become intimately acquainted with the "dropper." It is, however, a form, whether of renewal or of increase, which is not adopted by the full-sized flowering bulb. This produces the new one for the following year, upon the radical plate of the old one, while offsets are attached to the same part also, nestling at the base of the folds of the parent bulb. Occasionally an axillary offset is formed at the junction of the lowest leaf with the flower-stem, but never up and down the bulb in the way that the fat Window Onion (Ornithogalum longibracteatum) or Vallota purpurea produces offsets. Neither is the "dropper" but very occasionally formed by offset bulbs, unless they are very small, say from the size of a Hazel-nut downwards. It is in the seedling bulb of the Tulip in the years before it blooms that we find the "dropper" as the all but invariable form of reproduction.

Some "droppers" of the larger sort will have an offset or two, and there is very often a tiny bulb left behind on the site of the remains of the old exhausted bulblet. It is entirely owing to the tedious "dropper" that we cannot flower the Tulip from seed in less time than from five to seven years. It might not so much matter if but one "dropper" were produced, although the tube that carries it down is always at the cost of the "dropper's" substance. The loss and delay occur through there being several of these "droppers," varying but little in size in each case, and of which only the largest can be selected, to avoid growing a vast accumulation of what may be but worthless when they bloom. Thus the advance in the seedling Tulip bulb is very small up to the fourth year, by which time some are bold enough to renew the bulb on the radical plate, after which they rapidly attain a flowering size.

It is crediting the "dropper" with too much sagacity and too fine an instinct to suppose that it descends in order to place the bulb in a proper deepness of earth. The Tulip is not at all particular to an inch, though from 3 inches to 4 inches is the customary depth of planting. A bulb that may have accidentally been dug in will cheerfully come through 12 inches, and bloom, too. I have planted young seedling bulbs both deep and shallow, and always found the "dropper." I have left "droppers" two years in the ground, and found them "droppers" still. They are not soon out of their depth, and can easily avoid that, either by shortening their descent or by the upward direction at first of the hollow underground pipe, at the end of which, as in a sac, they are developed. I have unsuccessfully tried to discontinue the "dropper" by the experiment of planting two-year-old seedling bulbs so shallow that I could watch the "dropper" shoot appear. I have removed it forthwith, but only to find another one produced, and after the removal of this, another still, till at last I felt obliged to let one go for fear of exhausting the plant. It used to be a practice to offer a formidable check to "droppers" in the shape of large broken crocks or coarse drainage materials a little way below the

soil. These impediments, however, had no effect beyond that of distorting some of the new bulbs, according as a "dropper" had flattened its nose against a big crock, or had taken a sort of negative impression of a broken brick.

"Droppers" start either from the base of the young bulb downwards, or emerge from the top, and then descend, probably regulating their course at first by the way of the least resistance, or the direction in which their shooting point may be laid. But why the young seedling bulb should have no single leading bulb-germ like those mature in size, but several that strive for the mastery; and why these bulb-germs instead of clustering at a mother's side, as offsets do, should be sent away from home as "droppers," I think we cannot tell. We only know that it is the seedling habit of the Tulip always, and of very small offsets not infrequently. D. F. Horner.

Burton-in-Lonsdale.

Old double yellow Wallflower.—This is a favourite with cottagers in this locality; in summer bushes of it may be seen laden with golden blossoms, which render the air redolent with perfume. Like many old-fashioned flowers, this possesses so many good qualities, that one wonders how it could ever have fallen into disrepute. Of course, the comparative mildness of the climate on this coast has much to do with its abundance; it rarely gets injured by frost, and when once planted it lasts for years, spreading out into large bushes. The soil being naturally light and dry favours sturdy growth, which gets well ripened, and its hardiness is thereby increased. It is readily propagated by means of slips or cuttings. The usual plan with the cottagers is to slip off small side, flowerless shoots in autumn, and insert them in a shaded spot where they remain until the following spring; they are then transferred to permanent quarters. For supplying cut flowers this Wallflower is invaluable, as its bloom-spikes are large and expand regularly. Anyone desirous of growing this really fine plant in cold, wet soil where frost is severe should plant it close to a wall, and take the precaution of having a reserve of young plants in a cold frame. In many parts this old-fashioned Wallflower has been superseded by the double German variety, but the last is by no means equal to this fine old plant, and it ought to be more generally grown than it is.—J. G., *Gosport.*

Siphocampylos bicolor.—This is quite hardy at Newry, planted at the foot of a sunny wall where it never gets any other protection. When I first saw the coloured plate of Lobelia Cavanillesi, it struck me as being identical with this Siphocampylos, a plant not frequently met with, though good and ornamental. As a matter of course, it gets killed down annually, but it shoots up again in spring in a very vigorous manner. It usually attains 4 feet in height, and sometimes, in very genial summers, even more. Its pretty red and yellow blossoms are borne in great profusion, and continue long in beauty; in fact, this season they kept in good condition until the first week in December, when a frost-nip spoiled them. I hope that the identity, or otherwise, of these two plants will be clearly established.—T. Smith.

THE AFRICAN LILY.

(AGAPANTHUS UMBELLATUS.)

This fine old favourite is one of the many Cape plants that do good service in English gardens. Though not available as a hardy plant throughout the country, it is in very general use in pots or tubs to stand out in the summer. Its bold, massive character, both of flower and foliage, especially adapts it for association with masonry, hence its most frequent use as an ornament on terraces, steps and entrances. It grows and flowers admirably planted out in a cold greenhouse or conservatory where the glistening dark green leaves seem to be always in good order. The fast-growing roots have great bursting power, and woe betide any vase of ordinary pottery in which they are confined; they are only safe in wooden tubs strongly hooped with iron.

The African Lily (Agapanthus umbellatus). Engraved for The Garden from a photograph.

Hedychium carneum.—Of the various species of Hedychium this is one of the best. It has recently flowered in the Cambridge Botanic Garden, and has been much finer than the figures in the *Botanical Magazine* and Roscoe's "Scitamineæ" represent it to be. The flesh or salmon colour of the flowers, too, is much brighter. It grows about 4 feet high; the leaves are lanceolate and almost 18 inches long; the best spike measured about a foot in length. The colour of the flowers makes it very desirable. It is apparently rare, though introduced a number of years ago.

PLANTS FOR WINTER BORDERS.

A wise gardener will always make provision for furnishing lawn borders with spring-blooming plants and bulbs which would produce a pretty effect in spring, and also relieve the bare appearance of empty beds during the dullest and darkest time of the year, say from November to February, when people are often confined to the house, and the view from its windows is the only one obtainable. Many of the most effective spring flowers that are annually raised from seed, such as Silenes, Nemophilas, and others, will not stand ordinary winters if sown early enough to fill the beds before frost sets in; if sown late and the plants are small, they are hardy enough, but beds filled with them are by no means satisfactory until spring growth commences and the bulbs begin to break through the soil. After trying several combinations for producing a cheerful effect from the time the summer bedding plants are removed until the season comes round for replacing them, I find that the most satisfactory plan by which we can get beds really well furnished and full of brilliant or graceful foliage, supplemented by a mixture of flowering plants and bulbs as the spring advances, is to obtain a quantity of very dwarf well-rooted evergreen shrubs, such as Hollies, Rhododendrons, Euonymuses, Laurustinuses, Laurels, Barberries, Aucubas, Heaths, Arbor-vitæs, Cupressus, Junipers, Vincas, and others, and with them fill the centres of large beds or vases quite full, edging with hardy flowering or fine-foliaged plants and bulbs in proportion to size. In the case of large beds, an outer edging may be made of Golden Feather Pyrethrum, London Pride, Crocuses mixed; and a second line may be of Myosotis, Silene, &c., with Hyacinths or Tulips, and a back line of Wallflowers, with Narcissi or Jonquils. Smaller beds should only have one line of flowering plants, and the bulbs should be planted between the dwarf shrubs. These look at all times bright and cheerful, and, being perfectly hardy, defy all weathers. Shrubs are as easily obtainable in any quantity as bulbs, and if shortened back both root and branch in spring, when planted in their summer quarters they will last several seasons, or when too large for this purpose, they may be finally utilised for making new plantations and improving the borders of woodland walks. Sheltered positions might be reserved for Pansies, Daisies, and the earliest harbingers of spring, as in mild seasons they are seldom destitute of floral beauty.

G. H.

Fuchsia simplicaulis.—This is a very beautiful Fuchsia, somewhat similar to F. dependens. In the Cambridge Botanic Garden it grows close under the roof of a greenhouse, in which its pendulous racemes are very effective. The stems are long and branch

but little; the leaves are large and pass into leafy bracts among the flowers, which are long and bright crimson in colour. The petals are shorter than the sepals, while those of F. dependens are equal in length. It is a very suitable plant for pillars.

Fruit Garden.

DWARF APPLE TREES.

Where there is a possibility of establishing a good orchard of standard trees on the Crab stock this will be found to be by far the most profitable method of growing Apples. One fine tree will frequently produce more fruit than a dozen or more dwarfs, but the latter are not to be altogether despised, as they can be made very serviceable in small as well as in large gardens, and a few good fruits are better than none at all. We unfortunately have very few orchard trees, and have to depend principally upon the dwarf or bush-shaped trees which surround about one-half of the vegetable garden. Some of the latter have been established upwards of thirty years, and others have been quite recently planted. It is the comparatively young trees that are the most profitable, and it is my practice to gradually replace the worn-out, much too deeply-rooted old ones with young ones fresh from the nurseries. We purchase what are known as pyramids, but this shape is rather unsuited to the habit of the Apple, although it answers well for Pears. Our first proceeding, therefore, after planting is to boldly cut out the centre of the tree. This has the effect of diverting the sap to the formation of much stouter side branches, of which there are usually about fifteen. If there were much fewer, it might be advisable to cut back all the side branches to within 6 inches of the stem, the most weakly ones being the most severely shortened. Sometimes merely shortening one or two of the stoutest branches will be followed by sufficient breaks to complete the number required for the foundation of a good tree. Not being pressed for room, nor very particular about the shape of a tree so long as the branches are evenly distributed, we do not resort to the use of stakes, but those who may wish for well-formed specimens are advised to place a moderately strong and straight stake to each main branch; in this manner a good even double circle of straight limbs may be formed. From these a few laterals also allowed to extend are sufficient, and a profitable tree is thus formed without much trouble. I readily admit that a well formed pyramid is usually more attractive in appearance than these headed-down trees, but in most cases where the latter plan of training is adopted a maximum of growth and a minimum of fruit are the result. Unless every branch receives the full benefit of light and air little fruit will be produced, and many pyramids bear only on the outer surface of the tree; whereas a properly managed bush fruits as much on the inside as on the outside branches. Nothing in the shape of summer pruning is now attempted with our bush trees, whether these be 4 feet or 12 feet high; all the pruning which they receive is done about this time.

In the case of young trees only the surplus laterals, or those not required for furnishing the future main branches, are cut hard back to within 2 inches of the starting point, all the rest being retained at full length. Strong well matured wood, if shortened in the old style, only results in the production of still more strong shoots; whereas if left full length, it not unfrequently forms fruit buds at nearly every joint. Thus trees planted in 1883 bore well this year, three and four dozen fine fruits being taken from several of them, and I have noticed that the leading growths, as well as strong laterals, that were reserved full length last winter are now well set with fruit buds. No root-pruning has been resorted to in order to bring about this satisfactory state of affairs, nor is this often necessary when the knife is withheld. Some of the trees are on the Paradise stock, but the majority are on the Crab, and the latter soon become as fruitful as the former, besides being much more robust. When the trees have reached the desired height (many of ours are 12 feet high and 12 feet through) the main branches should be stopped at the winter pruning, and all lateral growths also spurred back, every main branch eventually becoming well clothed with fruit spurs. In a few instances, where the trees had become unfruitful from various causes, we left several laterals full length, and these have since borne well, also apparently renovating some of the more stunted of them, but, as before mentioned, I have more faith in young trees than renovated old ones—unless taken in hand at the roots as well as the tops. Very old trees will not always recover from the effects of rough root treatment; we have a row here only just recovering from the effects of lifting and replanting, operations which were to have done them so much good. Twelve years ago my predecessor took every pains with them, doing one half of the tree one winter and the remainder the next. They were too old for close pruning; but since I have allowed a thin sprinkling of laterals to remain, a marked improvement has been the result. I believe in lifting all the trees, no matter in what shape they may be trained, once early in their career, or, say, when they have been planted about three or four years, not so much with the view of inducing fruitfulness as to check the downward tendency of many strong roots. No sub-soils, and especially those of a cold, clayey nature, are suitable as a rooting medium, and trees kept rooting nearer the surface are the most fruitful and the longest to remain in good health.

Espaliers.—I have not seen many examples of espalier-trained trees in the western or midland districts, but in the home counties and in North Wales this old-fashioned plan of training Apple trees still finds adherents. It has still much to recommend it, and for small gardens it is especially suitable. A row of trees at the back of herbaceous borders serves to neatly divide these from the rest of the garden, and besides being fairly ornamental they bear generally heavy crops of good fruit. Then, instead of bush or pyramid trees in a line with and near the principal garden walks, espaliers may be substituted, these encroaching much less upon the limited garden space. Many nurserymen still supply small espalier or horizontally trained trees, and these, being duly planted on fairly good garden soil, soon attain a serviceable size. Each probably would have about three tiers of branches 9 inches apart, and a strong leading shoot. The latter should at planting time or soon after be shortened to about 10 inches of the topmost pair of branches, and from the young growths eventually resulting, the topmost should be staked upright, and two near to this, and as nearly oppositely placed as possible, should be trained horizontally, the rest being stopped. This should be annually repeated till such times as a height of 4 feet or 5 feet is reached, when no leader should be reserved. Some support the main branches with neat upright stakes placed about 18 inches apart, but these stakes, even if tarred or charred at the lower ends, naturally do not last long. A wire fence is neater and more durable. In the latter case as many wires as there are tiers of branches are required, and if the trees are planted from 15 feet to 18 feet apart, in the course of a few years a neat and continuous fence of Apple trees will be formed. If espaliers cannot be purchased, a start may be made with maidens. These, having one straight unpruned growth, will require to be cut back to within 9 inches of the ground, the subsequent treatment being exactly the same as that recommended for the older trained trees. Many now prefer to start with maidens, as they are found to grow more strongly than the more stunted older trees, and in time to surpass the latter. None of the reserved side branches should be shortened in any way till their limit is reached, but all lateral growth from these as well as the main stem may be lightly stopped in summer, when this can be done with the finger and thumb, spurring them back to within 2 inches of the old wood at the winter pruning. If this treatment is not accompanied with fruitfulness, then root-pruning should be resorted to, though this should not be done till the tree is of good size or has reached its full height, or the severe check necessarily given may stop all further healthy development. On no account should any strong central shoots be allowed to run up above the horizontal growths, or these will soon attract all the sap from the latter, rendering them comparatively useless. I ought to add that, if the trees are worked on the Paradise stock, they must be planted not more than 12 feet apart, otherwise gaps will always be observable in the fence.

Cordons do not as yet find much favour with gardeners, but they are suitable for all places, and for covering circular trellises and archways they are sometimes tried with very good results. At Sherborne Castle, Dorset, there is a fine lot of horizontally-trained cordons, three lines of them in different heights so as to slope to the front, completely surrounding one of the large quarters of the kitchen garden. Each tree consists of two main branches trained in opposite directions, and three unbroked lines, supported by strong wires, are in this manner obtained. Some of the trees when I saw them were fruited so as to resemble somewhat the proverbial rope of Onions, and the produce was also of a very superior character. It is a simple matter to train these cordons in any direction or form needed, the leading branches being regularly laid in to their full length, and all laterals treated as advised in the case of the espaliers. Any that are inclined to be very vigorous must be root-pruned occasionally, or no fruit will be obtained, and that is one drawback attached to the system, root-pruning in many gardens being necessarily, at least, a bi-yearly operation. Sometimes cordons commence bearing the season following planting, and continue annually to bloom and fruit if not damaged by frost. In this case they are liable to become stunted, and will require to be lifted and replanted in fresh and rather rich compost, much of the fruit also being removed early in order to induce a more free growth. Cordons on dwarfing stocks are particularly to be recommended to those who may require a quick return for their outlay, or who may wish to form a large collection of varieties. They commence to bear at once, and may be planted thickly, or, say, in lines 18 inches apart, and for training up stakes or over trellises 15 inches from plant to plant.

Selections of suitable varieties.—For bush, espalier, and cordon trees I have found the following most suitable, all being good, well tried varieties, and arranged somewhat in their order of ripening. For dessert purposes we have Beauty of Bath, Irish Peach, Kerry Pippin, Worcester Pearmain, Gravenstein, King of Pippins, Cox's Orange Pippin, Margil, Braddick's Nonpareil, Ross Nonpareil, Adam's Pearmain, Pearson's Plate, Court Pendu Plat, Northern Spy, Lamb Abbey Pearmain, Cockle Pippin, and Sturmer Pippin, and, if more than these are wanted, I can recommend Summer Golden Pippin, Wormsley Pippin, Court of Wick, Ribston Pippin, Wyken Pippin, Claygate Pearmain, Newtown Pippin, Nonpareil, and Duke of Devonshire. The best culinary Apples are Carlisle Codlin, Lord Suffield, Keswick Codlin, Duchess of Oldenburg, Stirling Castle, Emperor Alexander, Golden Noble, Cellini, Lord Derby, Echlinville, Kentish Pippin, Warner's King, Blenheim Pippin, Tower of Glamis, Dumelow's Seedling, Royal Somerset, Alfriston, London Pippin, Winter Greening, Hambledon Deux Ans, and Norfolk Beaufin.

W. I. M.

Fruit buds.—Seldom have leaf and bloom buds on Black Currant and on Gooseberry bushes shown up so prominently as now. Whatever may be the cause—and it is perhaps due to the very fine and lengthened autumn season which we have had—it will be exceedingly interesting to note next spring what is the result of this early development. Whilst some may regard it as indicative of a good crop next year, others may feel that such early budding renders the trees liable to injury from severe weather. On Apple

trees there is also an early swelling up of fruit buds visible, but that may be the natural result of sparse cropping during the past year. One advantage of this early plumping up of the buds is that winter pruning can be better done than if the buds were less prominent. Still further, it may be wise with such promise of strong growth before us to prune more freely than is usual, for if the trees are about to carry heavy crops, it should be our care to assist them by judicious thinning rather before the crop is due than afterwards. The roots are then less distressed and more capable of recuperating during the following year. When trees make gross growth and produce little fruit we find it desirable to furnish some root check, but when heavy crops are produced with, of course, lessened growth, then all possible root action is needful. The very best help in such cases is pruning in good time and mulching with manure.—A. D.

RENOVATING OLD VINES.

I was recently asked to look at a large vinery planted mostly with Black Hamburgh Grapes. The Vines were not very old, but a moment's inspection revealed the fact that they were badly managed, especially as regards the training of the young wood. Not only were they badly trained last season, but they had been badly managed from the first. Now Vines, such as those in question, which were certainly not more than twelve years old, could not be called old Vines in need of renovating; and yet if they were pruned and trained in the same way much longer, the bunches, which were very small, and the Grapes poor in quality, would get gradually smaller and smaller, until their value as a marketable commodity would not be sufficient to balance the expense of their culture. The system of training seemed to be this: The rods were led up too thickly in the first place, and by bad management had not broken regularly throughout their length. Some of the spurs were therefore too close to each other, and others too far apart. The pruning had been badly managed; one shoot from each spur is sufficient, but in this case several growths had been produced and allowed to grow. These, in their turn, were cut back until quite a cluster of growths pushed from each spur; and nowhere in the house were young rods being trained up to take the place of the old ones, and this in a house about 100 feet long and 24 feet wide. Such a house, if well managed, ought to produce a grand lot of Grapes year after year. But it should be well understood that good management consists not only in pruning properly at the resting season, but far more in training the young growths in the right way after they have been sufficiently thinned out.

I have more than once had to deal with Vines badly trained as well as exhausted, apparently from old age. In one instance the leaves and fruit were quite smothered with mildew, owing to the border being badly drained, an evil further intensified by the rain water being allowed to run from the roof on to the border. The first operation was to provide gutters to carry off the rain water, and a good tank in which to collect it. As the outside border was in the worst condition that was seen to first, and an examination revealed the fact that it had never been properly made. I had a deep trench dug out parallel with the vinery, and at the part of the intended border furthest removed from the front wall. This was dug out to the depth of 3 feet. The next operation was to fork out the whole of the soil contained in the border, taking care to save as many of the roots as possible. The latter were all tied up against the front wall and covered with mats to keep them fresh. We now put in about 6 inches of drainage composed of old brickbats; over this was placed some turf with the Grass side down. The compost, which had been previously prepared, was wheeled in, and the roots spread out at the level of the path. Six inches in depth of the compost were then placed over them, and over all a dressing of 3 inches or 4 inches of decayed stable manure. A drain to carry off superfluous water was also laid down at the outside of the border and parallel with it. The inside border was not disturbed, as it was supposed that the roots there would be required to start the Vines into vigorous growth. Three parts of the old, stumpy, and perfectly useless wood were cut out, its place being supplied during the season with vigorous young canes, made during the first season, the whole length of the rafters. They were also allowed sufficient space in which to develop laterals, and none of the growths were overcrowded. We had a very few good Grapes as well as sufficient young wood the first season, and no mildew; the latter, indeed, never appeared at all, proving conclusively that the precaution of thoroughly cleaning the wood, washing it first with soapy water and afterwards painting it over with similar water thickened with flowers of sulphur was sufficient to destroy this pest. The new border, it may be added, consisted of good material, viz., turfy loam mixed with crushed bones, mortar rubbish, and a sixth part of decayed manure; this became during the season quite permeated with fresh rootlets. Next season the whole extent of the roof glass was furnished with healthy young wood laden with good Grapes. The inside border required to be done subsequently in the same manner.

The training of the Vines during the growing season is a matter of considerable importance, and here I would remark that one lateral or leading growth that has sufficient space for development is worth six that have been over-crowded, but it seems very difficult indeed to impress this fact upon those who have but a superficial knowledge of gardening, and who have no idea that the leaves have important functions to perform. Indeed, I know of one case during the past season in which a person of ordinary intelligence and the owner of a large vinery called upon me to say that as his Black Hamburgh Grapes were not colouring well, he had "stripped off nearly half of the leaves to let the sun at them." I told him he had committed a grave error in so doing, and on visiting the house I found that the most important leaves on the laterals, those nearest the base, had been removed. Every one of those leaves so ruthlessly sacrificed for the supposed benefit of the Grapes ought to have been preserved with the greatest care. In the first place, the Grapes would not colour so well without them as with them. In the next, it is a fact that they are the most important leaves on the Vine, being essential to the perfect ripening of the fruit, and after that has been removed they are required to aid in the formation of the buds at their base. Indeed, those same leaves have been busily employed performing both functions all through the growing season, and up to the time when they become yellow and drop off, but not before the work allotted to them has been completed. Their work has been to form and store up in the buds at their base the material from which leaves and flowers will be developed next season. Many cultivators know this, but there are scores, nay, hundreds, who do not. If leaves are required for garnishing dishes containing fruit, there is always plenty of the right kind on the secondary laterals beyond the bunches; none ought to be removed between the bunches and the main stem. Ever since I was an apprentice, no season has passed that I have not had to train and prune Vines of all ages and under widely different conditions, and the conclusion at which I have arrived is this: that, with very few exceptions, the short-spur system of pruning is best—that is, rods trained at 2 feet 6 inches or 3 feet apart, with lateral growths on each side and as nearly opposite each other as convenient, the average distance apart being about 18 inches. Each of these growths would, if allowed, bear a bunch of Grapes, but it is necessary even with moderate-sized bunches to thin out more than half of them. In fact, every strong lateral will show three bunches, but two out of the three are removed before or at the time of stopping the laterals; and here I would specially remark, that all laterals formed subsequently to the first stopping should not be allowed to grow until it is necessary to cut them with a knife; indeed, where Vines are vigorous they grow so rapidly that it is desirable to go over them for the purpose of stopping laterals once every week. If this is done, all the stoppings removed would not be more than a handful or two. This does not check the Vines in the least; whereas, going into a vinery with a knife and cutting out later growths a foot or two in length at or before midsummer must be injurious. The late Mr. Pearson, of Chilwell, an ardent and successful Vine grower and seedling raiser, believed that it caused shanking in Grapes.

One rather important detail is that of renewing the rods. After a time the spurs get unsightly through lengthening out. This is caused by cutting back the laterals annually to a good eye, and in order to do this about an inch of young wood is left every year. I have seen some of these rods upwards of twenty years old, and the spurs anything but short. We never have any rods more than ten years old. They are cut out before they become more aged, and young ones are put in their place. Some grow one rod only from a root. This is very well to start with, but after a time it is desirable that two or more should be trained up from one root. The way in which we manage is this. Suppose there is room for ten rods in a new vinery, I would in the first place plant ten Vines. Every alternate one would be rather heavily cropped the first two or three years, and when they showed signs of exhaustion they would be cut out, but not all at once, as their place would be gradually supplied with the permanent Vines, from which a second rod would be trained up from near the base. J. Douglas.

GRAPES IN THE OPEN AIR.

I am very much interested in the cultivation of the Grape Vine both under glass and in the open, and few articles appear on the subject in any of the gardening periodicals that escape my notice. I read Mr. Cornhill's paper on the cultivation of Grapes in the open air in The Garden with much pleasure, and can endorse all that he has written about the adaptability of many varieties for open-air culture on walls in the southern counties. From my own experience, I believe that if Vines in this country received the attention pointed out by Mr. Cornhill in pruning and training, so that the leaves and fruit were fully exposed to the sun's rays at all times, as good Grapes could be grown on walls in many parts of England and Wales as in the neighbourhood of Paris. About 100 yards of the Castle wall here is covered with Vines trained perpendicularly to the height of from 50 feet to 60 feet. There are several varieties, but the Chasselas de Fontainebleau does best. It is a good bearer, and ripens its fruit to perfection in good seasons. I have gathered bunches of Grapes from these Vines more than 2 lbs. in weight, each of which are equal in quality to that of any Grape which I have seen at the table in France. The Vines are subject to mildew and suffer much some seasons from its effects. It was difficult, from the great height of the Vines here, to apply sulphur effectually to the leaves infected, and therefore I adopted the old-fashioned plan of painting the rods after they were pruned with a mixture of soft soap, sulphur, and lime, and mildew has not done harm to any extent since. The Vines in the open vineyard at Castle Coch have not been attacked with common mildew since they were planted, but sometimes they have had slight attacks of Oidium Tuckeri, which seems to burn holes through the tissues of the leaves. The best remedy I find for it is to pick off the affected leaves as soon as it makes its appearance, and burn them.—A. Pettigrew, *Cardiff.*

*** This is the most hopeful report that we have yet seen of Grape-growing in the open air in England. It would be interesting to hear from Mr. Pettigrew as to the quality of the fruit pro-

duced in the vineyard at Castle Coch. We believe that in favoured spots, and with such care as the French give at Thomery, certain Grapes might be ripened, but that does not lessen the danger of persons advising Grape culture generally for the open air in England, because the wisest and eldest gardeners know that it has been attempted a thousand times without success.—Ed.

—— Most people, I think, will admit that, taking one season with another, but slight hope can be entertained of succeeding with outdoor Grapes north of the Trent, although I have some recollection of seeing (many years ago) ripe Black Hamburghs produced by a Vine in the open air a few miles north from the town of Leicester, but the Vine occupied a sheltered and favourable situation, and the season had been exceptionally fine. Now, however, when glass is so reasonable in price, it is unadvisable to plant the Grape Vine extensively in the open air in either the northern or southern portions of the country. The Vine is, however, well worthy of consideration as an ornamental plant, independently of fruit, for as Mr. Cornhill truly says, "A well-trained Vine is at all times pleasant to see," and few plants are better adapted for clothing the front of a cottage or dwelling-house which may face the south than a Vine.

Near the ruins of the celebrated monastery at Bury St. Edmunds may yet be seen the terraces where were grown the Vines which produced the fruit from which the monks of old are said to have made excellent wine; and there is no reason for supposing that the climatic conditions of this locality in these days were in any respect more favourable than they are at the present time. At a much later period, too, than that of the monks, the late Mr. Darkin, of Westgate Street, Bury St. Edmunds, in his unique garden formed on the site of an ancient and extensive chalk pit, long unused, and open to the south, but sheltered on the three remaining sides, managed for years to ripen Grapes of many kinds. The Vines were trained to a high wall facing the south, to the perpendicular surface of the chalk, and also to short stakes like Raspberry canes; and the wine which he made from fruit thus produced was, and is still considered by connoisseurs to be equal, if not superior, to much of the wine imported from the Continent. This garden also affords a proof that very rich soil is not altogether indispensable to the production of Grapes of excellent quality. There are also other successful growers of Grapes in the open air in this town. And where the walls are low—that is, some 5 feet or 6 feet high—on which the Vines are trained, a young shoot is brought annually from the base to take the place of that which produced the fruit of the current year, which is annually removed. But in cases where Vines are trained to a high wall, such as that of a building or dwelling-house, what is known as the spurring system is doubtless the best; that is, training the rods vertically from a horizontal rod near the surface of the soil, at a distance of not less than 18 inches from each other. These rods will produce young shoots in abundance, which should be thinned out to the necessary distance apart, retaining the strongest and best placed. These will generally show a bunch at the fourth or fifth leaf, and the shoot should be stopped at the first leaf beyond the bunch. Each shoot with its embryo bunch should be loosely tied to the rod, thus leaving a portion of the wall between each vertical rod exposed to the influence of the sun. By this method the brickwork absorbs the heat communicated to it, and parts with it gradually, and a more equable temperature is the result. This mode of training also presents a very neat appearance, and prevents the fruit from coming in actual contact with the wall. If, however, fruit of fairly good quality is expected from Vines in the open air, not more than one bunch should be allowed to each shoot, and the berries of each bunch should be carefully thinned out. In this way I have this season (which has not been exceptionally favourable for outdoor Grapes) ripened bunches of Buckland's Sweetwater close upon 2 lbs. in weight.

I am surprised to see that the French have so many varieties of hardy Grapes which have never been introduced to this country. Surely English nurserymen will see to this matter before long. If a variety of the Grape Vine exists which in the south of Germany will ripen its fruit in August, it surely ought to do so in the south of England by the middle of October. Might not the Grape of Mr. Cornhill's boyhood have been the Esperione, which is the best black Grape for open-air culture with which I am acquainted? Indeed, the varieties of Grape Vine which can at present be recommended for open-air culture are but few, and may be said to consist of the Royal Muscadine, Black Cluster, and Esperione. Although Buckland's Sweetwater and Black Hamburgh have been mentioned as having ripened out of doors, they cannot safely be recommended to plant in the open air. But let us hope that the list of trustworthy hardy varieties suited for this purpose may soon be considerably extended.—P. G., *Bury St. Edmunds.*

—— I was pleased to see from the remarks made in The Garden (p. 570) that a practical view of this subject had been taken, a result thoroughly justified by past experience. To advise cottagers to plant Vines out of doors in England as a profitable speculation is a great mistake. From what source could profit possibly arise? Inferior Grapes are practically unsaleable at a profit at the time when these would be ripe; they cannot be utilised for preserving, and one would hardly recommend a cottager to plant them solely for wine-making. Better plant any fruit at once hardy and productive that can be sold at a remunerative price, or that can be used up as jam. Any cottage walls at liberty would be better covered with Victoria Plums or Red Currants than Vines; north aspects should be planted with Morello Cherries. I have given outdoor Grapes a thorough trial near London, and have obtained abundant crops and good sized bunches, but in berry and flavour they were only fit for wine-making. There is, however, one thing as yet untried, and that is thinning the bunches. There are so many things requiring immediate attention just at that particular time, that up to the present I have not been able to try the experiment. Our situation is about as favourable as it well could be for outdoor Vines. The border consists of light loam well drained, and it lies well up to the sun. It faces the south and south-east, and is well sheltered on all sides. Nevertheless, with all these natural advantages and contemplated thinning, I am by no means sure that we shall have good outdoor Grapes.—E. B.

ORANGE TREES AND ORANGERIES.

The introduction of fine-foliaged plants to our gardens, especially such hardy ones as Yuccas, which are thoroughly fitted for adorning terraces and parterres, has done much to supersede the Orange trees, which appeared equally out of place, either in the full glare of the terrace or when their defects were partially concealed in their dreary-looking winter quarters. When the old orangery was replaced here by a conservatory, the large beds in it intended for permanent plants provided a good situation for the old occupants of the orangery, some of which had been in their tubs for an indefinite period. The beds were emptied to the depth of 4 feet, and at the bottom we put broken bricks to the depth of 18 inches, and covered them with turf to keep the drainage perfect, the remainder being filled up with a compost of turf, peat, leaf-mould, and old mortar rubbish. In this the old worn-looking subjects were planted. By keeping up a moist genial atmosphere, and syringing the stems frequently, they soon showed signs of returning health, the Oranges especially sending out both flower and wood-buds from the bare hard stem that had not produced a leaf for years. The bloom was so abundant the following year, that we picked off thousands in order to concentrate the energy of the plants in the growing buds, only leaving enough for a good crop. These are now ripening as fine fruits as can be desired, that cluster amongst the deep green foliage, and are really interesting and decorative objects, very different from what they were in their best days in tubs, while the labour attending them is greatly reduced. When associated with Camellias, Myrtles, New Zealand Flax, and such plants as flourish in temperate houses, the Orange tree is indeed a noble object, bearing, as it does, three distinct crops of fruit at one time, and blossoms that rival our choicest Orchids for delicacy of perfume and purity of colour. I would therefore strongly advise all who have Oranges in tubs, the appearance of which is not satisfactory, or such specimens as one often sees in our public gardens, to plant them out, when they will repay all the care bestowed on them, and the owner will soon be able to gather his own Oranges in abundance. When arranged with some of their fresh green foliage attached, Oranges form a by no means unimportant addition to our home-grown dessert fruits. G.

GARDEN FLORA.

PLATE 576.

CHINESE HERBACEOUS PÆONIES.

(WITH A FIGURE OF P. ALBIFLORA VAR. ADRIAN.*)

The herbaceous Pæonies, noblest of hardy plants, yet long neglected in gardens, have within recent years gained the popularity which they deserved. At one time the common European Pæony (P. officinalis) was almost the only representative of this important genus in general cultivation. Now one sees the lovely Chinese varieties in nearly all good gardens, and since a few hybridists in France have turned their attention to them, we have varieties innumerable of every hue which the Pæony is capable of producing. All, too, are beautiful, and generally combine rich or delicate tints with exquisite fragrance, which vies even with that of a Tea Rose itself. The genus is a large one, and very widely distributed. Pæonies occur in various parts of Europe; one is widely distributed in America, while a few are natives of the extreme east, viz., China and Japan, and to the herbaceous species inhabiting this region our present notes are confined, leaving the Tree Pæony (P. Moutan) and the European species and varieties for comment, when coloured plates will be given representing each section. Nearly a century ago Mr. George Anderson devoted a deal of attention to this genus, and being a keen cultivator as well as a good botanist, he dealt with Pæonies both from a cultivator's and a botanist's point of view. The result of this study of the genus he published in the Journal of the Linnean Society in 1817, and to this day Anderson's monograph may be taken as the basis of all other works, so complete and full of reliable information is it. Sabine also worked with Anderson in producing the Linnean mongraph, and to them jointly gardeners are deeply indebted. Through Anderson many species of Pæonia were introduced and cultivated, but no one in after years appeared to pay much attention to the subject; indeed, several fine species and many charming varieties dropped out of cultivation, and Pæonies again suffered much from neglect. Until Mr. Baker took up the subject a few years ago, no one had reviewed the genus since Anderson's time. The review of the genus which Mr. Baker published in a contemporary is the most complete we now possess; in it he directs attention to various fine species either not introduced or very rare, and only in specialists' collections. To Mr. Peter Barr we are also indebted, not only for hunting up neglected species, but also for introducing others to cultivation; in short, he is endeavouring to do with

* Drawn for The Garden in Mr. Anthony Waterer's nursery, Knap Hill, Woking, in June.

PÆONIA ALBIFLORA ADRIAN.

Pæonies what he has done with Daffodils and Hellebores. Of the only three species not in his collection he has been promised two, and the third, which is also a Chinese one (P. obovata), he is in a fair way of obtaining.

The cultivation of these Chinese Pæonies is comparatively easy; indeed, a good garden soil not too stiff suits them to perfection. They are, however, voracious feeders, and can stand a large amount of stimulants, liquid and others. They require plenty of water during the summer season; indeed, the most robust we ever saw were in such a position that they could be flooded when necessary. Position, whether in sun or

Single-flowered Pæonia albiflora.

shade, seems to be immaterial, as they flower well under either condition. We once saw a large rough bed of them in a wood on the Surrey hills quite shaded, and flowering most profusely. We suggested sunshine, but were told that the flowers stood longer in the shade (often a fortnight or three weeks) than those exposed to sunshine. Great care is required in lifting or dividing them, operations which had best be resorted to as little as possible when once they are fully established. The following are a few of the best:—

P. ALBIFLORA.—This is by far the most fertile of all the hardy herbaceous Pæonies in cultivation as regards the production of garden varieties, and next to P. peregrina it is the latest to show flower. In the neighbourhood of London the blooms seldom appear until after the beginning of June. The albifloras, of which there are considerably over 200 in gardens, form a distinct set, easily distinguishable from the others by the dark shiny colour of their leaves, and the marked way in which the flowers stand above the tufts of foliage. From officinalis they differ in having more slender, rounder, and more rigid stems, scarcely grooved, while in officinalis they are deeply six or seven-grooved. The leaves also are much larger, biternate, with broader, smoother leaflets shining on both surfaces. The blooms have also a pleasant smell, which much resembles that of a Narcissus. The stems, which grow 2 feet or 3 feet long, are quite glabrous, generally branching and bearing from two to five large milk-white or pink flowers. They have long been in cultivation in this country, and Loureiro, in his "Flora Cochinensis," states that albiflora is found both wild and cultivated all over the Chinese Empire; it is therefore probable that many fine varieties of it could be picked up in those districts where it has been so long an object of attention. Anderson has described the following varieties in vol. xii. of the "Linnean Transactions," viz.:—

P. ALBIFLORA VAR. VESTALIS.—This was grown by Messrs. Lee and Kennedy as albiflora, and was at that time more common in gardens than the type. It is distinguished by its large white eight-petalled flowers, rarely or very slightly tinged with pink at the base. The leaves, which are broader, are more flat and shining than those of the others, and the stems are darker in colour.

P. A. VAR. CANDIDA differs from the foregoing in having its leaves and stalks hardly tinted at all, and the stigmas flesh-coloured instead of yellow. When opening, the buds are pink. It was first discovered in Mr. Knight's nursery at Chelsea.

P. A. VAR. TATARICA.—The original plant of this was sent from Tartary by Pallas. Its flowers are much larger than those of vestalis, and fuller of petals, which retain a pale pink colour until they drop; stigmas pink.

P. A. VAR. SIBIRICA.—This is said to have been first received by the Messrs. Loddiges from Siberia, through Pallas. The leaves are yellowish green; the flowers pure white, even in the bud; and it is altogether divested of that purple tint in the stalks and leaves which some others have. Flowers much larger than those of any of the others.

P. A. VAR. RUBESCENS.—This is a very diminutive variety, and its flowers are of the darkest colour. The leaves, too, are small, blunt, concave, or channelled above.

P. A. VAR. UNIFLORA.—This was introduced by Pallas. It has very narrow leaves, and is easily distinguished from all others. It has a disposition to produce only a single flower on each stem. The flowers are white, with a pale pink tint at the base; stigmas dull yellow.

P. A. VAR. WHITLEYI.—This charming variety was introduced by Mr. Whitley, nurseryman, of Fulham, from China, in the year 1808. When well grown the stems are fully 3 feet high. The leaves are rough and less shining than those of any of the others. The flowers are large, very double, with the outside of the petals red and the inner dull straw coloured, the whole becoming nearly white before they drop off, and emitting a scent not unlike that of Elder flowers. They appear about the middle of June.

P. A VAR. HUMEI.—This was brought from China in 1810. It is by far the largest of all the

Double-flowered Pæonia albiflora.

herbaceous Pæonies, its stems sometimes exceeding some 4 feet in height. The flowers are quite double, reddish coloured, and almost scentless The stems bear about three flowers each; leaflets broad, pitted, and invariably rough.

P. A. VAR. FRAGRANS.—This fine variety was introduced from China, by Sir Joseph Banks, about the year 1805. It has upright slender stalks, pale green leaves, which are often slightly serrated on the margins. It flowers about the end of June. The blooms are large and double, of a pale rose colour, and very sweetly scented. The centre petals are longer than the outside ones and erect.

Since the above varieties were described, florists have been most energetic in adding to the number many really charming and desirable forms, the following being only a few selected, and by no means exhausting the store:—

Adrian (see plate)
Carnea elegans, delicate pink
Candidissima, blush
Madame Calot, one of the finest, a delicate blush
Etendard du Grand Homme, brilliant rose, large
Festinæ maxima, pure white
Grandiflora nivea, white, large
Laciniata, very large pure white, one of the best
Leonie, blush
Noblissima, full deep rose
Prince Imperial, rose-purple
Reine des Fleurs, rich rose
Superbissima, purple-crimson
The Queen, blush-rose
Virgo Maria, pure white
W. E. Gladstone, blush, rose scented
Sir Garnet Wolseley, rose
Faust, blush white

and others with equal merits too numerous to mention in detail. D. K.

WORK DONE IN WEEK ENDING DEC. 21.

DECEMBER 15 TO 21.

WITH the exception of the morning of the 16th, when we had 0·06 in. of rain, the week has been fine throughout, and these last two mornings the frost has been sufficiently sharp to admit of our getting the remainder of manure wheeling and mulching done in the kitchen garden. All our Strawberry plots are now thickly covered; Asparagus the same, and so are Raspberries, and Apricots and Plum borders. We have no more good manure, else Pears, Cherries, and the less vigorous-growing Apples would also be mulched. Trenching has gone on without interruption. Some new ground that we are breaking up in which to plant Rhododendrons and Azaleas is covered with Bracken, which so protects it that we can keep on with the digging, no matter how great the frost. Continued the turning of gravel on paths that had got Moss grown, the verges being levelled and cut before the gravel is turned. For the Christmas decorations of the church we are responsible, and as a good length of wreathing is required, we are attempting to do two jobs at once; that is, to serve both church and garden. The latter we are doing by shearing over large bushes of Box and Yew, that if not done now would have to be done a few weeks hence, and the sprays that are now being clipped off make the finest wreaths imaginable. Box and Yew, with here and there a sprig of Holly, are simply perfection for the massive stone columns and arches that we have to deal with. The wreaths are made as light as possible, and we make up what they lack in bulk by using a couple on each pillar twisted across each other. The window-sills we do entirely with green Moss and flowers; of the latter, Christmas Roses, Roman Hyacinths, white Camellias, and white Chrysanthemums are amongst the best, both for effectiveness and length of time they continue in good condition. Holly berries are scarce, but Ivy and Cotoneaster are well fruited, and both are excellent substitutes for the Holly. We have quite completed the pruning of all bush fruits, and soon as may be the trees will now have a good splash over with fresh slaked lime and soot in about equal proportions, which, besides destroying Moss and Lichen, makes the buds distasteful to small birds that might otherwise destroy the prospects of a crop of fruit next year by picking out the buds. Work in the houses has been much the same as for a week or two past. Flowering plants we keep well freed from decaying flowers. Chrysanthemums we cut down soon as their flowers are over; nearly all our cuttings are now put in, and therefore a quantity of the old plants that were no longer required for stock has been wheeled to the fire heap, to be burnt up with the prunings from fruit trees, clippings from hedges, and rubbishy leaves that are not worth stacking for hotbed purposes. All tender bedding plants that require strong heat we have arranged on shelves in Pine stoves, and to less tender species in frames we have given all the space possible; we water them only once a week, and then very carefully. Damp and mildew are the evils to

avoid if we would safely winter these plants. The cold weather necessitates increased heat in plant-stoves, and with it we have had to be more free with the watering-pot, but over-head syringing we have quite discontinued, as Calanthe flowers began to spot, and thus syringing did more harm than counter-balanced the little good it did to Ferns, Palms, Dracænas, and Crotons. Early Peaches are just showing the pink of their flowers, and no further overhead syringing of these will now be done till the fruit has set. Present temperature by night, 45° to 50°, and 5° higher by day. The manure on the floor of the early vinery we turn once a week, at which time we take out any forcing plants that may be coming into flower too rapidly, and others are introduced. Callas, Lily of the Valley, Solomon's Seal, a few Tea Roses, and Spiræas have just now been put in. Tied late Peach trees to trellis; pruned young Vines, Madresfield Court and Gros Maroc, and gave the inside border a regular drenching, as the soil was cracking in all directions; sowed Tomatoes and Melons; put another batch of Potatoes in boxes to sprout, to be eventually planted in frames set on hotbeds of leaves and litter, and which is now being made up. Hants.

FRUITS UNDER GLASS.

Cucumbers.

So far, although the atmosphere has been heavy, the weather has been very mild, and winter plants have neither felt sudden depressions nor the ill effect of hard firing. How long this may go on it is impossible to say, but one thing is certain: preparations for the worst must be made, and in no way can a sudden change to wintry weather be better met than by keeping the beds replenished with well worked fermenting leaves and the provision of external covering. This, provided it is never allowed to exclude daylight, not only economises fuel on cold, wet, boisterous nights, but it prevents the escape of moisture, and maintains an even temperature between the foliage and the glass. Cucumber houses, as a rule, are low, compact structures, and by no means difficult to cover; but then the question arises, what is the best material for the purpose? Shutters are unwieldy. Mats in the morning are generally found where they are not wanted, but oiled canvas, now coming into general favour, both on the score of efficiency and economy, can be prepared to fit the roof at a very moderate price. Fruit in December is of little value; consequently growers for market husband the energies of their plants by cropping lightly and keeping them steadily progressing until the turn of the year, when the quantity they produce in some measure compensates for the low prices now realised. In private gardens a different system prevails; the space devoted to a few plants may include the back of a Pine stove, or perhaps one or two miniature compartments in a forcing range. The demand may not be heavy; perhaps not more than one fresh young fruit every day; but the mode of culture must be right, otherwise an acre of glass will not yield what is wanted. Two important items, as I have just remarked, are bottom heat and good covering; another is thin planting to allow for extension of the young growths; and the last is a succession of healthy maiden plants for throwing into bearing when old ones begin to fail and require cutting over. The present time is favourable for cutting over, if not a whole house, perhaps a plant or two, as the young growths not only favour root action, but come into bearing when good fruit is scarce, consequently valuable. When plants are so treated, every fruit and blossom and the worst of the old leaves should be cleared away. Those left should then be cleansed from spider by the persistent use of mild insecticides, and the bottom-heat being brisk, a portion of the exhausted or sour soil may be removed or replaced with a smaller quantity of sweet, warm compost. Lumps of light turf broken up by hand, a little fibry peat, rough lime rubble, and charcoal, make a suitable winter compost, as the roots lay hold quickly, and tepid water, of which they must have enough to keep them constantly moist, passes freely away. A supply of this compost kept constantly on hand can be used little and often as the roots show on the surface, and the stems of plants in pots, after the turn of the year, can be earthed up with great advantage. The enemies to which winter Cucumbers are exposed are innumerable, and must be dealt with before they have time to do mischief. Red spider springs up as if by magic after or during a period of hard firing or heavy cropping. For checking this, sulphur in some form is accepted as the best remedy, but a weak solution of soap or Gishurst compound used regularly is an excellent preventive. Where these do not produce the desired effect, the roots should be examined, as spider cannot be got rid of where dribbling is made an apology for good watering. Green-fly and thrips are not very active in winter, but the plants being also comparatively inactive, slight attacks soon affect them, whilst heavy smokings frequently prove quite as injurious as the insects. Still, tobacco smoke must be introduced, not in the old-fashioned way, but through the ingenious machine invented by Bloxham; not in opaque clouds, but little and often before these pests get established. We have had this handy puffer in use more than a year; never consumed so small a quantity of tobacco paper, and have never been so free from insects. When mildew attacks the foliage, as sometimes happens in badly ventilated pits, a sharp bottom-heat and plenty of tepid water must be applied to the roots, which may be dry or sluggish. The ground ventilators must be kept constantly open to admit fresh and force out vitiated air, and the foliage well syringed with sulphur water or a solution of sulphide of potassium by those who know how to use it. Yet one more enemy the winter Cucumber grower has to contend with, and that is canker. The best remedy for this is quicklime and flowers of sulphur well rubbed into the parts affected, but prevention being preferable to cure, rough lime rubble, lumps of charcoal, and other absorbents should be placed about the stems, and provision for the admission of air on or below the level of the bed should not be overlooked.

Young plants.—Where space is limited, and not more than one batch of plants is grown through the winter, it is necessary to get a stock of young ones ready for filling up gaps or replenishing a pit early in the new year. These may be raised by means of layers or cuttings from clean, healthy parents, or, an abundance of top and bottom heat being at command, a few seeds may be sown singly in small pots plunged to their rims in a temperature of 80°. If the pieces of light turf from which the fine particles have been shaken is damp, water will not be needed until after the young plants are through the surface, and then it must be given with the greatest caution. A small propagating pit is the best place for this early work, as the plants can then be kept close to the glass, which should be well covered every night to maintain an even temperature about the tender foliage. One of the great secrets of success in after-management is repotting in warm soil as soon as the young roots touch the sides of the seed pots, or, better still, transplanting to small cones of light, warm compost.

Melons.

Growers who intend cutting ripe fruit in April will now be putting in a few seeds of some favourite early variety. Like the preceding, they must have plenty of top and bottom heat, and light is a very important factor. Indeed, the treatment of the two through the early stages being so minutely similar, one and the same nursing pit will answer every purpose. Having so often enumerated good early sorts, and their name being legion, every grower who starts in December will do well to commence with his own special favourites. Moreover, he will not trust to one sowing, but follow up with others until his pits are furnished. Unless the pits are very narrow and the compost in which very early Melons are planted can be kept at a temperature of 80°, fruiting in 12-inch to 14-inch pots will be found the safest and most expeditious mode of culture. Although a few weeks will elapse before the fruiting pots are wanted, the pit should be cleansed and made as fresh and sweet as a living room at earliest convenience. Well-worked fermenting leaves or tan may then be introduced, and clean pots plunged ready for the compost. As success depends more upon quality than quantity, sound friable loam in a dry state may be broken up by hand, corrected or enriched, and placed where it will get thoroughly warm before it is put into them.

Figs.

Short, dark, wet days are not favourable to rapid progress in the forcing of heat-loving subjects like the Fig. Still, where ripe fruit is wanted in April, these, like all other exotic fruits whose season is changed, must be helped forward during the short hours of daylight, and rested through the night. Where the first crop is gathered from trees in pots, fermenting material is preferable to fire-heat, as it can be turned and renovated at pleasure, whilst the warmth and moisture which it gives off dispose of the necessity for constant syringing. If, as previously suggested, the pots have been placed on hollow pedestals, a quantity of loose leaves thrown in amongst them will gradually raise the temperature of the balls to figures ranging from 70° to 75°, when the well ripened buds will soon burst into leaf. Until this stage is reached, the night heat may range from 50° to 56°, according to the state of the weather, and 5° to 10° higher by day. Afterwards the latter may be increased, especially under gleams of sunshine in bright frosty weather—by no means the worst for early forcing; but for some time to come no advance should be made on the night. Figs being so subject to insect pests require copious supplies of water throughout the growing season and good syringing from the time the first leaves are formed to keep them free from spider. The walls, floors, and dry corners also should be well washed every day, but on no account should the foliage be found wet when daylight closes. Fruitful trees established in small pots, unless well mulched with rotten manure, may be watered with weak diluted liquid and occasionally with soot water from the time they are started. The latter may also be used for syringing purposes, not only in the Fig house, but also amongst Peaches, Strawberries, and in vineries, where it will be found an excellent insecticide and stimulant. It must not, however, be used strong, neither should new soot, which is fiery, be used if old can be obtained. Soot water, the uninitiated must be told, cannot be prepared and used immediately, as it must be bright and clear; but being grateful to the roots as well as to the foliage, a daily supply may be had by filling small bags and sinking them in the cisterns in the different houses. The water from these at first may require diluting, as this, like all other stimulants, is valuable in proportion to its reduction to a strength below that which the roots and foliage will bear.

Figs on trellises.—These are generally planted in well-drained internal borders, and force quite as well as trees in pots; indeed, many people now prefer this mode of culture, as the fruit is finer if not more abundant, quite as early, and the trees, having more root-room, are less addicted to casting the earliest fruit. If properly made, the borders will be divided into sections, with open spaces left between the trees for the introduction of fermenting materials, the warmth from which soon draws through the compost and drainage. Some build single brick walls across the borders, but I give preference to sods of light rich turf, which sustain the roots when they get into it, and, being open and elastic, they absorb warmth, ammonia, and moisture, and never become water-logged. Moreover, they can be forked down every autumn, replaced with fresh, extended or diminished in area according to the requirements of the roots. Brick walls, on the other hand, are cold, cumbersome fixtures, through which warmth passes

slowly, and, being non-elastic, the compost is apt to become wet, solid, and sour when the roots strike downwards into the drainage, and dropping follows. When trained trees in permanent borders are started, the soil should be thoroughly moistened with warm water, at a temperature of 80°, and the air-temperature may be precisely equal to that of the early vinery, viz., 50° to 55° through the night, and 60° to 65° by day. If sharply root pruned early in the autumn, and the trees are large, a good covering of rotten manure will do them no harm, or fermenting material may be placed on the surface as well as in the linings, to draw the young roots upwards to the influence of warmth and away from stagnant moisture. The young shoots being regularly trained on trellises within 1 foot or 18 inches of the glass, a syringe may be used two or three times a day, as the wood, owing to its elevated position, dries quicker than pot trees in low forcing pits.

Late houses.—If the trees in these have not been put in order, the knife should now be run through them before they are let down from the trellis. Autumn is the best time to cut out all superfluous wood, but no matter how carefully this work may be performed, a final dressing after the leaves have fallen is always necessary. When pruned they should be let down and washed with an insect-destroying solution more or less strong, in accordance with their freedom from these pests or otherwise. We find a strong solution of soap or Gishurst's compound quite sufficient, but where bug is present, all the old wood may be painted with the tar mixture recommended for Vines. The trellis and woodwork, too, must be painted with white lead, oil, and turps, and the walls carefully washed with quicklime, soft soap, and sulphur. Bug often travels down the main stems into the borders, and, notwithstanding the fact that every insect above ground has been destroyed, they soon find their way up again in the spring. To counteract this, all loose soil and surfacing should be removed and burned, and replaced with fresh compost. When tied in, late houses may be used for Strawberries or other plants capable of withstanding a few degrees of frost, but it is not good practice to allow them to fall below the freezing point.

Trees in cold houses and wall cases so far are safe, and being kept dry they will stand a few degrees of frost, but with all the winter yet to come and having no hot-water apparatus to fall back upon, no time must be lost in preparing for the worst. This is not a difficult matter, as Figs, so long as they are dormant and dry, take no harm from being kept in total darkness under a good covering of Bracken or straw. The better to accomplish this, all trees on trellises should be released and allowed to drop away from the glass, when they can be bundled and protected. Others on back walls, which are safer than trellises, can be securely thatched with Fern, and well mulched with the same to keep frost out of the borders.

Eastnor Castle, Ledbury. W. Coleman.

Hardy fruits.—Dr. Hoskins, says the *Country Gentleman*, writes to the Maine Board of Agriculture, that fully one-half of New England, all of New Brunswick and Quebec, a large part of Ontario, a fourth of New York, Wisconsin, Dakota, Minnesota, Montana, Eastern Washington, Northern Illinois and Iowa, and Manitoba must grow what are called ironclads, or grow nothing. Three varieties of the Apple have been well tested for this purpose, their hardiness being proved in the following order, namely, Red Astrachan, Alexander, Oldenburg, the latter enduring any climate. The Russian Apples vary in hardiness. The Oldenburg withstands 40° below zero without harm. Among the hardy summer Russian Apples he names Yellow Transparent, Tetofsky, Summer Red Calville, and Charlottenthaler. Autumn sorts —Alexander, Titovka, Oldenburg, Switzer, and Borovinka. Winter—Antonovka, Longfield, Cross Apple, Red Anis, Bogdanoff, and others. In addition to these Russian varieties, the following American seedlings are named—Wealthy, Wolf River, McMahon's White, Whitney's No. 20, and Scott's Winter. Some Pears and other fruits are under trial, but more time will be required for them.

Kitchen Garden.

SELECT VEGETABLES.

I never rely upon a new vegetable of any kind until I have proved it. This is especially necessary in the case of new Peas. These vary so much in the time at which they come into bearing, that until one has proved them there is risk of the supply being irregular, but if sown at the same time as proved kinds this risk is avoided, and opportunity is afforded for making comparisons under similar conditions. The best sorts of Peas for early sowing are Sangster's No. 1 and Kentish Invicta; the first-named is a white Pea, and the other green. These are, I think, amongst the earlies the two hardiest. The best dwarf sorts are American Wonder and Abundance placed in their order of merit, but they are a week later than the two just named. Laxton's Alpha is undoubtedly the best table Pea in the early section, but being a wrinkled variety, it is rather tender, and cannot be sown with safety until the middle of February; consequently, it is not so early as the others named. Amongst second earlies William the First is unequalled both for productiveness and high-class quality. If another sort is wanted, I should select Early Sunrise, a white marrow of fairly good quality. My favourite main crop varieties are Champion of England and Telephono. In a strong soil these grow from 6 feet to 7 feet high. Sorts in this section which grow from 4 feet to 5 feet high are numerous. My selection from these are Huntingdonian and G. F. Wilson. Where the soil suits it, Veitch's Perfection is, in my opinion, superior to any in regard to flavour. The best tall growers for late sowing are Ne Plus Ultra and British Queen. If dwarf sorts are required for the latest crops, there are none to surpass Omega and Hair's Dwarf Mammoth.

Broad Beans are not popular, but where they are required they are generally liked best when very young and small in size; large sorts are not much wanted. The old Mazagan is still as hardy and early as any, and, being small in size, it is often preferred to the large sorts. Leviathan is a wonderfully attractive large Bean. As to Runner Beans, a good selection of Champion is all that is wanted in this section. Of French Beans, Early Dun is the best for the first crop, and Canadian Wonder for successional sowings. These will be enough for most gardens.

Of Brussels Sprouts, a good strain from imported seed is still unsurpassed. Amongst Borecoles the tall Scotch Kale and the Cottager's Kale are the hardiest and most productive of any; and of Broccoli I would recommend Snow's Winter White, Early Penzance, Leamington, Chappell's Cream, Frogmore Protecting, and Veitch's Model. These will produce a good succession.

Of Cabbage, the best are Ellam's Early, Enfield Market, Chou de Burghley, and the Rosette Colewort.

Of Cauliflowers, the best are Early London, for standing through the winter, and Stadtholder for a successional summer crop. These will furnish a supply to the middle of August. Veitch's Autumn Giant should be sown in the autumn at the same time as the Early London, and then it will succeed the early summer crops. This sort should also be sown in April for a late autumn supply.

Of Celery I would select Turner's Incomparable Dwarf White and Major Clarke's Red. If larger sorts are wanted, I recommend Grove End White and a good strain of the Manchester Red.

Cucumbers for the winter supply should consist of Rollisson's Telegraph and Sion House. Carter's Model is a useful summer kind for growing in houses, and the same may be said of Tender and True. For frame work, Telegraph and Masters' Prolific are the best.

Of Endive, the best curled-leaved sort is Digswell Prize. The French Moss-curled is useful for autumn consumption, but rather tender. The round-leaved Batavian is the best of the plain-leaved kinds.

Of Lettuces for early spring use, the white-seeded Bath Cos is unequalled to stand through the winter. Hammersmith is a hardy Cabbage Lettuce that is fairly reliable. The best White Cos for summer use is the Paris Market and Kingsholme. The last-named is a distinct and useful sort. It is self-hearting, and grows to a large size. Of Cabbage Lettuces for summer use the best are Neapolitan and Perpignan. This last stands well in dry weather, and is crisp and tender.

Of Melons, I would grow Reid's Scarlet Flesh, and for a green flesh sort Victory of Bath. These two, if well grown, will disappoint no one, either as regards size or flavour.

Onions.—Of these there is a long list of names, but a good strain of the White Spanish and Brown Globe for winter supply will be all one wants; the last-mentioned sort I find to be the best keeper. For sowing in autumn there is no more hardy sort than the Tripoli.

Parsnips.—Of these the Student for main crop and the Maltese for early winter use are the best.

Parsley.—For the main supply none beats a good strain of Covent Garden Garnishing. The Fern-leaf kind is very distinct and handsome, but scarcely so hardy as the other.

Of Radishes, the best for early forcing is Wood's Early Frame. For summer culture the French Breakfast and Scarlet Olive-shaped are the best.

Spinach.—The Prickly-seeded for winter and the Round for sowing during summer are all the sorts that are needed.

Tomatoes.—Amongst these there is a great array of names, but for general usefulness the common Red is still unsurpassed. For exhibition purposes, Hathaway's Excelsior is equal to any of the newer sorts. Green Gage is useful for the sake of variety. The fruit is citron-coloured and nearly transparent, which adds considerably to its appearance.

Vegetable Marrows.—Muir's Prolific Hybrid is middle sized and wonderfully productive. Hibberd's Prolific and Green-striped are both good varieties.

Asparagus.—I have not been able to detect any difference between the ordinary Giant and Connover's Colossal. I therefore consider that one sort is sufficient.

Potatoes.—For the earliest crops no one can make a mistake if they choose the old Ashleaf and Myatt's Prolific. The best round sorts for second early are Porter's Excelsior and Early Coldstream. For late crops I would recommend Scotch Champion and Magnum Bonum.

J. C. C.

Early Broccoli.—I hear good accounts from a grower for market of Veitch's Protecting Broccoli as a valuable kind for present use. Everybody grows the Autumn Giant Cauliflower, but, as a rule, it is cleared off by the middle of November, and there is nothing left of the same character to follow it. It is just at this season when the Protecting Broccoli comes in so well, and those who have planted it find now a good market for it. This is just one of the things which in ordinary seasons will be certain to prove a safe crop, and it only needs to be more widely known to be widely grown. It may be that in exceptionally wet autumns the plants would not mature so as to enable them to flower early, but that would at least be a rare occurrence. It is not often that we get an exceptionally severe spell of frost before Christmas, so that the chances are greatly in favour of a good result. Many market growers fight shy of big, spreading, late Broccolies because they are not only subject to injury from hard frost, but also because the plants are so long on

the ground. The Protecting Broccoli happily avoids the first, and under the latter head is not troublesome. The seed of it should be sown about the end of March on good soil, and be well protected from birds until the plants have become strong. Many growers who complain of the moderate returns now obtained for the Autumn Giant Cauliflower would probably find it better worth their while to plant one-third less of that kind and make up with the Protecting Broccoli.—A. D.

MARKET GARDEN NOTES.

This is rather a slack time with growers for market as far as general work is concerned, only such things as must be done being now taken in hand. The principal crop now being taken into the markets in quantity is Cauliflowers, amongst which the Autumn Giant is still in fine condition. Its heads, which are very large, bear evidence of extra good culture. This variety will, however, soon be over, as a good sharp frost destroys all that are fully formed. Growers, however, take the precaution to break the leaves down over the heads, and thus save them from a few degrees of frost. Veitch's Winter Protecting Broccoli is getting into favour with market growers in this part for a Christmas supply. It is self-protecting, having plenty of foliage that curls close over the heads, thus keeping them perfectly white and safe from slight frost. When they realise good prices, growers lift them when nearly fit for use and shelter them in cold frames, sheds, &c.

Savoys never fail to put in an appearance about Christmas, let the season be ever so severe; in fact, a good sharp frost that cuts up the tenderer Cauliflowers increases the value of the Savoy. The Drumhead is the variety most in favour, and also the dwarf green curled.

Brussels Sprouts and Scotch Kale are in excellent condition this year, the season having been moist, and throughout favourable to growth; consequently, the Sprouts are fine and hard as bullets, and the heads of Kale beautifully curled. The dwarf green variety is almost universally grown.

Cabbages and Coleworts are plentiful and good; the former have formed beautiful little heads quite equal to what are generally thought to be the perfection of spring Cabbages from plantations made after Potatoes were lifted.

Celery in great quantities and very fine may now be seen on every wagon. The white varieties are being cleared off first, the red being hardier and better able to sustain a spell of severe weather, but covering up is not practised in this locality.

Turnips in bundles as white as snow are capitally got up by the market growers. Fine crops for this time of year are got by sowing after Peas, Beans, and Potatoes come off. The red-skinned and green round are left for a later supply, being much hardier. Chirk Castle Black Stone is one of the hardiest of all, and one of the best, being as white as any of the white skins under its rough exterior.

Horse Radish, although not in great request at all seasons, is sure to sell well at Christmas, good straight sticks realising good prices. It is one of those things which are made a specialty of by a few growers, who cultivate it thoroughly well, and which is not the rule in private gardens, it being a plant difficult to destroy, and one which grows in some sort of form without any attention; it gets very little care. Single crowns planted deeply in good soil, or long, thin sticks lifted carefully and planted full length, soon repay the extra trouble by yielding a very superior article that realises a good price.

Lettuces and Endive are now in great request. Brown Cos and the Cabbage varieties of Lettuces, such as Hardy Hammersmith, Grand Admiral, and others of that type that have been sown thinly in July, are the ones to be depended on at this date. Endive of the Green Curled and Batavian class, nicely blanched by tying up or laying slate on the leaves, makes excellent salading.

Beetroot is exceptionally good this season. I find the Turnip-rooted kind to be much grown in this district by market growers.

Radishes are much used hereabouts as a winter salad. The Black Spanish and China Rose Radish are the sorts grown for winter use, as, unlike summer sorts, they are eatable when fully grown.

Parsley is never in more request than at Christmas; the finest double curled only being in great demand. It is grown in any sheltered spot where protection can be given it in severe weather; up to the present frost has been merciful, and therefore there is an abundance of good vegetables of all kinds, the supply of Potatoes, Carrots, Parsnips, &c., being especially good this season.

Fruit of home growth is now very scarce, and those who declare that we are already overdone with orchards, should take note that we are really without fruit for half the year—at least such as cannot afford the luxury of glass forcing houses. Apples are now scarce, and sell freely at good prices; in fact, anything that will pass muster at all as fit for cooking is fetching 5s. and 6s. per sieve, and really good dessert fruits of home growth are worth double that price. American Apples are not nearly so much liked as they used to be. They sell because home-grown ones are scarce. Pears of dessert kinds are also getting scarce and realise good prices. Winter Nelis, Beurré Rance, and a few of the latest kinds are now the principal varieties obtainable. Culinary Pears are now in request; they are most useful at this season when anything is almost welcome in the shape of fresh fruit. I find that market growers are planting late-keeping Apples, but anything like a supply for market during the first three months of the year requires planting on a more extensive scale than has hitherto been done. We want, too, better systems of storage. At present we live too much from hand to mouth in the matter of home-grown fruit.

Gosport. J. Groom.

MARKET PRICES.

It is declared in some quarters that trade depression arises not so much from the falling off of trade as from the universal fall which has taken place in prices. A grower of market vegetables referring to this fact, said a day or two ago, "I have this morning sent up a big three-horse load of Brussels Sprouts, Savoys, Cabbages, Coleworts, &c., which a few years ago would have realised from £9 to £10, and now it will realise not more than from £3 10s. to £4. I remember that some twenty years ago prices were then as bad as they are now, but the fall was only temporary, and soon went up again." Now, all other things as well as vegetables have a downward tendency, and there is little prospect of a reaction. It would be exceedingly interesting to have the returns of this grower's market prices for the past twenty years. On every hand I see green crops spoiling, Cabbages bursting and decaying, and ample evidences that vegetables of the commoner class are far too abundant. If a check were to be put to this over-production, no doubt prices would go up to some extent, but the consumer would suffer; and still further, our deficits at home, whether purposely or accidentally produced, are very soon made good by foreigners. It is singularly contradictory to hear market growers, on the one hand, declaring that prices are unprofitable, and that with all their market knowledge and practical experience it is hard to make both ends meet; whilst in another direction we hear farmers advised to cultivate vegetables in place of Corn. My neighbour, allow me to state, does not send his vegetables into the market, and thus pay heavy dues and and take his chance of sale. He has regular and good shopkeeper customers, who always pay him fair market prices; hence he is in a better position than the ordinary market attendant. It is easy to talk about salesmen and market rings, but it may be taken for granted that the market trade is universally depressed, and that there is by no means any immediate hope of improvement. Kentish fruit growers have been taken to task because, market prices being unremunerative, they allowed their Plums to rot on and beneath the trees last autumn and did not convert the fruit into jam. Those who criticise in that way may not be aware that the jam trade even is overdone, and that jam manufacturers find stern competitors. Just now, for instance, the public can purchase for 4d. anywhere two-pound tins of the purest golden syrup, and no jam manufactured can compete with that. It is so highly rectified, that it is purer than honey. The days of the dark, thick compound called treacle or molasses have gone, and it is probable those of inferior jams have gone also. This result cannot certainly be deplored, for some of the jams were but miserable decoctions in which pure fruit figured infinitessimally. All must also remember that with fruit plentiful in private as well as in market gardens and sugar so cheap, great quantities of preserves are made at home, thus again checking the jam manufacturer's trade. Some more tangible suggestions for the removal of trade depression are therefore needed than have yet been offered as a solution of the difficulty.

A. D.

Indoor Garden.

PALMS FOR ROOM DECORATION.

(CHAMÆDOREAS.)

This genus consists of numerous dwarf-growing plants, with, for the most part, slender stems and elegant pinnate or feather-like foliage. In a wild state they are always found growing in comparatively elevated situations under the larger forest trees as underwood, and but rarely in the open. Under cultivation they thrive best in an intermediate house, well shaded and liberally supplied with moisture, and many of them are admirably adapted for room decoration, as, just after the first year from seed, they become extremely ornamental, and their bright, smooth, green leaves are easily cleansed from dust. Even in comparatively small pots they continue to increase in beauty and stature annually. As a matter of course, they should not be allowed to stand close to the windows in severe weather, nor should they be subjected to cold draughts. If the foliage is occasionally sponged and the roots well supplied with moisture, in the form of tepid water given at midday, few plants excel these Chamædoreas as decorative objects, a fact fully recognised in Germany, where they are largely used in this manner. Many of them flower annually, and their long branching inflorescence adds materially to the interest that attaches to them. As in most instances they perfect their seeds, a supply of young plants can be easily obtained at little expense, which is not the case with the majority of the Palm family. Chamædoreas should be potted in a mixture of peat and loam, and liberally supplied with water; indeed, failures with them are usually traceable to a meagre supply of moisture. The first year's seedlings produce broad, simple leaves, deeply divided at the ends, but even in this state they are ornamental. In the second year they begin to develop pinnate leaves, which increase in length and breadth as they get older. In a few instances, however, this broad, deeply-cleft leaf (bifid) is the normal condition of the species, of which C. geonomæformis affords an excellent example. The Chamædoreas are all natives of America, and the following kinds are amongst those which we have found to thrive best as indoor plants, viz., C. graminifolia. This is a slender, Grass-leaved kind, as its name implies, and it is one of the most elegant of the family. Its leaves are plume-like, dark glaucous-green, and when fully

developed attain a length of a yard or more ; its branching inflorescence is pendulous, and about a foot long. C. elegans has a more robust stem than graminifolia, and the foliage, which is gracefully arched, grows from 3 feet to 4 feet long in fully developed specimens, whilst the leaflets are some 6 inches long and about 1 inch broad, tapering at either end, and bright green. C. Sartori resembles elegans, but the leaflets are broader, and do not taper so much towards the base. It has a very hardy constitution, and is one of the best for the purposes indicated. C. Arenbergiana is also a very beautiful kind ; its bright green leaflets are pendent, and taper to a tail-like point. C. Wendlandi is another beautiful species, and perhaps the most useful of all for room decoration. Its bold, arching green leaves are about a yard long, whilst the leaflets are some 12 inches in length and 2 inches in breadth. C. glaucifolia is a slender-stemmed kind with long, arching, feather-like leaves, having a milky glaucous hue on both surfaces. C. geonomæformis attains a height of about 4 feet, and bears simple, deeply cleft or bifid, strongly ribbed, deep green leaves, which are some 9 inches or more in length, and from 4 inches to 6 inches in breadth. Its graceful pendent flower-spikes add much to the general effect, although the flowers are of the same hue as the leaves. C. Ernesti-Augusti is also a bifid-leaved species, which attains, when fully grown, a height of 5 feet or 6 feet. Its stem is about 2 inches in diameter, and conspicuously ringed by the scars of the fallen leaves ; these are broadly sheathing and stem-clasping at the base, from 1 foot to 2 feet long, cleft for about half their length, serrated at the edges, conspicuously ribbed, and dark green in colour. When in flower this little Palm is especially ornamental ; the male and female flowers are produced on separate plants. In the former the spadix is branched, the numerous long, slender branches being densely clothed with little round orange-scarlet flowers. The female plant produces a single (or more rarely a double) thick, fleshy green spadix, studded with numerous bead-like, coral-red flowers. W. H. G.

Roman Hyacinths at Christmas.—This charming early-flowering Roman Hyacinth, so dwarf and fine, and bearing chaste, delicately-scented, white flowers, is now largely imported fram France, Holland, and Belgium for forcing purposes. It forces with great rapidity, and the bulbs, though not nearly so large as those of our ordinary Hyacinths, produce several spikes of flowers each. There is a blue form of this early Hyacinth, sometimes called Parisian Hyacinth, that is a fortnight or so later than the white one, but is a useful succession notwithstanding. The early Roman Hyacinth is well worthy the attention of those who have a glass structure in which a few things can be got early into flower. Even when there is no artificial heat a few of these early Hyacinths can he had in bloom some time before our ordinary Hyacinths, even when planted at the same time. Last spring, having but little room to spare, I planted some of the ordinary Hyacinths in pots, using 6-inch ones, and placed one bulb in each. Round some of these I put a circle of Roman Hyacinths, using four, five, or six bulbs, according to their size, and I found that these started into growth, and actually came into flower, almost before the Hyacinths in the centre of the pots had made much growth. As soon as the flowers furnished by the Roman Hyacinths had died away, the foliage was removed with the decaying flowers, and thus the ordinary Hyacinth had space to grow, and in each case flowered finely, notwithstanding the presence of the bulbs just alluded to. Perhaps this practice is hardly to be commended, but I did it for economy's sake, and I was well pleased with the result. As a matter of course, the soil should be thoroughly good, and it is well to apply a little weak manure water, or a pinch of patent manure to the late Hyacinths. It matters not what care may be taken of the bulbs of the early Roman Hyacinth, or how carefully they may be preserved ; they never flower so early or so well as the newly imported bulbs do. —D.

NEW AND OTHER CHRYSANTHEMUMS.

New, or what are supposed to be new, varieties of these favourite flowers make their appearance in such numbers each year, that those who have not an opportunity to judge for themselves get bewildered as to the best varieties to select for the purpose of increasing their stock, which, however, should never be too large. Far better is it to grow a certain number of plants of acknowledged merit than to speculate in untried novelties. Let me, therefore, give an account of some of the best that have come under my notice during this season, and others brought out the year previous. In spite of the glowing terms in which some new varieties are described, many do not even equal older kinds, let alone excel them. It happens sometimes that some of our best, well tried varieties fail to produce what is yearly expected of them, but it would be folly to discard

Chamædorea geonomæformis.

such kinds on this account. Seasons vary greatly ; sometimes we have extremes of heat during summer and sometimes the reverse, and allowances are not always made for these contingencies. The plants do not receive treatment accordingly, and, as a matter of course, they suffer. Let me instance Belle Paule as an example of a Japanese variety which this season, owing to some cause or other, did not perfect its blooms, except in a very few cases, and these principally in the northern and midland counties. Perhaps next year it may come out again in true character. Princess of Wales in the incurved section has not been so good this season as usual, but who would think of discarding this, the finest, perhaps, of all the incurved class, on that account? By way of supplement to the list given by "C. H. P." (p. 561), allow me to furnish a few names of kinds which I consider worthy of a place in any collection.

New kinds belonging to the incurved section are produced so sparingly, that any addition to this class is always welcome. Only two sorts have appeared which promise to give satisfaction. The first is Mrs. Norman Davis, a yellow sport from Princess Teck. It is bright orange-yellow, and evidently possesses the form of flower and breadth of petal of its parent, which, as is well known, is quite first-rate. Yellows of this class are much needed. At present we have only two that can be called first-class, viz, Jardine des Plantes and Mrs. Bunn. The first cannot always be had in its best form, and the latter variety being naturally an early bloomer, it often happens that (in the south of England at least) the best blooms are past before the principal shows take place. This new kind just alluded to, if like its parent, will therefore be doubly useful.

Lord Eversley, a variety certificated at Reading last November, is also a sport from Princess Teck, which originated at Heckfield; hence its name. It is white, faintly tinged with cream. Its petals, which are very smooth, incurve better (if possible) than its parent, and being naturally a late bloomer, will be valuable. I should like to say a word in favour of Mrs. Ralph Brocklebank, the new yellow sport from Meg Merrilies—a grand stock. The sport is said to have even a better constitution than its parent. I regard it as the flower of the year in the Japanese section. Mrs. J. Wright is a seedling raised by Messrs. J. Laing, and an acquisition too. It is a lovely pure white with round, twisted florets of excellent form, and quite full in the centre. Alpha, another seedling, is likely to prove valuable. It is a full-centred flower with slightly twisted, round florets of a rosy purple colour, shaded with white. C. L. Teesdale, as shown by Mr. Cannell, is a creamy blush of excellent quality. Snowstorm, as exhibited by Mr. Davis, is a large-flowered, pure white sort, as its name infers. It produces blossoms in profusion, and is a valuable kind for cutting for indoor decorative purposes.

Of older Japanese kinds introduced a year ago, Mons. N. Davis deserves notice on account of its rich red colour. It is the nearest approach to a scarlet of any with which I am acquainted. Its florets are of a drooping character, which renders it graceful in appearance. Martha Hardinge, sent out last season, is sure to make headway. Its golden coloured thread-like petals are heavily suffused with bronze. An important point in its favour is the long time during which the blossoms last in perfection. Maiden's Blush, also sent out last spring, has come quite up to its representation. Some magnificent blooms of it have been shown this autumn. It possesses an admirable constitution, and its flowers are massive. The blush tint being of the faintest description renders it especially attractive, and it bids fair to take the place of Elaine as an exhibition flower.

Amongst new reflexed flowers of this season's introduction, Amy Furze comes first. It is a seedling, the colour of which is blush, mottled with pale magenta. It is of large size, excellent in form, and quite a type in the class to which it belongs. Temple of Solomon, an old variety again brought forward as shown by Mr. Davis, is excellent. It is rich yellow in colour, of medium size, and of good form, and should be extremely useful both as a decorative variety and for exhibition. Elsie is another of the reflexed type, the colour, a creamy white, being quite charming in appearance, and as shown by Mr. Cannell, it cannot fail to be much sought after. In addition to the varieties of Anemone-flowered kinds named by "C. H. P.," one belonging to the Japanese type, viz., Ratapoil, deserves notice. In colour it is buff or dull brown, with long guard florets and a medium-sized disc. This section being as yet not overloaded with good kinds, this should have a place on account of its peculiar colour.

A new departure has been obtained in regard to the varieties Chardoneret, Crœsus, and Scapin. They belong to what is termed the fimbriated section; the petals being deeply toothed give them a pleasing fringy appearance. The three just named received first-class certificates, and as shown were certainly worthy of them.

As to propagation, in my opinion, a good start goes a long way towards a successful issue in most matters connected with gardening, but in no case

does this apply more forcibly than in that of the Chrysanthemum, whether the plants be intended to produce cut blooms for exhibition or for home decoration. Opinions differ as to which is the best time to insert cuttings, but after careful comparison I have come to the conclusion that from now onwards is the best period at which to take the cuttings. By inserting them now the plants have an opportunity during their different stages to grow along quietly without any hurry or excitement, which is not good in the case of Chrysanthemums. Spring propagation is a mistake where first-class blooms for exhibition are required. The plants have not sufficient time in which to develop naturally, and in some stages have to be hurried, which does not answer. Another objection to late propagation is that valuable space must be occupied by the old roots which are to supply the cuttings. There are two classes of cuttings it should be borne in mind when selecting them. The wrong ones are those which come direct from the old stem, and which are likely to perfect a bloom-bud at a time when growth only is required. Cuttings terminated by a flower-bud should be discarded as worthless. Oftentimes some varieties throw up cuttings so freely that more can be had than what are required, and if allowed to grow, one injures the other by drawing it up weakly. The right thing to do, then, is to thin out the weakest, thus allowing more space for the strongest. This should be done some time previous to taking off the cuttings. The right kind of cutting to take is the one which comes up at a distance clear from the stem, and which does not form a flower-bud as previously described; select such cuttings about 3 inches in length and trim off the lower leaves. Some growers advocate the removal of wood-buds from the stems in order to prevent suckers being thrown up so freely during summer, but I do not consider this at all necessary. The cuttings should be inserted singly in small pots; those commonly called thumbs (2½ inches in diameter) are best. These should be perfectly clean. Place one crock over the hole at the bottom, and over this lay a little of the rougher material from the soil prepared for the cuttings, and fill up the pots nearly full with the following compost, viz., about equal parts of loam and leaf soil, with a free use of silver sand, all thoroughly well mixed by passing them through a half-inch sieve. Press the soil firmly, and over the top place a thin layer of sand to be pressed down with a blunt dibber for the cuttings to rest on, the rooting process being quicker in sand than in soil. In inserting the cuttings see that the base rests firmly on the bottom of the hole; press the soil around them firmly, and give a gentle watering through a fine rosed water-pot to settle the soil and sand. The next thing is to consider which is the best position for them to occupy while roots are being made. Many growers prefer to place them in cold frames, but I do not approve of this method, because much valuable time is lost during severe weather by the soil in the pots getting hard frozen. Such a state will not kill them, but they will not progress. The best place for them is inside a cool house in which there is just enough heat to keep out frost and damp. On the stage of such a house place some handlights or small propagating frames; inside of these, and also upon the stage, put some coal ashes, say 1 in. or 2 in. thick. These will stop draughts from coming through the latticed stages, and will keep the cuttings cool. Keep the lights closed until roots are formed, except for an hour in the morning, for the dissipation of moisture; in the evening, the glass coverings should be wiped dry to prevent damping off; shading will not be required. In about a month some of the cuttings will be rooted, the strongest growing varieties being the earliest to emit roots; a little air should be given to those rooted by tilting the sash; then gradually increase it until the sashes may be entirely removed. Some varieties will not root so readily as others. Those which show a tendency to flag should be removed to a separate compartment, where they can be kept close for a little longer. By keeping the frames closed little water is required during the process of rooting, yet the soil must nevertheless be kept sufficiently moist to suit the cuttings. E. Molyneux.

Swanmore Park, Bishop's Waltham.

Billardiera longiflora.—What a charming plant this is! Here a wall space 3 feet wide by 6 feet high is completely covered by it, and now and for a long time—months, in fact—it has been a mass of turquoise blue berries. It is planted in an ordinary, but fairly well made, Peach border. It grows in the most vigorous manner, runs up the wires and up the shoots of the trees, and at one time had got to the top of the 10 foot wall, entangling and threatening to strangle the trees themselves. It is never injured by any weather. Why is this beautiful plant so rarely seen?—T. Smith, *Newry.*

A much-neglected climber.—On visiting Drinkstone Park in October last, I was much pleased to see a grand plant on the roof of one of the stoves of Ipomæa Horsfalliæ. It had less foliage and more blossom-buds than I had ever seen before on this fine old plant. Some of the bunches of bloom were spiral-shaped and nearly a foot long, and I should be accused of exaggeration were I to give an estimate of the number of such bunches. Suffice it to say that, when expanded, the entire of one side of the roof must be crowded with brilliant blossoms. I have grown this plant fairly well in a pot, but when planted out it is apt to produce an excess of leafage. Mr. Palmer, however, has so managed this plant that when his profusion of shoots are tied down from the roof the latter will be all flower. Treated thus skilfully, we have hardly a plant to match this magnificent old Ipomæa either in brilliancy or usefulness for cutting. It enjoys direct sunlight; and Mr. Palmer attributes its abnormal floriferousness this season, partly at least, to his having rather severely pruned a fine Allamanda that used to encroach heavily on the preserve devoted to the Ipomæa. Be this as it may, this Ipomæa, as well as not a few other stove plants and climbers, the general collection of Orchids at Drinkstone, and the fine Grapes are worth a journey of many miles to see.—D. T. F.

Flowers at Mr. Arthur's funeral.—Klunder made a 3 foot cross of two shades of Heliotrope, Noir and Jersey Belle, for the casket of President Arthur. This was a rich design, as it looked as if cut from velvet, so evenly was it bedded, and the colours or shadings were so arranged that half the cross seemed to lie in a shadow. A mound of Marie Louise Violets was arranged by the same florist. This was 2½ feet high, and was composed of 3000 flowers. At one side there was a draping of two Cycas leaves (Cycas revoluta), and on this hung a large cluster of Perle Roses. A large cross of white Roses had at its base a bunch of Mermets and Lily of the valley. A cluster of 125 long-stemmed Niphetos Roses was held by a white ribbon sash, in which Jasmine and Lilies of the Valley were interspersed. Brower made a wreath of Russian Violets, which was fastened by a cluster of black Pansies. This was a superb piece. Gordon arranged a cross and crown composed of Lily of the Valley and Narcissus, with a sprinkling of fine Grasses and Ferns, which was an exquisite design. President Cleveland sent a scroll of Cape flowers lettered with purple immortelles—"Finis." A plaque of Cape flowers, inscribed "Requiescat in pace," was also sent from Washington.—*American Florist.*

Petræa volubilis.—This plant, though introduced more than a century ago, is still but little known. For profusion of bloom, grace, and exquisite delicacy of colour, it is, perhaps, without a rival. It is a twining stove shrub, with leaves not unlike those of some of the Bougainvilleas, but larger. The flowers are borne in marvellous profusion in elongated light airy racemes.—J. G.

GARDEN IN THE HOUSE.

PLANTS FOR HOUSE DECORATION.

DURING winter, and especially at this season, great numbers of plants are required for house decoration, and no one should object to this use of them, seeing how much they beautify the different sites assigned to them. So much are we accustomed to seeing and admiring well-grown plants in front halls, corridors, dining-rooms, drawing-rooms, and in other positions, that we really think a house desolate without them, and for this reason, as well as on account of the knowledge that plants thus employed are much more appreciated than those always kept where grown, that we never demur at any reasonable request for decorative flowering or fine-foliaged plants. Many are under the impression that a few days' sojourn in a house proves most injurious to plants so employed, and sometimes this is the case, the rubbish heap receiving many that have been ruined either from the effects of gas, neglect, or too long a stay in a darkened corner. Those who grow the plants, or someone equally experienced, ought also to attend to them when in a house. Over-zealous and inexperienced persons are apt to be too free with the watering-pot or jug, a daily saturation quickly ruining a plant. Many under-gardeners are also very reckless in this respect, both giving too much and too cold water. Some of the most effective decorative plants have to be taken from plant stoves, and, therefore, when in a cooler atmosphere they ought to receive less water than usual rather than more of it, and it ought always to be slightly warmed. Even cool-house plants require less water than usual in much-darkened rooms, where they are often placed, and where they suffer when watered daily almost as badly as stove plants. Not a few stands are water-tight, and unless a little judgment is exercised, the plants may soon be standing in water. Our plan is to change most of the plants every Saturday morning, those to be introduced being properly moistened at the roots before they are taken into the house. About three times during the ensuing week all are carefully examined, and if approaching dryness a little water is given. No house or window plant ought to stand in tins or saucers partly filled with water, yet such is too often their lot, and this is bound to soon ruin them beyond recovery. Nor, on the other hand, should they suffer from want of water, though they are more likely to recover from this check than they are from being over-watered.

It is really surprising how long some plants, notably the Maiden-hair Fern, will remain healthy either in a window or in a fairly light position, provided no cold draughts of air or water are given them, and they are carefully watered. Several other Adiantums, notably palmatum, gracillimum, assimile, Capillus-veneris (of which magnificum is the best form), mundulum, Lawsonianum, formosum, and Williamsi are very serviceable for house decoration, and will keep fresh for a long time. The same may be said of Pteris serrulata and its various crested forms. P. tremula, Asparagus plumosus scandens, and such Palms as Areca Baueri, Chamærops, Kentia australis, Latania borbonica, Phœnix dactylifera, and Seaforthia elegans are all good for house decoration, and these and other kinds mentioned are available for those who may only possess a greenhouse or cool conservatory in which to grow them when not required in the house. Pans or pots of Selaginellas are very effective in the house; and I know instances where they are kept near a window all the year round and always look fresh. For this purpose I can recommend S. Kraussiana (denticulata) and its golden and silver forms, Wildenovi and stolonifera. I know a case in which a handsome plant of the Filmy Fern (Todea superba) has been grown in a large pan under a bell-glass for six years, and it annually improves. It stands under a stained-glass window at the end of the principal staircase, and being frequently watered and never allowed to become very dry overhead, it

is always attractive in appearance. Begonias of the Rex type are also good house plants, and everybody must know what a good servant Ficus elastica is. Of greenhouse flowering plants Arum Lilies prove the most difficult to kill, and under fairly good treatment plants in 7-inch pots will flower freely in a window. Cyclamen persicum also thrives and blooms well under similar conditions; but Chinese Primulas are apt to lose colour, and present a miserable appearance unless much favoured. Cinerarias are not easily kept clean. Cypripedium insigne will last on a table, not far from the light, longer than any other flowering plant, provided always it does not suffer from want of water. Epiphyllum truncatum, or Crab Cactus, as cottagers prefer to term it, will, if not over-watered or over-potted at any time, flower beautifully in a window, and the old Cactus speciosissimus is still a favourite for house decoration. W. I.

CHRISTMAS FLOWERS.

The dead season is now almost banished from our gardens. The Orchids are a host in themselves. Forced pot plants *ad libitum* consist of Deutzias, Lilacs, Valley Lilies, Azaleas, and these are but samples of the flowers of the season which every day become more numerous and brilliant and fragrant; for among the latter, what flowers at any season can match the fragrance of the Violet, Valley Lilies, and early Narcissus, single or double? Where frames and sheltered warm nooks abound, Violets are almost as plentiful, and generally far larger and more fragrant, in December than March. Christmas Roses, too, add a special purity and richness to the flowers of the season where these abound, and form a charming combination with brilliant Poinsettias in dinner-table or other arrangements. There is something specially pleasing in thus crowning the Christmas festivities, and preparing to deck the infant brow of the yet unborn year with the delicate tenderness, fragrance, and sweetness of pure and beautiful flowers. Dust and care, toil and sorrow, disappointment and loss will come all too soon; and hence it is well to start with our fairest, sweetest, and best. When all without is frost-bound and bitten, or hidden behind the yellow veil of winter's foul fogs, the other side of the glass should wear its sunniest looks and its brightest apparel.

It is winter without, though there is a strange beauty, a powerful fascination, in the fair rime frost that so richly clothes each branchlet and twiglet, and clothes all the trees with beauty. But it is impossible to imagine a richer contrast to a world thus bejewelled in pearls than a brave display of colour under glass. Who loves a garden should love a greenhouse too, and there are few better methods of proving our love than the filling all such with beauty, especially in the time of winter. To enjoy all this with the thermometer down to 12°, a liberal amount of artificial warmth is needful; and fortunately plants are not now nearly so easily injured by any excess of heat as they are after the new year, so that now a comfortable atmosphere of from 45° to 60° may be enjoyed among our beautiful flowers under glass without damage to the plants in bloom. With the outside world frost-bound it is poor enjoyment at the best to shiver among our favourite flowers. I have seen many such cases where the stoker would have given more pleasure than a fresh batch of plants from the forcing pit or intermediate house—the latter is what all conservatories should be during the cold season. Just now they may safely bear more for a month or so towards the comfort of their owners in the matter of heat than merely providing for the safety of the plants.

Hortus.

Ivy in hanging baskets.—Amongst the very best plants for filling wire baskets that are hung up in corridors, verandahs, and other exposed places all the year round are some of the many beautiful varieties of Ivy, especially those with very small foliage and graceful trailing shoots. Some years ago I was very much pleased with the excellent effect produced by means of the common English Ivy alone, that an amateur friend used to employ in a great variety of ways, for decoration, and especially for filling hanging baskets both indoors and out, the windows being draped with elegant shoots from plants growing in the smallest possible root space. Since that time I have employed Ivies for baskets, for brackets, and balconies, and with excellent effect. Anyone who has not tried them can have little idea of the variety of form and colour to be found amongst these common hardy plants, and the smaller the root-space the better do they display their variegation. The golden blotched variety, that only produces a few golden leaves at wide intervals apart when planted in rich soil, becomes beautifully variegated when starved at the root, and some of the silver variegated sorts are equally interesting. The large-leaved kind called Hedera maculata, that in rich soil assumes a dull white variegation, is very much improved by basket culture, and the best of such hardy subjects is that they impart a cheerful look to a dwelling-house at a time when other less hardy plants need the shelter of heated glass structures. For lining the base of hanging baskets nothing is equal to the Stonecrops; they look fresh and green at all times of the year, except when covered with white or yellow flowers.—J. G., *Hants.*

Room plants.— I was much interested in reading Mr. Douglas's description of the exhaustion and subsequent renewal of the bulbs of the Amaryllis. Allow me to ask him whether a similar process takes place with regard to other bulbs In Vallota, for instance, which flowers at the end instead of the beginning of its leaf growth, has the bulb to be renewed after flowering and before going to rest? If so, it appears to me that late flowering must be injurious to it. I cannot succeed with Vallota as a room plant, though every care is taken as to watering sufficiently, but not over much. It loses its leaves and dwindles away, the roots dying. Yet my next-door neighbour grows it admirably, keeping it in a room without fire and even exposing it to a white frost. It also flourishes and multiplies in cottage rooms in Derbyshire. Imantophyllum miniatum, on the other hand, grows and flowers admirably with me in a window which it never leaves.—A. Johnson, *Blackheath.*

Trees and Shrubs.

TREES AND SHRUBS FOR THE SEASIDE.

In many cases the soil near the seacoast is sandy, and few things, indeed, will grow luxuriantly in it, but the impression is very common that sandy soil produces a great many roots, and so it does; but it does not promote a robust top-growth so strong and healthy as to resist storms to any extent, and this is one reason why seaside vegetation is so stunted. The remedy is to give more attention in planting by introducing new and good soil to the roots, or mixing some heavy material up with the sand. Manure, too, is beneficial, and may be applied largely, especially in the form of top-dressings, at the present time. This applies more particularly to trees planted at the outset without manure and are now in a half-starved condition. In planting, the manure should be introduced in the operation, and it is a good plan to trench it down to the depth of several feet, as this induces the plants to root deeply, and thereby resist the pressure of the wind; in fact, seaside trees should never be planted in shallow soil, as the roots will only run along the surface, and when the plants become large and present a large surface to the wind, they almost invariably get blown over; and this leads me to remark that beautiful as tall, well-furnished trees are in parks and inland, those of a tall-growing habit should never be planted on the seaside, or anywhere exposed to the high sea winds. Such trees may grow for a time, and even give promise of becoming handsome specimens; but this is only temporary, as they are blown down before gaining anything like maturity, and then the vacancy they leave behind them makes their owners wish they had confined themselves to dwarf and robust-growing subjects. This is the secret of successful seaside planting everywhere, and, speaking from experience and observation, I would advise planters to confine themselves mainly to the following plants:—

The evergreen Euonymuses merit special attention, as they are free rooting plants of compact growth. Excepting, perhaps, the Ivies, there is no class of variegated Evergreens to equal them in attractive colours, and they succeed admirably on the very margin of the sea. They may be used as hedges, planted as isolated specimens, or trained up a wall, and in every instance they will remain fresh and healthy from year's end to year's end. The Escallonias, especially E. macrantha, are excellent for the seaside. Their leaves are very pretty, and salt spray or strong gales do not injure them in the least. They are much of the same habit as the Euonymuses, and may always be planted with them. The Aucuba does not always thrive well on the sea-coast, and it is not recommended. The Arbutus is amongst the tall-growing seaside trees, and it does very well if sheltered by others, but we have had it injured when fully exposed, and although remarkably pretty when in flower, and showy above all berry-bearing plants when in fruit, I would only plant it to a limited extent on the margin of the sea, but a mile or two inland it may be more freely used. The Cotoneasters all do well near the sea, and as they are so very ornamental in berry at this season, they should be planted freely as wall plants, and to associate with other subjects. Few open-air shrubs are more valuable than Myrtles, and it is much in their favour that they can be safely classed amongst seaside plants; indeed, they grow much more luxuriantly near the sea than inland, and I know of many fine specimens in Wales that are frequently drenched with the spray from the sea. The Sweet Bay is another favourite that can be recommended as coming under this heading. Its leaves are valuable in many ways besides placing the plant in the foremost rank of Evergreens. In the early summer it becomes a mass of yellow flowers, and by the autumn it often droops under a heavy load of purple berries. The Laurustinus is not surpassed in its adaptability of withstanding the weather on the nearest borders of the sea, and, apart from its being a pretty evergreen bush, it is wreathed in white flowers from November until April or May. None of the Coniferæ are very meritorious in this respect, as they are all so much inclined to ascend. The Austrian and Corsican Pines are amongst the best of their class to weather the storms, and I would limit the Pine tribe to these two. Common varieties of Fuchsias grow and bloom profusely near the sea, and they should be included in all collections. Gorse is one of the hardiest of all, as it is squatty in growth and is never killed, but it is rather common. It does well for a margin to more choice subjects. The Guelder Rose is more valuable, as it is a very beautiful flowering shrub, and its drooping or curving habit of growth prevents it from being injured by the wind. The Privets are all extremely hardy, and may be planted freely, and the Sea Buckthorn is another which should not be forgotten. J. Muir.

Leycesteria formosa.—This is a capital plant for the shrubbery border, remaining, as it does, attractive for a great length of time. Towards the end of the summer the inflorescence appears in the form of long tassels, and as the flowers fade they are succeeded by black berries, which, with their peculiarly bronzy-coloured appendages, are curiously pretty. Leycesteria is not quite hardy in all places; it is, therefore, desirable to plant it where it is somewhat sheltered. It is, however, merely the young wood that gets injured, and that only during very severe frost. By judicious pruning at the end of March, when some of the old wood should be cut out

and some of the young branches shortened back, very handsome plants may be obtained. The pruning should never be done until the winter is past.—S.

CLETHRA ARBOREA.

Shrubs which blossom naturally in autumn are few and far between, but Clethra arborea is a conspicuous exception. It flowers with remarkable profusion in October and November. In some tree lists it is classed amongst hardy shrubs, but it would not, I apprehend, prove hardy in all parts of the country. We have four bushes of it here, but none of them are left out during the whole of the winter. They are grown in large square boxes like Orange trees, and are moved out in summer and are indoors in winter. The largest of them is 20 feet in height and 10 feet through, and very bushy. The others are about 6 feet in height, and the whole of them flower with the greatest freedom. Their blossoms, which are almost pure white, are produced in upright clusters or little racemes, which extend about 6 inches above the leaves, and the flowers emit a fragrance almost as sweet as that of Lily of the Valley. In fact, this Clethra is commonly called the Lily of the Valley tree, and it well deserves the name, as the blooms are very much like those of the Valley Lily. They are exceedingly pretty on the tree, and very effective when cut and arranged in glasses. The flowers, indeed, are admired by everyone, and the plant merits attention, as it is easily grown and capable of making a good return for the labour devoted to it. It may be placed in the open air in April, and allowed to remain there until the end of November. It will bloom in the open air, but rough autumn winds are apt to spoil the blossoms, and before this occurs it should be placed under cover. It grows freely in a mixture of two parts loam, one part sand, and one part half-decayed manure. It is not liable to be attacked by insects; indeed, I never saw one on it. It requires large quantities of water at the root when growing, but in winter it may be kept rather dry. After flowering it forms a great many seed pods, which should be removed. Some of our plants are very much root-bound, but that is rather an advantage than otherwise, as it prevents them from making too much wood, and causes them to produce a wonderful amount of bloom. J. Muir.

Sambucus racemosa.—The scarlet-fruited Elder is very seldom found in British gardens of such a size as to display its beauty. When laden with its large dense cymes of fruit, "which resemble miniature bunches of Grapes of the most brilliant scarlet," the tree truly presents a splendid appearance. Planted in open, dry situations it does not seem to thrive properly, but in a rather damp, cool spot it soon attains a considerable size, and fruits freely. For the woodland walk or the wild garden, where low-growing shrubs keep the ground shaded and cool about its roots, the scarlet Elder grows as freely, and would, perhaps, attain as large a size as our common native Elder, Sambucus nigra. S. racemosa is widely distributed throughout Central and Southern Europe, and in some of the alpine valleys makes a splendid show with its masses of brilliantly coloured fruits. Like most of the Elders, it sports freely, and a cut-leaved form and also one with variegated foliage are in cultivation in continental gardens.

Azara microphylla.—Though it can only be safely pronounced as perfectly hardy in very favoured localities, this South American shrub is such a beautiful Evergreen, that it is well worth the protection of a greenhouse, for it is one of those subjects that can be kept outside during the summer, and in the winter are available for the decoration of the conservatory, or for indoor furnishing in places where the more delicate plants might be injured by draughts or cutting winds. The glossy character of the foliage of this Azara is a considerable advantage when employed in this manner, as the accumulation of dust which sooner or later collects on room plants can be readily removed by the syringe. The Azaras are all ornamental evergreen shrubs, natives of South America; but the most graceful is A. microphylla, introduced a few years ago. It is a regular-growing shrub, reaching a height of 6 feet or 8 feet, with the branches arranged in a fan-shaped manner, and thickly clothed with small, deep green, glossy leaves. The flowers are inconspicuous, but this is atoned for by the beautiful foliage. When occupying an isolated position it forms a somewhat globular-shaped bush, built up, as it were, by numerous tiers of flat, fan-like branches. This Azara is not difficult to strike from cuttings of the half-ripened shoots put in a sandy soil and kept close till rooted.—Alpha.

THE HAWTHORN IN HAMPSHIRE.

No English landscape can be considered complete without the Hawthorn, adding, as it does, a richness to the scenery. When dispersed in clumps or singly in the park it possesses a charm which is not to be neglected by the landscape gardener; it forms the universal hedge plant, and for efficiency it has no equal, and when to this is added that it will grow in almost any soil, it is in use everywhere for the purpose. I have recommended where it is planted as a fence round plantations or meadow land that it should be trimmed on the sides only. From experience, I have found that it will still form an effective fence, while, at the same time, it affords shelter and allows the blossoms to make a beautiful fringe round the paddock or plantation.

There are two parks in this county, namely, Hursley Park, near Winchester, and Hackwood, near Basingstoke, which are notable for the number and age of their trees. "O'ergrown with Lichens to the very top and hung with heavy tufts of Moss," they present such a hoary appearance, that they seem to be the oldest of all living trees. In Hackwood Park, near the bridge over the ponds, is one with three stems springing from the ground and spreading with twisted limbs in most picturesque form baffling description. Those in Hursley Park are remarkable for the quantity of Mistletoe on them, giving the tree a green appearance in winter. The quantity is so great and the boughs so fine, that a watch is set for six weeks before every Christmas to prevent depredators. As a matter of course, it is abundant in this county, and what I have mentioned in a former paper with regard to the Holly will apply to the Hawthorn, that being so abundant it is difficult to say where the largest may be or that I have been fortunate enough to find it, and, further, I do not recollect ever having seen the girth of one recorded.

In front of the "Seven Stars" Inn at Tidcombe Bridge, near Fullerton Railway Station, stands one "with seats beneath the shade;" it has a circumference of 4 feet 3 inches, and a height of 20 feet. Soil, alluvium by the river Test. Measured in 1880.

On the breezy bare downs where the Stockbridge Races are held a solitary tree is conspicuous, and which is difficult to approach in consequence of all the broken bottles found on the racecourse being collected around it. The "broken bottle" Thorn consists of two stems closely united, and together have a circumference of 3 feet 9 inches. Soil, thin vegetable mould on the chalk. Measured in 1879.

A very fine specimen stands on the bank of the field at the cross roads on the west side of the road leading from Braishfield to Romsey; it is said to blossom every year, and it has a finely rounded head; the circumference is 4 feet 7 inches, with a bole of 7 feet and a sheer height of 30 feet. Soil, gravelly on the lower Bagshot beds. Measured in 1880. The one with the largest circumference is in the park of the rectory at Farley Chamberlayne; the girth is 5 feet 3 inches, bole 7 feet, and a height of 30 feet. Soil, clayey on the chalk. Measured in 1879. R. S. J.

The Silver Lime (Tilia argentea).—This handsome Lime stands out conspicuous from all the rest on account of its noble growth and silvery undersurfaces of the leaves—features which render it so distinct from all other kinds. Its greatest merit, however, is that of the foliage remaining in perfection long after that of the common Lime has fallen; it is, therefore, highly valuable on this account alone. It is somewhat remarkable that such a fine tree as this has been overlooked for such a long time, for it is a very old introduction. We have no instance of it, but we see no reason why it should not make a serviceable tree for streets and avenues, where its silvery foliage and bold habit of growth would be shown off to advantage.

PERNETTYAS IN WINTER.

In winter the Pernettyas are among the most beautiful of low-growing shrubs at that season. The many beautiful varieties raised in the Hillsborough Nurseries and put into commerce a few years since have already become very popular, and deservedly so, for there is amongst them great diversity not only in the colour of the fruits, but to a lesser extent in other particulars, especially in the habit of the plant. The common form, that is, Pernettya mucronata, is a low-growing evergreen bush, with sharp-pointed leaves, and the berries, which are about the size of Peas, are crimson in colour. It is a native of the extreme southern part of America, bordering on the Straits of Magellan, and is perfectly hardy in this country. Indeed, it is sometimes used for game coverts, and as birds are very fond of the berries, that should be a point in its favour when employed for such a purpose. In the berries of the newer varieties some beautiful shades are to be found, and, apart from the value of the plants as outdoor shrubs, they show to great advantage in a greenhouse during winter. The plants should be lifted carefully from the open ground and potted just before the berries begin to colour, and very beautiful they are throughout the winter, for the plants do not suffer any injury by being moved. In common with many other Eriaceous plants the Pernettyas can be lifted at almost any season without danger, owing to the dense mass of their hair-like roots. One thing to bear in mind is that, as the small fibres are very delicate, they should be exposed as little as possible to the drying effects of the atmosphere. Seeds not only of the older kind, but also of the newer varieties, come up readily enough; indeed, we have quite a crop of seedlings, the produce of the named varieties, but as yet none of them are large enough to fruit. The berries were simply rubbed up, and mixed with some silver sand to dry up the pulp and separate them from each other, when they were sown in a compost consisting of peat and sand, and were protected by a frame. Apart from any consideration as to their berry-bearing qualities, the Pernettyas are very pretty flowering shrubs; indeed, about May, when densely laden with small, but pure white Lily-of-the-Valley-like flowers, they at once arrest attention, and have the additional merit of remaining a long time in perfection. If a few sprays are cut just as the blooms are on the point of expanding and placed in water, they will keep fresh indoors for a long time. H. P.

Platanus californica.—The leaves of this Plane far exceed in size those of any other; it is a most distinct kind, and may easily be distinguished from all others. It is also said to be the hardiest of all, having been the least injured of any during the past two winters. Even a young plant of it is a noble object, and too much cannot be said in its favour as an ornamental tree. The plants are of course all young, but, judging by the rapid growths which they have made even this season, they will soon make fine trees, especially well adapted for avenues, streets, &c. One would think that such large leaves would be injured by wind and wet, but such is not the case; indeed, on exposed places they succeeded the best during the past season. It is the same as P. racemosa of Nuttall.

Malus Halleana.—In general characters this resembles the now well-known Malus floribunda, the principal point of difference being that the blooms of Halleana are considerably deeper in colour, and consequently, when seen in masses, are more starry than in the older kind. It is a remarkably handsome flowering shrub, and, like floribunda, very useful for small-sized gardens, as it does not require much space, and may always be relied on to flower well. When treated as a standard, the branches grow in a very graceful manner, or, as a bush, the outline is totally devoid of any stiffness or formality. Besides their great value

as flowering shrubs for the open ground, these kinds may be readily forced into bloom early in the season, and are then very valuable for the greenhouse.—A. P.

THE BROAD-LEAVED KALMIA.

(K. LATIFOLIA.)

Grounds of small size might be made much more interesting and enjoyable by introducing a few choice flowering shrubs, such as the above, instead of a repetition of Laurel, Box, and plants of that description. The Kalmia is a native of North America, and is there found growing on rocks slightly covered with vegetable soil. It is also found overhanging the margins of streams, and on the sides of hills in sterile looking soils containing a large quantity of grit. Notwithstanding this, the plant, like other American shrubs—the Rhododendron, for example is fond of moisture, a good supply of which is necessary to its successful cultivation. The Kalmia forms a small compact, dense growing little shrub, admirably suited for the embellishment of the front of shrubbery borders, or for forming beds or clumps on lawns or pleasure grounds. The foliage being of a lively deep green shining hue sets off the lovely pink flowers to great advantage. There are several varieties now in cultivatien, but the old latifolia is still one of the best. Any soil in which the Rhododendron thrives will be thoroughly adapted for the growth of Kalmias. It is not necessary for either that the soil should be peat, although this is best suited to the cultivation of both, and where it is only a question of a single clump, or a few plants, it is better to make sure of success, and begin with that material to grow them in. Where this is not readily obtainable, the parings from the sides of roads or paths, having plenty of grit in them, are a good substitute. With this, mix about a third of thoroughly rotten leaves, and, in planting, tread the soil firmly about the roots. It must be borne in mind that these plants, like Rhododendrons, have a strong aversion to chalk, and any soil containing this in any form is sure to prove fatal to them. The Kalmia is a plant which is somewhat fond of shade; therefore, in planting, make choice of a position where this can be afforded naturally for a few hours during the day. When growing, give a good soaking of water, as the succeeding year's bloom depends on the kind of growth that is made by the plant previous to the flower-buds being formed on the terminal ends of the young shoots. These swell gradually on during the autumn and spring, and at the beginning of June they burst forth, forming a compact bunch of rich pale pink crimped-looking flowers, as singular in that respect as they are beautiful. The Kalmia is a first-rate subject for forcing, and may be bought for that purpose well set with bloom buds at a moderately cheap rate.

Ribes Lobbi.—Though this Ribes cannot compare with R. speciosum, it is still worth consideration as a flowering shrub, for the blooms, which are borne in profusion in May, are in shape a good deal like a Fuchsia, and of a brownish crimson colour, while the petals are pinkish. The individual blooms are rather less than an inch in length. It is a native of California, and was originally introduced by Lobb. The name Lobbi is given it by Dr. Asa Gray in "The Flora of California," but in the *Botanical Magazine* it is figured under the name of R. subvestitum.—A.

December bouquet flowers.—Though this is far from being a favourable time of year for obtaining a good supply of cut flowers, still many varieties are offered for sale in our markets, and those, too, unusually useful for decorative purposes. Among them are the following, viz, Bouvardias, Begonias, Camellias, Chrysanthemums, Cyclamens, Heaths, Epiphyllums, Eucharis, Fuchsias, Gardenias, Gloxinias, Roman Hyacinths, Heliotropes, Lilies, Lilacs, Mignonette, Daffodils, Pelargoniums, Primroses, Spiræas, Roses, Stephanotis, Tuberoses, Tulips, Violets, and Veronicas. Surely, therefore, with such flowers as these at hand, there is no necessity for having flower vases and tubes standing empty, as one often sees them about this season. It may be remarked that flowers are expensive at this time of the year. True, some varieties are so, but not all; and a handful need not cost much, yet this handful, lightly arranged, will fill several specimen glasses, and, if varieties only be chosen which are lasting, such little bouquets will remain fresh for at least a week, provided the water is daily changed, and they are otherwise freshened up a little. Should Fern fronds be introduced, only those which have been well hardened off should be selected. From the list of flowers just given, enough may be obtained for vases, bouquets, wreaths, button-holes, and, indeed, for nearly every kind of floral arrangement, either large or small, according to the taste, or expense to which the decorator may wish to go. The bell-like flowers of the Arbutus are also very useful at this season for cutting, as are also the berries of the same plant a little later in the season. For small decorations, the Gladwin is too heavy; but for large ones it is most effective.

FILLING THE ICEHOUSE.

The proverbial fickleness and uncertainty of the English climate render the season of ice-getting a time of some anxiety to those who are held responsible for securing a supply of a luxury that has of late become almost an article of necessity in large establishments. For ice to keep well when collected, it is of the greatest importance that plenty of good clean straw should be used. This should be got in readiness by having it tied in small bundles that measure about 9 inches through, and are used for the purpose of lining the walls of the house, and for covering the ice-well. The main point is to have the house thoroughly air-tight, for, unless it is well-lined, a cavity is sure to occur between the ice and the brickwork; and, when this takes place, it melts at a rapid rate. Many, although in possession of good houses, fail to keep ice throughout the year, from not using a sufficiency of straw, probably thinking that, because they have a larger supply, they can afford to lose some of it, and yet have sufficient for use as long as it is wanted. This, however, will not prove to be the case, as the whole art of keeping ice is to preserve it from the atmosphere; and the only effectual means of doing this is to pack it well in straw. When this is not done a space is left between the ice and the brickwork, and the whole body of air surrounding the ice is changed every time the house is opened. This, of course, has a very wasting effect on the ice, as the volume of warm air shut in every time the ice is removed is some time in being cooled down. By the use of small bundles of straw, however, it can be done with the greatest regularity, much more so than when loose straw is used, as the pressure of the ice reduces the thickness of the bundles forming the lining to about 6 inches. Till I adopted this plan, I had always a difficulty in having the house regularly lined, as it generally happened that the loose straw which I then used would be bulky in one part and not sufficient in others, on account of getting displaced while filling the house. I may just observe that the bundles of straw are placed on end up the wall of the house, as they remain best in that position. The ice should be well smashed up by using long-handled mallets made for the purpose. This should be done before pushing it into the well of the house, as then it can be done more readily, and a man or two will be able to ram it well round the sides of the house as fast as it can be delivered to them. Sufficient room should be left for plenty of straw to be placed on the top. This should be thrust in as tightly as possible, and the passages filled with the same material. In taking ice out for use when wanted, the outer door of the house should always be kept closed while the inner one is open, so as to prevent the external air from entering. Those not having the convenience of an ice-house may easily have a supply by forming a good large stack, which, if properly made and covered, will last through the summer months. This should be formed on the surface of the ground, and as near the pond as possible, so as to save labour in carting. First of all, a rough circle, of about 15 feet in diameter, should be marked out, round which are placed hurdles to support the sides of the stack. These should be kept in position by driving some large stakes on the outside, so as to withstand the pressure of the ice till the mass has time to freeze together. The inside of the hurdles should then be lined with straw, Bracken, leaves, or any dry littery stuff that may be at hand. Whatever is used should be placed at least a yard thick, as less than that would not exclude the air. This will allow room for a stack about 9 feet through, which, if carried 7 feet or 8 feet high, will form a large body of ice. The bottom of the stack should have a few rough bushes laid over it, and on these some clean straw, so as to secure free drainage. In forming the stack, the ice should be well rammed and broken, much in the same way as when filling the house. As soon as sufficient is got together, the whole should be covered in with a good thick layer of dry litter or Braken, over which a coating of straw should be placed, so as to form a rough kind of thatching to keep out the wet. S.

Winter Violets.—Violets, when well grown, are of great value during the dull months. To be successful with them they should be placed in their winter quarters about the middle of October. Many fail to bloom them well in early winter, simply because they are too late in planting in frames. They ought to be well rooted in the new soil before winter sets in. When planted in the frames a good watering should be given them, the lights kept off night and day till such time as frost appears. Violets delight in being kept cool; place them near the glass, over which put mats when frosty. If wanted to bloom in pots, pot them so as to have them well rooted, for without plenty of roots Violets always fail. I consider the good old Neapolitan to be the best for every purpose. Cannell's White or Comte de Brazza is also a good kind.—W. B. Leach, *Albury Park.*

Blechnum corcovadense a good room plant.—This noble Fern is very effective during winter in rooms, the dry air, warmth, and light of which seem to suit it. It is easily cultivated, requiring in summer only ordinary care and attention; but in a low temperature it dislikes moisture on the fronds. It delights to grow in bright sunshine, and the stronger the light the more beautiful the deep red of the young fronds becomes, and the longer they will retain their warm tints.—A. B.

Ferns for room decoration.—Few plants are so well adapted for indoor decoration as the cool-house Ferns called Pteris serrulata, P. longifolia, and P. cretica albo-lineata, also the several varieties of Adiantum known as Maidenhair Ferns. These, if allowed to make their growth in a cool temperature, form excellent room or window plants the whole year round. It is after forced growth in a high moist temperature that they so quickly suffer from cold draughts, which have little effect on plants gradually and well hardened off.—G.

OBITUARY.

Papers from Honolulu, Sandwich Islands, announce the death of Mr. Thomas Brown, many years ago the senior partner in the firm of Messrs. Thomas and Edward Brown, Royal Nursery, Slough. About 1840 Thomas Brown gave up the nursery business founded by his grandfather at Slough nearly a century previously, and soon afterwards emigrated to Honolulu, where he has just died at the age of eighty-two. He will be remembered as the introducer of Lilium Brownii, Lonicera Brownii, and as the raiser of the once popular white herbaceous Phlox, P. omniflora.

QUESTIONS.

5538.—**Fruit shrivelling.**—I would be glad to know why Cox's Orange Pippin and Ribston Pippin Apples, and Pears shrivel soon after being gathered, although they were well grown and apparently ripe. The trees are young and healthy, and the soil is sandy loam.—Constant Reader.

5539.—**Medicinal plants.**—I have a plant said to be recommended by doctors in Switzerland to be kept in the wards of hospitals as a preventive against rheumatism. It resembles a Coleus somewhat, but has very light green, large leaves and a woody stem. The leaves, when bruised, have an aromatic camphor-like smell. I should much like to know its name.—A. J. C.

Names of plants.—*W. H. M.*—1, Cotoneaster buxifolia; 2, C. microphylla; 3, C. thymifolia.—*A. B. C.*—1, Coelogyne speciosa; 2, Odontoglossum cordatum, not maculatum; 3, Masdevallia infracta.—*R. T.*—Erica gracilis.—*C. W. R. Paignton.*—Brassavola nodosa.

WOODS & FORESTS.

ENGLISH FIREWOOD.

Fires made of resinous woods are harmless and useful enough in the open forest, but in dwelling-houses they are both disagreeable and dangerous. But we are in nowise bound to the use of the Pine tribe, as among the commonest of our native trees we have excellent firewood. It is claimed by some, I know, that Yew makes the best firewood, but this, on account of its scarcity, is quite out of the question. Therefore in the first group I place Ash, Beech, Maple (this is seldom to be had in any quantity in the form of cordwood), Oak, and Elm. There are comparatively few places where one or the other of these kinds are not to be found, and in many the whole of them. The choice must be controlled by the woods in most abundance, but, on the whole, I regard those consumers living in Beech districts as being the most favoured in the matter of firewood. This is certainly so if the ease with which it ignites when seasoned is taken into the reckoning. Ash is equally good, except that it is less abundant, commands a higher price, and the corresponding portions of the tree which, in the case of Beech are of little value for anything but firewood, can generally be sold at a figure which would make it bad economy to burn it. Oak in such counties as Sussex, where it predominates, is naturally the chief firewood. In other counties where Elm is plentiful, it is a wood largely used; it is, however, more suited for keeping up a constant fire than for igniting it. There is quite another group formed by the kinds which do not usually grow to timber size, and which, instead of being subdivided by beetle and wedge, are of such small dimensions as to require to be bound together for convenience of removal and stacking. The very small branches of trees are, of course, treated in the same way. Chief among these smaller woods, then, for firewood occurs the Hazel, the Hawthorn, the Blackthorn, and the Willow. The last-named, perhaps, is not usually ranked as a firewood, but, judiciously used, makes a very good fire. With regard to the Thorns, with the very small branches there is the disadvantage of the crackling sound they emit. With the larger and more solid portions this objection does not exist.

The sources from which these different firewoods may be drawn are many, but for such as come under the heading of cord-wood, the larger branches of trees is the chief. The precise amount and size of the wood which will go respectively to the fire and to the merchant will be regulated according to the supply of firewood wanted and the smallest size saleable in the market. With the larger trees, such as Ash, Beech, Oak, and Elm, except in special cases, it will be found that there is very little to be gained by selling anything under 6 inches in diameter. Where the trees are very gross in growth, or have begun to die back from the branches, it will be often advisable to cut up much larger sizes for the fire. If the wood is burnt on the open hearth, so much the better, as it will only be necessary to saw it into lengths of from 18 inches to 2 feet or so. Generally, however, the dimensions of the fireplace will not admit of such a simple method of preparation. In this case the cross-cutting and cleaving must either be done upon the spot where the trees fall, or in the wood-yard or shed. When the wood is prepared for sale, there is a good reason for cleaving it in the open field or forest, but when it is for home consumption, it is obviously a saving of labour to remove the logs entire and for the work of preparation to be completed where the wood has to remain until wanted for consumption. Here may be added a word as to seasoning and preservation. To judge from the way in which firewood is commonly dealt with, it would seem that no such processes are necessary. For due economy they are, and it is highly desirable that if a suitable building is not at hand, the stack in which the wood is placed should be thatched, or in some way covered and kept dry. The proper preparation and care of firewood is a thing which would repay a little more attention than is usually given it. The preparation is perhaps better understood than the care of it afterwards. This applies to the fagot or small wood, as well as to the cord or larger cleft wood. The first season it may perhaps be neglected, but if it is likely that it will not be used during the current year, some precaution must be taken to keep it dry. If kept dry the second and third year, the cleft wood especially will burn so much the better; but if left exposed, each month after the first season will tell detrimentally. After removal from the woods to the place where it has to be prepared or stacked, it matters but little at what time it is prepared, providing it is fairly dry weather. It very often happens, however, that the time when firewood is cleft is when it is so excessively wet that no other occupation can be followed. Where, therefore, a building, no matter how rough, can be had, it is well to get a supply of the logs as they come from the forest put in whilst they are dry. This is much more important when the place of storage is a close building than when it is a stack. In the latter case the stack is merely roofed, and the air has the opportunity of penetrating every portion of it. With a close building the moisture must remain, and consequently decay sets in. Considering that fagot wood is as easily built into stacks as Corn sheaves, and that the cleft cordwood can be just as easily manipulated where there are no buildings of sufficient extent to contain the main stock of firewood, there is no excuse for getting it spoilt. The slope of the roof can be formed of the same material as the body of the stack, and all that is wanted is a few inches of rough thatch. This, so long as it keeps out the bulk of the rain, will answer all that is required of it. It need not be straw, as Reeds or Sedge Grasses, or, in fact, anything of the sort which may be within reach, will be just as satisfactory as the most costly material, and fagots may be put above the cordwood stack to keep off the wet.—D. J. Y.

*** The way our English trees, native and commonly cultivated, burn is a very interesting subject, and we shall be grateful for any notes readers may send on it. More about the way each particular tree burns is required, and the age at which it burns best. For instance, what are the burning qualities of such very common trees as the Spruce and the Scotch? They are often considered almost useless as firewood, and yet we have seen old roots of Scotch give out a flame richer and prettier than from any other tree, or from the best coal. The many old Apple trees of poor sorts, are they useful as fuel? And our Field Maple and Sycamore and the common Lime, only to name a few of the commoner trees in cultivation.—Ed.

OUR TIMBER SUPPLY.

It is a pretty general belief that timber merchants never consider, or care a straw, about the state of the timber supply in this country so long as they can get hold of just enough to keep their yards and mills going from year to year. In many instances this may be so, but a few days ago I happened to be in the company of some members of the trade who introduced the question quite spontaneously. The subject was, therefore, discussed, I do not say very deeply, but still enough to show that those whose occupation it is to consume our forest products are not altogether insensible to the other side of the business. For the most part, I must confess they seemed but little acquainted with what has been done in the past, or is being done now in the direction of calling attention to the matter by means of the press; but all seemed ready to admit the necessity of bestowing more thought on the future. From this the discussion turned to timber as a paying crop, and instances were quoted which had come under the personal notice of the parties present where large amounts had been realised off what had previously been useless ground, and other cases were cited where the cost of replanting had reached very nearly to what the matured crop of timber had sold at. One portion of the company seemed to think that we need be under no apprehension as to where timber is to come from, as when it is exhausted here there would be unlimited supplies from abroad. On entering this phase of the inquiry I referred to what the foreigners themselves say. It may not directly bear upon what is or may be grown here, but there is one thing which I think calculators of how long different countries' supply will last generally overlook, and that is, as soon as the value of timber becomes appreciably enhanced through approaching scarcity, different materials will at once be substituted for purposes for which timber is now so greatly used. Take America, for instance, whence a great deal of alarmist literature on vanishing forests comes. So long as timber can be had for little beyond the work of clearing, where labour is a consideration, it will, no doubt, continue to be very largely used in building and similar operations, but as soon as a difficulty comes in of getting enough and at suitable figures, some other material will be brought into use which will gradually, but surely, supplant timber as the price rises and it becomes more scarce. I do not think this is likely to happen in the near future, but if the time does come when the timber supply is really within a measurable distance of exhaustion, some such natural remedy will step in and restore the balance by affording time for new supplies to mature The instance in our country which most clearly bears this out is perhaps the substitution of iron and steel in ship-building. Had the supply of timber continued sufficient, or more than sufficient, for the needs of the navy, it is extremely doubtful whether much would have been heard of any other material. Directly this is likely to fail the necessity arises for some other product which will take its place, and this is found in iron. According to many reports, there is now more Oak in the market than can be profitably disposed of, and this is the natural outcome of what occurred a generation or two ago, when, concurrently with the discovery of new products to take the place of timber which had become scarce and dear, a new era of planting commenced. The demand is reduced and the supply increased, and in this way in the course of a generation or two the balance is restored. In the discussion which has led to these remarks, we did not get upon this particular line of argument, but it seems to me that in many respects it is a true one. Simply left alone, the recuperative powers of Nature are marvellous, and in more than one district I know where heavy cuttings have from time to time taken place, there seems but little diminution in the supply. If the view which I have taken be sound, it is the forester's duty merely to preserve and replenish the kinds of trees which he knows to be the most scarce, and leave each other description to come in for attention as the necessity arises. At the present moment, upon these lines it is clear that the Ash is the one tree the supply of which needs to be increased, and this has often been urged when the question has been looked at in a totally different aspect. J.

HOW TIMBER IS VALUED.

I am not at all anxious to have the last word in this discussion, nor do I wish to misrepresent matters in the least; far from it; but I must say either the "Forester on the Duncombe Estate" or myself are very far out in our calculations. Your correspondent is not quite straightforward in his replies. The dispute as to prices between him and I does not refer to sales he may have transacted "a few weeks ago," or since this discussion commenced, but to sales anterior to that and during the past few months, or year, we may say. The present winter's sales are irrelevant as yet, but I will deal with the Duncombe Park prices for these also before I finish. I saw one of the purchasers the other day who bought some of the Larch near Helmsley (which I understand was taken to that station), and I asked him the question again about prices paid early in the season, as we know each other intimately, and his reply was, "about 4d. per foot as far as I can recollect, and it cost from 1½d. to 3½d. to lead it to the station." Now this figure correspondents reasonably with the rates of delivery in this neighbourhood about the same date, and corroborates what I have asserted. The Duncombe Park

forester knows perfectly well, I have no doubt, what lots I allude to, and yet he attempts to evade a plain question relative to them by quoting recent prices that nobody but himself at present knows anything about. But let us examine these recent prices of his, 8d. and 9d.—felling not allowed for, I notice—and I believe his estate fells all and sells the timber fallen and lotted, which entails much expense which is not deducted either. But let that go. It appears that "nine-tenths" of his Larch goes to Durham and the Cleveland district, where at present trade is duller than here, not to mention the fact that the carriage from Helmsley cannot be much, if any, less than it is to South Yorkshire. By the time his timber gets to Durham stations it will have reached consumer's price and have still to be delivered by the purchaser at a profit. And all this we are apparently expected to believe is going on when the vendors of Larch in the Durham and the Cleveland districts, or near there, are delivering Larch eighty or ninety miles distant at the other end of the country for 1s. per foot to the consumer. In other words, the Cleveland and Durham consumers are carrying Larch from the south for which they must be paying from 15d. to 18d. per foot, while the Larch from their own neighbourhood is passing their door at half that price, probably for want of a market at home! Does anybody believe it, especially considering the depressed condition of the Larch trade owing to the constantly increasing supplies of prop wood from abroad, delivered at the pit mouth all over Yorkshire at about 8d. per foot? The station, I may add in reply to the Duncombe Park forester, where the 1s. per foot Larch (from North Yorkshire, or near the border of Durham) was delivered is close to Sheffield, and it was delivered at two separate works. Let not the reader forget that all this discussion relates to the difficult art of valuing as portrayed by some of your correspondents, but which recent revelations show consists, on some large estates, in felling and lotting the trees and selling them to the highest bidder—a mysterious art truly. Y.

MATERIALS FOR FENCES.

Apropos of "T. B.'s" remarks upon the use of wood with iron supports for garden fences, I have seen such supports used for light paled fences round allotments and the like, but I doubt, unless the posts were very strong, whether it would answer for anything so high as 10 feet. The suggestion, however, is worth consideration, and is capable of being adapted in other ways. A height of 4 feet or 5 feet would be quite as much as would be likely to answer well with light iron supports, as the wind pressure above this would be so great. For heights above this the following plan, I believe, would be better. Build brick piers at intervals of say 10 feet, which would make a square bay or panel. This distance could, of course, be varied, but I give it as an illustration. Cement angle iron rails into these piers, and if necessary have a support in the centre of the bay. To these angle iron rails, which of course would be drilled before for the purpose, fix 1¼-inch or 1½-inch Elm boards, and when dry, tar them in the same way as would be done with the Spruce. The brick piers would be built with their greatest thickness at right angles to the line of fence so as to resist a side thrust, and the angle irons fixed as nearly as may be to the outside—in fact, just far enough from the back edge of the pier to allow of sufficient hold for the rail and for the boarding, which would be fixed on the outside, to finish level with the back edge. In this way each panel would be sheltered by the pier standing well out into the border, and if at any time a coping was wanted to further protect the trees or whatever may happen to be growing upon the fence, some boards could be kept for the purpose which would rest each end upon a pier, and on the top of the wood fence for the whole distance. The piers would, of course, be also available for stretching any protecting material across the bays in front of the trees, as they would have the advantage of standing a greater distance into the garden than in the case of the ordinary wall. Constructed in this way there would be the disadvantage of the angles of the iron standing out from the inside. This could be obviated by fixing the rails as nearly as possible to the back edge of the pier, but with the angles reversed and boarded inside. The drawbacks of this plan are that it would afford a foothold on the outside and would reduce the width of the pier on the inside. Other adaptations would suggest themselves according to circumstances, as there seems no good reason why brick alone should be rigidly adhered to. D. J. Yeo.
