OSMOTIC pressure is a phenomenon of such importance in the theory of solutions, and in the interpretation of all vital processes, and so much valuable work has recently been directed to its elucidation, that, although it is a somewhat thorny and difficult subject, no apology is needed for any serious attempt, however inadequate, at its explanation.

One of the earliest recorded experiments on osmotic pressure is that of the Abbé Nollet, who found that a bladder containing alcohol, when immersed in water, absorbed water so greedily as in many cases to burst the bladder. The experiment illustrates in an imperfect manner the fundamental property of all animal and vegetable membranes of allowing some substances to pass through them by osmosis more easily than others. In many cases such membranes, while freely permeable to water, are practically impermeable to certain substances in solution, and play the part of sieves in directing and controlling diffusion. It will readily be understood that results of the greatest importance to biology have been obtained by studying this property of *semipermeability*, as it is called, but the application of natural membranes to the physical study of the subject is necessarily limited on account of the difficulty of obtaining sufficiently large and perfect membranes capable of withstanding any considerable pressure.

[1] Discourse delivered at the Royal Institution on Friday, February 26, by Prof. H. L. Callendar, F.R.S.

Artificial membranes of sufficient fineness to be impermeable to such substances as sugar in solution, were first prepared by Traube by means of precipitated pellicles of substances like copper-ferrocyanide. The first quantitative measurements of osmotic pressures of considerable magnitude were made by Pfeffer with membranes of this kind deposited in the pores of earthenware pots fitted with suitable manometers for indicating the pressure developed. Pfeffer found that when a semipermeable vessel, filled with sugar solution, was immersed in water, the membrane being freely permeable to water, but not to the dissolved sugar, the solution absorbed water through the membrane by osmosis until the internal pressure reached a certain magnitude sufficient to balance the tendency to absorption. The osmotic pressure developed in the state of equilibrium was found to be proportional to the strength of the solution, and to increase with rise of temperature at the same rate as the pressure of a gas at constant volume. A few years later van 't Hoff, reviewing these experiments in the light of thermodynamics, showed that the osmotic pressure of a dilute solution should be the same as the pressure exerted by a number of molecules of gas equal to those of the dissolved substance in a space equal to the volume of the solution, that it should be the same for all solutions of equal molecular strength, and that osmotic pressure followed the well-known laws of gas-pressure in all respects. This most important generalisation was hailed as the first step to a complete kinetic theory of solution, and the osmotic pressure itself has generally been regarded as due to the bombardment of the sides of the semipermeable membrane by the particles of solute, as though they were able to move freely through the solution with velocities comparable to those of the molecules of a gas. Such a view would not now be seriously maintained, but the fascinating simplicity of the gas-pressure analogy has frequently led to the attempt to express everything in terms of the osmotic pressure, regarded simply, but inaccurately, as obeying the gaseous laws, and has done much to divert attention from other aspects of the phenomena, which, in reality, are more important and have the advantage of being more easily studied. It was very soon discovered that the gaseous laws for osmotic pressure must be restricted to very dilute solutions, and that the form of the laws was merely a consequence of the state of extreme dilution, and did not necessarily involve any physical identity between osmotic pressure and gas-pressure. Many different lines of argument might be cited to illustrate this point, but it will be sufficient to take some of the more recent experimental measurements of osmotic pressure by the direct method of the semipermeable membrane.

Morse and Frazer in 1905 succeeded in preparing ferrocyanide membranes impermeable to sugar, and capable of withstanding pressures of more than 20 atmospheres. They operated by Pfeffer's original method, allowing water to diffuse into the solution in a porous pot until the maximum pressure was developed. There are many serious experimental and manipulative difficulties which the authors carefully considered and discussed in applying this method, but they succeeded in obtaining very consistent results. As a first deduction from their investigations they considered that they had established the relation that the osmotic pressure of cane-sugar was the same as that exerted by the same number of molecules of gas at the same temperature in the volume occupied by the solvent, and not in the volume occupied by the solution. In other words, the osmotic pressure of a strong solution was greater than that given by van 't Hoff's formula for a dilute solution in proportion as the volume of the whole solution exceeded the volume of the solvent contained in it. It was a very natural extension of the gas-pressure analogy to deduct the volume occupied by the sugar molecules themselves in order to arrive at the space in which they were free to move. Unfortunately, the later and more accurate series of measurements by the same experimentalists at 0° C. and 5° C. gave nearly the same osmotic pressures as at 24° C., and would appear to show either that there is little or no increase of osmotic pressure with temperature, and that the pressures at 0° C. are much greater than those given by their extension of the gas-pressure analogy, or that one or other of the series of experiments are in error.

About the same time Lord Berkeley and E. J. Hartley undertook a series of measurements of the osmotic pressures of solutions of various kinds of sugar at 0° C. by a greatly improved experimental method, which permitted the range of pressure to be extended to upwards of 100 atmospheres. Instead of allowing the solvent to diffuse into the solution until the equilibrium pressure was reached, they applied pressure to the solution until balance was attained. The method of Lord Berkeley and Hartley possesses several obvious advantages, and it is impossible to study the original memoir without being convinced that they have really measured the actual equilibrium pressures with an order of certainty not previously attained or even approached. The pressures found were in all cases greatly in excess of those calculated from the gas-pressure of the sugar molecules in the volume occupied by the solution (according to van 't Hoff's formula for dilute solutions), or even in the restricted volume occupied by the solvent (according to Morse and Frazer's assumption).

Lord Berkeley endeavoured to represent these deviations on the gas-pressure analogy by employing a formula of the van der Waals type, with three disposable constants. Out of some fifty formulæ tested, the two most successful were those given in Table I. The constants A, a, and b were calculated to fit the three highest observations for each solution. Values calculated by the formulæ for the lower points were then compared with the observations at these points, with the results given in Table I. for cane-sugar.

TABLE I.—OSMOTIC PRESSURES OF CANE-SUGAR SOLUTIONS.

Osmotic Pressures calculated by various Formulae.

Vant 't Hoff	Morse and Frazer	Lord B. (1)	Lord B. (2)	C.	Do. observed Lord B.
35·6	53·2	68·4	67·7	67·6	67·5
27·6	37·4	45·0	43·4	43·7	44·0
19·7	24·4	27·7	25·4	26·8	26·8
11·2	13·3	14·6	12·2	14·1	14·0

Lord Berkeley's equations :—

$$(A/v - P + a/v^2)(v - b) = RT \quad . \quad . \quad . \quad (1)$$

$$(A/v + P - a/v^2)(v - b) = RT \quad . \quad . \quad . \quad (2)$$

It is at once evident that, even with three constants, the gas-pressure analogy does not represent the results satisfactorily within the limits of error of experiment. Moreover, with three constants the equation cannot be interpreted, so that the gas-pressure analogy becomes useless as a working hypothesis or as a guide to further research. On the vapour-pressure theory, to be next explained, the results are much better represented, as shown in column C, with but a single constant, and that a positive integer with a simple physical meaning.

Vapour-pressure Theory.

On the vapour-pressure theory, osmotic equilibrium depends on equality of vapour-pressure, and not on an imaginary pressure which the particles of the dissolved substance would exert if they were in the state of gas at the same volume and temperature. The vapour-pressure of any substance is a definite physical property of the substance which is always the same under the same conditions of pressure and temperature and state, and is easily measured in most cases for liquids and solutions. Equality of vapour-pressure is one of the most general, as well as the simplest, of all conditions of physical equilibrium. Ice and water can only exist together without change under atmospheric pressure at the freezing point 0° C., at which their vapour-pressures are the same. Below the freezing point the vapour-pressure of water is greater than that of ice. Either is capable of stable existence separately within certain limits, but if the two are put in communication, the vapour, being mobile, passes over from the water at higher pressure to the ice at lower pressure until equality of vapour-pressure is restored by change of temperature, or until the whole of the water is converted into ice.

In the case of ice and water, equality of vapour-pressure can also be restored by a suitable increase of pressure.

This is the well-known phenomenon of the lowering of the freezing point by pressure. By considering the equilibrium of water and vapour in a capillary tube, Lord Kelvin showed that the vapour-pressure of water, or any other liquid, was increased by pressure according to a very simple law, the ratio of the increase of vapour-pressure, dp, to the increase of pressure, dP, on the liquid being simply equal to the ratio of the densities of the vapour and liquid, or inversely as the specific volumes, v and V. This relation, which may be written $VdP=vdp$, is merely a special case of Carnot's principle, and was deduced by assuming the impossibility of perpetual motion. Assuming a similar relation to apply to ice, Poynting showed that when a mixture of ice and water was subjected to pressure, the vapour-pressure of the ice must be increased more than that of the water (since the specific volume of ice is greater than that of water). Consequently, some of the ice must pass over into water, and the temperature must fall until the vapour-pressures are again equal. The lowering of the freezing point by pressure, as observed by Lord Kelvin, and calculated by James Thomson, agrees precisely with that deduced as above from the condition of equality of vapour-pressure.

Similar considerations apply to the equilibrium between a solution and the pure solvent, or between solutions of different strengths. To take a simple case, the vapour-pressure p'' of a sugar solution is always less than the vapour-pressure p' of water at the same temperature, and the ratio p''/p' of the vapour-pressures depends simply on the concentration of the solution, diminishing regularly with increase of concentration and being independent of the temperature. If separate vessels containing solution and water are placed in communication at the same temperature by a tube through which the vapour has free passage, vapour will immediately pass over from the water to the solution in consequence of the pressure difference, and will condense in the solution. The immediate effect is to produce equality of vapour-pressure by change of temperature. This takes only a few seconds. The vapour-pressure then remains practically uniform throughout. As diffusion proceeds and the temperature is slowly equalised, the water will gradually distil over into the solution, but the process of diffusion is so infinitely slow compared with the equalising of vapour-pressure that the final attainment of equilibrium would take years unless the solution were continually stirred.

The reason why equality of vapour-pressure is so important as a condition of physical equilibrium is that the vapour is so mobile and so energetic as a carrier of energy in the form of latent heat. The first effect is generally a change of temperature, but if the temperature is kept constant there must then be a change of concentration. Thus if two parts of the same solution are maintained at different constant temperatures, the concentrations will change so as to restore equality of vapour-pressure, if possible. Thus in a tube of solution the two ends of which are maintained at different temperatures, the dissolved substance will appear to move towards the hotter end. What really happens is that the vapour, which is the mobile constituent, moves towards the colder end. If the tube is horizontal, with a free space above the liquid for the vapour, this transference will be effected with extreme rapidity. In fact, it will be practically impossible to establish an appreciable difference of temperature until the transfer is effected. If the vapour has to diffuse through the solution in a vertical column heated at the top, the process is greatly retarded, but the final effect is the same, and can be readily calculated from the relation between the vapour-pressure and the concentration.

In explaining the production of osmotic pressure as a necessary consequence of the laws of vapour-pressure, there is one difficulty which, though seldom expressed, has undoubtedly served very greatly to retard progress. How can an insignificant difference of vapour-pressure, which may not amount to so much as one-thousandth part of an atmosphere in the case of a strong sugar solution at 0° C., be regarded as the cause of an osmotic pressure exceeding 100 atmospheres, or 100,000 times as great as itself? The answer is that the equilibrium does not depend at all on the absolute magnitude of the vapour-pressure, but only on the work done for a given ratio of expansion, which is the same in the limit for a gram-molecule of any vapour at the same temperature, however small the vapour-pressure. Indirectly, the smallness of the vapour-pressure may have a great effect in retarding the attainment of equilibrium, especially if obstructive influences, such as other vapours or liquids, are present. Thus mercury at ordinary temperatures in the open air is regarded as practically non-volatile. Its vapour-pressure is less than a millionth of an atmosphere, and cannot be directly measured, though it may easily be calculated. When, however, we take mercury in a perfect vacuum, such as that of a Dewar vessel, the presence of the vapour is readily manifested by its rapid condensation on the application of liquid air in the form of a fine metallic mirror of frozen mercury. The least trace of air or other gas in the vacuum will retard the condensation excessively.

Under the conditions of an osmotic-pressure experiment we have solvent and solution in practical contact, separated only by a thin porous membrane. It will facilitate our conception of the conditions of equilibrium if we imagine the membrane to be a continuous partition pierced by a large number of very fine holes of the order of a millionth of an inch in diameter. If the holes are not wetted by the solution or the water, the liquid cannot get through unless the pressure on it exceeds 100 atmospheres, but the vapour has free passage. If the solvent and solution are under the same hydrostatic pressure the vapour-pressure of the solvent will be the greater, and the vapour will pass over into the solution. Since the surfaces are practically in contact, no appreciable difference of temperature can be maintained. If the solution is confined in a rigid envelope, so that its volume cannot increase, the capillary surfaces of the solution will rapidly bulge out as the vapour condenses on them, and the pressure on the solution will increase until condensation finally ceases, when the vapour-pressure of the solution is raised to equality with that of the pure solvent. The osmotic pressure is simply the mechanical pressure-difference which must be applied to the solution in order to increase its vapour-pressure to equality with that of the pure solvent. If any pressure in excess of this value is applied to the solution, the vapour will pass in the opposite direction, and solvent will be forced out of solution. The osmotic work required to force a gram-molecule of the solvent out of the solution is the product of the osmotic pressure P by the change of volume U of the solution per gram-molecule of solvent abstracted. In the state of equilibrium of vapour-pressure, this osmotic work PU must be equal to the work which the vapour could do by expanding from the vapour-pressure p' of the pure solvent to the vapour-pressure p'' of the solution. Neglecting minor corrections, we thus obtain the approximate relation

$$PU = R\theta \log (p'/p'').[1]$$

From this point of view the osmotic pressure of a solution is not a specific property of the solution in the same sense as the vapour-pressure, or the density, or the concentration, but is merely the mechanical pressure required under certain special conditions to produce equilibrium of vapour-pressure when neither the temperature nor the concentration are allowed to vary. One might with almost equal propriety speak of the "osmotic temperature" of a solution, meaning by that phrase the difference of temperature required to make the vapour-pressure of the solution equal to that of the pure solvent. The observation of the elevation of the boiling point of a solution above that of the pure solvent is a familiar instance of a special case of such a temperature difference. It is just as much a specific property of the solution as the osmotic pressure, and would only require a perfectly non-conducting membrane for its production. No one would regard the rise of boiling point as being the fundamental property of a solution in terms of which its other properties should be expressed. By similar reasoning osmotic pressure should not be regarded as existing *per se* in the solution, and as being the cause of the relative lowering of vapour-pressure and other phenomena. This point of view does not detract in any way from the reality and physical

[1] Obtained by integrating $UdP=vdp$. Planck, "Thermodynamik," also *Zeit. Phys. Chem.*, xli. 212, 1902, and xlii. 584, 1903.

importance of the effects of osmotic pressure when it comes into play, but it puts the phenomena in their true light as consequences of the law of vapour-pressure.

Regarded as a verification of the laws of vapour-pressure, direct measurements of the osmotic pressure are of the highest value, but there are comparatively few cases known at present in which such direct measurements are possible. In other cases the osmotic pressure, if it exists, can always be calculated from a knowledge of the vapour-pressure. For the elucidation of osmotic phenomena and many other problems in the theory of solutions we are compelled to make a systematic study of the relations of vapour-pressure. Much has been done in this direction in the past, but, owing to the difficulty of the measurements, much remains yet to do. I may, therefore, be pardoned if I allude briefly to some of the methods which I have employed for this purpose, and some of the conclusions at which I have so far arrived.

It is often a difficult matter, when the difference of vapour-pressure between a solution and the solvent is small, to measure the pressure difference directly to a sufficient degree of accuracy. A method very commonly employed, which has been brought to a high degree of accuracy by Lord Berkeley and his assistants, depends on the observation of the losses of weight of two vessels, containing solution and solvent respectively, when the same volume of air is aspirated slowly through them in succession. To secure accurate results, the air must pass very slowly. One complete observation takes about a week to perform successfully, and involves many difficult manipulations. I have endeavoured to avoid this difficulty by measuring the temperature difference in place of the pressure difference, since the temperature difference remains nearly constant, while the pressure difference tends to diminish in geometrical progression with fall of temperature. The method adopted for this purpose is that indicated in the diagram of the vapour-temperature balance. The temperatures of solution and solvent, contained in separate vessels communicating through a tap, are adjusted until, on opening communication between them, there is no flow of vapour from one to the other, as indicated by a change in the reading of a pair of thermojunctions immersed in the solvent respectively. The corresponding difference of temperature is observed, and since the vapour-pressures of the solvent are known, it is easy to calculate the required ratio or difference of the vapour-pressures of solvent and solution at the same temperature. When the vapour-pressures are very small it may be difficult to observe the change of temperature on opening the tap unless the apparatus is very carefully exhausted. A more delicate method in this case is to observe the direction and magnitude of the current of vapour from solution to solvent, or *vice versâ*, by means of the "vapour-current indicator," illustrated in the companion diagram. This consists of a delicately suspended vane, the deflections of which are read by a mirror, and will readily indicate a difference of pressure less than the thousandth part of a millionth of an atmosphere.

The vapour-current indicator is so constructed that its deflections are very accurately proportional to the pressure difference, much more so, in fact, than any form of electric galvanometer. It can also be employed for direct measurements of small differences of vapour-pressure. The chief difficulty in this case is to ensure the absence of air or other disturbing factors. A method of avoiding this difficulty is to work at atmospheric pressure, and to measure the pressure difference between two vertical columns of air saturated with the vapours of the solvent and solution respectively.[1] The temperature difference may be adjusted to balance, and is preferably measured by means of a pair of differential platinum thermometers, which permits a higher order of accuracy to be attained than the thermoelectric method.

Vapour-pressure in relation to Molecular Constitution.

The well-known law of Raoult, according to which the relative lowering of vapour-pressure of a solution is equal to the ratio of the number of molecules n of the solute to the number of molecules of solvent N in the solution, has thrown a great deal of light on the molecular state of the dissolved substance in dilute solutions, but fails notably in many cases when applied to strong solutions. In the case of homogeneous mixtures of two indifferent volatile substances, such as benzol (C_6H_6) and ethylene chloride ($C_2H_4Cl_2$), which mix in all proportions without mutual action, a slightly different but equally simple law is known to hold very accurately throughout the whole range of concentration from 0 per cent. to 100 per cent. The vapour-pressure of each ingredient is simply proportional to its molecular concentration. In other words, the ratio of the partial vapour-pressure p' of either constituent at any concentration to its vapour-pressure p_0' in the pure state at the same temperature is equal to the ratio of the number of its molecules n' in the solution to the whole number of molecules $n'+n''$ of both substances in the solution. Such is evidently the form of the simple mixture law. For substances which form compounds in the solution, or the molecules of which are associated or dissociated, this simple law is widely departed from. In a recent paper, "On Vapour-pressure and Osmotic Pressure of Strong Solutions" (Proc. R.S.A., vol. lxxx., p. 466, 1908), I have endeavoured to extend this simple relation to more complicated cases by making the obvious assumption that, if compound molecules are formed, they should be counted as single molecules of a separate substance in considering their effect on the vapour-pressure. With this proviso the vapour-pressures of strong solutions are well represented by a natural extension of the simple mixture law, and it becomes possible to investigate the nature of the compounds formed in any case. To take a simple instance, suppose that each of the n molecules of the dissolved substance combines with a molecules of the solvent, the total number of molecules of the solvent being N. The ratio of the vapour-pressure p'' of the solvent in the solution to the vapour-pressure p' of the pure solvent at the same temperature will then be the same as the ratio of the number $N-an$ of molecules of *free* solvent in the solution, to the whole number of molecules $N-an+n$ in the solution, each compound molecule being counted as a single molecule.

With the simple formula

$$p'/p''=(N-an+n)/(N-an),$$

the values of the vapour-pressure are very easily calculated from the molecular concentration n for simple integral values of the hydration factor a. The osmotic pressures are also readily deduced from the ratio of the vapour-pressures (p'/p'') by the formula

$$PU=RT\log(p'/p'').$$

The value $a=5$ fits the osmotic pressures for cane-sugar very well, as shown in the column headed C in Table I. The value $a=2$ fits Lord Berkeley's observations on dextrose equally well up to pressures of 130 atmospheres. The same value $a=5$ for cane-sugar also fits the observations on the depression of the freezing point and the rise of the boiling point, as it necessarily must, since these phenomena also depend on the vapour-pressure. The freezing-point method is the easiest for getting the ratio of the vapour pressures to compare with the formula. At the freezing point of an aqueous solution the vapour-pressure of the solution must be the same as that of ice, provided that ice separates on freezing in the pure state. The ratio of the vapour-pressure of ice to that of water at any temperature below 0° C. is easily calculated. All the best recorded results, except those of a few associating substances, give simple positive integral values of a. Even in the case of associating substances, like formic acid and acetone, the curves are of the same type, but the value of a is negative. Dissociating substances, like strong electrolytes, present greater difficulties, on account of the ionisation factor; but, allowing for the uncertainty of the ionisation data, they seem to follow satisfactorily the same law of vapour-pressure.

It appears from the form of the proposed law that the hydration factor a makes very little difference to the vapour-pressure in weak solutions, which follow Raoult's law as a limiting case, but it makes a very great difference in strong solutions, when nearly all the free water is used up, and the denominator $N-an$ is small. Thus

[1] I first showed this experiment ten years ago, in illustration of the delicacy of the apparatus, at a Friday Evening Lecture at the Royal Institution.

the depression of the freezing point of a strong solution of calcium chloride is more than five times as great as that calculated from the number of ions present in the solution. Each ion appears to appropriate no less than 9 molecules of water. The factor $a=9$ gives a very good approximation to the freezing-point curve, as far as the uncertainty of the data permit. When $N=an$, the vapour-pressure would be reduced to zero, according to the formula, but the formula ceases to apply when the vapour-pressure of the compound molecules themselves becomes equal to that of the solution. At or before this point the molecules will dissociate with the formation of lower hydrates. Many analogous phenomena are already known, and a more complete study of the vapour-pressures of strong solutions may be expected to throw additional light on the subject.

The essential point of the theory here sketched is that the equilibrium existing in a solution is one between definite chemical compounds and the solvent, giving rise to a simple vapour-pressure relation by means of which the phenomena may be studied and elucidated. There is a great deal of work to be done before such a theory can be regarded as established, but in the meantime it may serve very well as a working hypothesis for correlating experimental results and suggesting new lines of investigation. Regarded in this light, the vapour-pressure theory may serve a useful purpose, and, judging by the experimental data at present available, I think I may fairly claim to have made out a good *primâ-facie* case for the theory.

NOTE.—The vapour-current indicator is a development of the old smoke-jack. A light spiral vane with a mirror attached is suspended in a tube, which nearly fits it, by means of a quartz fibre. Joule (Proc. Phil. Soc., Manchester, vii., 35) employed a wire spiral suspended by a silk fibre for indicating air currents, but does not seem to have adapted it for purposes of exact measurement. The instrument shown in the lecture gave a deflection of 30° (500 mm. at 1 metre) for a velocity of air current 0·01 cm./sec. The sensitiveness might easily have been increased, but the above amply suffices for most purposes.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

REUTER'S Agency states that the Hong Kong and Shanghai Bank has made a donation of about 4500*l.* to the Hong Kong University.

PROF. W. OSLER, F.R.S., will deliver the inaugural address of the winter session of the London School of Tropical Medicine on Tuesday, October 26.

MR. W. H. HADOW, fellow and tutor of Worcester College, Oxford, has been appointed principal of Armstrong College of Durham University at Newcastle-on-Tyne, in succession to Sir Isambard Owen, who has accepted the Vice-Chancellorship of Bristol University.

WE learn from *Science* that the College of Agriculture of the University of the Philippines, situated at Los Banos, opened on June 14 last with about sixty students. Prof. E. B. Copeland is dean and professor in botany; Prof. H. Cuzner, professor of agronomy; Prof. E. M. Ledyard, professor of zoology; and Prof. S. B. Durham, professor of animal husbandry.

A CORRESPONDENT asks us to mention that a man with a science training and degree is wanted for a vacant post in an advanced mission college in South China. The Chinese are eager to acquire the secrets of Western power, and a teacher with the science qualifications required would have a fine opportunity of assisting to make history in that great land.

WE learn from the *Pioneer Mail* that on July 14 the Governor of Madras opened a new agricultural college and research institute at Coimbatore. The building is designed both for teaching and research work. A special set of rooms is set apart for chemistry, botany, entomology, and mycology. A physical laboratory is provided, as well as ample accommodation for the Madras herbarium and a library. The cost of the new institution, including the surrounding farm, has been eight lakhs. The Governor, during the course of his remarks, said that as the demands of scientific agriculture grow and the necessity for expansion arises, the Government will not hesitate to increase the capacity of the institution.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 9.—M. Bouquet de la Grye in the chair.—The thermal effects of moistening soils: A. **Müntz** and H. **Gaudechon.** Certain dry soils, when moistened, give out an appreciable amount of heat, and it is possible that this thermal phenomenon may have an effect on the growth of plants. Measurements with different soils gave an evolution of heat varying from 0·9 to 6·6 calories per kilogram, and a systematic levigation showed that the finest particles caused nearly all the heat evolution.—Magneto-anodic phenomena: M. **Gouy.** The phenomenon described accords to a certain extent with the theory of M. Fortin, which regards the magneto-kathode rays as formed of spirals of electrons.—Discontinuous singularities of uniform analytical functions: A. **Denjoy.**—Tides and the crust and the elasticity of the terrestrial globe: Ch. **Lallemand.** The author has shown in a previous note that the principal modes of determination of the rigidity of the globe lead to different results. The theory developed in the present paper removes this anomaly.—The different species of asymmetrical intensities, observed for the magnetic components, polarised circularly, of the absorption bands of uniaxial crystals: Jean **Becquerel.**—The decomposition of carbon dioxide by the ultra-violet rays: H. **Herchefinkel.** The decomposition of carbon dioxide into oxygen and carbon monoxide by the action of the ultra-violet rays has been proved; a similar result has been obtained with the radium emanation, confirming the observations of Ramsay and Cameron.—The intervention of osmotic pressure in dyeing: M. **Rosenstiehl.**—A method for the rapid estimation of metallic aluminium: E. **Kohn-Abrest.** The metal is heated to 300° C. first in hydrogen, and then in pure hydrochloric acid gas, followed again by hydrogen. The aluminium is volatilised as chloride, and the metal determined indirectly by a determination of the chlorine.—Attempts at benzidination in the diphenyl, diphenylamine, and diphenylethane series: H. **Duval.**—The ethyl acetal of tetrolic aldehyde: P. L. **Viguer.** Dibromo butyric aldehyde was obtained by the addition of bromine to crotonaldehyde; the application of Claisen's method to this aldehyde gave, not the tetrolic aldehyde desired, but its ethyl acetal.—Some parasitic diseases of *Cinnamomum zeylanicum* of Ceylon: D. **Bois** and C. **Gerber.**—Vaccination of cattle against tuberculosis: M. **Rappin.** The bacilli used in these injections were modified by the action of sodium fluoride; it has been shown that the resistance of the animal to tuberculous infection is increased by the treatment almost to the point of immunisation.—The glucoses of the urine: F. **Landolph.** Each species of glucosuria or diabetes corresponds, in the urine, to the presence of mixtures of several kinds of sugars, and it may be supposed that these differences correspond to diseases of different organs.—The preservation and increase of digestibility of distillery pulps and of green ensilage by a rational fermentation by inoculation: J. **Crolbois.**—The suprarenal capsules and their exchanges between the blood and tissues: J. **Athanasiu** and A. **Gradinesco.** The experiments on a dog and a cat described lead to the conclusion that the death of animals deprived of the suprarenal capsules is due to the arrest of the exchanges between the blood and the tissues.—Contribution to the study of urinary indosis in diabetic subjects: H. **Labbé** and G. **Vitry.**—The variation of an oxidising enzyme during metamorphosis in *Limnophilus flavicornis*: Xavier **Roques.**

CAPE TOWN.

Royal Society of South Africa, June 16.—Dr. R. Marloth in the chair.—Some points in the morphology and biology of a new species of Haworthia: Dr. S. **Schönland.** The author gives a full description of the only species of Haworthia with strictly distichous arrangement of leaves. The leaves are to a large extent underground, the exposed parts resembling small pebbles, so that this plant may be classed amongst the so-called "mimicry-plants." The structure of the leaves is adapted to the peculiar mode of life of the plant. The truncate apex is without chlorophyll, thus forming a "window," through which light can reach, by way of the central transparent tissue, the assimilating tissue which extends to the underground basal parts of the leaves.—The absorption of water by the aërial organs of some succulents: Dr. S. **Schönland.** The author describes numerous experiments, from which he has drawn the following conclusions:—*Mesembrianthemum barbatum* and *Anacampseros flamentosa* cannot absorb any appreciable quantity of water through their aërial organs. *Crassula cymosa* can do so to a small extent, which, however, cannot be of any practical importance under natural conditions. The marginal papillæ of this species are certainly not water-absorbing organs.—Note on an abnormal seedling of *Widdringtonia cupressoides*: E. P. **Phillips**, and a brief account of the vascular system of the normal seedling: H. S. **Morris.**—Some new South African succulents, part ii.: Dr. R. **Marloth.** Among the succulents described in this paper are a few with a very peculiar structure of their leaves. Last year the author exhibited a species of Bulbine with window-leaves, pointing out that such a structure had not been observed as yet on any other plant. The very succulent, nearly egg-shaped leaves of the plant remain embedded in the ground, hence the blunt apex only becomes visible. Here the green tissue is absent, being confined to the sides of the leaf. As the sides are surrounded by soil, the light cannot reach them in the ordinary way, but only by entering through the window at the apex, illuminating the leaf from within. Since then the writer found five other species of plants with such window-leaves. They are all stemless succulents, their leaves remaining embedded in the ground, and showing only the flat or convex apex, which is entirely devoid of green tissue. Hence, as in the case of the Bulbine, the light can reach the green tissue of the leaf only through the window, illuminating the leaf from within. It is considered that this structure is principally a contrivance for the protection of the green tissue against the destructive action of too severe sunlight.

NEW SOUTH WALES.

Linnean Society, June 30.—Mr. C. Hedley, president, in the chair.—Studies on Tunicata, No. 1: H. L. **Kesteven.** One genus allied to Polyclinum and Sidnyum (Polyclinidæ), and three species referable to the genera Corella, Molgula, and Dendrodoa, from Tasmania or New South Wales, are described as new, and detailed descriptions are given of *Ciona intestinalis*, var. *sydneiensis*, Stimpson, and var. *diaphnea*, Quoy and Gaimard.—Second supplement to the "Revision of the Cicindelidæ of Australia": T. G. **Sloane.**—The hexone bases of egg-white: Dr. J. M. **Petrie** and Dr. H. G. **Chapman.** This paper deals with the separation and estimation of the hexone bases among the products of the hydrolysis of the proteins of egg-white. By the method of Kossel and Patten, arginin, histidin, and lysin were isolated and identified from egg-white digested with 25 per cent. H_2SO_4. The amounts of lysin, histidin, and arginin present in 100 gm. protein of egg-white were:—lysin, 3·19 gm.; histidin, 0·66 gm.; and lysin, 2·39 gm. Certain improvements in the method of separation are also described.—Notes on the native flora of New South Wales, part vii., eastern Monaro: R. H. **Cambage.** The general botany of the area lying chiefly to the east of Cooma and Nimitybelle is reviewed. The absence of forest growths on the Monaro plains, which are largely basaltic, is a striking feature, and it is suggested that the rigid winter climate, dry summer atmosphere, moderate rainfall (being less than 20 inches annually at Cooma), together with the basic nature of the rocks, in view of the low rainfall, all contribute to hinder the growth of large trees. Where the formation contains a high percentage of silica forest trees are found, and this is thought to be possibly owing to physical properties rather than to chemical constituents, resulting in capillarity being induced by the siliceous particles in the soil, thereby enabling it to supply moisture in dry times better than the soils formed from the basic rocks. The unexpected occurrence of a rare species of Eucalyptus, *E. pulvigera*, first discovered by Allan Cunningham nearly ninety years ago at Cox's River, and now known to occur only in three localities, was of interest. The abrupt change in the flora, where the eastern and western aspects meet on the Main Dividing Range near the head of the Kybean River, is commented upon.—Description of a new species of Eucalyptus from the Monaro district, N.S.W.: R. H. **Cambage.** This species, for which the name *Eucalyptus parvifolia* is suggested, has so far only been found near the head of the Kybean River, on eastern Monaro. It frequents the flats in company with *E. stellulata*, attaining a height of from 20 feet to 30 feet, and having a smooth gum-tree bark. Its most remarkable feature is that it retains a large percentage of the juvenile foliage until the trees are nearly full-grown, the length of these leaves being rather less than 1 inch.

THURSDAY, AUGUST 26, 1909.

TREE-FLORA OF JAVA.

Mikrographie des Holzes der auf Java vorkommenden Baumarten. By Dr. J. W. Moll and H. H. Janssonius. Erste Lieferung (1906), pp. 368; and Zweite Lieferung (1908), pp. 369–568+160. (Leyden: E. J. Brill.) Price 6 marks each.

THIS work, like the earlier tree-flora of Java, was undertaken at the suggestion of Prof. M. Treub, director of the Botanic Garden at Buitenzorg. It will be convenient to begin by making a short reference to this earlier publication.

In the year 1888 Dr. S. H. Koorders began to collect material for a tree-flora of Java. The work connected with the compilation of this flora was carried out in a most careful and methodical manner. More than four thousand trees, many of which were in the primeval forest, were marked, and a special system of numbering the trees, and of indexes and maps, was instituted, so that each tree could be easily found again, and the rate of growth, leaf fall, &c., could be studied. In the course of naming and studying the plants for the tree-flora of Java ("Flora arborea Javanica," by S. H. Koorders and Th. Valeton), a collection of fifteen thousand specimens was made to illustrate the species dealt with in the flora.

This collection included a series of wood-specimens, which were sent in 1904 from Buitenzorg to the University of Gröningen for microscopic examination and description, and this work has been carried out, under the direction of Prof. J. W. Moll, by Herr H. H. Janssonius. The results appear in the present work, which may therefore be described as a counterpart to Koorders and Valeton's flora in the province of the anatomy of the wood. Hence a most important asset in the value of the work lies in the fact that there is no uncertainty as to the origin of the specimens. They have all been obtained from trees which have been carefully studied and determined by an expert, and, moreover, herbarium material from the same trees is to be found in the herbaria at Buitenzorg, Leyden, Berlin, &c.

In this work the authors have adopted a very orderly arrangement of the information. Under each species there are five principal headings, beneath which are given the literature, information on the material, the preparations made, the reagents used, and, lastly, under the name of micrography, a description of the structure of the wood. The section on micrography is generally subdivided into one on topography, dealing chiefly with the distribution of the tissues and elements as seen in transverse section, and another giving descriptions of the individual elements, based on a study of radial, tangential, and transverse sections, sometimes supplemented by macerated preparations. A separate paragraph is devoted to each kind of element, and gives full details of measurements, pitting, contents, &c. The section on topography is elucidated, in cases where this is advisable, by means of a diagrammatic figure showing the distribution of the vessels, wood-parenchyma, medullary rays, &c., in a portion of a transverse section. When several species of a genus are found to differ only slightly in the structure of the wood, one of them is fully described, and the description of the others is shortened by comparative treatment. Under each family, except where only one species is dealt with, there is a description of the structure of the wood, founded on that of the different species described, and an analytical key for distinguishing the species, so far as this is possible by means of the wood, is added.

Part i. contains, first (pp. 5–62), general information, including the history of the material and an exposition of the method adopted in presenting the information in the succeeding pages. The remainder of part i. (pp. 63–368) is occupied by the description of the microscopic structure of the wood in species from Dilleniaceæ to Dipterocarpaceæ. Part ii. (pp. 369–547) continues the same from Dipterocarpaceæ to Tiliaceæ, followed by the index and contents of vol. i., after which pp. 1–160 form a first instalment of vol. ii., extending from Geraniaceæ to Meliaceæ. The last page of part ii. reaches species No. 230, twenty-one families having been dealt with up to this point.

The foregoing description of this work will serve to indicate its value, which lies in the authentic nature of the specimens, the large number of species and families dealt with, the completeness of the description of the microscopic structure, and, lastly, the strict uniformity of treatment adhered to by the authors.

This book will be an important aid in the determination of wood-specimens, and the authors are to be congratulated on the efficient way in which they are carrying out a difficult and laborious task.

L. A. B.

TWO AMERICAN MATHEMATICAL BOOKS.

(1) *Plane and Spherical Trigonometry and Four-place Tables of Logarithms.* By Dr. Wm. A. Granville. Pp. xii+264+38. (London: Ginn and Co., n.d.) Price 5*s.* 6*d.*

(2) *A Course of Mathematics for Students of Engineering and Applied Science.* By Fredk. S. Woods and Fredk. H. Bailey. Vol. II. Pp. xii+410. (London: Ginn and Co., n.d.) Price 10*s.* 6*d.*

(1) THE type and diagrams in this book are models of elegance and excellence; evidently no pains have been spared in making both as clear and perfect as possible, and the logarithm tables at the end of the book add greatly to its completeness. One useful feature in them is the table of circular functions with the angles expressed in degrees and decimals of a degree, in addition to the usual table in degrees and minutes. The author also supplies a neat celluloid combined protractor and scale in a pocket attached to the cover.

In the plane trigonometry the author introduces the student to practical examples in connection with right triangles in the first chapter, but does not proceed to the solution of oblique triangles until chapter vii., after discussion of functions of the generalised angle, the addition theorems, inverse notation, and trigonometric equations, but to a certain extent teachers can choose their own order in taking these chapters.

The proof of the addition theorem is not very satisfactory. The author proves the theorems for sin $(x+y)$ and cos $(x+y)$ for *acute* angles (using a revolving line of unit length, and so denoting the sines and cosines by lengths of lines instead of ratios, which seems a pity), and then says "it is a fact, however, that these formulæ hold for angles of any magnitude, positive or negative." This he illustrates by a couple of cases. Then, in the next section, he says "it was shown" that the formulæ hold good for all angles. The proof by projection now customary in the best English books would have been much more satisfactory.

The directions for solving trigonometrical equations are not altogether satisfactory, and would lead to difficulties in the case of such an equation as $\sin 3x = \cos 4x$. This part of the subject would need amplifying. The similar instructions for proving identities, though sometimes leading to rather heavy work, would always lead to success and be useful in the last resort, though not conducive to elegance.

The solutions of triangles are well explained, and there is a good chapter on the theory and use of logarithms and their applications to nautical and other problems, but one is sorry not to see the value of the characteristic given as the distance of the highest significant figure from the unit's place, plus or minus according as it is to the left or right. It is more fundamental and easier to remember than the old-fashioned method given in the text.

This part of the book finishes with a discussion of acute angles near 0° and 90°, and a collection of miscellaneous practical examples of the usual type, followed by a useful recapitulation of formulæ, with the pages on which they are proved.

The spherical trigonometry assumes some previous knowledge on the part of the reader, as far as the properties of the polar triangle, and one or two of the more advanced formulæ are quoted without proof. The chief features of this part are a good exposition of Napier's rules for right-angled triangles, and the use of the exterior angles (α, β, γ) in all the formulæ for oblique triangles, a most excellent innovation which the reviewer has advocated for many years, but has never before seen in a text-book. By this means all formulæ become dual without any change except the interchance between a, b, c and α, β, γ. It leads, perhaps, to a preponderance of obtuse angles in the practical applications, but the author in his logarithmic work, which is most excellently exemplified, disposes of them by the simple device of putting (n) to the logarithms of negative quantities, a method often used by practical computers, but not often seen in text-books. The book concludes with applications to astronomical and other problems, well explained and illustrated by good diagrams, with a fair number of examples for the student to solve.

(2) This volume completes the authors' plan of a course of mathematics for students of engineering and physics. The first chapter discusses infinitesimals, and defines differentials of functions of a single variable. Then come chapters on integration, with applications to geometry and mechanics, followed by special methods of integration applicable to partial fractions and trigonometric functions, including the use of reduction formulæ. Chapter viii. deals with simple differential equations, with mechanical and geometric examples illustrating their importance. Chapters ix. and x. deal with solid geometry; chapter xi. with partial differentiation; chapters xii. and xiii. treat of multiple integrals and applications, with carefully drawn diagrams well illustrating the building up of such integrals, in rectangular, polar, and cylindrical coordinates. Then follows an introduction to line integrals and their connection with surface integrals (Stokes's theorem). Chapter xv. is devoted to infinite series, giving the easier tests of convergence, followed by Maclaurin's and Taylor's series and an introduction to Fourier's series, and finishing with the evaluation of indeterminate forms. Chapter xvi. contains a short treatment of complex numbers and conjugate functions. The remaining chapters are devoted to differential equations, total and partial.

The whole book is very solid reading, but the explanations are well given, and when proofs are not fully given references are made to other treatises. The intention of the authors evidently is to take the students over as much ground as possible, and introduce them to all the functions and processes which they are likely to need in their scientific work. There are numerous problems for solution throughout the book, and there is an index at the end to facilitate reference.

A. L.

ELEMENTARY PETROLOGY AND ORE FORMATION.

(1) *Rocks and Rock Minerals.* A Manual of the Elements of Petrology without the Use of the Microscope for the Geologist, Engineer, Miner, Architect, &c., or for Instruction in Colleges and Schools. By L. V. Pirsson. Fifth edition. Pp. vi+414. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1908.) Price 10s. 6d. net.

(2) *Genesis of Metallic Ores and of the Rocks which Enclose Them.* By B. Symons. Pp. xxxiii+494. (London: *The Mining Journal*, 1908.)

THE growing recognition of the economic uses of petrology and the increasing complexity of petrographic methods are rendering necessary the development of a less technical rock nomenclature for use in the field and by general geologists. No one who has acquired sufficient knowledge of petrology to determine the approximate chemical composition and qualities of a rock from a short study of a thin section is likely to discontinue the use of the microscope. The increasing number of students of mining, chemistry, engineering, and agriculture who have to study rocks, but have not much time to devote to the subject, is leading to the issue of special text-books on petrography without the microscope, and, thanks to its revelations, much can now be learnt from rocks by the examination of hand specimens.

(1) Prof. Pirsson's "Rocks and Rock Minerals" is the most advanced of the manuals of petrology without the microscope, but it may be recommended even to students who can use that instrument owing to its clear statement of the principles of petrogenesis and of the mode of occurrence of the sedimentary and

igneous rocks. It summarises the characters of the chief rock-forming minerals, and of the origin and classification of rocks, and is illustrated by an admirable series of photographs and diagrams showing the field relations of igneous rocks. The author makes a useful protest against the appropriation by geologists of popular rock names in new and technical meanings. The term granite, for example, is used in the stone trade in its correct historical and etymological sense, which is entirely different from its use in geology. This system is as inconvenient, as Prof. Pirsson points out, as if botanists had re-defined the terms bush, tree, and shrub, limiting each to a particular species. Prof. Pirsson's protest is justified, and though some American geologists are using the familiar terms in their popular meanings, this reform has probably been proposed too late.

(2) Mr. Brenton Symons's "Genesis of Metallic Ores and the Rocks which Enclose Them" is also intended to appeal to the general elementary student, and is an attempt to explain the formation of ore deposits free from unnecessary technicalities. It is a book, however, of very different standard from Prof. Pirsson's; it is written by a practical engineer, who is keenly interested in the theoretical study of mining geology, but whose knowledge of the subject is a little unequal.

The book begins with a general introduction on geological principles, followed by a section on rock metamorphism; the third part of the book deals with the ore deposits. Though the author avoids so far as possible technical scientific terms, his text is often repellent by the abundant use of such Americanisms as cavations for spaces, such reformed spellings as "lentiles" for "lenticles," and vegetal for vegetable, and mining terms of only local value. The most valuable part of the book is its collection of diagrams of ore occurrences; the instances drawn from Cornwall are the most satisfactory, for some of his diagrams and views regarding ores in other parts of the world are a little out of date. Mr. Symons takes, moreover, an extreme position as to the genesis of ores. He has a great belief in the agency of geosynclinals, by which sediments are carried down to depths where they are melted, and then forced to re-ascend as igneous rocks into overlying strata; and though he describes many ores as plutonic, he appears to regard the vast majority of ores as having been derived from the destruction of Archæan rocks and precipitated in the sea. He says, on p. 381, "It has been already observed that nearly all the ores that can come within the reach of man have been derived from the Archean strata"; from these rocks, according to Mr. Symons, the metals are removed in solution and "precipitated on the bottom of the sea by chemical reactions that were principally set up by organic matter." He has no doubt, for example, that the gold in the reefs of Nova Scotia and the copper ores of Mansfeld were deposited in the rocks of those mining fields during their deposition in the sea. His view of the origin of crystalline rocks of most ores is shown by the following quotation.

"The presence of such minute proportions in all formations is natural, since the crystalline rocks, as far as known, were originally deposited as marine strata, and, consequently, retain some part of the minerals that were precipitated during sedimentation from the oceanic waters. The proportion of these metals appears to be just the same, whether districts are metalliferous or not" (p. 363).

This extract shows that the author adopts such an extreme position in regard to the genesis of ores that his book must be read with caution.

ZOOLOGICAL PRIMERS.

(1) *Die Säugetiere Deutschlands.* By Dr. C. Hennings. Pp. 174. (Leipzig: Quelle und Meyer, 1909.) Price 1.25 marks.

(2) *Korallen und andere gesteinsbildende Tiere.* By Dr. Walther May. Pp. iii+122. (Leipzig: B. G. Teubner, 1909.) Price 1.25 marks.

(3) *Die Fortpflanzung der Tiere.* By Dr. R. Goldschmidt. Pp. iv+124. (Leipzig: B. G. Teubner, 1909.) Price 1.25 marks.

(4) *Die Stammesgeschichte unserer Haustiere.* By Prof. Dr. T. Keller. Pp. iii+114. (Leipzig: B. G. Teubner, 1909.) Price 1.25 marks.

(5) *Biology.* By Prof. R. J. Harvey Gibson. Pp. viii+120. (London: J. M. Dent and Co., 1909.) Price 1s. net.

(1) THE most useful portion of this sketch of the mammalia of Germany lies in the synoptic tables placed at the head of each order; but these can hardly be considered as complete, since they do not include any account of the subspecies, which are of the greatest interest.

A complete list prefixed to this book would have made comparisons with the fauna of other countries a much easier matter. As it is, one has to search through the index in order to discover what forms are included in this work.

(2) Dr. May is a well-known writer on the anatomy of corals, and in this little work he brings together descriptions of a heterogeneous assemblage of animals, the common feature amongst which is the property of producing a hard exoskeleton, or of contributing otherwise by their remains to the formation of strata.

The question inevitably arising out of this treatment is, What determines the difference between, say, a soft anemone and an encrusted coral? To this Dr. May has, so far as we can see, no answer. Nevertheless, his book contains a good sketch of the various hypotheses accounting for the origin and formation of coral-reefs, and for this, if for nothing else, it is welcome. The corals and lamellibranchs appear to us the best parts of the work.

(3) Dr. Goldschmidt has undertaken to compress into a hundred small pages an account of the methods of animal reproduction, with especial reference to the number of the young, their state on hatching, their habits and adaptations. The work cannot be considered as really up to date, but the treatment is interesting, and the subject is one of such importance that we regret more space could not have been allotted to it. The illustrations are better than those of any other booklet of this series we have so far seen.

(4) In an earlier and larger work, published some

three years ago, Dr. Keller advanced his views on the origin of domesticated animals. The present little work is an abstract of the larger one, and gives only the most meagre outline of the evidence on this difficult subject. The time has not yet arrived when such a work can be successfully written. We know far too little to establish conclusions on the origin of most of our familiar animals, and we can only recommend this work on a most interesting subject with considerable reserve. Prof. Ewart's work on horses appears to be unknown to the author. The book has no index.

(5) The general scheme of this primer is excellently devised. Beginning with a sketch of function, the author passes on to differentiation. The values, transformations, and elaboration of food-stuffs are next dealt with, and a special section is given to "sensitivity." The adaptations of organisms are briefly considered, and a short account of reproduction is given. The primer concludes with a sketch of the theory of natural selection. Such a concise statement of the general principles of animal and plant life should be of considerable use to teachers of elementary science.

The value of the book would have been increased by better illustrations. Many of those employed (for example, Nos. 8, 9, 18, 19, 37, 40, and 47) are so incompletely described as to lose much of their value. The figure of Padina (Fig. 2) is extremely vague. The text as a whole is what we should expect from such an experienced teacher as Prof. Harvey Gibson, and it has had the benefit of revision from his colleagues. The account of the destruction of life as illustrated by a dinner (p. 114) is perhaps open to criticism. The benefits of cultivation in increasing the number and variety of edible organisms are not pointed out. Moreover, in contrast to wild species, the individuals of cultivated ones have surely not remained "fairly constant" in numbers. Demand has in this case created supply. So far from illustrating natural selection, such an example seems to typify artificial selection. The statement about green Hydra on p. 43 goes beyond our present knowledge.

SOME NEW ELECTRICAL BOOKS.

(1) *The Bell Telephone.* The Deposition of A. G. Bell in the Suit brought by the United States to annul the Bell Patents. Pp. iv+469. (Boston: The American Bell Telephone Co., 1908.)

(2) *How Telegraphs and Telephones Work.* Explained in non-technical language by C. R. Gibson. Pp. vi+156. (London: Seeley and Co., Ltd., 1909.) Price 1*s.* 6*d.* net.

(3) *Technical Electricity.* By H. T. Davidge and R. W. Hutchinson. Second edition. Pp. xi+539. (Cambridge: University Tutorial Press, Ltd., 1909.) Price 4*s.* 6*d.*

(1) THE printing of the full deposition made by Mr. Bell in the suit brought by the United States to annul the Bell telephone patents doubtless furnishes a valuable historical record of the experiments which led to the invention of the telephone, and, since the deposition was never officially printed, the American Bell Telephone Co. has performed a useful service in the publication of this book. To any who may still be interested in the legal aspects of the case the book should also prove valuable. But for the general reader, even when specially interested in telephony, the verbatim report of a legal examination and cross-examination is a very unsatisfactory medium for conveying information. The constant repetitions, the frequent insistence on what must be regarded from the broader point of view as wholly irrelevant details, and, above all, the clumsiness of a dialogue devoid of literary merit, make very poor reading, and one is liable to be overcome with ennui before any salient points have been gleaned.

By judicious, if comprehensive, skipping, however, many facts of both scientific and general interest may be obtained from this volume, and to many the detailed descriptions of the earlier struggles and difficulties leading to an invention of enormous utility and importance will have a particular fascination. It is only to be regretted that the book was not written in consecutive narrative form, though possibly some of its value as a record might have been sacrificed thereby.

(2) That Mr. Gibson has an aptitude for the description in non-technical language of the achievements of modern technology has been amply proved by his earlier books which have been reviewed in these columns. The present small volume shares the merits of its predecessors. The very large degree to which the telegraph and telephone enter into the daily life of the community should make this book particularly useful, and it should find a large circle of readers. The book is more or less an amplification of the chapters dealing with this branch in earlier more general books. The subjects covered are telegraphy and telephony, both with wires and without; there is a short chapter on lightning, the reason for the inclusion of which "by request" does not seem clear, and three concluding chapters of a more general character on electrical units and theory. The volume is well printed and illustrated.

(3) This text-book was originally published in 1906, and the present is the third impression. Advantage has been taken of the new edition to bring some parts of the book more up to date, but the revision has not been very thorough, as reference to the chapter on lamps (in which there has been very marked progress since 1906) will show. The tungsten lamp is allotted seven lines of small print, but the osmium lamp, almost if not quite defunct, remains in possession of what we presume was its original position in the main text. The whole chapter on lamps seems to us poor; the drawing of an arc in Fig. 128 is purely imaginary, and the authors would do well to refer to Mrs. Ayrton's book before they issue their next edition; the section on flame arcs and the reference to the Bremer arc lamp lead us to the conclusion that the authors have no correct idea of the real difference between the flame and the ordinary arc.

It is perhaps somewhat unkind to take exception to such errors in what is only one chapter amongst four-and-twenty. But it is deplorable that a text-book should give incorrect or misleading information; the authors' aim "at spanning the gulf which too often divides pure theory and practical engineering" will not be realised if the student is obliged to unlearn much that they teach him when he becomes a practical engineer. We do not profess to be experts in the whole subject of electrical engineering, and cannot criticise the whole book, therefore, on the same lines as we have criticised the section on lamps; but the authors, by writing such a book, lay claim—at least so far as fundamentals are concerned—to be such experts, and if we find them at fault at one part we are led to suspect the whole.

The book covers the whole electrical field; the arrangement is that usually adopted, opening with electrostatics and magnetism, and passing on to electric currents. The diagrams and illustrations are for the most part good, but the process blocks (fortunately few) come out badly on the class of paper used. There are numerous exercises for the student to work out at the end of each chapter.

M. S.

OUR BOOK SHELF.

Gas-engine Theory and Design. By A. C. Mehrtens. Pp. v+256. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 10s. 6d. net.

THE writer of this book is an instructor in mechanical engineering in the Michigan Agricultural College. His aim, he tells us, has been to prepare a book for all who are interested in gas engines, whether students, draughtsmen, engineers, or engine operators.

This is an ambitious aim, and we may well doubt the possibility of its being carried out in such a small compass; but there can be no doubt that the cardinal virtues of simplicity and conciseness of language which any such intention must require are here presented in no usual degree. The reviewer does not remember any book hitherto written on the gas engine which presents its subject with such lucidity.

The chief entry to be made on the debit side of the account is that the extent of the field covered is far too great. It will be found, on perusing the volume, that it not only deals with the history and present position of gas-engine invention, and with the properties of the gases and fuels used, but also with such a big subject as the design of engine details and the dimensions of parts. Students usually learn their physics and machine design independently of the steam or gas engine, and a book on the gas engine which includes a great deal of what has already been studied separately is wasting space. The result in so small a book as this is that the truth and applicability of a great number of formulæ are taken for granted, which may account for the poor compliment paid to them by the author on p. 123, where he remarks:—

"A number of formulas will be given in the following paragraphs, but machinery cannot be designed by formulas alone. The author has frequently found that empirical, and other, formulas would sometimes come within 500 per cent. of the correct result."

There are also the inevitable slips of a "first edition," but they are not numerous. The author should, however, make a point in the next edition of correcting his description (on p. 33) of carbon monoxide as an unstable compound; his omission on p. 39, in the discussion of the apparent suppression of heat on explosion, of any reference to the increase of specific heats admitted on p. 25; the error in saying (on p. 44) that it is usual to increase the compression pressure in an engine which is to run on kerosene, and he should also correct the general confusion of the table on p. 167. It is difficult to understand what the author means in his description (on p. 52) of the working of the gas producer by the remark:—"The limit of the ratio of steam to coal by weight is about 1 to 40."

Although, as has been stated, the author has attempted to get too much into so small a volume, it must be acknowledged that he has produced a book at once interesting in treatment and clear in language.

La materia radiante e i raggi magnetici. By Prof. A. Righi. Pp. vii+308. (Bologna: N. Zanichelli, 1909.) Price 8 lire.

IN a recent number of NATURE a brief account was given of Righi's "magnetic rays," this being the name applied to a peculiar luminosity near the kathode of a vacuum tube, when the latter is placed in a longitudinal magnetic field. Righi supposes that this luminous column is due to electrically neutral doublets, which are not in sufficiently stable equilibrium to be looked upon as atoms or molecules, which owe, in fact, such stability as they possess to the action of the magnetic field. Several papers on this subject have been published by the author, and the main object of the present small volume is to give a connected account of the whole research. About one-third of the book is devoted to an extremely lucid and interesting summary of our present knowledge concerning the corpuscular theory of matter, written in a style which, as far as possible, is free from technical terms. The remainder, except for three short mathematical appendices, deals with the evidence for and against the existence of neutral doublets or magnetic rays. Here, while very suggestive, the experiments are not altogether convincing—this is evidently the opinion of Prof. Righi himself—but this is due in great measure to the difficult experimental conditions. While no one experiment can be said to have demonstrated the existence of magnetic rays, the results as a whole certainly tend to support the author's view. One point might have been treated more fully, viz., the conditions under which a magnetic field lowers the potential difference at the terminals of the discharge tube. Experiments are described, in some of which an increase, in others a decrease, of potential is brought about by the magnetic field, but it is not clear to what difference in the conditions this is due.

R. S. W.

Brassolidae. By Dr. H. Stichel. (Das Tierreich, 25 Lieferung.) Pp. xiv+244. (Berlin: R. Friedländer und Sohn, 1909.) Price 15 marks.

THIS is a very elaborate monograph of a comparatively small group of butterflies found only in Tropical America. They form a subfamily of the great family Nymphalidæ, and are most nearly allied to the great blue Morphidæ, but differ from them by their stouter bodies, darker colours, and the closed cell of the hind wings, which are generally ornamented with three large eye-spots on the under-surface. Their flight is crepuscular, while that of the Morphidæ (which are represented in the East Indies as well as in Tropical America), is diurnal.

In 1823, Latreille and Godart, in the second part of "Papillons" in the "Encyclopédie méthodique," were acquainted with only twenty-three species now referred to the Brassolidæ. Of these, twenty-one formed the bulk of the second section of the genus Morpho, while the remaining two species were placed in Brassolis. In Kirby's Catalogue of Diurnal Lepidoptera and Supplement (1871 and 1877) we find eight genera of Brassolidæ and fifty-four species, while Dr. Stichel now enumerates eleven genera and seventy-five species, in addition to a very considerable number of forms treated for the present as subspecies.

Dr. Stichel describes the species at great length, adding tables of the genera, species, and subspecies. The synonymy of the genera and species is very fully given, and the excellent text-illustrations include the neuration of one species of each genus, and also the markings of the wings of a large number of species, both surfaces being usually figured. Descriptions are also given of the eggs, larvæ and pupæ of the insects, as far as known at present, and the range of each species is also indicated. On pp. 3 and 4 we find general information on the habits of the butterflies, and should have liked more detail under the various species; but we presume that there was either no room, or the available information on the subject was too meagre to be worth giving, except in a general manner. W. F. K.

The Volcanic Origin of Coal and Modern Geological Theories: a Plea for Lessening Demands on Geological Time; and for Further Separating the Life Histories of the Aqueous and Volcanic Formations. By Col. A. T. Fraser (late R.E.). Pp. 21. (London: R. Banks and Sons, 1909.)

THE old Wernerians used to account for volcanic action by the supposed combustion of coal within the earth's crust, but the author of this pamphlet turns the tables upon them by making the volcanoes produce the coal! The way in which this feat is performed is as follows:—first by pointing out that in the sides of the active volcano Gedeh in Java the tuffs are seen to be well stratified, and look, *at a distance,* like old red sandstone; then the mud deposits ejected by the eruption of Tarawera in New Zealand are also stratified. Next, we have somewhat of a leap in the advance of the argument. The Java experience showed, *though coal was absent,* another way in which it (coal) might originate; namely, being rained down in a shower of bitumen alternately with sandstones, shales, &c. In support of this view we are told that a visit to "the quarries of Carrara and Parnassus" show that "marble is a volcanic rock," "ejected, accompanied by high-pressure steam, from a fissure and showered down." We must leave our author with the coal and marble, and not attempt to follow his leading among geological theories, old and new. We fear, judging from books advertised on a fly-leaf at the end of the one before us, that the author has been so much occupied with psychical research, occult powers of Eastern nations and the religions of the world, that he has not found time for even a very little elementary chemistry.

Cassell's "Nature" Copies (Wild Flowers). Aids to Nature Study, Brushwork, and Drawing. In twelve packets. (London: Cassell and Co., Ltd., n.d.) Price 6*d*. net per packet.

EACH of these packets of drawing copies contains ten examples of pictures of wild flowers executed in colours on stout plate paper. Though the best plan is to have wild flowers drawn from actual specimens, these copies may serve a useful purpose in town schools, where it is very difficult or impossible to procure the plants themselves; in any case they will add variety to the art work, and familiarise children with the beauty of common wild flowers.

August Meteoric Shower.

I HAVE summarised in a form which may be convenient for comparison some of the results of Perseid observations this year. The differences in some cases are remarkable, and sufficiently prove that to arrive at definite conclusions respecting the character of a shower a large number of materials should be consulted and averaged. Weather conditions are dissimilar, the places of observation are not equally well situated (certain positions in towns are much affected by artificial light), and there are other causes which must introduce discordances. Though comparatively few Perseids were observed at Bristol and Meltham on August 10, they were fairly numerous at Blaina and Antwerp, and on the night of August 12, when a rich display of brilliant meteors was remarked at Bristol, there was no striking exhibition witnessed at several other places.

Apparently few determinations of the radiant have been made, but so many values have been found for this at previous returns that further estimates are not much needed. Photographic impressions of the trails would be of essential value as giving, not only a very exact position for the radiant, but as indicating its character and the extent of its diffusion. W. F. DENNING.

The Ringing of House-bells without Apparent Cause.

UNTIL I read the two letters in NATURE of July 22 and August 12 I had no idea that the ringing of house-bells without apparent cause was so fascinating a subject, as my own experience of it has been rather prosaic. One of my bells occasionally rings when no one is in the room, but it is entirely due to bad workmanship. The strength of the spring which draws the wire back after it has been pulled is only about equal to the friction of the wires, and the result is that, though it generally draws the wire back immediately after it has been pulled, yet it sometimes fails to do so at the time; but after some time, it may be hours, owing to some change in the conditions, it succeeds in drawing back the wire, when the bell again rings when no one is touching it. The bell thus rings once when it is pulled, and a second time when the spring succeeds in drawing back the wire.

The electrical explanation of any mysterious ringings seems hopeless in any conditions, save possibly in a thunderstorm, when we remember that all the bells and wires are in good electric contact with each other, and in more or less indifferent contact at many places with pipes, walls, &c. Further, only the bell at the end of a row could be rung by electrical attraction to the opposite wall, because the bells swing parallel to the wall on which they are fixed, and considerable force is required to make them move in a direction at right angles to their free swing.

In the case referred to by Mr. C. L. Tweedale, it might have been worth while to see if the wire attached to the lively bell he mentions did not come in contact with any other wires at any part of its length. What makes me suggest this is that in one of my rooms I can tell when the front-door bell is rung by a sympathetic movement of the bell-pull in the room, due to the wires rubbing against each other at some part and the wire to the door bell pulling the wire to the room.

When one considers the class of workmanship put into bell-hanging, one need not be surprised at the vagaries of the bells. Like plumber work, it is mostly out of sight, and as the work has often to be done in very imperfect light and under cramped conditions, anything that will work is considered good enough.

JOHN AITKEN.

Ardenlea, Falkirk, August 21.

FLYING ANIMALS AND FLYING MACHINES.

UNTIL quite recently human flight was considered by the mass of mankind as so impracticable that "I can no more do that than fly" was a phrase used to denote something not to be accomplished. It is no wonder, then, that the fact that several people (probably some dozens at the present moment) have actually flown should appeal to the popular imagination, and the appeal is especially strong in such a case as M. Blériot's flight over the English Channel, although there is nothing really more formidable in a flight over water than over land. It may be of some interest to show briefly how it is that what was formerly looked on as a typical impossibility has now become a matter of everyday occurrence.

It will be a help to take first the case of such animals as have wings, and to see why it is that no creature the height of which approaches even one-quarter that of a man has been able to fly either in present or former times. In order that the wings may support the body, their movement must generate a downward current of air of which the momentum per unit of time is equivalent to the downward momentum which the body and wings would acquire in the same time under the influence of gravity. This does not necessarily involve a large expenditure of work. For instance, when a weight is attached to a parachute and is dropped from a height the speed of descent soon becomes constant, and the work done in the air by the parachute is then just equal to the product of the weight into the distance fallen. The resistance of the parachute is proportional to its area, and the speed of descent can be made as small as we please if the area is made large enough. The work, therefore, expended in a given time, that is, the power delivered to the air, is diminished in the same proportion.

Suppose now that instead of an inanimate weight an animal is suspended from the parachute by a long rope ladder. When the speed of descent is slow enough, the animal will have no difficulty in climbing the ladder at such a rate that the centre of gravity of the "system" may remain stationary in the air, and this by an expenditure of work which can be diminished indefinitely by increasing the area of the parachute.

This case is analogous to the hovering of a bird in the air without horizontal velocity during the downstroke of the wings, and as no means are here provided for restoring the wing to its primitive position the time of support is limited. The illustration suffices, however, to show that the work required in order to maintain a stationary position in the air by means of wings is equal to the work required to raise the total weight involved at the same rate as that at which it would fall were no work to be expended.

Of the total weight supported, namely, the animal and the parachute, the animal only is a source of power. Thus, while in "dynamically similar" combinations the total weight varies as the cube of the linear dimensions, the supporting area varies as the square, and the living power available varies, not as the total weight, but as the total weight less the weight of the supporting wing. It will be readily seen that if the animal can only deliver a certain amount of power per unit weight of body these conditions lead to an absolute limit to the weight of an animal which can sustain itself stationary in the air. For, suppose the total weight is $w = w_a + w_s$ (the weights, namely, of the animal and the parachute of area s), w_s must vary as $s^{\frac{3}{2}}$, and if the downward velocity is to be constant s must be proportional to w. From this it can be shown that the greatest weight an animal (incapable of climbing faster than some given speed) can have is $2b^3/3c^2$, where $b = w'/s'$ and $c = w_s'/s'^{\frac{3}{2}}$, w_s' and s' being known values of wing weight and wing area fulfilling the condition of falling with the required velocity when the total weight is w'. If we take $w_s' = w'/n$, the expression $2b^3/3c^2$ becomes $\frac{2}{3}w'n^2$.

As an example, suppose that 30 feet per minute is the limiting velocity at which an animal can continue to climb, and that the area of the parachute which will drop at the appropriate speed when the total weight of parachute and load is 1 lb. is 100 square feet, and also that the weight of the parachute alone is $\frac{1}{4}$ lb., then it appears that no animal could maintain itself stationary in the air by means of a parachute the weight of which exceeded $\frac{2}{3}(4)^2$ (or about $10\frac{1}{2}$ lb.), and the area required for this weight would be more than 1600 square feet. Thus, if no more favourable way of supporting a weight was available than the down stroke of a wing in still air, flight would be impossible for all except the very smallest animals.

As is well known, however, the vertical reaction on a slightly inclined plane moving rapidly in a horizontal direction enormously exceeds that which it would experience in dropping through still air, and although the proportionalities between the weights and the supporting area still remain, viz. $s \propto w$ and $w_s \propto s^{\frac{3}{2}}$, the actual weight which can be supported by a given area increases indefinitely as the horizontal speed increases.

If there were no such thing as air friction, the work expended in supporting a given load might also be reduced indefinitely, for the resistance to the horizontal motion (which, when the inclination of the plane is small, may be regarded as the horizontal component of the normal force) could be diminished indefinitely by decreasing the inclination.

Air friction, however, fixes a limit beyond which the inclination of the plane to the direction of motion cannot be advantageously reduced. Experiments have shown that this inclination is about 5°, and that then the ratio of the supporting force to the resistance lies between 5 and 7 (depending partly on the shape of the plane). A knowledge of the best angle of inclination and the ratio of the resistance to the force on the plane at right angles to its path afford means of determining the possible efficiency (see "Experiments on

Model Screws," R. E. Froude, F.R.S., Proc. Naval Architects, 1908).

Among birds, those which fly continuously seldom have the ratio of weight to wing area more than 1 lb. per square foot, and in many cases, such as hawks and swallows, the ratio is something like $\frac{1}{3}$ lb. per square foot; but whatever the ratio may be, so long as the animal can only give out a limited amount of power proportional to its weight, a definite limit can be assigned to the size and weight of the body which can sustain itself in flight by muscular action.

If the weight of the wing increased directly as its area such a limit would not exist. The weight of a flock of birds, for example, is limited simply by the numbers in the flock, and we only have to suppose the individuals to be connected by a light framework to convert the flock into a flying machine the wing weight of which is proportional to the wing area. To a certain extent, the biplane flying machine carries out the same idea, but in most of the existing types the weight of the connecting framework must to a great extent neutralise the reduction of weight which should accompany the reduced linear dimensions.

From what has been said it will be seen that so long as no engine was available which, with all adjuncts, such as fuel supply, framing, and wings, could raise the total weight much faster than could an animal of the weight of the engine only, there was no chance for the addition of flight to human accomplishments, and it is due to the advent of the internal-combustion engine that it is now possible to carry air-borne loads of more than 1000 lb. To carry heavy loads with a moderate wing area requires large horizontal velocities, and in such machines as have succeeded the load per square foot generally exceeds 2 lb.

The high velocity requisite is advantageous when the machine is launched and is pursuing a straight course, but it adds to the difficulties of starting and stopping, and is a restriction on manœuvring power: that is, it increases the radius of the circle in which the machine can turn. When a flying machine of weight w travels in a circle of radius r with velocity v the centrifugal force, F, is wv^2/rg, and if the plane of the circle is horizontal the upward component of the normal force on the wings is w, and hence the normal force is $(w^2+F^2)^{\frac{1}{2}}$ (nearly), and the inclination (β) of the wings to the horizontal in the direction of r is F/w.

The normal force on a straight course differs little from w. In flying in a horizontal curve, therefore, the normal force must be increased in the ratio $(w^2+F^2)^{\frac{1}{2}}/w$ if the velocity is to remain constant. To effect this the engine revolutions must be quickened and the fore and aft trim of the wings altered. In other words, it requires more power to fly in a curve than in a straight course at the same speed, although the increase is not important so long as F/w is small.

For example, if $v=50$ f.s. and $r=200$ feet, $F/w=0{\cdot}256$, the increase of power required is about 3 per cent., and $\beta=14°$. For the same radius if $v=100$ f.s., $F/w=1{\cdot}56$. The power required is 1·86 times that for the straight course, and $\beta=56°$ about.

I am not aware that any exact experiments have yet been made on the manœuvring capacity of flying machines, but the subject will have to be carefully investigated.

The three most important lines along which the development of flying machines should be pursued are those relating to intrinsic stability, ease of starting and stopping, and manœuvring capacity. It is improbable that any form is intrinsically stable at all speeds, but automatic devices may be introduced (as mentioned in my letters to NATURE of January 30 and December 24 1908) which will relieve the aëronaut of responsibility in this respect. Ease in starting and stopping implies the power of flying (at any rate, for a short time) at low velocities; while manœuvring capacity demands ready control of the angles at which the various supporting surfaces are presented to the air.

A. MALLOCK.

THE BRITISH ASSOCIATION AT WINNIPEG.

As we go to press the seventy-ninth annual meeting of the British Association is being opened at Winnipeg, under the presidency of Sir J. J. Thomson, F.R.S., whose inaugural address is reprinted below. Following our usual custom, the addresses of presidents of most of the sections will be published in future issues of NATURE, and also accounts of the scientific proceedings of the sections.

This is the fourth time the association has met outside the British Isles, the previous occasions being Montreal (1884), Toronto (1897), and South Africa (1905). The last meeting of the association in Canada was very successful, the number of members and associates present being 1362. During the twelve years that have since elapsed, great progress has been made in all branches of science, and, though the people of Western Canada do not expect to contribute a very large part to the scientific proceedings of the sections, they anticipate interest in many of the subjects to be dealt with or discussed. Much interest in the meeting has been manifested in Canada and the United States, as well as on this side of the Atlantic. It is estimated that between 400 and 500 members have gone to Winnipeg from Europe, and it is hoped that the total number of members and associates attending the meeting will be at least 1500.

Generous financial support towards the expenses of the meeting has been given by the Dominion Government, the Government of Manitoba, and the city of Winnipeg, while the western provinces and cities have agreed to defray the expenses of an excursion to the Pacific Coast of a party of about two hundred office-bearers and distinguished guests of the association.

Excursions have been arranged for Saturday, August 28, to points of interest in the vicinity of Winnipeg, including Stony Mountain and the municipal stone quarries; Lake Winnipeg, St. Andrew's Rapids, and Selkirk; the wheat fields of Manitoba; the hydro-electric plant on the Winnipeg River. Members have also the opportunity of visiting various industrial works in the city of Winnipeg.

Evening receptions will be held by the Lieutenant-Governor at Government House, and by the local executive committee. Garden-parties have been arranged for several afternoons during the meeting including those to be given at the historic Lower Fort Garry by the Commissioner of the Hudson's Bay Company, at the Provincial Agricultural College, and by the Hon. Chief Justice Howell.

INAUGURAL ADDRESS BY PROF. SIR J. J. THOMSON, M.A., LL.D., D.Sc., F.R.S., PRESIDENT OF THE ASSOCIATION.

TWENTY-FIVE years ago a great change was made in the practice of the British Association. From the foundation of our Society until 1884 its meetings had always been held in the British Isles; in that year, however, the Association met in Montreal, and a step was taken which changed us from an Insular into an Imperial Association. For this change, which now I think meets with nothing but approval, Canada is mainly responsible. Men of science welcome it for the increased opportunities it gives them of studying under the most pleasant and favourable conditions different parts of our Empire, of making new friends; such meetings as these not only promote the progress of science, but also help to strengthen the bonds which bind together the different portions of the King's Dominions.

This year, for the third time in a quarter of a century, we are meeting in Canada. As if to give us an object lesson in the growth of Empire, you in Winnipeg took the opportunity at our first meeting in Canada in 1884 to invite our members to visit Manitoba and see for themselves the development of the Province at that time. Those who were fortunate enough to be your guests then as well as now are confronted with a change which must seem to them unexampled and almost incredible. Great cities have sprung up, immense areas have been converted from prairies to prosperous farms, flourishing industries have been started, and the population has quadrupled. As the President of a scientific association I hope I may be pardoned if I point out that even the enterprise and energy of your people and the richness of your country would have been powerless to effect this change without the resources placed at their disposal by the labours of men of science.

The eminence of my predecessors in the chair at the meetings of the British Association in Canada makes my task this evening a difficult one. The meeting at Montreal was presided over by Lord Rayleigh, who, like Lord Kelvin, his colleague in the chair of Section A at that meeting, has left the lion's mark on every department of physics, and has shown that, vast as is the empire of physics, there are still men who can extend its frontiers in all of the many regions under its sway. It has been my lot to succeed Lord Rayleigh in other offices as well as this, and I know how difficult a man he is to follow.

The President of the second meeting in Canada—that held in 1897 at Toronto—was Sir John Evans, one of those men who, like Boyle, Cavendish, Darwin, Joule, and Huggins, have, from their own resources and without the aid derived from official positions or from the universities, made memorable contributions to science: such men form one of the characteristic features of British science. May we not hope that, as the knowledge of science and the interest taken in it increase, more of the large number of men of independent means in our country may be found working for the advancement of science, and thereby rendering services to the community no less valuable than the political, philanthropic, and social work at which many of them labour with so much zeal and success?

I can, however, claim to have some experience of, at any rate, one branch of Canadian science, for it has been my privilege to receive at the Cavendish Laboratory many students from your universities. Some of these have been holders of what are known as the 1851 scholarships. These scholarships are provided from the surplus of the Great Exhibition of 1851, and are placed at the disposal of most of the younger universities in the British Empire, to enable students to devote themselves for two or three years to original research in various branches of science. I have had many opportunities of seeing the work of these scholars, and I should like to put on record my opinion that there is no educational endowment in the country which has done or is doing better work.

I have had, as I said, the privilege of having as pupils students from your universities as well as from those of New Zealand, Australia, and the United States, and have thus had opportunities of comparing the effect on the best men of the educational system in force at your universities with that which prevails in the older English universities. Well, as the result, I have come to the conclusion that there is a good deal in the latter system which you have been wise not to imitate. The chief evil from which we at Cambridge suffer and which you have avoided is, I am convinced, the excessive competition for scholarships which confronts our students at almost every stage of their education. You may form some estimate of the prevalence of these scholarships if I tell you that the colleges in the University of Cambridge alone give more than 35,000*l*. a year in scholarships to undergraduates, and I suppose the case is much the same at Oxford. The result of this is that preparation for these scholarships dominates the education of the great majority of the cleverer boys who come to these universities, and indeed in some quarters it seems to be held that the chief duty of a schoolmaster, and the best test of his efficiency, is to make his boys get scholarships. The preparation for the scholarship too often means that about two years before the examination the boy begins to specialise, and from the age of sixteen does little else than the subject, be it mathematics, classics, or natural science, for which he wishes to get a scholarship; then, on entering the university, he spends three or four years studying the same subject before he takes his degree, when his real life-work ought to begin. How has this training fitted him for this work? I will take the case in which the system might perhaps be expected to show to greatest advantage, when his work is to be original research in the subject he has been studying. He has certainly acquired a very minute acquaintance with his subject—indeed, the knowledge possessed by some of the students trained under this system is quite remarkable, much greater than that of any other students I have ever met. But though he has acquired knowledge, the effect of studying one subject, and one subject only, for so long a time is too often to dull his enthusiasm for it, and he begins research with much of his early interest and keenness evaporated. Now there is hardly any quality more essential to success in research than enthusiasm. Research is difficult, laborious, often disheartening. The carefully designed apparatus refuses to work, it develops defects which may take months of patient work to rectify, the results obtained may appear inconsistent with each other and with every known law of Nature, sleepless nights and laborious days may seem only to make the confusion more confounded, and there is nothing for the student to do but to take for his motto "It's dogged as does it," and plod on, comforting himself with the assurance that when success does come, the difficulties he has overcome will increase the pleasure—one of the most exquisite men can enjoy—of getting some conception which will make all that was tangled, confused, and contradictory clear and consistent. Unless he has enthusiasm to carry him on when the prospect seems almost hopeless and the labour and strain incessant, the student may give up his task and take to easier, though less important, pursuits.

I am convinced that no greater evil can be done to a young man than to dull his enthusiasm. In a very considerable experience of students of physics beginning research, I have met with more—many more—failures from lack of enthusiasm and determination than from any lack of knowledge or of what is usually known as cleverness.

This continual harping from an early age on one subject, which is so efficient in quenching enthusiasm, is much encouraged by the practice of the colleges to give scholarships for proficiency in one subject alone. I went through a list of the scholarships awarded in the University of Cambridge last winter, and, though there were 202 of them, I could only find three cases in which it was specified that the award was made for proficiency in more than one subject.

The premature specialisation fostered by the preparation for these scholarships injures the student by depriving him of adequate literary culture, while when it extends, as it often does, to specialisation in one or two branches of science, it retards the progress of science by tending to isolate one science from another. The boundaries between the sciences are arbitrary, and tend to disappear as science progresses. The principles of one science often find most striking and suggestive illustrations in the phenomena of another. Thus, for example, the physicist finds in astronomy that effects he has observed in the laboratory are illustrated on the grand scale in the sun and stars. No better illustration of this could be given than Prof. Hale's recent discovery of the Zeeman effect in the light from sun-spots; in chemistry, too, the physicist finds in the behaviour of whole series of reactions illustrations of the great laws of thermodynamics, while if he turns to the biological sciences he is confronted by problems, mostly unsolved, of unsurpassed interest. Consider for a moment the problem presented by almost any plant—the characteristic and often exquisite detail of flower, leaf, and habit—and remember that the mechanism which controls this almost infinite complexity was once contained in a seed perhaps hardly large enough to be visible. We have here one of the most entrancing problems in chemistry and physics it is possible to conceive.

Again, the specialisation prevalent in schools often prevents students of science from acquiring sufficient knowledge of mathematics; it is true that most of those who study physics do some mathematics, but I hold that, in general, they do not do enough, and that they are not as efficient physicists as they would be if they had a wider knowledge of that subject. There seems at present a tendency in some quarters to discourage the use of mathematics in physics; indeed, one might infer, from the statements of some writers in quasi-scientific journals, that ignorance of mathematics is almost a virtue. If this is so, then surely of all the virtues this is the easiest and most prevalent.

I do not for a moment urge that the physicist should confine himself to looking at his problems from the mathematical point of view; on the contrary, I think a famous French mathematician and physicist was guilty of only slight exaggeration when he said that no discovery was really important or properly understood by its author unless and until he could explain it to the first man he met in the street.

But two points of view are better than one, and the physicist who is also a mathematician possesses a most powerful instrument for scientific research with which many of the greatest discoveries have been made; for example, electric waves were discovered by mathematics long before they were detected in the laboratory. He has also at his command a language clear, concise, and universal, and there is no better way of detecting ambiguities and discrepancies in his ideas than by trying to express them in this language. Again, it often happens that we are not able to appreciate the full significance of some physical discovery until we have subjected it to mathematical treatment, when we find that the effect we have discovered involves other effects which have not been detected, and we are able by this means to duplicate the discovery. Thus James Thomson, starting from the fact that ice floats on water, showed that it follows by mathematics that ice can be melted and water prevented from freezing by pressure. This effect, which was at that time unknown, was afterwards verified by his brother, Lord Kelvin. Multitudes of similar duplication of physical discoveries by mathematics could be quoted.

I have been pleading in the interests of physics for a greater study of mathematics by physicists. I would also plead for a greater study of physics by mathematicians in the interest of pure mathematics.

The history of pure mathematics shows that many of the most important branches of the subject have arisen from the attempts made to get a mathematical solution of a problem suggested by physics. Thus the differential calculus arose from attempts to deal with the problem of moving bodies. Fourier's theorem resulted from attempts to deal with the vibrations of strings and the conduction of heat; indeed, it would seem that the most fruitful crop of scientific ideas is produced by cross-fertilisation between the mind and some definite fact, and that the mind by itself is comparatively unproductive.

I think, if we could trace the origin of some of our most comprehensive and important scientific ideas, it would be found that they arose in the attempt to find an explanation of some apparently trivial and very special phenomenon; when once started the ideas grew to such generality and importance that their modest origin could hardly be suspected. Water vapour we know will refuse to condense into rain unless there are particles of dust to form nuclei; so an idea before taking shape seems to require a nucleus of solid fact round which it can condense.

I have ventured to urge the closer union between mathematics and physics, because I think of late years there has been some tendency for these sciences to drift apart, and that the workers in applied mathematics are relatively fewer than they were some years ago. This is no doubt due to some extent to the remarkable developments made in the last few years in experimental physics on the one hand and in the most abstract and metaphysical parts of pure mathematics on the other. The fascination of these has drawn workers to the frontiers of these regions who would otherwise have worked nearer the junction of the two. In part, too, it may be due to the fact that the problems with which the applied mathematician has to deal are exceedingly difficult, and many may have felt that the problems presented by the older physics have been worked over so often by men of the highest genius that there was but little chance of any problem which they could have any hope of solving being left.

But the newer developments of physics have opened virgin ground which has not yet been worked over, and which offers problems to the mathematician of great interest and novelty—problems which will suggest and require new methods of attack, the development of which will advance pure mathematics as well as physics.

I have alluded to the fact that pure mathematicians have been indebted to the study of concrete problems for the origination of some of their most valuable conceptions; but though no doubt pure mathematicians are in many ways very exceptional folk, yet in this respect they are very human. Most of us need to tackle some definite difficulty before our minds develop whatever powers they may possess. This is true for even the youngest of us, for our schoolboys and schoolgirls, and I think the moral to be drawn from it is that we should aim at making the education in our schools as little bookish and as practical and concrete as possible.

I once had an illustration of the power of the concrete in stimulating the mind which made a very lasting impression upon me. One of my first pupils came to me with the assurance from his previous teacher that he knew little and cared less about mathematics, and that he had no chance of obtaining a degree in that subject. For some time I thought this estimate was correct, but he happened to be enthusiastic about billiards, and when we were reading that part of mechanics which deals with the collision of elastic bodies I pointed out that many of the effects he was constantly observing were illustrations of the subject we were studying. From that time he was a changed man. He had never before regarded mathematics as anything but a means of annoying innocent undergraduates; now, when he saw what important results it could obtain, he became enthusiastic about it, developed very considerable mathematical ability, and, though he had already wasted two out of his three years at college, took a good place in the Mathematical Tripos.

It is possible to read books, to pass examinations without the higher qualities of the mind being called into play. Indeed, I doubt if there is any process in which the mind is more quiescent than in reading without interest. I might appeal to the widespread habit of reading in bed as a prevention of insomnia as a proof of this. But it is not possible for a boy to make a boat or for a girl to cook a dinner without using their brains. With practical things the difficulties have to be surmounted, the boat must be made watertight, the dinner must be cooked, while in reading there is always the hope that the difficulties which have been slurred over will not be set in the examination.

I think it was Helmholtz who said that often in the course of a research more thought and energy were spent in reducing a refractory piece of brass to order than in devising the method or planning the scheme of campaign. This constant need for thought and action gives to original research in any branch of experimental science great educational value even for those who will not become professional men of science. I have had considerable experience with students beginning research in experimental physics, and I have always been struck by the quite remarkable improvement in judgment, independence of thought and maturity produced by a year's research. Research develops qualities which are apt to atrophy when the student is preparing for examinations, and, quite apart from the addition of new knowledge to our store, is of the greatest importance as a means of education.

It is the practice in many universities to make special provision for the reception of students from other universities who wish to do original research or to study the more advanced parts of their subject, and considerable numbers of such students migrate from one university to another. I think it would be a good thing if this practice were to extend to students at an earlier stage in their career; especially should I like to see a considerable interchange of students between the universities in the Mother Country and those in the Colonies.

I am quite sure that many of our English students, especially those destined for public life, could have no more valuable experience than to spend a year in one or other of your universities, and I hope some of your students might profit by a visit to ours.

I can think of nothing more likely to lead to a better understanding of the feelings, the sympathies, and, what is not less important, the prejudices, of one country by another, than by the youths of those countries spending a part of their student life together. Undergraduates as a rule do not wear a mask either of politeness or any other material, and have probably a better knowledge of each other's opinions and points of view—in fact, know each other better than do people of riper age. To bring this communion of students about there must be cooperation between the universities throughout the Empire; there must be recognition of each other's examinations, residence, and degrees. Before this can be accomplished there must, as my friend Mr. E. B. Sargant pointed out in a lecture given at the McGill University, be cooperation and recognition between the universities in each part of the Empire. I do not mean for a moment that all universities in a country should be under one government. I am a strong believer in the individuality of universities, but I do not think this is in any way inconsistent with the policy of an open door from one university to every other in the Empire.

It has usually been the practice of the President of this Association to give some account of the progress made in the last few years in the branch of science which he has the honour to represent.

I propose this evening to follow that precedent and to attempt to give a very short account of some of the more recent developments of physics, and the new conceptions of physical processes to which they have led.

The period which has elapsed since the Association last met in Canada has been one of almost unparalleled activity in many branches of physics, and many new and unsuspected properties of matter and electricity have been discovered. The history of this period affords a remarkable illustration of the effect which may be produced by a single discovery; for it is, I think, to the discovery of the Röntgen rays that we owe the rapidity of the progress which has recently been made in physics. A striking discovery like that of the Röntgen rays acts much like the discovery of gold in a sparsely populated country; it attracts workers who come in the first place for the gold, but who may find that the country has other products, other charms, perhaps even more valuable than the gold itself. The country in which the gold was discovered in the case of the Röntgen rays was the department of physics dealing with the discharge of electricity through gases, a subject which, almost from the beginning of electrical science, had attracted a few enthusiastic workers, who felt convinced that the key to unlock the secret of electricity was to be found in a vacuum tube. Röntgen, in 1895, showed that when electricity passed through such a tube, the tube emitted rays which could pass through bodies opaque to ordinary light; which could, for example, pass through the flesh of the body and throw a shadow of the bones on a suitable screen. The fascination of this discovery attracted many workers to the subject of the discharge of electricity through gases, and led to great improvements in the instruments used in this type of research. It is not, however, to the power of probing dark places, important though this is, that the influence of Röntgen rays on the progress of science has mainly been due; it is rather because these rays make gases, and, indeed, solids and liquids, through which they pass conductors of electricity. It is true that before the discovery of these rays other methods of making gases conductors were known, but none of these was so convenient for the purposes of accurate measurement.

The study of gases exposed to Röntgen rays has revealed in such gases the presence of particles charged with electricity; some of these particles are charged with positive, others with negative electricity.

The properties of these particles have been investigated; we know the charge they carry, the speed with which they move under an electric force, the rate at which the oppositely charged ones recombine, and these investigations have thrown a new light, not only on electricity, but also on the structure of matter.

We know from these investigations that electricity, like matter, is molecular in structure, that just as a quantity of hydrogen is a collection of an immense number of small particles called molecules, so a charge of electricity is made up of a great number of small charges, each of a perfectly definite and known amount.

Helmholtz said in 1880 that in his opinion the evidence in favour of the molecular constitution of electricity was even stronger than that in favour of the molecular constitution of matter. How much stronger is that evidence now, when we have measured the charge on the unit and found it to be the same from whatever source the electricity is obtained. Nay, further, the molecular theory of matter is indebted to the molecular theory of electricity for the most accurate determination of its fundamental quantity, the number of molecules in any given quantity of an elementary substance.

The great advantage of the electrical methods for the study of the properties of matter is due to the fact that whenever a particle is electrified it is very easily identified, whereas an uncharged molecule is most elusive; and it is only when these are present in immense numbers that we are able to detect them. A very simple calculation will illustrate the difference in our power of detecting electrified and unelectrified molecules. The smallest quantity of unelectrified matter ever detected is probably that of neon, one of the inert gases of the atmosphere. Prof. Strutt has shown that the amount of neon in 1/20th of a cubic centimetre of the air at ordinary pressures can be detected by the spectroscope; Sir William Ramsay estimates that the neon in the air only amounts to one part of neon in 100,000 parts of air, so that the neon in 1/20th of a cubic centimetre of air would only occupy at atmospheric pressure a volume of half a millionth of a cubic centimetre. When stated in this form the quantity seems exceedingly small, but in this small volume there are about ten million million molecules. Now the population of the earth is estimated at about fifteen hundred millions, so that the smallest number of molecules of neon we can identify is about 7,000 times the population of the earth. In other words, if we had no better test for the existence of a man than we have for that of an unelectrified molecule we should come to the conclusion that the earth is uninhabited. Contrast this with our power of detecting electrified molecules. We can by the electrical method, even better by the cloud method of C. T. R. Wilson, detect the presence of three or four charged particles in a cubic centimetre. Rutherford has shown that we can detect the presence of a single α particle. Now the α particle is a charged atom of helium; if this atom had been uncharged we should have required more than a million million of them, instead of one, before we should have been able to detect them.

We may, I think, conclude, since electrified particles can be studied with so much greater ease than unelectrified ones, that we shall obtain a knowledge of the ultimate structure of electricity before we arrive at a corresponding degree of certainty with regard to the structure of matter.

We have already made considerable progress in the task of discovering what the structure of electricity is. We have known for some time that of one kind of electricity —the negative—and a very interesting one it is. We know that negative electricity is made up of units all of which are of the same kind; that these units are exceedingly small compared with even the smallest atom, for the mass of the unit is only 1/1700th part of the mass of an atom of hydrogen; that its radius is only 10^{-13} centimetre, and that these units, "corpuscles" as they have been called, can be obtained from all substances. The size of these corpuscles is on an altogether different scale from that of atoms; the volume of a corpuscle bears to that of the atom about the same relation as that of a speck of dust to the volume of this room. Under suitable conditions they move at enormous speeds, which approach in some instances the velocity of light.

The discovery of these corpuscles is an interesting example of the way Nature responds to the demands made upon her by mathematicians. Some years before the discovery of corpuscles it had been shown by a mathematical investigation that the mass of a body must be increased by a charge of electricity. This increase, however, is greater for small bodies than for large ones, and even bodies as small as atoms are hopelessly too large to show any appreciable effect; thus the result seemed entirely academic. After a time corpuscles were discovered, and these are so much smaller than the atom that the increase in mass due to the charge becomes not merely appreciable, but so great that, as the experiments of Kaufmann and Bucherer have shown, the whole of the mass of the corpuscle arises from its charge.

We know a great deal about negative electricity; what do we know about positive electricity? Is positive electricity molecular in structure? Is it made up into units, each unit carrying a charge equal in magnitude though opposite in sign to that carried by a corpuscle? Does, or does not, this unit differ, in size and physical properties, very widely from the corpuscle? We know that by suitable processes we can get corpuscles out of any kind of matter, and that the corpuscles will be the same from whatever source they may be derived. Is a similar thing true for positive electricity? Can we get, for example, a positive unit from oxygen of the same kind as that we get from hydrogen?

For my own part, I think the evidence is in favour of the view that we can, although the nature of the unit of positive electricity makes the proof much more difficult than for the negative unit.

In the first place we find that the positive particles—"canalstrahlen" is their technical name—discovered by our distinguished guest, Dr. Goldstein, which are found when an electric discharge passes through a highly rarefied gas, are, when the pressure is very low, the same, whatever may have been the gas in the vessel to begin with. If we pump out the gas until the pressure is too low to allow the discharge to pass, and then introduce a small quantity of gas and restart the discharge, the positive particles are the same whatever kind of gas may have been introduced.

I have, for example, put into the exhausted vessel oxygen, argon, helium, the vapour of carbon tetrachloride, none of which contain hydrogen, and found the positive particles to be the same as when hydrogen was introduced.

Some experiments made lately by Wellisch, in the Cavendish Laboratory, strongly support the view that there is a definite unit of positive electricity independent of the gas from which it is derived; these experiments were on the velocity with which positive particles move through mixed gases. If we have a mixture of methyl-iodide and hydrogen exposed to Röntgen rays, the effect of the rays on the methyl-iodide is so much greater than on the hydrogen that, even when the mixture contains only a small percentage of methyl-iodide, practically all the electricity comes from this gas, and not from the hydrogen.

Now if the positive particles were merely the residue left when a corpuscle had been abstracted from the methyl-iodide, these particles would have the dimensions of a molecule of methyl-iodide; this is very large and heavy, and would therefore move more slowly through the hydrogen molecules than the positive particles derived from hydrogen itself, which would, on this view, be of the size and weight of the light hydrogen molecules. Wellisch found that the velocities of both the positive and negative particles through the mixture were the same as the velocities through pure hydrogen, although in the one case the ions had originated from methyl-iodide and in the other from hydrogen; a similar result was obtained when carbon tetrachloride, or mercury methyl, was used instead of methyl-iodide. These and similar results lead to the conclusion that the atom of the different chemical elements contains definite units of positive as well as of negative electricity, and that the positive electricity, like the negative, is molecular in structure.

The investigations made on the unit of positive electricity show that it is of quite a different kind from the unit of negative, the mass of the negative unit is exceedingly small compared with any atom, the only positive units that up to the present have been detected are quite comparable in mass with the mass of an atom of hydrogen; in fact they seem equal to it. This makes it more difficult to be certain that the unit of positive electricity has been isolated, for we have to be on our guard against its being a much smaller body attached to the hydrogen atoms which happen to be present in the vessel. If the positive units have a much greater mass than the negative ones, they ought not to be so easily deflected by magnetic forces when moving at equal speeds; and in general the insensibility of the positive particles to the influence of a magnet is very marked, though there are cases when the positive particles are much more readily deflected, and these have been interpreted as proving the existence of positive units comparable in mass with the negative ones. I have found, however, that in these cases the positive particles are moving very slowly, and that the ease with which they are deflected is due to the smallness of the velocity and not to that of the mass. It should, however, be noted that M. Jean Becquerel has observed in the absorption spectra of some minerals, and Prof. Wood in the rotation of the plane of polarisation by sodium vapour, effects which could be explained by the presence in the substances of positive units comparable in mass with corpuscles. This, however, is not the only explanation which can be given of these effects, and at present the smallest positive electrified particles of which we have direct experimental evidence have masses comparable with that of an atom of hydrogen.

A knowledge of the mass and size of the two units of electricity, the positive and the negative, would give us the material for constructing what may be called a molecular theory of electricity, and would be a starting-point for a theory of the structure of matter; for the most natural view to take, as a provisional hypothesis, is that matter is just a collection of positive and negative units of electricity, and that the forces which hold atoms and molecules together, the properties which differentiate one kind of matter from another, all have their origin in the electrical forces exerted by positive and negative units of electricity, grouped together in different ways in the atoms of the different elements.

As it would seem that the units of positive and negative electricity are of very different sizes, we must regard matter as a mixture containing systems of very different types, one type corresponding to the small corpuscle, the other to the large positive unit.

Since the energy associated with a given charge is greater the smaller the body on which the charge is concentrated, the energy stored up in the negative corpuscles will be far greater than that stored up by the positive. The amount of energy which is stored up in ordinary matter in the form of the electrostatic potential energy of its corpuscles is, I think, not generally realised. All substances give out corpuscles, so that we may assume that each atom of a substance contains at least one corpuscle. From the size and the charge on the corpuscle, both of which are known, we find that each corpuscle has 8×10^{-7} ergs of energy; this is on the supposition that the usual expressions for the energy of a charged body hold when, as in the case of a corpuscle, the charge is reduced to one unit. Now in one gram of hydrogen there are about 6×10^{23} atoms, so if there is only one corpuscle in each atom the energy due to the corpuscles in a gram of hydrogen would be 48×10^{16} ergs, or 11×10^{9} calories. This is more than seven times the heat developed by one gram of radium, or than that developed by the burning of five tons of coal. Thus we see that even ordinary matter contains enormous stores of energy; this energy is fortunately kept fast bound by the corpuscles; if at any time an appreciable fraction were to get free the earth would explode and become a gaseous nebula.

The matter of which I have been speaking so far is the material which builds up the earth, the sun, and the stars, the matter studied by the chemist, and which he can represent by a formula; this matter occupies, however, but an insignificant fraction of the universe, it forms but minute islands in the great ocean of the æther, the substance with which the whole universe is filled.

The æther is not a fantastic creation of the speculative philosopher; it is as essential to us as the air we breathe. For we must remember that we on this earth are not living on our own resources; we are dependent from minute to minute upon what we are getting from the sun, and the gifts of the sun are conveyed to us by the æther. It is to the sun that we owe, not merely night and day, springtime and harvest, but it is the energy of the sun, stored up in coal, in waterfalls, in food, that practically does all the work of the world.

How great is the supply the sun lavishes upon us becomes clear when we consider that the heat received by the earth under a high sun and a clear sky is equivalent, according to the measurements of Langley, to about 7000 horse-power per acre. Though our engineers have not yet discovered how to utilise this enormous supply of power, they will, I have not the slightest doubt, ultimately succeed in doing so; and when coal is exhausted and our water-power inadequate, it may be that this is the source from which we shall derive the energy necessary for the world's work. When that comes about, our centres of industrial activity may perhaps be transferred to the burning deserts of the Sahara, and the value of land determined by its suitability for the reception of traps to catch sunbeams.

This energy, in the interval between its departure from the sun and its arrival at the earth, must be in the space between them. Thus this space must contain something which, like ordinary matter, can store up energy, which can carry at an enormous pace the energy associated with light and heat, and can, in addition, exert the enormous stresses necessary to keep the earth circling round the sun and the moon round the earth.

The study of this all-pervading substance is perhaps the most fascinating and important duty of the physicist.

On the electromagnetic theory of light, now universally accepted, the energy streaming to the earth travels through the æther in electric waves; thus practically the whole of the energy at our disposal has at one time or another been electrical energy. The æther must, then, be the seat of electrical and magnetic forces. We know, thanks to the genius of Clerk Maxwell, the founder and inspirer of modern electrical theory, the equations which express the relation between these forces, and although for some purposes these are all we require, yet they do not tell us very much about the nature of the æther.

The interest inspired by equations, too, in some minds is apt to be somewhat Platonic; and something more grossly mechanical—a model, for example, is felt by many to be more suggestive and manageable, and for them a more powerful instrument of research, than a purely analytical theory.

Is the æther dense or rare? Has it a structure? Is it at rest or in motion? are some of the questions which force themselves upon us.

Let us consider some of the facts known about the æther. When light falls on a body and is absorbed by it, the body is pushed forward in the direction in which the light is travelling, and if the body is free to move it is set in motion by the light. Now it is a fundamental principle of dynamics that when a body is set moving in a certain direction, or, to use the language of dynamics, acquires momentum in that direction, some other mass must lose the same amount of momentum; in other words, the amount of momentum in the universe is constant. Thus when the body is pushed forward by the light some other system must have lost the momentum the body acquires, and the only other system available is the wave of light falling on the body; hence we conclude that there must have been momentum in the wave in the direction in which it is travelling. Momentum, however, implies mass in motion. We conclude, then, that in the æther through which the wave is moving there is mass moving with the velocity of light. The experiments made on the pressure due to light enable us to calculate this mass, and we find that in a cubic kilometre of æther carrying light as intense as sunlight is at the surface of the earth, the mass moving is only about one-fifty-millionth of a milligram. We must be careful not to confuse this with the mass of a cubic kilometre of æther; it is only the mass moved when the light passes through it; the vast majority of the æther is left undisturbed by the light. Now, on the electromagnetic theory of light, a wave of light may be regarded as made up of groups of lines of electric force moving with the velocity of light; and if we take this point of view we can prove that the mass of æther per cubic centimetre carried along is proportional to the energy possessed by these lines of electric force per cubic centimetre, divided by the square of the velocity of light. But though lines of electric force carry some of the æther along with them as they move, the amount so carried, even in the strongest electric fields we can produce, is but a minute fraction of the æther in their neighbourhood.

This is proved by an experiment made by Sir Oliver Lodge in which light was made to travel through an electric field in rapid motion. If the electric field had carried the whole of the æther with it, the velocity of the light would have been increased by the velocity of the electric field. As a matter of fact, no increase whatever could be detected, though it would have been registered if it had amounted to one-thousandth part of that of the field.

The æther carried along by a wave of light must be an exceedingly small part of the volume through which the wave is spread. Parts of this volume are in motion, but by far the greater part is at rest; thus in the wave front there cannot be uniformity, at some parts the æther is moving, at others it is at rest—in other words, the wave front must be more analogous to bright specks on a dark ground than to a uniformly illuminated surface.

The place where the density of the æther carried along by an electric field rises to its highest value is close to a corpuscle, for round the corpuscles are by far the strongest electric fields of which we have any knowledge. We know the mass of the corpuscle, we know from Kaufmann's experiments that this arises entirely from the electric charge, and is therefore due to the æther carried along with the corpuscle by the lines of force attached to it.

A simple calculation shows that one-half of this mass is contained in a volume seven times that of a corpuscle. Since we know the volume of the corpuscle as well as the mass, we can calculate the density of the æther attached to the corpuscle; doing so, we find it amounts to the prodigious value of about 5×10^{10}, or about 2000 million times that of lead. Sir Oliver Lodge, by somewhat different considerations, has arrived at a value of the same order of magnitude.

Thus around the corpuscle æther must have an extravagant density: whether the density is as great as this in other places depends upon whether the æther is compressible or not. If it is compressible, then it may be condensed round the corpuscles, and there have an abnormally great density; if it is not compressible, then the density in free space cannot be less than the number I have just mentioned.

With respect to this point we must remember that the forces acting on the æther close to the corpuscle are prodigious. If the æther were, for example, an ideal gas the density of which increased in proportion to the pressure, however great the pressure might be, then if, when exposed to the pressures which exist in some directions close to the corpuscle, it had the density stated above, its density under atmospheric pressure would only be about 8×10^{-16}, or a cubic kilometre would have a mass less than a gram; so that instead of being almost incomparably denser than lead, it would be almost incomparably rarer than the lightest gas.

I do not know at present of any effect which would enable us to determine whether æther is compressible or not. And although at first sight the idea that we are immersed in a medium almost infinitely denser than lead might seem inconceivable, it is not so if we remember that in all probability matter is composed mainly of holes. We may, in fact, regard matter as possessing a bird-cage kind of structure in which the volume of the æther disturbed by the wires when the structure is moved is infinitesimal in comparison with the volume enclosed by them. If we do this, no difficulty arises from the great density of the æther; all we have to do is to increase the distance between the wires in proportion as we increase the density of the æther.

Let us now consider how much æther is carried along by ordinary matter, and what effects this might be expected to produce.

The simplest electrical system we know, an electrified sphere, has attached to it a mass of æther proportional to its potential energy, and such that if the mass were to move with the velocity of light its kinetic energy would equal the electrostatic potential energy of the particle. This result can be extended to any electrified system, and it can be shown that such a system binds a mass of the æther proportional to its potential energy. Thus a part of the mass of any system is proportional to the potential energy of the system.

The question now arises, Does this part of the mass add anything to the weight of the body? If the æther were not subject to gravitational attraction it certainly would not; and even if the æther were ponderable, we might expect that as the mass is swimming in a sea of æther it would not increase the weight of the body to which it is attached. But if it does not, then a body with a large amount of potential energy may have an appreciable amount of its mass in a form which does not increase its weight, and thus the weight of a given mass of it may be less than that of an equal mass of some substance with a smaller amount of potential energy. Thus the weights of equal masses of these substances would be different. Now, experiments with pendulums, as Newton pointed out, enable us to determine with great accuracy the weights of equal masses of different substances. Newton himself made experiments of this kind, and found that the weights of equal masses were the same for all the materials he tried. Bessel, in 1830, made some experiments on this subject which are still the most accurate we possess, and he showed that the weights of equal masses of lead, silver, iron, brass did not differ by as much as one part in 60,000.

The substances tried by Newton and Bessel did not, however, include any of those substances which possess the marvellous power of radio-activity; the discovery of these came much later, and is one of the most striking achievements of modern physics.

These radio-active substances are constantly giving out large quantities of heat, presumably at the expense of their potential energy; thus when these substances reach their final non-radio-active state their potential energy must be less than when they were radio-active. Prof. Rutherford's measurements show that the energy emitted by one gram of radium in the course of its degradation to non-radio-active forms is equal to the kinetic energy of a mass of 1/13th of a milligram moving with the velocity of light.

This energy, according to the rule I have stated, corresponds to a mass of 1/13th of a milligram of the æther, and thus a gram of radium in its radio-active state must have at least 1/13th of a milligram more of æther attached to it than when it has been degraded into the non-radio-active forms. Thus if this æther does not increase the weight of the radium, the ratio of mass to weight for radium would be greater by about one part in 13,000 than for its non-radio-active products.

I attempted several years ago to find the ratio of mass to weight for radium by swinging a little pendulum, the bob of which was made of radium. I had only a small quantity of radium, and was not, therefore, able to attain any great accuracy. I found that the difference, if any, in the ratio of the mass to weight between radium and other substances was not more than one part in 2000. Lately we have been using at the Cavendish Laboratory a pendulum the bob of which was filled with uranium oxide. We have got good reasons for supposing that uranium is a parent of radium, so that the great potential energy and large æthereal mass possessed by the radium will be also in the uranium; the experiments are not yet completed. It is, perhaps, expecting almost too much to hope that the radio-active substances may add to the great services they have already done to science by furnishing the first case in which there is some differentiation in the action of gravity.

The mass of æther bound by any system is such that if it were to move with the velocity of light its kinetic energy would be equal to the potential energy of the system. This result suggests a new view of the nature of potential energy. Potential energy is usually regarded as essentially different from kinetic energy. Potential energy depends on the configuration of the system, and can be calculated from it when we have the requisite data; kinetic energy, on the other hand, depends upon the velocity of the system. According to the principle of the conservation of energy the one form can be converted into the other at a fixed rate of exchange, so that when one unit of one kind disappears a unit of the other simultaneously appears.

Now in many cases this rule is all that we require to calculate the behaviour of the system, and the conception of potential energy is of the utmost value in making the knowledge derived from experiment and observation available for mathematical calculation. It must, however, I think, be admitted that from the purely philosophical point of view it is open to serious objection. It violates, for example, the principle of continuity. When a thing changes from a state A to a different state B, the principle of continuity requires that it must pass through a number of states intermediate between A and B, so that the transition is made gradually, and not abruptly. Now, when kinetic energy changes into potential, although there is no discontinuity in the quantity of the energy, there is in its quality, for we do not recognise any kind of energy intermediate between that due to the motion and that due to the position of the system, and some portions of energy are supposed to change *per saltum* from the kinetic to the potential form. In the case of the transition of kinetic energy into heat energy in a gas, the discontinuity has disappeared with a fuller knowledge of what the heat energy in a gas is due to. When we were ignorant of the nature of this energy, the transition from kinetic into thermal energy seemed discontinuous; but now we know that this energy is the kinetic energy of the molecules of which the gas is composed, so that there is no change in the type of energy when the kinetic energy of visible motion is transformed into the thermal energy of a gas—it is just the transference of kinetic energy from one body to another.

If we regard potential energy as the kinetic energy of portions of the æther attached to the system, then all energy is kinetic energy, due to the motion of matter or of portions of æther attached to the matter. I showed, many years ago, in my "Applications of Dynamics to Physics and Chemistry," that we could imitate the effects of the potential energy of a system by means of the kinetic energy of invisible systems connected in an appropriate manner with the main system, and that the potential energy of the visible universe may in reality be the kinetic energy of an invisible one connected up with it. We naturally suppose that this invisible universe is the luminiferous æther, that portions of the æther in rapid motion are connected with the visible systems, and that their kinetic energy is the potential energy of the systems.

We may thus regard the æther as a bank in which we may deposit energy and withdraw it at our convenience. The mass of the æther attached to the system will change as the potential energy changes, and thus the mass of a system the potential energy of which is changing cannot be constant; the fluctuations in mass under ordinary conditions are, however, so small that they cannot be detected by any means at present at our disposal. Inasmuch as the various forms of potential energy are continually being changed into heat energy, which is the kinetic energy of the molecules of matter, there is a constant tendency for the mass of a system such as the earth or the sun to diminish, and thus as time goes on for the mass of æther gripped by the material universe to become smaller and smaller; the rate at which it would diminish would, however, get slower as time went on, and there is no reason to think that it would ever get below a very large value.

Radiation of light and heat from an incandescent body like the sun involves a constant loss of mass by the body. Each unit of energy radiated carries off its quota of mass, but as the mass ejected from the sun per year is only one part in 20 billionths (1 in 2×10^{13}) of the mass of the sun, and as this diminution in mass is not necessarily accompanied by any decrease in its gravitational attraction, we cannot expect to be able to get any evidence of this effect.

As our knowledge of the properties of light has progressed, we have been driven to recognise that the æther, when transmitting light, possesses properties which, before the introduction of the electromagnetic theory, would have been thought to be peculiar to an emission theory of light and to be fatal to the theory that light consists of undulations.

Take, for example, the pressure exerted by light. This would follow as a matter of course if we supposed light to be small particles moving with great velocities, for these, if they struck against a body, would manifestly tend to push it forward, while on the undulatory theory there seemed no reason why any effect of this kind should take place.

Indeed, in 1792, this very point was regarded as a test between the theories, and Bennet made experiments to see whether or not he could find any traces of this pressure. We now know that the pressure is there, and if Bennet's instrument had been more sensitive he must have observed it. It is perhaps fortunate that Bennet had not at his command more delicate apparatus. Had he discovered the pressure of light, it would have shaken confidence in the undulatory theory and checked that magnificent work at the beginning of the last century which so greatly increased our knowledge of optics.

As another example, take the question of the distribution of energy in a wave of light. On the emission theory the energy in the light is the kinetic energy of the light particles. Thus the energy of light is made up of distinct units, the unit being the energy of one of the particles.

The idea that the energy has a structure of this kind has lately received a good deal of support. Planck, in a very remarkable series of investigations on the Thermodynamics of Radiation, pointed out that the expressions for the energy and entropy of radiant energy were of such a form as to suggest that the energy of radiation, like that of a gas on the molecular theory, was made up of distinct units, the magnitude of the unit depending on the colour of the light; and on this assumption he was able to calculate the value of the unit, and from this deduce incidentally the value of Avogadro's constant—the number of molecules in a cubic centimetre of gas at standard temperature and pressure.

This result is most interesting and important, because if it were a legitimate deduction from the Second Law of Thermodynamics, it would appear that only a particular type of mechanism for the vibrators which give out light and the absorbers which absorb it could be in accordance with that law.

If this were so, then, regarding the universe as a collection of machines all obeying the laws of dynamics, the Second Law of Thermodynamics would only be true for a particular kind of machine.

There seems, however, grave objection to this view, which I may illustrate by the case of the First Law of Thermodynamics, the principle of the Conservation of Energy. This must be true whatever be the nature of the machines which make up the universe, provided they obey the laws of dynamics, any application of the principle of the Conservation of Energy could not discriminate between one type of machine and another.

Now, the Second Law of Thermodynamics, though not a dynamical principle in as strict a sense as the law of the Conservation of Energy, is one that we should expect to hold for a collection of a large number of machines of any type, provided that we could not directly affect the individual machines, but could only observe the average effects produced by an enormous number of them. On this view, the Second Law, as well as the First, should be incapable of saying that the machines were of any particular type: so that investigations founded on thermodynamics, though the expressions they lead to may suggest—cannot, I think, be regarded as proving—the unit structure of light energy.

It would seem as if in the application of thermodynamics to radiation some additional assumption has been implicitly introduced, for these applications lead to definite relations between the energy of the light of any particular wave-length and the temperature of the luminous body.

Now a possible way of accounting for the light emitted by hot bodies is to suppose that it arises from the collisions of corpuscles with the molecules of the hot body, but it is only for one particular law of force between the corpuscles and the molecules that the distribution of energy would be the same as that deduced by the Second Law of Thermodynamics, so that in this case, as in the other, the results obtained by the application of thermodynamics to radiation would require us to suppose that the Second Law of Thermodynamics is only true for radiation when the radiation is produced by mechanism of a special type.

Quite apart, however, from considerations of thermodynamics, we should expect that the light from a luminous source should in many cases consist of parcels, possessing, at any rate to begin with, a definite amount of energy. Consider, for example, the case of a gas like sodium vapour, emitting light of a definite wave-length; we may imagine that this light, consisting of electrical waves, is emitted by systems resembling Leyden jars. The energy originally possessed by such a system will be the electrostatic energy of the charged jar. When the vibrations are started, this energy will be radiated away into space, the radiation forming a complex system, containing, if the jar has no electrical resistance, the energy stored up in the jar.

The amount of this energy will depend on the size of the jar and the quantity of electricity with which it is charged. With regard to the charge, we must remember that we are dealing with systems formed out of single molecules, so that the charge will only consist of one or two natural units of electricity, or, at all events, some small multiple of that unit, while for geometrically similar Leyden jars the energy for a given charge will be proportional to the frequency of the vibration; thus, the energy in the bundle of radiation will be proportional to the frequency of the vibration.

We may picture to ourselves the radiation as consisting of the lines of electric force which, before the vibrations were started, were held bound by the charges on the jar, and which, when the vibrations begin, are thrown into rhythmic undulations, liberated from the jar and travel through space with the velocity of light.

Now let us suppose that this system strikes against an uncharged condenser and gives it a charge of electricity, the charge on the plates of the condenser must be at least one unit of electricity, because fractions of this charge do not exist, and each unit charge will anchor a unit tube of force, which must come from the parcel of radiation falling upon it. Thus a tube in the incident light will be anchored by the condenser, and the parcel formed by this tube will be anchored and withdrawn as a whole from the pencil of light incident on the condenser. If the energy required to charge up the condenser with a unit of electricity is greater than the energy in the incident parcel, the tube will not be anchored and the light will pass over the condenser and escape from it. These principles that radiation is made up of units, and that it requires a unit possessing a definite amount of energy to excite radiation in a body on which it falls, perhaps receive their best illustration in the remarkable laws governing Secondary Röntgen radiation, recently discovered by Prof. Barkla. Prof. Barkla has found that each of the different chemical elements, when exposed to Röntgen rays, emits a definite type of secondary radiation whatever may have been the type of primary; thus lead emits one type, copper another, and so on; but these radiations are not excited at all if the primary radiation is of a softer type than the specific radiation emitted by the substance; thus the secondary radiation from lead being harder than that from copper, if copper is exposed to the secondary radiation from lead the copper will radiate, but lead will not radiate when exposed to copper. Thus, if we suppose that the energy in a unit of hard Röntgen rays is greater than that in one of soft, Barkla's results are strikingly analogous to those which would follow on the unit theory of light.

Though we have, I think, strong reasons for thinking that the energy in the light waves of definite wave-length is done up into bundles, and that these bundles, when emitted, all possess the same amount of energy, I do not think there is any reason for supposing that in any casual specimen of light of this wave-length, which may subsequent to its emission have been many times refracted or reflected, the bundles possess any definite amount of energy. For consider what must happen when a bundle is incident on a surface such as glass, when part of it is reflected and part transmitted. The bundle is divided into two portions, in each of which the energy is less than the incident bundle, and since these portions diverge and may ultimately be many thousands of miles apart, it would seem meaningless still to regard them as forming one unit. Thus the energy in the bundles of light, after they have suffered partial reflection, will not be the same as in the bundles when they were emitted. The study of the dimensions of these bundles, for example, the angle they subtend at the luminous source, is an interesting subject for investigation; experiments on interference between rays of light emerging in different directions from the luminous source would probably throw light on this point.

I now pass to a very brief consideration of one of the most important and interesting advances ever made in physics, and in which Canada, as the place of the labours of Profs. Rutherford and Soddy, has taken a conspicuous part. I mean the discovery and investigation of radio-activity. Radio-activity was brought to light by the Röntgen rays. One of the many remarkable properties of these rays is to excite phosphorescence in certain substances, including the salts of uranium, when they fall upon them. Since Röntgen rays produce phosphorescence, it occurred to Becquerel to try whether phosphorescence would produce Röntgen rays. He took some uranium salts which had been made to phosphoresce by exposure, not to Röntgen rays, but to sunlight, tested them, and found that they gave out rays possessing properties similar to Röntgen rays. Further investigation showed, however, that to get these rays it was not necessary to make the uranium phosphoresce, that the salts were just as active if they had been kept in the dark. It thus appeared that the property was due to the metal and not to the phosphorescence, and that uranium and its compounds possessed the power of giving out rays which, like Röntgen rays, affect a photographic plate, make certain minerals phosphoresce, and make gases through which they pass conductors of electricity.

Niepce de Saint-Victor had observed some years before this discovery that paper soaked in a solution of uranium nitrate affected a photographic plate, but the observation excited but little interest. The ground had not then been prepared, by the discovery of the Röntgen rays, for its reception, and it withered and was soon forgotten.

Shortly after Becquerel's discovery of uranium, Schmidt found that thorium possessed similar properties. Then M. and Mme. Curie, after a most difficult and laborious investigation, discovered two new substances, radium and polonium, possessing this property to an enormously greater extent than either thorium or uranium, and this was followed by the discovery of actinium by Debierne. Now the researches of Rutherford and others have led to the discovery of so many new radio-active substances that any attempts at christening seem to have been abandoned, and they are denoted, like policemen, by the letters of the alphabet.

Mr. Campbell has recently found that potassium, though far inferior in this respect to any of the substances I have named, emits an appreciable amount of radiation, the amount depending only on the quantity of potassium, and being the same whatever the source from which the potassium is obtained or whatever the elements with which it may be in combination.

The radiation emitted by these substances is of three types, known as α, β, and γ rays. The α rays have been shown by Rutherford to be positively electrified atoms of helium, moving with speeds which reach up to about one-tenth of the velocity of light. The β rays are negatively electrified corpuscles, moving in some cases with very nearly the velocity of light itself, while the γ rays are unelectrified, and are analogous to the Röntgen rays.

The radio-activity of uranium was shown by Crookes to arise from something mixed with the uranium, which differed sufficiently in properties from the uranium itself to enable it to be separated by chemical analysis. He took some uranium, and by chemical treatment separated it into two portions, one of which was radio-active and the other not.

Next Becquerel found that if these two portions were kept for several months, the part which was not radio-active to begin with regained radio-activity, while the part which was radio-active to begin with had lost its radio-activity. These effects and many others receive a complete explanation by the theory of radio-active change which we owe to Rutherford and Soddy.

According to this theory, the radio-active elements are not permanent, but are gradually breaking up into elements of lower atomic weight; uranium, for example, is slowly breaking up, one of the products being radium, while radium breaks up into a radio-active gas called radium emanation, the emanation into another radio-active substance, and so on, and that the radiations are a kind of swan's song emitted by the atoms when they pass from one form to another; that for example, it is when a radium atom breaks up and an atom of the emanation appears that the rays which constitute the radio-activity are produced.

Thus, on this view, the atoms of the radio-active elements are not immortal; they perish after a life the average value of which ranges from thousands of millions of years in the case of uranium to a second or so in the case of the gaseous emanation from actinium.

When the atoms pass from one state to another they give out large stores of energy; thus their descendants do not inherit the whole of their wealth of stored-up energy; the estate becomes less and less wealthy with each generation; we find, in fact, that the politician, when he imposes death duties, is but imitating a process which has been going on for ages in the case of these radio-active substances.

Many points of interest arise when we consider the rate at which the atoms of radio-active substance disappear. Rutherford has shown that whatever be the age of these atoms, the percentage of atoms which disappear in one second is always the same; another way of putting it is that the expectation of life of an atom is independent of its age—that an atom of radium one thousand years old is just as likely to live for another thousand years as one just sprung into existence.

Now this would be the case if the death of the atom were due to something from outside which struck old and young indiscriminately; in a battle, for example, the chance of being shot is the same for old and young; so that we are inclined at first to look to something coming from outside as the cause why an atom of radium, for example, suddenly changes into an atom of the emanation. But here we are met with the difficulty that no changes in the external conditions that we have as yet been able to produce have had any effect on the life of the atom; so far as we know at present, the life of a radium atom is the same at the temperature of a furnace as at that of liquid air—it is not altered by surrounding the radium by thick screens of lead or other dense materials to ward off radiation from outside, and, what to my mind is especially significant, it is the same when the radium is in the most concentrated form, when its atoms are exposed to the vigorous bombardment from the rays given off by the neighbouring atoms, as when it is in the most dilute solution, when the rays are absorbed by the water which separates one atom from another. This last result seems to me to make it somewhat improbable that we shall be able to split up the atoms of the non-radio-active elements by exposing them to the radiation from radium; if this radiation is unable to affect the unstable radio-active atoms, it is somewhat unlikely that it will be able to affect the much more stable non-radio-active elements.

The evidence we have at present is against a disturbance coming from outside breaking up the radio-active atoms, and we must therefore look to some process of decay in the atom itself; but if this is the case, how are we to reconcile it with the fact that the expectation of life of an atom does not diminish as the atom gets older? We can do this if we suppose that the atoms when they are first produced have not all the same strength of constitution, that some are more robust than others, perhaps because they contain more intrinsic energy to begin with, and will therefore have a longer life. Now if when the atoms are first produced there are some which will live for one year, some for ten, some for a thousand, and so on; and if lives of all durations, from nothing to infinity, are present in such proportion that the number of atoms which will live longer than a certain number of years decreases in a constant proportion for each additional year of life, we can easily prove that the expectation of life of an atom will be the same whatever its age may be. On this view the different atoms of a radio-active substance are not, in all respects, identical.

The energy developed by radio-active substances is exceedingly large, one gram of radium developing nearly as much energy as would be produced by burning a ton of coal. This energy is mainly in the α particles, the positively charged helium atoms which are emitted when the change in the atom takes place; if this energy were produced by electrical forces it would indicate that the helium atom had moved through a potential difference of about two million volts on its way out of the atom of radium. The source of this energy is a problem of the deepest interest; if it arises from the repulsion of similarly electrified systems exerting forces varying inversely as the square of the distance, then to get the requisite amount of energy the systems, if their charges were comparable with the charge on the α particle, could not when they start be further apart than the radius of a corpuscle, 10^{-13} cm. If we suppose that the particles do not acquire this energy at the explosion, but that before they are shot out of the radium atom they move in circles inside this atom with the speed with which they emerge, the forces required to prevent particles moving with this velocity from flying off at a tangent are so great that finite charges of electricity could only produce them at distances comparable with the radius of a corpuscle.

One method by which the requisite amount of energy could be obtained is suggested by the view to which I have already alluded—that in the atom we have electrified systems of very different types, one small, the other large; the radius of one type is comparable with 10^{-13} cm., that of the other is about 100,000 times greater. The electrostatic potential energy in the smaller bodies is enormously greater than that in the larger ones; if one of these small bodies were to explode and expand to the size of the larger ones, we should have a liberation of energy large enough to endow an α particle with the energy it possesses. Is it possible that the positive units of electricity were, to begin with, quite as small as the negative, but while in the course of ages most of these have passed from the smaller stage to the larger, there are some small ones still lingering in radio-active substances, and it is the explosion of these which liberates the energy set free during radio-active transformation?

The properties of radium have consequences of enormous importance to the geologist as well as to the physicist or chemist. In fact, the discovery of these properties has entirely altered the aspect of one of the most interesting geological problems, that of the age of the earth. Before the discovery of radium it was supposed that the supplies of heat furnished by chemical changes going on in the earth were quite insignificant, and that there was nothing to replace the heat which flows from the hot interior of the earth to the colder crust. Now when the earth first solidified it only possessed a certain amount of capital in the form of heat, and if it is continually spending this capital and not gaining any fresh heat it is evident that the process cannot have been going on for more than a certain number of years; otherwise the earth would be colder than it is. Lord Kelvin in this way estimated the age of the earth to be less than 100 million years. Though the quantity of radium in the earth is an exceedingly small fraction of the mass of the earth, only amounting, according to the determinations of Profs. Strutt and Joly, to about five grams in a cube the side of which is 100 miles, yet the amount of heat given out by this small quantity of radium is so great that it is more than enough to replace the heat which flows from the inside to the outside of the earth. This, as Rutherford has pointed out, entirely vitiates the previous method of determining the age of the earth. The fact is that the radium gives out so much heat that we do not quite know what to do with it, for if there was as much radium throughout the interior of the earth as there is in its crust, the temperature of the earth would increase much more rapidly than it does as we descend below the earth's surface. Prof. Strutt has shown that if radium behaves in the interior of the earth as it does at the surface, rocks similar to those in the earth's crust cannot extend to a depth of more than forty-five miles below the surface.

It is remarkable that Prof. Milne from the study of earthquake phenomena had previously come to the conclusion that rocks similar to those at the earth's surface only descend a short distance below the surface; he estimates this distance at about thirty miles, and concludes that at a depth greater than this the earth is fairly homogeneous.

Though the discovery of radio-activity has taken away one method of calculating the age of the earth it has supplied another.

The gas helium is given out by radio-active bodies, and since, except in beryls, it is not found in minerals which do not contain radio-active elements, it is probable that all the helium in these minerals has come from these elements. In the case of a mineral containing uranium, the parent of radium in radio-active equilibrium, with radium and its products, helium will be produced at a definite rate. Helium, however, unlike the radio-active elements, is permanent, and accumulates in the mineral; hence if we measure the amount of helium in a sample of rock and the amount produced by the sample in one year we can find the length of time the helium has been accumulating, and hence the age of the rock. This method, which is due to Prof. Strutt, may lead to determinations, not merely of the average age of the crust of the earth, but of the ages of particular rocks and the date at which the various strata were deposited; he has, for example, shown in this way that a specimen of the mineral thorianite must be more than 240 million years old.

The physiological and medical properties of the rays emitted by radium is a field of research in which enough has already been done to justify the hope that it may lead to considerable alleviation of human suffering. It seems quite definitely established that for some diseases, notably rodent ulcer, treatment with these rays has produced remarkable cures; it is imperative, lest we should be passing over a means of saving life and health, that the subject should be investigated in a much more systematic and extensive manner than there has yet been either time or material for. Radium is, however, so costly that few hospitals could afford to undertake pioneering work of this kind; fortunately, however, through the generosity of Sir Ernest Cassel and Lord Iveagh a Radium Institute, under the patronage of his Majesty the King, has been founded in London for the study of the medical properties of radium, and for the treatment of patients suffering from diseases for which radium is beneficial.

The new discoveries made in physics in the last few years, and the ideas and potentialities suggested by them, have had an effect upon the workers in that subject akin to that produced in literature by the Renaissance. Enthusiasm has been quickened, and there is a hopeful, youthful, perhaps exuberant, spirit abroad which leads men to make with confidence experiments which would have been thought fantastic twenty years ago. It has quite dispelled the pessimistic feeling, not uncommon at that time, that all the interesting things had been discovered, and all that was left was to alter a decimal or two in some physical constant. There never was any justification for this feeling, there never were any signs of an approach to finality in science. The sum of knowledge is at present, at any rate, a diverging, not a converging, series. As we conquer peak after peak we see in front of us regions full of interest and beauty, but we do not see our goal, we do not see the horizon; in the distance tower still higher peaks, which will yield to those who ascend them still wider prospects, and deepen the feeling, the truth of which is emphasised by every advance in science, that "Great are the Works of the Lord."

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. E. RUTHERFORD, M.A., D.Sc., F.R.S., PRESIDENT OF THE SECTION.

IT is a great privilege and pleasure to address the members of this Section on the occasion of the visit of the British Association to a country with which I have had such a long and pleasant connection. I feel myself in the presence of old friends, for the greater part of what may be called my scientific life has been spent in Canada, and I owe much to this country for the unusual facilities and opportunity for research so liberally provided by one of her great Universities. Canada may well regard with pride her Universities, which have made such liberal provision for teaching and research in pure and applied science. As a physicist, I may be allowed to refer in particular to the subject with which I am most intimately connected. After seeing the splendid home for physical science recently erected by the University of Toronto, and the older but no less serviceable and admirably equipped laboratories of McGill University, one cannot but feel that Canada has recognised in a striking manner the great value attaching to teaching and research in physical science. In this, as in other branches of knowledge, Canada has made notable contributions in the past, and we may confidently anticipate that this is but an earnest of what will be accomplished in the future.

It is my intention to-day to say a few words upon the present position of the atomic theory in physical science, and to discuss briefly the various methods that have been devised to determine the values of certain fundamental atomic magnitudes. The present time seems very opportune for this purpose, for the rapid advance of physics during the last decade has not only given us a much clearer conception of the relation between electricity and matter and of the constitution of the atom, but has provided us with experimental methods of attack undreamt of a few years ago. At a time when, in the vision of the physicist, the atmosphere is dim with flying fragments of atoms, it may not be out of place to see how it has fared with the atoms themselves, and to look carefully at the atomic foundations on which the great superstructure of modern science has been raised. Every physicist and chemist cannot but be aware of the great part the atomic hypothesis plays in science to-day. The idea that matter consists of a great number of small discrete particles forms practically the basis of the explanation of all properties of matter. As an indication of the importance of this theory in the advance of science it is of interest to read over the Reports of this Association and to note how many addresses, either wholly or in part, have been devoted to a consideration of this subject. Amongst numerous examples I may instance the famous and oft-quoted lecture of Maxwell on Molecules, at Bradford in 1873; the discussion of the Kinetic Theory of Gases by Lord Kelvin, then Sir William Thomson, in Montreal in 1884; and the Presidential Address of Sir Arthur Rücker in 1901, which will be recalled by many here to-day.

It is, far from my intention to discuss, except with extreme brevity, the gradual rise and development of the atomic theory. From the point of view of modern science, the atomic theory dates from the work of Dalton about 1805, who put it forward as an explanation of the combination of elements in definite proportions. The simplicity of this explanation of the facts of chemistry led to the rapid adoption of the atomic theory as a very convenient and valuable working hypothesis. By the labour of the chemists matter was shown to be composed of a number of elementary substances which could not be further decomposed by laboratory agencies, and the relative weights of the atoms of the elements were determined. On the physical side, the mathematical development of the kinetic or dynamical theory of gases by the labours of Clausius and Clerk Maxwell enormously extended the utility of this conception. It was shown that the properties of gases could be satisfactorily explained on the assumption that a gas consisted of a great assemblage of minute particles or molecules in continuous agitation, colliding with each other and with the walls of the containing vessel. Between encounters the molecules travelled in straight lines, and the free path of the molecules between collisions was supposed to be large compared with the linear dimensions of the molecules themselves. One cannot but regard with admiration the remarkable success of this statistical theory in explaining the general properties of gases and even predicting unexpected relations. The strength and at the same time the limitations of the theory lie in the fact that it does not involve any definite conception of the nature of the molecules themselves or of the forces acting between them. The molecule, for example, may be considered as a perfectly elastic sphere or a Boscovitch centre of force, as Lord Kelvin preferred to regard it, and yet on suitable assumptions the gas would show the same general statistical properties. We are consequently unable, without the aid of special subsidiary hypotheses, to draw conclusions of value in regard to the nature of the molecules themselves.

Towards the close of the last century the ideas of the atomic theory had impregnated a very large part of the domain of physics and chemistry. The conception of atoms became more and more concrete. The atom in imagination was endowed with size and shape, and unconsciously in many cases with colour. The simplicity and utility of atomic conceptions in explaining the most diverse phenomena of physics and chemistry naturally tended to enhance the importance of the theory in the eyes of the scientific worker. There was a tendency to regard the atomic theory as one of the established facts of nature, and not as a useful working hypothesis for which it was exceedingly difficult to obtain direct and convincing evidence. There were not wanting scientific men and philosophers to point out the uncertain foundations of the theory on which so much depended. Granting how useful molecular ideas were for the explanation of experimental facts, what evidence was there that the atoms were realities and not the figments of the imagination? It must be confessed that this lack of direct evidence did not in any way detract from the strength of the belief of the great majority of scientific men in the discreteness of matter. It was not unnatural, however, that there should be a reaction in some quarters against the domination of the atomic theory in physics and in chemistry. A school of thought arose that wished to do away with the atomic theory as the basis of explanation of chemistry, and substitute as its equivalent the law of combination in definite proportions. This movement was assisted by the possibility of explaining many chemical facts on the basis of thermodynamics without the aid of any hypothesis as to the particular structure of matter. Everyone recognises the great importance of such general methods of explanation, but the trouble is that few can think, or at any rate think correctly, in terms of thermodynamics. The negation of the atomic theory has not, and does not, help us to make new discoveries. The great advantage of the atomic theory is that it provides, so to speak, a tangible and concrete idea of matter which serves at once for the explanation of a multitude of facts and is of enormous aid as a working hypothesis. For the great majority of men of science it is not sufficient to group together a number of facts on general abstract principles. What is wanted is a concrete idea, however crude it may be, of the mechanism of the phenomena. This may be a weakness of the scientific mind, but it is one that deserves our sympathetic consideration. It represents an attitude of mind that appeals, I think, very strongly to the Anglo-Saxon temperament. It has no doubt as its basis the underlying idea that the facts of nature are ultimately explicable on general dynamical principles, and that there must consequently be some type of mechanism capable of accounting for the observed facts.

It has been generally considered that a decisive proof of the atomic structure of matter was in the nature of things impossible, and that the atomic theory must of necessity remain an hypothesis unverifiable by direct methods. Recent investigations have, however, disclosed such new and powerful methods of attack that we may well ask the question whether we do not now possess more decisive evidence of its truth.

Since molecules are invisible, it might appear, for example, an impossible hope that an experiment could be devised to show that the molecules of a fluid are in that state of continuous agitation which the kinetic theory leads us to suppose. In this connection I should like to direct your attention for a short time to a most striking phenomenon known as the "Brownian movement," which has been closely studied in recent years. Quite apart from its probable explanation the phenomenon is of unusual interest. In 1827 the English botanist Brown observed by means of a microscope that minute particles like spores of plants introduced into a fluid were always in a state of continuous irregular agitation, dancing to and fro in all directions at considerable speeds. For a long time this effect, known as the Brownian movement, was ascribed to inequalities in the temperature of the solution. This was disproved by a number of subsequent investigations, and especially by those of Gouy, who showed that the movement was spontaneous and continuous, and was exhibited by very small particles of whatever kind when immersed in a fluid medium. The velocity of agitation increased with decrease of diameter of the particles and increased with temperature, and was dependent on the viscosity of the surrounding fluid. With the advent of the ultra-microscope it has been possible to follow the movements with more certainty and to experiment with much smaller particles. Exner and Zsigmondy have determined the mean velocity of particles of known diameter in various solutions, while Svedberg has devised an ingenious method of determining the mean free path and the average velocity of particles of different diameter. The experiments of Ehrenhaft in 1907 showed that the Brownian movement was not confined to liquids, but was exhibited far more markedly by small particles suspended in gases. By passing an arc discharge between silver poles he produced a fine dust of silver in the air. When examined by means of the ultra-microscope the suspended particles exhibited the characteristic Brownian movement, with the difference that the mean free path for particles of the same size was much greater in gases than in liquids.

The particles exhibit in general the character of the motion which the kinetic theory ascribes to the molecules themselves, although even the smallest particles examined have a mass which is undoubtedly very large compared with that of the molecule. The character of the Brownian movement irresistibly impresses the observer with the idea that the particles are hurled hither and thither by the action of forces resident in the solution, and that these can only arise from the continuous and ceaseless movement of the invisible molecules of which the fluid is composed. Smoluchowski and Einstein have suggested explanations which are based on the kinetic theory, and there is a fair agreement between calculation and experiment. Strong additional confirmation of this view has been supplied by the very recent experiments of Perrin (1909). He obtained an emulsion of gamboge in water which consisted of a great number of spherical particles nearly of the same size, which showed the characteristic Brownian movement. The particles settled under gravity, and when equilibrium was set up the distribution of these particles in layers at different heights was determined by counting the particles with a microscope. The number was found to diminish from the bottom of the vessel upwards according to an exponential law—*i.e.* according to the same law as the pressure of the atmosphere diminishes from the surface of the earth. In this case, however, on account of the great mass of the particles, their distribution was confined to a region only a fraction of a millimetre deep. In a particular experiment the number of particles per unit volume decreased to half in a distance of 0·038 millimetre, while the corresponding distance in our atmosphere is about 6000 metres. From measurements of the diameter and weight of each particle, Perrin found that, within the limit of experimental error, the law of distribution with height indicated that each small particle had the same average kinetic energy of movement as the molecules of the solutions in which they were suspended; in fact, the particles in suspension behaved in all respects like molecules of very high molecular weight. This is a very important result, for it indicates that the law of equipartition of energy among molecules of different masses, which is an important deduction from the kinetic theory, holds, at any rate very approximately, for a distribution of particles in a medium the masses and dimensions of which are exceedingly large compared with that of the molecules of the medium. Whatever may prove to be the exact explanation of this phenomenon, there can be little doubt that it results from the movement of the molecules of the solution, and is thus a striking if somewhat indirect proof of the general correctness of the kinetic theory of matter.

From recent work in radio-activity we may take a second illustration which is novel and far more direct. It is well known that the α rays of radium are deflected by both magnetic and electric fields. It may be concluded from this evidence that the radiation is corpuscular in character, consisting of a stream of positively charged particles projected from the radium at a very high velocity. From the measurements of the deflection of the rays in passing through magnetic and electric fields the ratio e/m of the charge carried by the particle to its mass has been determined, and the magnitude of this quantity indicates that the particle is of atomic dimensions.

Rutherford and Geiger have recently developed a direct method of showing that this radiation is, as the other evidence indicated, discontinuous, and that it is possible to detect by a special electric method the passage of a single α particle into a suitable detecting vessel. The entrance of an α particle through a small opening was marked by a sudden movement of the needle of the electrometer which was used as a measuring instrument. In this way, by counting the number of separate impulses communicated to the electrometer needle, it was possible to determine by direct counting the number of α particles expelled per second from one gram of radium. But we can go further and confirm the result by counting the number of α particles by an entirely distinct method. Sir William Crookes has shown that when the α rays are allowed to fall upon a screen of phosphorescent zinc sulphide, a number of brilliant scintillations are observed. It appears as if the impact of each α particle produced a visible flash of light where it struck the screen. Using suitable screens, the number of scintillations per second on a given area can be counted by means of a microscope. It has been shown that the number of scintillations determined in this way is equal to the number of impinging α particles when counted by the electric method. This shows that the impact of each α particle on the zinc sulphide produces a visible scintillation. There are thus two distinct methods—one electrical, the other optical—for detecting the emission of a single α particle from radium. The next question to consider is the nature of the α particle itself. The general evidence indicates that the α particle is a charged atom of helium, and this conclusion was decisively verified by Rutherford and Royds by showing that helium appeared in an exhausted space into which the α particles were fired. The helium, which is produced by radium, is due to the accumulated α particles which are so continuously expelled from it. If the rate of production of helium from radium is measured, we thus have a means of determining directly how many α particles are required to form a given volume of helium gas. This rate of production has recently been measured accurately by Sir James Dewar. He has informed me that his final measurements show that one gram of radium in radioactive equilibrium produces 0·46 cubic millimetre of helium per day, or $5{\cdot}32\times10^{-6}$ cubic millimetres per second. Now from the direct counting experiments it is known that $13{\cdot}6\times10^{10}$ α particles are shot out per second from one gram of radium in equilibrium. Consequently it requires $2{\cdot}56\times10^{19}$ α particles to form one cubic centimetre of helium gas at standard pressure and temperature.

From other lines of evidence it is known that all the α particles, from whatever source, are identical in mass and constitution. It is not, then, unreasonable to suppose that the α particle, which exists as a separate entity in its flight, can exist also as a separate entity when the α particles are collected together to form a measurable volume of helium gas, or, in other words, that the α particle on losing its charge becomes the fundamental unit or atom of helium. In the case of a monatomic gas like helium, where the atom and molecule are believed to be identical, no difficulty of deduction arises from the possible combination of two or more atoms to form a complex molecule.

We consequently conclude from these experiments that one cubic centimetre of helium at standard pressure and temperature contains $2{\cdot}56\times10^{19}$ atoms. Knowing the density of helium, it at once follows that each atom of helium has a mass of $6{\cdot}8\times10^{-24}$ grams, and that the average distance apart of the molecules in the gaseous state at standard pressure and temperature is $3{\cdot}4\times10^{-7}$ centimetres.

The above result can be confirmed in a different way. It is known that the value of e/m for the α particle is

5070 electromagnetic units. The positive charge carried by each α particle has been deduced by measuring the total charge carried by a counted number of α particles. Its value is $9 \cdot 3 \times 10^{-10}$ electrostatic units, or $3 \cdot 1 \times 10^{-20}$ electromagnetic units. Substituting this number in the value of e/m, it is seen that m, the mass of the α particle, is equal to $6 \cdot 1 \times 10^{-24}$ grams—a value in fair agreement with the number previously given.

I trust that my judgment is not prejudiced by the fact that I have taken some share in these investigations; but the experiments, taken as a whole, appear to me to give an almost direct and convincing proof of the atomic hypothesis of matter. By direct counting, the number of identical entities required to form a known volume of gas has been measured. May we not conclude that the gas is discrete in structure, and that this number represents the actual number of atoms in the gas?

We have seen that under special conditions it is possible to detect easily by an electrical method the emission of a single α particle—*i.e.* of a single charged atom of matter. This has been rendered possible by the great velocity and energy of the expelled α particle, which confers on it the power of dissociating or ionising the gas through which it passes. It is obviously only possible to detect the presence of a single atom of matter when it is endowed with some special property or properties which distinguishes it from the molecules of the gas with which it is surrounded. There is a very important and striking method, for example, of visibly differentiating between the ordinary molecules of a gas and the ions produced in the gas by various agencies. C. T. R. Wilson showed in 1897 that under certain conditions each charged ion became a centre of condensation of water vapour, so that the presence of each ion was rendered visible to the eye. Sir Joseph Thomson, H. A. Wilson, and others have employed this method to count the number of ions present and to determine the magnitude of the electric charge carried by each.

A few examples will now be given which illustrate the older methods of estimating the mass and dimensions of molecules. As soon as the idea of the discrete structure of matter had taken firm hold, it was natural that attempts should be made to estimate the degree of coarse-grainedness of matter, and to form an idea of the dimension of molecules, assuming that they have extension in space. Lord Rayleigh has directed attention to the fact that the earliest estimate of this kind was made by Thomas Young in 1805, from considerations of the theory of capillarity. Space does not allow me to consider the great variety of methods that have later been employed to form an idea of the thickness of a film of matter in which a molecular structure is discernible. This phase of the subject was always a favourite one with Lord Kelvin, who developed a number of important methods of estimating the probable dimensions of molecular structure.

The development of the kinetic theory of gases on a mathematical basis at once suggested methods of estimating the number of molecules in a cubic centimetre of any gas at normal pressure and temperature. This number, which will throughout be denoted by the symbol N, is a fundamental constant of gases; for, according to the hypothesis of Avogadro, and also on the kinetic theory, all gases at normal pressure and temperature have an identical number of molecules in unit volume. Knowing the value of N, approximate estimates can be made of the diameter of the molecule; but in our ignorance of the constitution of the molecule, the meaning of the term diameter is somewhat indefinite. It is usually considered to refer to the diameter of the sphere of action of the forces surrounding the molecule. This diameter is not necessarily the same for the molecules of all gases, so that it is preferable to consider the magnitude of the fundamental constant N. The earliest estimates based on the kinetic theory were made by Loschmidt, Johnstone Stoney, and Maxwell. From the data then at his disposal, the latter found N to be $1 \cdot 9 \times 10^{19}$. Meyer, in his "Kinetic Theory of Gases," discusses the various methods of estimating the dimensions of molecules on the theory, and concludes that the most probable estimate of N is $6 \cdot 1 \times 10^{19}$. Estimates of N based on the kinetic theory are only approximate, and in many cases serve merely to fix an inferior or superior limit to the number of the molecules. Such estimates are, however, of considerable interest and historical importance, since for a long time they served as the most trustworthy methods of forming an idea of molecular magnitudes.

A very interesting and impressive method of determining the value of N was given by Lord Rayleigh in 1899 as a deduction from his theory of the blue colour in the cloudless sky. This theory supposes that the molecules of the air scatter the waves of light incident upon them. This scattering for particles, small compared with the wave-length of light, is proportional to the fourth power of the wave-length, so that the proportion of scattered to incident light is much greater for the violet than for the red end of the spectrum, and consequently the sky which is viewed by the scattered light is of a deep blue colour. This scattering of the light in passing through the atmosphere causes alterations of brightness of stars when viewed at different altitudes, and determinations of this loss of brightness have been made experimentally. Knowing this value, the number N of molecules in unit volume can be deduced by aid of the theory. From the data thus available, Lord Rayleigh concluded that the value of N was not less than 7×10^{18}. Lord Kelvin in 1902 re-calculated the value of N on the theory by using more recent and more accurate data, and found it to be $2 \cdot 47 \times 10^{19}$. Since in the simple theory no account is taken of the additional scattering due to fine suspended particles which are undoubtedly present in the atmosphere, this method only serves to fix an inferior limit to the value of N. It is difficult to estimate with accuracy the correction to be applied for this effect, but it will be seen that the uncorrected number deduced by Lord Kelvin is not much smaller than the most probable value $2 \cdot 77 \times 10^{19}$ given later. Assuming the correctness of the theory and data employed, this would indicate that the scattering due to suspended particles in the atmosphere is only a small portion of the total scattering due to molecules of air. This is an interesting example of how an accurate knowledge of the value of N may possibly assist in forming an estimate of unknown magnitudes.

It is now necessary to consider some of the more recent and direct methods of estimating N which are based on recent additions to our scientific knowledge. The newer methods allow us to fix the value of N with much more certainty and precision than was possible a few years ago.

We have referred earlier in the paper to the investigations of Perrin on the law of distribution in a fluid of a great number of minute granules, and his proof that the granules behave like molecules of high molecular weight. The value of N can be deduced at once from the experimental results, and is found to be $3 \cdot 14 \times 10^{19}$. The method developed by Perrin is a very novel and ingenious one, and is of great importance in throwing light on the law of equipartition of energy. This new method of attack of fundamental problems will no doubt be much further developed in the future.

It has already been shown that the value $N = 2 \cdot 56 \times 10^{19}$ has been obtained by the direct method of counting the particles and determining the corresponding volume of helium produced. Another very simple method of determining N from radio-active data is based on the rate of transformation of radium. Boltwood has shown by direct experiment that radium is half transformed in 2000 years. From this it follows that initially in a gram of radium 0·346 milligram breaks up per year. Now it is known from the counting method that $3 \cdot 4 \times 10^{10}$ α particles are expelled per second from one gram of radium, and the evidence indicates that one α particle accompanies the disintegration of each atom. Consequently the number of α particles expelled per year is a measure of the number of atoms of radium present in 0·346 milligram. From this it follows that there are $3 \cdot 1 \times 10^{21}$ atoms in one gram of radium, and taking the atomic weight of radium as 226, it is simply deduced that the value of N is $3 \cdot 1 \times 10^{19}$.

The study of the properties of ionised gases in recent years has led to the development of a number of important methods of determining the charge carried by the ion, produced in gases by α rays or the rays from radio-active substances. On modern views, electricity, like matter, is supposed to be discrete in structure, and the charge carried by the hydrogen atom set free by the electrolysis of water is taken as the fundamental unit of quantity of electricity. On this view, which is supported by strong evidence, the charge carried by the hydrogen atom is the smallest unit of electricity that can be obtained, and every quantity of electricity consists of an integral multiple of this unit. The experiments of Townsend have shown that the charge carried by a gaseous ion is, in the majority of cases, the same and equal in magnitude to the charge carried by a hydrogen atom in the electrolysis of water. From measurement of the quantity of electricity required to set free one gram of hydrogen in electrolysis, it can be deduced that $Ne = 1 \cdot 29 \times 10^{10}$ electrostatic units, where N, as before, is the number of molecules of hydrogen in one cubic centimetre of gas, and e the charge carried by each ion. If e be determined experimentally, the value of N can at once be deduced from this relation.

The first direct measurement of the charge carried by the ion was made by Townsend in 1897. When a solution of sulphuric acid is electrolysed, the liberated oxygen is found in a moist atmosphere to give rise to a dense cloud composed of minute globules of water. Each of these minute drops carries a negative charge of electricity. The size of the globules, and consequently the weight, was deduced with the aid of Stokes's formula by observing the rate of fall of the cloud under gravity. The weight of the cloud was measured, and, knowing the weight of each globule, the total number of drops present was determined. Since the total charge carried by the cloud was measured, the charge e carried by each drop was deduced. The value of e, the charge carried by each drop, was found by this method to be about $3 \cdot 0 \times 10^{-10}$ electrostatic units. The corresponding value of N is about $4 \cdot 3 \times 10^{19}$.

We have already referred to the method discovered by C. T. R. Wilson of rendering each ion visible by the condensation of water upon it by a sudden expansion of the gas. The property was utilised by Sir Joseph Thomson to measure the charge e carried by each ion. When the expansion of the gas exceeds a certain value, the water condenses on both the negative and positive ions, and a dense cloud of small water-drops is seen. J. J. Thomson found $e = 3 \cdot 4 \times 10^{-10}$, H. A. Wilson $e = 3 \cdot 1 \times 10^{-10}$, and Millikan and Begeman $4 \cdot 06 \times 10^{-10}$. The corresponding values of N are 3·8, 4·2, and $3 \cdot 2 \times 10^{19}$ respectively. This method is of great interest and importance, as it provides a method of directly counting the number of ions produced in the gas. An exact determination of e by this method is, however, unfortunately beset with great experimental difficulties.

Moreau has recently measured the charge carried by the negative ions produced in flames. The values deduced for e and N were respectively $4 \cdot 3 \times 10^{-10}$ and $3 \cdot 0 \times 10^{19}$.

We have referred earlier in the paper to the work of Ehrenhaft on the Brownian movement in air shown by ultra-microscopic dust of silver. In a recent paper (1909) he has shown that each of these particles carries a positive or negative charge. The size of each particle was measured by the ultra-microscope, and also by the rate of fall under gravity. The charge carried by each particle was deduced from the measured mass of the particle, and its rate of movement in an electric field. The mean value of e was found to be $4 \cdot 6 \times 10^{-10}$, and thus N becomes $2 \cdot 74 \times 10^{19}$.

A third important method of determination of N from radio-active data was given by Rutherford and Geiger in 1908. The charge carried by each α particle expelled from radium was measured by directly determining the total charge carried by a counted number of α particles. The value of the charge on each α particle was found to be $9 \cdot 3 \times 10^{-10}$. From consideration of the general evidence, it was concluded that each α particle carries two unit positive charges, so that the value of e becomes $4 \cdot 65 \times 10^{-10}$, and of N $2 \cdot 77 \times 10^{19}$. This method is deserving of considerable confidence, as the measurements involved are direct and capable of accuracy.

The methods of determination of e, so far explained, have depended on direct experiment. This discussion would not be complete without a reference to an important determination of e from theoretical considerations by Planck. From the theory of the distribution of energy in the spectrum of a hot body, Planck found that $e = 4 \cdot 69 \times 10^{-10}$, and $N = 2 \cdot 80 \times 10^{19}$. For reasons that we cannot enter into here, this theoretical deduction must be given great weight.

When we consider the great diversity of the theories and methods which have been utilised to determine the values of the atomic constants e and N, and the probable experimental errors, the agreement among the numbers is remarkably close. This is especially the case in considering the more recent measurements by very different methods, which are far more trustworthy than the older estimates. It is difficult to fix on one determination as more deserving of confidence than another; but I may be pardoned if I place some reliance on the radio-active method previously discussed, which depends on the charge carried by the α particle. The value obtained in this way is not only in close agreement with the theoretical estimate of Planck, but is in fair agreement with the recent determinations by several other distinct methods. We may consequently conclude that the number of molecules in a cubic centimetre of any gas at standard pressure and temperature is about $2 \cdot 77 \times 10^{19}$, and that the value of the fundamental unit of quantity of electricity is about $4 \cdot 65 \times 10^{-10}$ electrostatic units. From these data it is a simple matter to deduce the mass of any atom the atomic weight of which is known, and to determine the values of a number of related atomic and molecular magnitudes.

There is now no reason to view the values of these fundamental constants with scepticism, but they may be employed with confidence in calculations to advance still further our knowledge of the constitution of atoms and molecules. There will no doubt be a great number of investigations in the future to fix the values of these important constants with the greatest possible precision; but there is every reason to believe that the values are already known with reasonable certainty, and with a degree of accuracy far greater than it was possible to attain a few years ago. The remarkable agreement in the values of e and N, based on so many different theories, of itself affords exceedingly strong evidence of the correctness of the atomic theory of matter and of electricity, for it is difficult to believe that such concordance would show itself if the atoms and their charges had no real existence.

There has been a tendency in some quarters to suppose that the development of physics in recent years has cast doubt on the validity of the atomic theory of matter. This view is quite erroneous, for it will be clear from the evidence already discussed that the recent discoveries have not only greatly strengthened the evidence in support of the theory, but have given an almost direct and convincing proof of its correctness. The chemical atom as a definite unit in the subdivision of matter is now fixed in an impregnable position in science. Leaving out of account considerations of etymology, the atom in chemistry has long been considered to refer only to the smallest unit of matter that enters into ordinary chemical combination. There is no assumption made that the atom itself is indestructible and eternal, or that methods may not ultimately be found for its subdivision into still more elementary units. The advent of the electron has shown that the atom is not the unit of smallest mass of which we have cognisance, while the study of radio-active bodies has shown that the atoms of a few elements of high atomic weight are not permanently stable, but break up spontaneously with the appearance of new types of matter. These advances in knowledge do not in any way invalidate the position of the chemical atom, but rather indicate its great importance as a subdivision of matter the properties of which should be exhaustively studied.

The proof of the existence of corpuscles or electrons with an apparent mass very small compared with that of the hydrogen atom marks an important stage in the extension of our ideas of atomic constitution. This discovery, which has exercised a profound influence on the development of modern physics, we owe mainly to the genius of the President of this Association. The existence of the electron as a distinct entity is established by similar methods and with almost the same certainty as the existence of individual α particles. While it has not yet been found possible to detect a single electron by its electrical or optical effect, and thus to count the number directly as in the case of the α particles, there seems to be no reason why this should not be accomplished by the electric method. The effect to be anticipated for a single β particle is much smaller than that due to an α particle, but not too small for measurement. In this connection it is of interest to note that Regener has observed evidence of scintillations produced by the β particles of radium falling on a screen of platinocyanide of barium, but the scintillations are too feeble to count with certainty.

Experiment has shown that the apparent mass of the electron varies with its speed, and, by comparison of theory with experiment, it has been concluded that the mass of the electron is entirely electrical in origin, and that there is no necessity to assume a material nucleus on which the electrical charge is distributed. While there can be no doubt that electrons can be released from the atom or molecule by a variety of agencies, and, when in rapid motion, can retain an independent existence, there is still much room for discussion as to the actual constitution of electrons, if such a term may be employed, and of the part they play in atomic structure. There can be little doubt that the atom is a complex system, consisting of a number of positively and negatively charged masses which are held in equilibrium mainly by electrical forces; but it is difficult to assign the relative importance of the *rôle* played by the carriers of positive and negative electricity. While negative electricity can exist as a separate entity in the electron, there is yet no decisive proof of the existence of a corresponding positive electron. It is not known how much of the mass of an atom is due to electrons or other moving charges, or whether a type of mass quite distinct from electrical mass exists. Advance in this direction must be delayed until a clearer knowledge is gained of the character and structure of positive electricity and of its relation to the negative electron.

The general experimental evidence indicates that electrons play two distinct *rôles* in the structure of the atom, one as lightly attached and easily removable satellites or outliers of the atomic system, and the other as integral constituents of the interior structure of the atom. The former, which can be easily detached or set in vibration, probably play an important part in the combination of atoms to form molecules, and in the spectra of the elements; the latter, which are held in place by much stronger forces, can only be released as a result of an atomic explosion involving the disintegration of the atom. For example, the release of an electron with slow velocity by ordinary laboratory agencies does not appear to endanger the stability of the atom, but the expulsion of a high-speed electron from a radio-active substance accompanies the transformation of the atom.

The idea that the atoms of the elements may be complex structures, made up either of lighter atoms or of the atoms of some fundamental substance, has long been familiar to science. So far no direct evidence has been obtained of the possibility of building up an atom of higher atomic weight from one of lower atomic weight, but in the case of the radio-active substances we have decisive and definite evidence that certain elements show the converse process of disintegration. It may be significant that this process has only been observed in the atoms of highest atomic weights, like those of uranium, thorium, and radium. With the exception possibly of potassium, there is no trustworthy evidence that a similar process takes place in other elements. The transformation of the atom of a radio-active substance appears to result from an atomic explosion of great intensity in which a part of the atom is expelled with great speed. In the majority of cases an α particle or atom of helium is ejected, in some cases a high-speed electron, while a few substances are transformed without the appearance of a detectable radiation. The fact that the α particles from a simple substance are all ejected with an identical and very high velocity suggests the probability that the charged helium atom before its expulsion is in rapid orbital movement in the atom. There is at present no definite evidence of the causes operative in these atomic transformations.

Since in a large number of cases the transformations of the atoms are accompanied by the expulsion of one or more charged atoms of helium, it is difficult to avoid the conclusion that the atoms of the radio-active elements are built up, in part at least, of helium atoms. It is certainly very remarkable, and may prove of great significance, that helium, which is regarded from the ordinary chemical standpoint as an inert element, plays such an important part in the constitution of the atoms of uranium, thorium, and radium.

The study of radio-activity has not only thrown great light on the character of atomic transformations, but it has also led to the development of methods for detecting the presence of almost infinitesimal quantities of radioactive matter. It has already been pointed out that two methods—one electrical, the other optical—have been devised for the detection of a single α particle. By the use of the optical or scintillation method, it is possible to count with accuracy the number of α particles when only one is expelled per minute. It is not a difficult matter, consequently, to follow the transformation of any radio-active substance in which only one atom breaks up per minute, provided that an α particle accompanies the transformation. In the case of a rapidly changing substance like the actinium emanation, which has a half period of 3·7 seconds, it is possible to detect with certainty the presence, if not of a single atom, at any rate of a few atoms, while the presence of a hundred atoms would in some cases give an inconveniently large effect. The counting of the scintillations affords an exceedingly powerful and direct quantitative method of studying the properties of radio-active substances which expel α particles. Not only is it a simple matter to count the number of α particles which are expelled in any given interval, but it is possible, for example, by suitably arranged experiments to decide whether one, two, or more α particles are expelled at the disintegration of a single atom.

The possibility of detection of a single atom of matter has opened up a new field of investigation in the study of discontinuous phenomena. For example, the experimental law of transformation of radio-active matter expresses only the average rate of transformation, but by the aid of the scintillation or electric method it is possible to determine directly by experiment the actual interval between the disintegration of successive atoms and the probability law of distribution of the α particles about the average value.

Quite apart from the importance of studying radio-active changes, the radiations from active bodies provide very valuable information as to the effects produced by high-velocity particles in traversing matter. The three types of radiation, the α, β, and γ rays, emitted from active bodies, differ widely in character and their power of penetration of matter. The α particles, for example, are completely stopped by a sheet of notepaper, while the γ rays from radium can be easily detected after traversing twenty centimetres of lead. The differences in the character of the absorption of the radiations are no doubt partly due to the difference in type of the radiation and partly due to the differences of velocity.

The character of the effects produced by the α and β particles is most simply studied in gases. The α particle has such great energy of motion that it plunges through the molecules of the gas in its path, and leaves in its train more than a hundred thousand ionised or dissociated molecules. After traversing a certain distance, the α particle suddenly loses its characteristic properties and vanishes from the ken of our observational methods. It no doubt quickly loses its high velocity, and after its charge has been neutralised becomes a wandering atom of helium. The ionisation produced by the α particle appears to consist of the liberation of one or more slow-velocity electrons from the molecule, but in the case of complex gases there is no doubt that the act of ionisation is accompanied by a chemical dissociation of the molecule itself, although it is difficult to decide whether this dissociation is a primary or secondary effect. The chemical dissociation produced by α particles opens up a wide field of investigation, on which, so far, only a beginning has been made.

The β particle differs from the α particle in its much greater power of penetration of matter, and the very small number of molecules it ionises compared with the α particle traversing the same path in the gas. It is very easily deflected from its path by encounters with the gas molecules, and there is strong evidence that, unlike the α particle, the β particle can be stopped or entrapped by a molecule when travelling at a very high speed.

When the great energy of motion of the α particle and the small amount of energy absorbed in ionising a single molecule are taken into consideration, there appears to be no doubt that the α particle, as Bragg pointed out, actually passes through the atom, or rather the sphere of action of the atom which lies in its path. There is, so to speak, no time for the atom to get out of the way of the swiftly moving α particle, but the latter must pass through the atomic system. On this view, the old dictum, no doubt true in most cases, that two bodies cannot occupy the same space, no longer holds for atoms of matter if moving at a sufficiently high speed.

There would appear to be little doubt that a careful study of the effects produced by the α or β particle in passing through matter will ultimately throw much further light on the constitution of the atom itself. Work already done shows that the character of the absorption of the radiations is intimately connected with the atomic weights of the elements and their position in the periodic table. One of the most striking effects of the passage of β rays through matter is the scattering of the β particles, *i.e.* the deflection from their rectilinear path by their encounters with the molecules. It was for some time thought that such a scattering could not be expected to occur in the case of the α particles in consequence of their much greater mass and energy of motion. The recent experiments of Geiger, however, show that the scattering of the α particles is very marked, and is so great that a small fraction of the α particles, which impinge on a screen of metal, have their velocity reversed in direction and emerge again on the same side. This scattering can be most conveniently studied by the method of scintillations. It can be shown that the deflection of the α particle from its path is quite perceptible after passing through very few atoms of matter. The conclusion is unavoidable that the atom is the seat of an intense electric field, for otherwise it would be impossible to change the direction of the particle in passing over such a minute distance as the diameter of a molecule.

In conclusion, I should like to emphasise the simplicity and directness of the methods of attack on atomic problems opened up by recent discoveries. As we have seen, not only is it a simple matter, for example, to count the number of α particles by the scintillations produced on a zinc sulphide screen, but it is possible to examine directly the deflection of an individual particle in passing through a magnetic or electric field, and to determine the deviation of each particle from a rectilinear path due to encounters with molecules of matter. We can determine directly the mass of each α particle, its charge, and its velocity, and can deduce at once the number of atoms present in a given weight of any known kind of matter. In the light of these and similar direct deductions, based on a minimum amount of assumption, the physicists have, I think, some justification for their faith that they are building on the solid rock of fact, and not, as we are often so solemnly warned by some of our scientific brethren, on the shifting sands of imaginative hypothesis.

NOTES.

A MEETING of the permanent commission of the International Association of Seismology will be held at Zermatt on August 30, under the chairmanship of Prof. Arthur Schuster, F.R.S. At this meeting reports will be presented from a number of committees, appointed at the last general meeting, which took place at The Hague in 1907, and questions of organisation will be discussed. Papers will be read by Mr. H. F. Reid, on some lessons of the Californian earthquake and a method of foretelling certain earthquakes; by Mr. Albert Heim, on the objects of earthquake investigations; and by Prof. Palazzo, on a projected seismic triangulation by means of wireless telegraphy. The Central Government of the Confederation has charged the Swiss Naturforschende Gesellschaft with the organisation of the meeting, and arrangements have been made for the accommodation of the delegates taking part in the conference, who will also be able to travel on the railway between Visp and the Gorner Grat at half fares.

ON Tuesday next, August 31, at the ordinary fortnightly meeting of the Royal Horticultural Society, Vincent Square, S.W., there will be exhibited on behalf of Prof. Sargent and the president and fellows of Harvard University, Cambridge, Mass., U.S.A., a selection of photographs illustrating the flora, fauna, and scenery of central and western China. These photographs are from the large collection taken by Mr. E. H. Wilson during his last (third) journey to China. The exhibit will be of importance to all who are interested in the recent new plant introductions from China; it is also hoped that from its varied character the selection made will appeal to a wider circle. The photographs are whole-plate size ($8\frac{1}{2} \times 6\frac{1}{2}$ inches), with liberal mounts for herbarium purposes, and all are labelled. The work of developing and printing has been done by the well-known worker in floral photography, Mr. E. J. Wallis, of Kew.

THE preliminary mineralogical and geological survey of Northern Nigeria, carried out under the auspices of the Colonial Office and the Imperial Institute, has just been completed by Dr. J. D. Falconer after five seasons' work. Valuable deposits of tinstone have been located within the Protectorate, as well as less important occurrences of gold, argentiferous galena, monazite, and numerous ores of iron. The economic results of the survey are being issued as colonial reports by Prof. Dunstan, while the scientific results will be published by Dr. Falconer in the course of the coming winter. Important observations have been made as to the age and origin of Lake Chad and the Bauchi plateau, while sufficient data have been secured for the compilation of a geological map of the Protectorate which will largely fill up the existing blank in our knowledge of the structure of this portion of the Central Sudan.

MR. ASQUITH announced in the House of Commons on August 19 that the Government has decided to recommend Parliament to make a grant of 20,000*l.* in aid of the expenses of Mr. Shackleton's expedition in Antarctic regions. Mr. Shackleton has informed a Press representative that this sum will meet all his guarantees. The total cost of the expedition is said to have been nearly 45,000*l.* Of this amount, 6000*l.* was subscribed in Australia and New Zealand, and the rest was provided by Mr. Shackleton's friends. In a letter communicating the decision of the Government to Mr. Shackleton, the Prime Minister said:—"The Government have been induced to take this course as they are much impressed both by the great value of the discoveries made in the course of your voyage and by the efficient and economical manner in which the whole of the enterprise was conducted, as is shown by the fortunate return of your entire party, and by the comparatively small total outlay incurred."

WE learn from *Science* of the death, in his eighty-third year, of Dr. R. E. C. Stearns, known for his work on the geographical distribution and variation of mollusca and for other work in natural science.

THE death is announced, in his sixty-seventh year, of Dr. Otto von Bollinger, rector of the University of Munich and professor of general pathology and pathological anatomy in the University. Prof. von Bollinger was the author of a number of medical works, among them being books on meat poisoning and on the heredity of diseases, and the "Atlas und Grundriss der pathologischen Anatomie," which appeared in 1896.

The daily papers announce that the Select Committee on the Daylight Saving Bill has adopted a report approving the principle of the proposals made, but adverse to legislation which would make the seasonal change of time obligatory. The committee has arrived at the conclusion that the principle, if applied compulsorily, would tend to cause serious dislocations in certain industries, such as agriculture and railways, where an alteration in the hours of labour would cause great confusion. The hope is expressed, however, that the principle of daylight saving will be adopted voluntarily in cases where it is found to be practicable and desirable.

The Berlin correspondent of the *Times* reports that the fifth International Dental Congress opened its proceedings there on Monday, August 23, under the presidency of Prof. O. Walkhoff, of Munich. In his opening address Prof. Walkhoff referred to the increasing recognition of the public importance of dental surgery, which no longer holds a subordinate place in the field of science. Prof. Waldeyer, director of the anatomical institute of the University of Berlin, referred to the important problems which dental surgery embraces in anatomy, physiology, pathology, and palæontology.

An "American colony" of a very interesting character has recently been installed near Guildford, in Surrey, where an attempt is being made to acclimatise the American robin (*Merula migratoria*) in England. Seventeen birds—nine cocks and eight hens—were imported last spring, and after being kept for a short time in a large open-air aviary, all, with the exception of two or three pairs, were liberated about the middle of June. They mated immediately, and began nest-building almost at once. The nests—coarse, bulky constructions—were placed in trees, with little attempt at concealment, and clutches of from four to five blue eggs, about the size of those of the thrush, were laid. Old and young, the birds now number between forty and fifty. Fears are entertained that at the approach of winter these robins, impelled by their strong migratory instinct, will leave England and become hopelessly dispersed; but those who know the nature of the birds are confident that by feeding them abundantly as cold weather draws on they can be induced to remain as permanent residents. They are cheery birds, their "Kill 'em, cure 'em, give 'em physic" being the climax of optimism.

It is matter of just reproach against our statesmen and administrators that, in devising and carrying out measures intended for the amelioration of social conditions, they are very commonly blind to the teachings of science. This point is well brought out in a striking article by Mr. E. B. Iwan-Müller in the August number of the *Fortnightly Review*. In the course of his article, which is entitled "The Cult of the Unfit," the writer argues with great effect that, judged by the standard of biological principles, much recent legislation must be condemned as ill-adapted for its purpose and likely to be harmful in its results. Socialism, he maintains, and any legislation tending in that direction, runs directly counter to all the lessons that can be derived from the contemplation of evolution by struggle and survival. "The new Trades Unionism aims at the establishment and endowment of mediocrity by the elimination of competition." The facts of parasitism and other causes of degeneration are dwelt upon, and stress is laid on the warning they convey against the policy of making the conditions of life too easy—a warning still needed, though not now delivered for the first time. Apposite quotations are given from Sir E. Ray Lankester's Romanes lecture at Oxford. While opinions may differ as to Mr. Iwan-Müller's applications, there can be no doubt that his plea for a recognition of scientific principle on the part of our public men is both reasonable and necessary.

The Pasteur Institute of Paris will receive in a few days the sum of 1,200,000*l.* which was bequeathed to it by the late M. Osiris. The Paris correspondent of the *Daily News* describes the following interesting circumstances relating to this generous gift. M. Osiris founded in 1903 a triennial prize of 4000*l.* to be bestowed on "the person who had rendered the greatest service to the human race during the three preceding years." The prize was awarded to Dr. Roux, the head of the Pasteur Institute, for the discovery of the anti-diphtheria serum, which has been the means of saving the lives of many thousand children, and the whole of the money was made over by him to the institute. M. Osiris was struck by the unselfish conduct of the man of science, and asked him one day why he had given the money to the institute. "All that I am," replied Dr. Roux, "I owe to the Pasteur Institute, for all my experiments and discoveries have been made there. Besides, the institute is very poor, for we have no income except what we make by the sale of serum, and though that brings in enough to keep the establishment going, some fresh remedy may any day be discovered, in which case I fear the institute would have to close its doors for want of funds." M. Osiris said nothing at the time, adds the *Daily News* correspondent; but at his death, which occurred a year or two afterwards, it was found that he had left the bulk of his wealth to the Pasteur Institute as a token of admiration for the scientific attainments and self-abnegation of Dr. Roux.

No. 4 of vol. i. of the ornithological publications of the Field Museum of Natural History is devoted to a catalogue of birds from British East Africa, by Mr. N. Dearborn.

In vol. vi., No. 4, of the University of Colorado Studies Prof. T. D. H. Cockerell describes and figures a skull of a ground-sloth from Colorado provisionally referred to the genus Mylodon. It differs from Paramylodon, of the Nebraskan Pliocene, by having the normal five in place of four pairs of upper cheek-teeth.

We have to acknowledge the receipt of vols. xxx. (1907) and xxxi. (1908) of *Mémoires de la Société des Naturalistes de la Nouvelle-Russie*, Odessa. In the former, Dr. A. Brauner points out that while naturalists regard the green-headed starling of Western Europe as the true *Sturnus vulgaris* of Linnæus, and class the purple-headed bird as distinct, under the name of *S. intermedius*, the latter, as occurring in Sweden, should properly be called *S. vulgaris*. Hence the English starling requires another designation.

The articles in the July number of the *National Geographic Magazine* are mostly devoted to Alaska and its products, General Greely opening the subject with an account of the economic evolution of Alaska, while Mr. T. Riggs follows with the story of marking the Alaskan boundary, and Messrs. R. H. Sargent and W. H. Osgood respectively discuss the mountains and the big game of the country. In the last of the articles referred to special attention is directed to the uncertainty still existing with regard to the number of forms of Alaskan brown bears.

We have received the monthly journals of the Meteorological Society of Japan for the first half of this year. These contain notices of recent conspicuous meteorological occurrences, and articles on climatological and other interesting subjects, among which is a discussion of the winds on the east coast of Asia, by Mr. M. Ishida, which runs through several numbers. The practice of summarising the more important articles in a European language has been discontinued; this considerably lessens the usefulness of the journals, so far as western readers are concerned.

IN the July number of the *Museums Journal*, Dr. E. Howarth records his resignation of the editorship, a position he has filled for the last eight years. When that periodical was started in 1901, early failure was predicted; but the prediction has proved altogether untrue, and the *Museums Journal* is now established on a firm, and, it is hoped, lasting base. The issue also contains Mr. Henry Balfour's presidential address, delivered at the Maidstone meeting on July 13th, in which the need for a national museum of British ethnology is strongly advocated. "What is required is a National Folk-Museum, dealing exclusively and exhaustively with the history of culture of the British nation within the historic period, and illustrating the growth of ideas and indigenous characteristics. Until such an institution is founded, there will remain a very serious *lacuna* in the list of our museums, and we shall remain open to the fire of just criticism from other countries, on the score of our almost pathetic anxiety to investigate and illustrate the ethnology of other races and peoples, while we neglect our own."

ZOOLOGICAL students are much indebted to Prof. Spengel for the publication of that very useful and interesting journal, the *Ergebnisse und Fortschritte der Zoologie*, the second part of the second volume of which has just reached us. This part contains two important memoirs of general interest. The first is a very complete and valuable *résumé* of our present knowledge of sponge spicules, by Prof. E. A. Minchin. The spicules of sponges are amongst the most beautiful and at the same time the most incomprehensible objects with which the microscopist has to deal, and a considerable amount of light has lately been thrown upon their nature and origin. Prof. Minchin himself is one of the foremost investigators in this department, which modern methods of research have raised to the level of a branch of cytology. The subject, indeed, is one which of recent years has attracted much attention, and given rise to no little controversy amongst spongologists, and specialists and non-specialists alike will be interested in Prof. Minchin's essay. The second paper in the same journal deals with the excretory organs of invertebrates, our knowledge of which has also progressed by leaps and bounds during the last few years. The author, Prof. Meisenheimer, confines himself for the present to protonephridia and typical segmental organs, drawing largely for his information upon the classical and pioneer work of Mr. Goodrich, especially with regard to solenocytes.

THE July number of the Transactions of the Royal Scottish Arboricultural Society contains a large quantity of information useful to forest owners as well as to foresters. Articles from many able pens deal with afforestation, and we need only mention the names of Lord Lovat, Mr. Munro Ferguson, Dr. Nisbet, Profs. Somerville and Schlich. The report of the Royal Commission on Afforestation from a landowner's point of view, by Sir John Stirling Maxwell, contains many useful hints. A report is given of a lecture on trees of California, by Mr. F. R. S. Balfour, delivered to the society, as well as a report of an excursion to Forglen and Hatton, made by the Aberdeen Branch of the society. The volume also contains interesting notes and queries, reviews and notices of books, and altogether it is full of information likely to be of interest to foresters. The price of the volume is 3*s*.

THE first portion of an account dealing with mitosis in higher plants, communicated by Dr. H. A. Haig, is published in the August number of *Knowledge and Scientific News*. A full description is given of methods and materials examined, so that readers, if disposed, may make their own preparations. The first chapters deal with technique and the early stages of division in the cells found near the root-apices of Hyacinthus and Allium.

THE botanists in the Philippine Islands are vigorously prosecuting their identifications of indigenous plants, in pursuance of which Dr. C. B. Robinson publishes in the first part a revision of Philippine Phyllanthineæ and Mr. E. D. Merrill contributes revisions of the families Connaraceæ and Loranthaceæ to the second part of the botanical section of the *Philippine Journal of Science* (vol. iv.). Dr. Robinson accepts the separation from Phyllanthus of Glochidion, which becomes a large genus by reason of several species established by Mr. Elmer and the author. Six genera are recognised by Mr. Merrill for the Loranthaceæ, including the segregation of Phrygilanthus and a new genus, Cleistoloranthus. The number of endemic species is inordinately great, as out of forty-three species of Loranthus—the only large genus—no fewer than thirty-six are endemic.

DR. M. RACIBORSKI contributes to the *Bulletin international de l'Académie des Sciences de Cracovie* (March) a long series of descriptions of parasitic and epiphytic fungi collected and examined in Java. A peculiar formation of the basidium was observed in Cintractia, as it is abstricted directly from the resting spore, and is at once shed; three or more septa are formed in the basidium, and each cell gives rise to a basidiospore. The group of Septobasidieæ furnishes some of the commonest epiphytes. The Javanese species are separated by the author into three genera; Ordonia is characterised by a fibrous mycelium and absence of a special hymenial layer; Mohortia has a sterile layer below the hymenium, while Septobasidium develops three distinct layers. Several of the new species fall into the families Microthyriaceæ and Sphæriaceæ.

THERE are several noteworthy points in the revision of the American group of Thibaudieæ, a section of the family Ericaceæ communicated by Mr. R. Hörold to Engler's *Botanische Jahrbücher* (vol. xlii., part iv.). It provides an independent account of a section which was required to correlate the diverse views of Hooker and Klotzch. In this respect the author follows the latter in splitting the large genus Thibaudia. The classification of the genera based on staminal characters furnishes an interesting study in the variation of this organ, which is a special characteristic of the family; modifications of apical dehiscence are indicated in a text-figure. A list of new plants includes one genus and many additions to the genera Cavendishia, Psammisia, and Thibaudia. In addition, the author sketches the main features in the geographical distribution of the genera.

WE are in receipt of several important bulletins from the Wisconsin Agricultural Experiment Station dealing with subjects of considerable agricultural interest. Messrs. Whitson and Stoddart discuss the importance of phosphates in fertility, and show that the tendency of the local system of farming has been to deplete the stock of phosphates in the soil. Some of the soils are acid, and it is pointed out that acidity and lack of available phosphates usually go hand in hand. In such cases naturally occurring calcium phosphate gives excellent crop returns, and does not require the preliminary treatment with sulphuric acid usually given; fortunately, large deposits of rock phosphate occur in Florida, and can be purchased by farmers at low prices. Two bulletins by Messrs. Russell and Hoffmann deal with bovine tuberculosis. This disease has appeared in Wisconsin, and has spread, especially in the southern parts of the State, where more than 43 per cent. of the herds are infected. The most common mode of herd infection is through the purchase of infected animals, and State regulation is strongly recommended. In another bulletin Mr. Sandsten gives the results of experiments, which are said to have been entirely satisfactory, on the improvement of Wisconsin tobacco through seed selection. The "King" system of ventilating barns and cow-sheds is described in Bulletin No. 164. Its essential feature is that fresh air is introduced by means of flues running in the walls from the bottom to the top of the barn, and thus enters the building from *above*, whilst the foul air is withdrawn by flues running from the bottom to the top of the building, and terminating outside in a ventilator. This inversion of the ordinary system is said to work well, without draught and without great loss of temperature.

Mr. E. Philippi, of Jena, justly observes that the stratified structure of rocks is one of the phenomena that remain inadequately explained on account of their very familiarity. In a paper, "Über das Problem der Schichtung und über Schichtbildung am Boden der heutigen Meere" (*Zeitsch. deutsch. geol. Gesell.*, Bd. 60, 1908, p. 346), he summarises what is already known as to the bedding of sediments in waters at some distance from a coast, and urges that the German South Polar Expedition has shown stratification to be the rule and not the exception in such materials. Globigerina ooze, for example, seems regularly to contain more terrigenous matter, and to be poorer in calcium carbonate, 30 cm. or so below its surface, and Philippi attributes this to the former greater extension of the antarctic ice, with consequent production of drift. Climatic changes are probably the normal causes of stratified structure in deep-sea deposits. Deep-sea sands are ascribed to the weathering of submarine slopes and of ridges formed of solid rock, some of which may only recently have been forced towards sea-level. As new earth-ridges rise in submarine areas, new material from them gathers in the concomitant geosynclinals. Regular changes in the character of strata may thus indicate a periodicity in crust-movement in the past.

The *Philippine Journal of Science* for December last is given up to an elaborate somatological study of the Benguet Igorots, a tribe occupying the Benguet and Lepanto-Bontoc provinces of Luzon, by Mr. R. B. Dean, of the Anatomical Laboratory, Manila. The result is that the writer is able to distinguish four groups:—Tall dolichocephalic types with long arms; small dolichocephalic with short arms; mixed mesocephalic; and brachycephalic with intermediate arm form. One example, of which an illustration is given, is of a type curiously European in appearance. The race, it is clear, has been subjected to repeated modification by the introduction of new varieties. The original type seems to have been small and dolichocephalic, with relatively short arms, conjoined with a brachycephalic element, which became mingled with the former and partially fused. Upon these people intruded a tall, dolichocephalic, long-armed race; and the process of fusion was continued uninterruptedly up to quite recent times. At present the brachycephalic race is more distinct as a type than either the tall or small dolichocephalic people, and they are also present in larger numbers. The memoir, which is fully illustrated and provided with full statistical apparatus, supplies a singularly interesting example of race fusion, and may be expected to throw much light on the ethnological history of the Philippine Islands and the cognate races of that region.

In the August number of *Man* Mr. W. G. Smith discusses the character of the eoliths said to have been found in association with remains of *Elephas meridionalis* in undisturbed beds at Dewlish in Dorsetshire. This discovery has been assumed by Dr. C. A. Windle and others to prove the existence of man in the Pliocene period. Mr. Smith shows that the evidence of the association of these eoliths with remains of the Pliocene period is more than doubtful. He has examined the remains found at Dewlish by the Rev. Osmund Fisher, and finds that one of them is an undoubted sponge of the Cephalitis order, while none of the others, in his opinion, exhibit the faintest trace of human work. The case of the flints found in the same locality by Dr. Blackmore in 1814 is similar; and an iron stain on one example suggests that it was a surface find. He sums up the question as follows:—"If bulbed flakes of undoubted human origin have been found at Dewlish (none were sent to me) with *Elephas meridionalis*, this cannot prove that the elephant and the stones are Pliocene in age; it only suggests that the elephant had survived into Palæolithic times, for the sufficient reason that Dewlish is an old and well-known locality for Palæolithic implements. It is mentioned in Evans's 'Stone Implements,' ed. i., 1872, p. 559, and ed. ii., 1897, p. 638. I have not written this and former notes on 'eoliths' in an attempt to show that a Pliocene ape-man probably never existed. It is, to me, possible that such an animal did live somewhere in pre-Glacial and Pliocene times. When the evidence—geological, osteological, and archæological—is conclusive, I shall be one of the first to accept it."

It has been shown experimentally that the incidence of β or γ rays from a radio-active substance on a dielectric increases its conductivity, and Dr. H. Greinacher, of the University of Zürich, describes, in the July number of *Le Radium*, his endeavours to detect a corresponding effect in the case of the α rays. The rays were derived from a layer of polonium, and fell on the dielectric of a condenser placed in series with an electrometer and a battery of storage cells. Although at first a considerable increase of the conductivity of the dielectric appeared to be produced when the radiation fell on it, Dr. Greinacher finally traced the effect to the improved contact between the dielectric and the electrodes of the condenser, and found no effect of the radiation on the conductivity. This he attributes to the closeness of the ions together in a solid, and the rapid re-combination of them which in consequence ensues.

The best method of determining an electrical resistance in absolute measure has hitherto been that of Lorenz, but in the Bulletin of the Bureau of Standards for May, Mr. E. B. Rosa proposes to substitute for it a method which depends on the revolution of a coil in the magnetic field due to an electric current in another fixed coil. The fixed coil consists of two portions set a little further apart than in the Helmholtz galvanometer. The revolving coil consists also of two parts wound in planes at right angles to each other. The balancing is done by means of a differential galvanometer provided with three coils. Of these, two are each in series with a part of the revolving coil, and the third is connected to the ends of the resistance to be measured, which is in series with the fixed coil. By means of this apparatus Mr. Rosa hopes to obtain an accuracy ten times that which has been obtained with the Lorenz apparatus.

We note from an article on machine-tool practice in the *Engineering Magazine* for July an interesting example of the standardisation of lathe and planer tools on a large scale. A central tool-dressing plant has been established recently at the Philadelphia Navy Yard, which supplies high-speed lathe and planer tools to all navy yards on the Atlantic coast. These tools are forged, treated, and ground to standards. Each of the various yards is equipped for re-grinding the tools until they require re-dressing, when they are returned to the central tool-dressing plant at Philadelphia for replacement by newly dressed tools. The advantages of this system are that all yards are equipped with tools of standard shapes and of uniformly high quality, and as the forging, dressing, and grinding of tools are done in large lots, substantial reductions in cost result.

The necessity for keeping records of the steam consumption in the various prime-movers in use in large factories and generating stations has given a stimulus to the development of means of measuring and recording automatically the flow of water. In the Lea water-recorder, illustrated in *Engineering* for August 13, advantage is taken of the accuracy of the Thompson V-notch, the magnitude of the angle of the notch being selected to suit the flow. The recording arrangement consists essentially of a float having a vertical rod attached to it; a rack on this rod gears with a pinion fixed to the spindle of a horizontal drum. The angle of rotation of this drum will therefore be proportional to the head of water over the notch. A spiral wire coil or screw thread is wound round the drum, and has a contour similar to the curve of flow for the notch, this curve being plotted with head for abscissæ and gallons or pounds per hour for ordinates. A bar capable of sliding parallel to the axis of the drum is actuated by the spiral on the drum, and has an arm carrying the recording pencil. The movement horizontally of the pencil will therefore be a measure of the quantity of water flowing per hour. The record is made on a chart wrapped round a drum which is clock-driven; hence the total flow in a given time is easily ascertained by means of a planimeter. The makers are the Lea Recorder Company, 28 Deansgate, Manchester.

The tenth edition of Messrs. Townson and Mercer's catalogue of scientific apparatus for physical laboratories should prove of service to science masters and others. The volume runs to 413 large pages, and contains well-illustrated information of a great variety of instruments designed to be of assistance in giving instruction in all branches of physics. Some parts of the catalogue, with their full descriptions and well-executed drawings of important pieces of apparatus, partake of the character of a practical text-book of physics. Teachers in charge of physical laboratories should see that a copy of the catalogue is added to their works of reference.

We have received from the Geographical Model Works, Middlesbrough, a photograph of a hypsometrical model of the district of Ingleborough, near Settle, by Mr. J. Foster Stackhouse. The model is said to be correct within 2 feet of the actual district dimension at every part. The area covered is 42 square miles, and the horizontal scale 6 inches to a mile. Vertically, the measurements are one-sixteenth of an inch to every 25 feet. The model is built up of a series of ninety-four layers of cardboard, and between 500 and 600 pieces were used in its formation. The weight of the model in its complete state is above a hundredweight and a half. Accurate full-size copies of the model are now available, and particulars concerning them may be obtained on application to the offices of the Geographical Model Works at Emerson Chambers, Blackett Street, Newcastle-on-Tyne.

OUR ASTRONOMICAL COLUMN.

Comet 1909*b* (Perrine's, 1896 vii.).—The re-discovery of Perrine's, 1896 vii., comet by Herr Kopff is confirmed by a notice in No. 4347 of the *Astronomische Nachrichten*, where it is stated that perihelion passage should occur about October 31·35 (Berlin M.T.). This comet, according to Herr Ristenpart, passed through perihelion for the first time since its discovery in 1896, in April, 1903, but, owing to its small angular distance from the sun, was not found at that return. According to an ephemeris given by Prof. Kobold in No. 4348 of the *Astronomische Nachrichten* (p. 62, August 18), the position of the comet on August 26 will be α=oh. 49·3m., $\delta=+42^\circ\ 35'$, and it is travelling in a direction parallel to, and slightly north of, the line joining ν and 51 Andromedæ; since its discovery on August 12 the magnitude has increased 0·5. A photograph of this object was obtained at Greenwich on August 14.

The Recent Perseid Shower.—Further observations of the recent display of Perseids are published in the *Yorkshire Weekly Post* for August 21 by Mr. J. H. Elgie, of Leeds. A number of bright meteors was seen by him, between 11 p.m. and midnight, on August 11, and he gives the positions of the limits of their tracks. The brightest object seen appeared at 11.30, and, increasing in brightness, travelled from 210°, +35° to 222·5°, +10°. A number of the meteors observed appeared to radiate from a small group of stars which includes β and ξ Draconis. A party of four observers at Sandfield, Moor Allerton, saw 105 meteors between 11h. and 11h. 45m. p.m. on August 11, and one of the party, Mr. J. C. Jefferson, considers it the finest display he has seen since 1866. Another observer, Mr. E. Hawks, of Leeds, recorded 175 meteors between 9 p.m. on August 11 and dawn on August 12.

The Spectroscopic Binary β Orionis.—The radial velocity of Rigel was first determined at Potsdam in the years 1888–91, and variability was suspected, but the measures were not sufficiently definite to confirm the suspicion. Similarly, Frost and Adams obtained a range of about 8·5 km., and Campbell and Curtis suspected one of 10 km., but in neither case were the results considered sufficiently definite to affirm the variability of the velocity. Results now published, by Mr. J. Plaskett, in No. 1, vol. xxx., of the *Astrophysical Journal* (July, p. 26), show, however, from 275 plates taken on fifty-five nights in 1908–9, that the star is probably a binary, with a period of velocity-variation of about 21·90 days. There is, further, a variation of amplitude which suggests the interference of a third body, and may account for the difficulties encountered by the previous observers, but more evidence must be obtained before this can be considered certain.

The elements now published give the eccentricity as 0·296±0·059, the range of velocity as +26·09 km. to +18·55 km., the velocity of the system as +22·616±0·158 km., and the length of the semi-major axis of the orbit as 1,108,900 km. These results are based on the measures of the three lines Mg λ 4481, He λ 4472, and Hγ λ 4341.

Ephemeris for Comet 1909*a* (Borrelly-Daniel).—An ephemeris for comet 1909*a* is published by Dr. M. Ebell in No. 4347 of the *Astronomische Nachrichten* (p. 42, August 13). As the present brightness is given as 0·07, that at discovery being taken as 1·0, it is unlikely that this object will be observed again except with the largest telescopes or by photography.

Maximum of Mira, 1908.—Mr. Naozo Ichinohe, having observed the magnitude of Mira Ceti during the period which included the last three maxima, publishes the results of his observations in No. 4346 of the *Astronomische Nachrichten*, the measures made during the period October, 1907, to February, 1909, being given in detail. The following table shows the observed dates of, and magnitudes at, the maxima, and compares the dates with those calculated by Guthnick :—

Guthnick		Observed date		Magnitude
1906, Dec. 19·6	...	Dec. 12	...	2·00
1907, Nov. 15·5	...	Nov. 1	...	3·60
1908, Oct. 11·3	...	Oct. 11	...	3·33

The Assumed Planet, O, beyond Neptune.—Replying to a criticism which appeared in the previous number, Prof. W. H. Pickering has a letter in the current number of the *Observatory* (No. 412, August, p. 326) in which he recounts some of his reasons for assuming the existence of a planet beyond Neptune, which is exercising a perturbative force on Uranus. After pointing out essential differences between the present problem and that which presented itself to Leverrier and Adams, Prof. Pickering states that in the observations of Uranus he finds six distinct deviations from the computed course of the planet which occur where they should if produced by such a perturbing body as his assumed planet O; without the assumption three must remain unexplained. He then points out that the Greenwich observations of the last ten years show a steadily increasing deviation from those of the previous sixty years, a deviation which he considers is, of itself, a strong argument in favour of the existence of a hitherto unrecognised disturbing force.

With regard to the suggestion, made in Nature for June 17, that the time is ripe for the discussion of the observations of Neptune, for the determination of any perturbing influence, Prof. Pickering suggests that such a discussion would probably be more hopeful in twenty years' time, when the deviations of Neptune should amount to two or three seconds. Another maximum of Uranus will occur about then, and a graphical solution would be likely to furnish trustworthy data concerning the perturbing force, or forces, very quickly.

AGRICULTURE IN THE TRANSVAAL.

THE issue of the annual report of the Transvaal Department of Agriculture is an important event in the agricultural world, and each year's report furnishes fresh proof of what science can do for agriculture. The work has outgrown the accommodation, and Mr. Smith puts in a strong plea for buildings which, in the Transvaal, is not likely to be disregarded.

An account is given by the heads of the separate departments of the work that has been going on. Dr. Theiler reports further experiments with *Piroplasma mutans* and *P. bigeminum*, two organisms causing serious animal diseases, and is making considerable progress with inoculation methods of coping with them. The botanical division, under Mr. Burtt-Davy, has occupied itself with the improvement of the seed maize. Already the Transvaal farmer exports maize, and could export more; he would secure higher prices and greater profits if supplies of trustworthy seed were available. New and promising plants have also been investigated, and one or two appear as if they will be useful, especially the Florida beggar weed, a leguminous plant suitable for the bushveld, and much liked by stock.

The plant pathologist, Mr. Pole Evans, finds that the potato-rot fungus, *Nectria solani*, Pers., hitherto regarded as a saprophyte, is, in the Transvaal at any rate, an active parasite, attacking the tubers at all stages of growth, and causing a putrid rot in them while still in the soil. Infected potatoes are not admitted into the Transvaal, and steps are being taken to eradicate the disease, but the other South African colonies are doing nothing to prevent the disease from establishing itself within their borders. A uniform system of dealing with plant diseases will be not the least among the advantages of unification.

Locust destruction has received much attention from the Entomological Division. There was a serious invasion of brown locusts, doing damage estimated at about 1,000,000*l.*, but the swarms were marked down, and the voetgangers destroyed by spraying with sodium arsenite solution. Unfortunately, some of the farmers and many of the natives are still indifferent about the work, and look upon locusts as a scourge against which it would be impious to contend; thus places where eggs are laid are not always notified.

There is also a general rise in the standard of agriculture in the colonies, in which the experimental farms of the department have played a conspicuous part. An increased area of land has come under the plough. Thrashing machines are being used more commonly; wheat is being taken up. The quality of the live stock is improving; there is a large demand for well-bred animals, and competition for the pedigree stock raised on the Government farms is very keen. Some farmers are interesting themselves in ostrich farming, which is likely to be a valuable industry in some parts of the colony, where the wild birds are fairly numerous.

Altogether the record is a highly satisfactory one, and the director, Mr. F. B. Smith, and the staff, are to be congratulated on what they have accomplished.

SPONTANEOUS COMBUSTION.

DR. JOHN KNOTT has published in the *New York Medical Journal* (April 17 and 24) an article on spontaneous combustion, with the object of showing that the cases of death reported as occurring from that cause are mere fancy legends which were partly the result of ignorance and mainly of imagination. Many years ago Liebig, and later Casper, wrote treatises with the same object; but Dr. Knott's contribution is not devoid of interest, if only for the exhibition of gentle sarcasm with which he attacks the writings and statements of past Fellows of the Royal Society and others of equal standing who lent the sanction of their names to these idle fables. He does not include among his cases the one which is probably best known to English readers, namely, the celebrated case of Mr. Krook recorded by Dickens in "Bleak House." The evidence in favour of spontaneous combustion as the cause of Mr. Krook's death is just about as convincing (or the reverse) as in the majority of the others.

We fancy, however, that Dr. Knott is preaching to the converted, for we can hardly believe him when he states that "spontaneous combustion is still accepted as an article of pathological faith by our recognised leaders in the domain of medico-legal opinion and teaching."

The belief in spontaneous combustion in the human body doubtless originated in the observation of electrical phenomena long before electricity was understood or even discovered. The "will-of-the-wisp" was endowed, as its name suggests, with a personality. The saintly halo and the fiery tongues of painters and poets familiarised the onlooker with imaginary exhalations; the easy combustibility of certain organic substances, the occurrence of phosphorescence in the sea and in decaying organisms, were then mysteries which combined to lend credence in an unusual combustibility of the human frame in those inclined to believe in the miraculous on the slenderest of evidence.

This point of view was accentuated and stimulated by the discovery of a new element, phosphorus, especially as it was first isolated from human urine and bones. The discovery of phosphorus in its day excited just the same kind of interest and imaginative thought as the discovery of radium is doing at the present time.

ETHNOLOGY IN AMERICA.

THE American Ethnological Society has reprinted in facsimile the first part of their Proceedings, originally published in 1853. The most interesting article is that contributed by W. Bartram, which was written in 1789, entitled "Observations on the Creek and Cherokee Indians," being replies to a series of ethnological questions prepared by Dr. B. S. Barton, vice-president of the Philosophical Society of Philadelphia. The connection of this tribe with the Iroquois, of whom they formed the southern branch, has now been established by Horatio Hale and Gatschet. This paper gives a singularly interesting account of the ethnography of a tribe now practically extinct, describing their probable origin, relations with other tribes, their picture records, religious beliefs, forms of tribal government, physical characteristics, social relations, their "Chunkey-yards" or earthworks, tenures of land and conditions of property, diseases and their remedies, food and means of subsistence. In connection with the divine kings of Prof. J. G. Frazer, it is interesting to find that the King of the Seminoles threatened a certain Mr. McLatche that "if he did not comply with his requisitions, he would command the thunder and lightning to descend upon his head, and reduce his stores to ashes." They had also a remarkable cult of the sacred fire. "The Spiral Fire, on the hearth and floor of the Rotunda, is very curious; it seems to light up in a flame of itself at the appointed time, but how this is done I know not."

Another important article in the same reprint is that by E. G. Squier on "The Archæology and Ethnology of Nicaragua." He describes a curious kind of spindle, resembling a gigantic top, which revolved in a calabash, and an equally primitive hand-loom. Mr. Squier was the first traveller who collected a vocabulary and prepared a grammar of the speech of these tribes. They used, he says, the vigentesimal system of counting by twenties instead of the decimal, while the Eskimos, Algonkins, and Choctaws counted by fives. They were emigrants from Mexico, "and presented the extraordinary phenomenon of a fragment of a great aboriginal nation, widely separated from the parent stock, and intruded among other and hostile nations; yet from the comparative lateness of the separation, or some other cause, still retaining its original, distinguishing features, so as to be easily recognised." Their arms were identical with those of the Mexicans—lances and arrows pointed with flint, copper, and fish-bones, with blades of obsidian set on the edges. These papers are specially interesting, because they were written before the age of scientific ethnography, and were prepared without reliance on any particular theory of the origins, social organisation, or beliefs of the tribes which were studied by their authors. The re-publication of this valuable material is a laudable enterprise on the part of the Ethnological Society.

PURIFICATION OF WATER BY STORAGE.

THE third annual report, compiled by Dr. Houston, of the Metropolitan Water Board, on the results of the chemical and bacteriological examination of the London waters for the twelve months ended March 31 has just been issued, and contains a mass of valuable information. The chief conclusions formulated by Dr. Houston may be summarised as follows. The raw waters from which the supplies are derived are usually unsatisfactory, particularly during the winter months, and a judicious selection for waterworks purposes is important. The storage is unequal, and in some cases inadequate in the different works; filtration is also unequal, and in some instances too rapid. The quality of the filtered water is likewise variable, and in some cases not altogether satisfactory, though a remarkable percentage improvement in the quality of the raw water is effected by storage and filtration; on the whole, however, the water supplied to the consumer is of satisfactory quality. Storage has been clearly proved to be advantageous in all respects. The recent investigations of the Board point to the fact that the present sources of the water supply of the metropolis may be regarded with less disfavour than previously.

Dr. Houston, in a fourth report on research work, also details the results of an investigation on the vitality of the cholera microbe in artificially infected samples of raw Thames, Lee, and New River water, which may be considered to be supplementary to his previous report on the vitality of the typhoid bacillus in similar circumstances (see NATURE, vols. lxxviii., p. 377, lxxix., p. 259, and lxxx., p. 286). A number of different strains of the cholera vibrio was dealt with, and only those which, after investigation, might be regarded as undoubted cholera vibrios were employed in the research, and their bacteriological characteristics are detailed. The conclusions are that cholera vibrios rapidly die in the raw waters as a result of storage in the laboratory. At least 99·9 per cent. of the organisms perish within one week, and none could be isolated even from 100 c.c. of the water three weeks after infection. These results are of considerable interest now that cholera is prevalent in Russia and other parts of Europe, and emphasise the importance of storage of the raw water as a safeguard against water-borne disease.

R. T. HEWLETT.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. R. K. MCCLUNG has been appointed lecturer in physics in the University of Manitoba, Winnipeg.

DR. FRITZ COHN, extraordinary professor of mathematics and astronomy at the University of Königsberg, has been appointed professor of theoretical and mathematical astronomy, and director of the Königliche Astronomischen Recheninstitut, at Berlin; he enters upon his new duties on October 1.

THE Central News Agency reports from New York that, by the will of the late Mr. Cornelius C. Cuyler, the sum of 100,000 dollars is bequeathed for the immediate benefit of the Princeton University, and on the death of Mr. Cuyler's widow several million dollars will pass into the hands of the University authorities.

WE have received a copy of the Directory for higher education, 1909–10, issued by the Education Committee of the Staffordshire County Council. The directory contains the regulations of the committee and the details of schemes in operation throughout Staffordshire. We notice that a very complete scheme of technological instruction is provided throughout the county by the committee. In the case of mining, instruction is given by two lecturers, whose whole time is devoted to the work, and their assistants. For this purpose the county is divided into two portions, comprising the North Staffordshire Coalfields and the South Staffordshire Coalfields respectively. Theoretical and practical classes in metallurgy and iron and steel manufacture are conducted in accordance with the regulations of the Board of Education and the City and Guilds of London Institute. Lectures and laboratory work in pottery and porcelain manufacture will be given during the coming session at Burslem, Longton, Stoke, and Tunstall. The services of an instructor in boot and shoe manufacture are engaged jointly by the committee and the Education Committee of the Borough of Stafford. Silk manufacture is taught at Leek, glass manufacture at Stourbridge, and art metal-work at Bilston. To enable teachers in elementary and secondary schools to impart instruction in various branches of technical and manual training, special classes are provided at convenient centres by the committee. Courses of lectures on health and the care of children are delivered at suitable localities in both rural and urban districts, and demonstrations and lectures are also provided on gardening, bee-keeping, and poultry-keeping. An elaborate system of scholarships is in vogue, including training scholarships for teachers and midwives, extensive aid is given to secondary schools, university extension lectures are provided, useful work has been arranged in rural districts, and numerous evening classes are available. Altogether the Staffordshire committee is making adequate provision for the education of young men and women anxious to equip themselves properly for their work in life.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 17.—M. Bouquet de la Grye in the chair.—The synthesis of unsaturated fatty ketones: F. **Boudroux** and F. **Taboury.** Calcium carbide attacks the ketones of the fatty series. Acetone gives mesityl oxide and other condensation products; butanone is dehydrated in a simpler manner, the unsaturated ketone $C_2H_5.C(CH_3)=CH-CO.C_2H_5$ being formed.—The influence of the reaction of the medium on the development and proteolytic activity of Davaine's bacteridium: Mlle. Eleonore **Lazarus.** The limits of acidity or alkalinity between which it is possible for the organism to develop, as well as the reaction corresponding to the maximum proteolysis, depends, not only on the strain, but also on the nature of the food material.—The mitochondria of the muscular fibres of the heart: Cl. **Regaud.**—The geological history of the Tellian Atlas of eastern Numidia (Algeria): J. Dareste **de la Chavanne.**

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part ii. for 1909, contains the following memoirs communicated to the society:—

March 6.—Seismic records at Göttingen in 1907, with an introduction on the working out of seismic diagrams: L. **Geiger.**—Contributions to the theory of tensions in plastic and sand-like media: A. **Haar** and T. **von Karmán.**

May 8.—Procedure for the determination of magnetic inclination by means of the induction-inclinometer: O. **Venske.**—New developments in linear differential equations: E. **Hilb.**—New members of the systems β, γ, δ, ϵ, ζ Ursæ Majoris: E. **Hertzsprung.**—The notion of the work of deformation in the theory of the elasticity of solid bodies: J. J. **Weyrauch.**

The "Business Communications," part i., 1909, include the report of the Samoa Observatory for 1908, a communication on certain notes of Riemann's lectures, and a memorial address on Hermann Minkowski, by D. **Hilbert.**

CAPE TOWN.

Royal Society of South Africa, July 21.—Prof. L. Crawford in the chair.—Notes on the absorption of water by aërial organs of plants: Dr. **Marloth.** Numerous experiments were made with various Karroo plants in order to ascertain whether they are able to absorb water by means of their leaves, and thus to utilise the dew, which is of common occurrence in the Karroo every night during the winter. The results showed that some plants possess specially constructed hairs, like *Mesembrianthemum barbatum* and *Crassula tomentosa*; others, peculiar stipules like *Anacampseros Telephiastrum* and *A. filamentosa*; others, an unusually modified epidermis like *Crassula decipiens*; and others, again, aërial rootlets like *Cotyledon cristata*. These organs absorb sufficient moisture to supply the requirements of the plants during a part of the year, thus enabling them to exist in arid regions like some parts of the Karroo or the desert coast-belt of Namaqualand.—Evaporation in a current of air (part i.): J. R. **Sutton.** The results of previous observations upon the rate of evaporation made under natural conditions at Kenilworth (Kimberley) with gauges of various patterns suggest that the relative humidity of the air is of more importance than the absolute humidity in determining the loss of water from a given surface, and that there is no simple correspondence between the wind and the evaporation. In this paper the author describes some experiments made to determine the rate of evaporation under different conditions of moisture and temperature in the forced draught generated by an electrically driven fan.—The genesis of the chemical elements: James **Moir.** The author has found a relationship between the atomic weights, whereby the accepted values can be calculated with remarkable accuracy. The scheme brings out closer relationship between such groups as the alkali metals and the halogens, and although it follows the periodic law, it would require the latter to be modified in important particulars.—Some flowering plants from the neighbourhood of Port Elizabeth: S. **Schönland.**—Statement of Silavi, a Tembu of the Zemba tribe, with reference to his life among the Bushmen: W. E. **Stanford.** This communication contains interesting information about a clan of Bushmen whose haunts were in the Drakensberg Mountains, and could muster forty-three men. It is a narrative of cattle lifting in various ways and devices, as well as of their domestic habits and mode of life, and also of the ultimate destruction of the clan by the Tembu chief.

CALCUTTA.

Asiatic Society of Bengal, August 4.—The constitution of the roots of *Arisaema concinnum*, Schott, and *A. speciosum*, Mart.: B. B. **Dutta.** These roots contain an abundance of carbohydrates, and are used as food by the Lepchas of Sikkim in case of need, after taking precautions in the cooking to get rid of the irritant needle crystals.—The ova of a Distoma found in the skeletal muscles of *Saccobranchus fossilis*: G. C. **Chatterjee** and T. C. **Ghosh.** Last year, during the small-pox epidemic, a peculiar eruption was noticed on fish offered for sale in the Calcutta markets, and popularly connected with small-pox. This fish disease, on examination, was found to be due to a flat worm of the parasitic genus Distoma. The authors have found the ova in various parts of the body of the fish, but particularly near the dorsal fins in the skeletal muscles towards the posterior third of the body. Two actual moving worms were found in water where diseased fish were which are described as presumably the adult form of the worm.—Chemical examination of aurvedic metallic preparations, part i., "Shata-puta lauha and Shahasra-puta lauha" (iron roasted hundred times and thousand times): Panchanan **Neogi** and Birendra Bhusan **Adhicary.** The method of preparing "Shata-puta" and "Shahasra-puta" lauha, as given in Rasendra-Shara-Shangraha, as well as that followed by modern aurvedic physicians, are given in this paper. Samples of iron heated once, ten times, seventy-eight times, 100 times, and 1000 times have been collected and analysed. Samples which have undergone a fewer number of "putas" are magnetic, and contain ferroso-ferric oxide. As the number of roastings (puta) increases the amount of ferrous oxide diminishes, and "Shata-puta" and "Shahasra-puta" lauhas contain ferric oxide only, and are not magnetic. "Shata-puta" and "Shahasra-puta" lauhas are almost identical in composition, the amount of ferric oxide varying from 78·1 per cent. to 84·6 per cent. Siliceous matter is present in considerable quantities, varying from 10·1 per cent. to 34·1 per cent. These "lauhas" are very light and porous, and "swim on water like a duck," but precipitated ferric oxide does not "swim." It is on account of their fineness and lightness that these "lauhas" are efficacious. Ordinary ferric oxide is not incorporated in the British Pharmacopœia. Incidentally, a method of estimating metallic iron in presence of ferrous iron is given.

THE USE AND MISUSE OF DRUGS.

Drugs and the Drug Habit. By Dr. Harrington Sainsbury. (New Library of Medicine.) Pp. xv+307. (London: Methuen and Co., n.d.) Price 7s. 6d. net.

THERE is required no little courage on the part of both writer and publisher to issue a book with this forbidding title, which to the layman brings memories of the nauseous ransom paid for release from disabilities, and to the medical man renews the griefs of "lectures on materia medica at 8 o'clock on a winter's morning" which Darwin found "something fearful to remember." To those who are not repelled by the exterior, however, we can promise much enjoyment from the perusal of this volume, which is written with the same distinction of literary style and with the same felicity of illustration as marked the author's "Principia Therapeutica." He writes for the educated layman, and, avoiding the technical pitfalls with which medicine is so bestrewn, gives a clear view of the principles on which treatment must rest. Commencing with a short historical review of the deductive medicine of the "systems," among which he places that curious survival homœopathy, he passes quickly to the definition of his subject, noting by the way the etymological connection between drug and dry, and then discusses the general aim of drug-giving and the grounds on which it is based. Here, as throughout, the author draws many analogies between familiar physical phenomena and the action of drugs, and attempts to dispel the mysticism in which therapeutics is still involved to the lay mind.

The mental effect of treatment as apart from the actual effects of the drug and the psychology of the placebo are dealt with at some length. Drugs are thrown into large classes as nutrients, incitants, depressants, alteratives, antiseptics, and sedatives, which may perhaps find justification in treatises of this kind, but which it is difficult to reconcile with the canons of modern pharmacology. The newer methods of therapeutics, such as organotherapeutics and serum therapeutics, are the subjects of an interesting chapter, in which they are claimed as the modern developments of ancient theory and in no way distinct in character from other forms of medication. Is not the theory underlying the use of thyroid extract the same as that which suggested the administration of pepsin, and is not the newest vaccine a direct descendant, even in terminology, from that of Jenner?

A third of the book is devoted to the habitual use or abuse of the narcotic and soporific drugs, such as opium, alcohol, and chloral, and to the treatment of the consequent "drug habits." Here the importance of re-building the character and self-control of the victim is insisted on, and no medicinal treatment is considered of value except in a purely subsidiary and incidental way. Some support is given to the mental treatment of these cases, but its difficulties and drawbacks are recognised. Improvement is often obtained when the environment of the subject is changed and the possibility of indulgence is restricted, so that the impulses to satisfy the craving are not aroused, while those tending to develop control gain ascendancy. The difficulty arises on return to the habitual environment, when the old impulses throng through the well-beaten paths, and the feeble, newly-acquired, guardian impulses are not aroused by the surroundings. One form of drug habit which finds no mention we should like to have seen discussed from the author's standpoint, the most prevalent, and not least pernicious of them all, that of self-drugging with all sorts of nostrums, which becomes an obsession with many of the laity, and is often accompanied by profound distrust of the medical profession.

The drink problem receives some attention, and the solution suggested is not legislation and restriction so much as education in self-control. The shortcomings of the recent Sale of Poisons Act are subjected to criticism; but should we have a Sale of Poisons Act at all? Might we not trust to education here also? On p. 231 it is stated that morphia may be detected in the urine in subjects of the opium habit, which is not in agreement with ordinary experience, and the direct inheritance of drug habits, as apart from the inheritance of the mental weakness which underlies these, requires further confirmation.

EUCLID'S ELEMENTS IN ENGLISH.

The Thirteen Books of Euclid's Elements. Translated from the Text of Heiberg, with Introduction and Commentary, by T. L. Heath, C.B. 3 vols. Vol. i., Introduction and Books i.–ii., pp. x+424; Vol. ii., Books iii.–ix., pp. 436; Vol. iii., Books x.–xiii. and Appendix, pp. 554. (Cambridge: University Press, 1908.) Price *2l. 2s.* net.

OUR island is the last home of ignorant Euclidolatry; *argal*, a German scholar has been allowed to edit, and a German firm to publish, the best and only critical text of Euclid's works. Our ancient universities maintain compulsory Greek; *argal*, Dr. Heath has thought it necessary to undertake, in addition to his commentary, an English translation of the text. Accepting these facts as part of the eternal fitness of things, those who can beg, borrow, or buy these three handsome volumes will be able to learn the actual contents of the "Elements," the history of their propagation and influence on mathematical study, and their relation to Greek science and philosophy in general. Dr. Heath has been so long a devoted student of Greek geometry that he is able to give his readers a very good idea of its developments and peculiar limitations; his commentary seems to cover every point of real interest, and he has rightly given, by way of comparison, some account of the modern theory of irrationals.

Naturally, the definitions and postulates receive a good deal of attention. The definition of a straight line is translated "a straight line is a line which lies evenly with the points on itself," and the same rendering of ἐξ ἴσου is given in the definition of a plane. Readers of the notes on these definitions will probably agree with the editor that ἐξ ἴσου, thus applied, was an obscure phrase even to a Greek, and that it was meant to refer to what we may call the indifferent distribution of points and lines on a line and a plane respectively. At any rate, Proclus's explanation is clearly wrong, though it very likely contains the substance of what a teacher would often say in commenting on Euclid's text.

Another very interesting note is that on the Greek notion of "angle." As this included curvilinear angles, it led to a variety of discussions and some paradoxes; for example, taking a semicircle AMB and a tangent BT at one end of the diameter AB, it was argued that the angle at B between the circle and diameter is less than the rectilineal angle ABT, because BT is outside the circle, while, on the other hand, any acute rectilineal angle can be proved less than the curvilinear angle in question. However (p. 176, bottom), there is some evidence of a way of looking at angles such as we should now express in terms of the differential calculus.

To the famous postulate 5 (generally referred to as the 11th axiom) eighteen pages are devoted. Here it must suffice to say that sufficient references are given to the principal authorities on the theory of parallels and non-Euclidean geometry, and that attention is properly directed to the work of the Jesuit Saccheri.

The books least familiar to students are, of course, the arithmetical books (vii.–ix.) and Book x. With regard to the former, Dr. Heath has given diagrams consisting of straight lines, just like those in Book v.; this is rather misleading, and it would surely have been better to give rows of dots, or, at any rate, graduated straight lines to the same scale. In this part of the work, Dr. Heath gives algebraical paraphrases of the less obvious propositions; these will be found very helpful to those not familiar with Greek methods of reasoning.

As De Morgan said long ago, the most remarkable (and in some ways most characteristically Greek) book of the "Elements" is the tenth. If we turn its propositions into algebra, we find that they contain an exhaustive classification of a certain set of irrationals (or irrational ratios), all, of course, constructible from a given line by means of rule and compass. Dr. Heath, in his introductory note, gives the irrationals in question in an algebraic form, which is perhaps the best suited for comparison with the propositions, but hardly so neat as De Morgan's in his article ("Penny Cyclopædia") on "Irrational Quantities," which is still worth careful reading.

It should be mentioned that there is an appendix containing the spurious Book xiv. (by Hypsicles), and a note on the so-called Book xv., two elaborate indexes, and a beautiful facsimile of a page of the Bodleian MS. D'Orville 301.

Those who are really interested in Greek geometry will be deeply grateful to Dr. Heath for putting together, in such an attractive form, such a large amount of historical information, and thus saving students from an immense amount of toilsome research. Finally, the excellence of the diagrams, especially in Book xiii., should not be overlooked.

G. B. M.

HYPNOTISM AND OCCULTISM.

Hynotism, including a Study of the Chief Points of Psycho-therapeutics and Occultism. By Dr. Albert Moll. Translated from the fourth enlarged edition by A. F. Hopkirk. Pp. xvi+610. (London and Felling-on-Tyne: The Walter Scott Publishing Co., 1909.) Price 6s.

THIS book is a translation from the fourth edition of the original work. The author presents his readers with a survey of all that is most important in the whole province of hypnotism, and indeed has left little unsaid which could be of any value. An opening chapter on the history of hypnotism indicates the gradual progress of the science from the stage in which it was almost hopelessly mixed up with superstitious quackery, through periods of utter neglect on the part of the scientific world, to the era, which is even now only dawning, in which the subject is submitted to the strictest critical examination of physiologists and psychologists. The literature that has grown up round the subject is enormous, and its volume almost daily increases.

Dr. Moll's work is not one which is likely to appeal to the general reader, and, indeed, we are of opinion that this is one of its greatest merits. In this country hypnotism has too long been a subject in which a certain class of mind has taken an interest alternatively to spiritualism, "Christian Science," or other occult system of the day. To such, a carefully attentive and balanced criticism is positively repellent, and it is, unfortunately, in this class that hypnotism has hitherto had its vogue. Dr. Moll deals in very considerable detail with the symptoms of hypnosis. Indeed, by far the longest chapter of his book is devoted to a minute account of the psychological, physiological and even anatomical changes which may be noted during, or as a result of, hypnosis. The various explanations which have from time to time been put forward as to the hypnotic state are subjected to searching analysis, and the confident assertions of many of them are shown to have no foundation. What we know about mental processes is confined to a few concomitant phenomena, while the real nature of such processes appears for ever debarred us, and to our author the endeavours of some investigators to explain mental processes by means of our present knowledge of the central nervous system indicate a disquieting tendency to overestimate the gifts of physiology. It is, at any rate, plain that authorities take up diametrically opposite sides in their hypotheses as to the nature of the hypnotic phenomena.

The medical and legal aspects of hypnotism are dealt with at much length, and an important conclusion that emerges from the consideration of hypnotism from these points of view is that its practice should be confined to those who are properly trained in the diagnosis of the affections which it is sought to treat. To hypnotise those who should not be hypnotised, and to seek to cure disease which is not amenable to such treatment, is to bring hypnotism into disrepute and to wrong the sufferer. Dr. Moll winds up his work with a chapter upon occultism, not because there is any internal affinity between hypnotism and occultism, but because the two subjects are often mentioned together, a connection determined by their historic development. We wish that all enthusiastic investigators of the occult could be induced to peruse this part of the book. With a candid admission of the depth of our ignorance, our author asserts that we have no right flatly to refuse to recognise any domain of research. Yet if the conditions of research into the phenomena of occultism be severe, and if none of the assertions of occultists be accepted without proof, there is, according to Dr. Moll, no single series of experiments that carries with it a convincing proof of the reality of occultistic phenomena. We can warmly recommend this work to our readers as a thorough exposition of an abstruse subject.

ELECTRO-TECHNICS.

Einführung in die Elektrotechnik. By Dr. C. Heinke. Pp. xviii+501. (Leipzig: S. Hirzel, 1909.) Price 13 marks.

AT a first glance this seems a very interesting book, but a closer study of its pages produces a feeling of mental fatigue, not to say impatience; and this is probably due to the fact that many obvious points are set out at great length whilst really important or difficult matters are passed over with tantalising brevity. Thus the author gives us many pages on the calculation of the current in a circuit containing inductance and resistance, or capacity and resistance, but the subject of single-phase commutator motors is dismissed in exactly two and one-third pages.

After a long-winded introduction, in which the author develops his ideas as to what should be taught at a technical high school and what constitutes the real difference between the mere technical man and the scientific engineer, we find a chapter which a less pedantic writer would have simply headed "mechanical analogies," but which bears the title "Conceptions of a Mechanical Nature to facilitate the Mental Connection between all Basic Electromagnetic Phenomena." The fifty-odd pages in which the author develops his analogies are very interesting, but they can only be read with advantage by persons who are already well acquainted with the subject. A beginner will find the analogy more difficult to understand than the electrical phenomenon itself.

Next follows a chapter entitled "Pressure Producers" (German Spannungserzeuger), and in this we find the old-fashioned frictional machine (but not the Wimshurst), Armstrong's experiment, primary batteries, thermopiles, and the dynamic generation of E.M.F. discussed. The latter leads to the following chapter, on "The Technical Production of Electrical Energy." This occupies some 200 pages, and contains a most bewildering collection of all possible things either directly or very remotely connected with dynamos. A few titles of the matters treated will suffice to show how varied is the character of the subjects collected under this head:—mechanical details of armature; commutator and field system; characteristics; interpoles; the Thury system as applied to the Moutiers-Lyon installation; relay for field regulation; mechanical analogy of alternating currents; a number of obsolete alternators; some modern alternators; form factor; oscillograms; vector diagrams; currents in branch circuits; resonance; stationary waves in the antenna of a wireless station; the Slaby-Arco-Braun system of wireless; Dobrovolsky's balancing transformer for three-wire system; electric bells; Rhumkorff interrupter; Wehnelt interrupter; selenium cell; buzzer; maximum cut-out; high-frequency arc; wireless telephony; power of electric currents.

The fifth chapter deals with the application of electricity, and here we get also a great variety, such as Geissler tubes, lifting magnets, bells, telephones, transformers, motors, the Kjellin furnace, a catalogue picture of a chain-welding machine, glow lamps, arc lamps, secondary batteries, a load diagram of a central station, switchboard diagrams for D.C. and A.C. stations. The final chapters deal with measuring instruments, cables and overhead lines, switches, and accessory apparatus. The grouping of all these different matters as adopted by the author may be logically right, but it is not convenient for the reader; it is also irritating to find a page or so of elementary mathematical treatment interleaved between catalogue pictures of some firm's apparatus, whilst the important features of the thing illustrated are hardly mentioned. The book has interesting parts, but to find them the reader must know a good deal of the subject; and even then the search will be rather troublesome, as there is no index.

GISBERT KAPP.

OUR BOOK SHELF.

(1) *Leitfaden der Tierkunde für höhere Lehranstalten.* By Dr. K. Smalian. IV. and V. Teilen. (Leipzig: G. Freytag, 1909.) Price 1.80 marks each.

(2) *Naturwissenschaftliches Unterrichtswerk für höhere Mädchenschulen.* By Dr. K. Smalian and K. Bernan. I. Teil. Pp. 50; illustrated. (Leipzig: G. Freytag, 1909.) Price 1.20 marks.

(1) WITH the two parts referred to under the title of the work first quoted, Dr. Smalian brings to a conclusion his "Leitfaden," of which the earlier parts have been already noticed in NATURE. The fourth part, which is devoted to the Arthropoda, is stated to be for lower third form teaching (Lehrstoff der Untertertia), while the fifth part, dealing with the other invertebrates, is intended for upper third form instruction (Lehrstoff der Obertertia). Whether the parts intended for the higher forms are considered to comprise more difficult zoology than those for the lower grades is not very easy to decide. As regards style of treatment, the two parts before us seem to follow very much the lines of their predecessors, and contain a vast store of information, conveyed in a very condensed and concise manner, this technicality of the text being in some degree relieved by the coloured plates, the subjects of which are well selected, and illustrate the life-history of a number of species.

(2) This text-book has been written by the authors in accordance with the requirements of a new scheme of instruction authorised for higher grade girls' schools in Prussia, and in order to conform exactly

with these regulations Dr. Smalian has enlisted the services of a teacher in one of these schools at Halle. The first half of the part before us is devoted to the elements of botany, and the second to the rudiments of zoology, as exemplified by mammals and birds, the plan being to describe one particular species of plant and animal in considerable detail, and then to discuss some of its relatives. The illustrations, coloured and otherwise, are, if we mistake not, the same as those used in the "Leitfaden," although in certain instances reduced in size. This part is intended for the instruction of the seventh class (Lehrstoff der vii Klasse), so that in this case also the various sections of the work are to be read in consecutive order by the different classes. Both textbooks appear well suited for their respective purposes.

Die Photographie. By W. Zimmermann. Pp. iv+104. (Leipzig: Quelle und Meyer, n.d.) Price 1.80 marks.

In twenty-three short chapters and an introduction the author has provided a general guide for beginners in photography similar to the numerous small guides that we have in English, but differing from them in being more fundamental and less detailed in the matter of manipulation and precautions. The difference may be due to the more general diffusion of elementary scientific knowledge in Germany than in this country. Formulæ for the preparation of various printing papers and plates are given, as well as instructions for their use, so that the volume is in no sense a mere collection of instructions for the manipulation of commercial products. This being as it is and the volume so small, it is interesting to note the selection that the author makes from the innumerable alternatives now available. The formulæ for developers are in the following order:—Ferrous oxalate, pyro-soda, pyrocatechin, pyrocatechin without sulphite, hydroquinone, and metol-hydroquinone.

In a chapter on "the chemical action of light and development" the ionic theory is employed, a commendable procedure if those for whom the book is written may be presumed to understand it. But the author evidently has his doubts, for he sets forth in detail the chief fundamental facts upon which the theory rests. In this case it appears to us that so far as the very little chemistry introduced is concerned, the explanations would have been more simple and still sufficient if the facts had been dealt with on the older plan, without reference to electric charges and their migrations. We notice a few old-fashioned errors with regard to actual products of certain chemical changes, but on the whole the text is trustworthy, interesting, clear, and very concise, and the illustrations are apt.

Science in Modern Life. Edited by Prof. J. R. Ainsworth Davis. Vol. iii. Pp. ix+187. (London: The Gresham Publishing Co., 1909.) Price 6s. net.

The two earlier volumes of this work—which is to be completed in six volumes—were noticed in Nature of March 4 (vol. lxxx., p. 1). The intention of the work is to give a broad outline of the principles of science and their relations to human progress and industry. The various departments of natural knowledge are surveyed by eleven different authors, each of whom is well qualified to deal with his particular subject. The present volume is devoted chiefly to light, sound, magnetism, electricity, and other branches of physics not dealt with in the second volume; and, in addition, about seventy pages are given to general biology and botany.

Mr. J. H. Shaxby's treatment of physics seems to us to be appropriate to the design of the work and calculated to create and foster interest in the subject. Attention is given to the studies of recent years, such as radiation pressure, radio-activity, Hertzian waves, and wireless telephony, and the style of description is both readable and attractive. Dr. H. J. Fleure deals with the difficult subject of the cell and nuclear division, and gives a general survey of simple forms of life. Neither this section, however, nor that by Mr. J. M. F. Drummond on botany which follows it, will be intelligible without preliminary knowledge of the subject, and will not appeal, therefore, to general readers.

A work on various subjects, written by several authors, is rarely uniform in character and scope, and the present series of volumes is no exception to the rule. In spite of this fact, we are glad to express the hope that the work will be the means of bringing problems and advances of modern science under the notice of a wide circle of readers.

The Central Nervous System of Vertebrates. By J. B. Johnston. Pp. 170. (Jena: G. Fischer, 1909.)

This interesting monograph appears in Dr. J. W. Spengel's "Ergebnisse und Fortschritte der Zoologie." It gives an excellent account of the structure and mechanism of the central nervous system founded on morphological and physiological facts, as these have been laboriously collected by the most modern methods by which the nervous elements have been examined. The author deals with the plan of reflex mechanisms, he describes the architecture and localisation of the central ganglia and nerve-roots, and his illustrations are drawn from morphological studies of the simpler types. One of the most important sections is No. vii., in which he discusses the functions of the great divisions of the nervous system. Nowhere have we seen a better discussion of the relations and functions of the cerebellum, or a more lucid account of the remarkable deep connections of the auditory nerves. The author has evidently received illumination from the researches and constructive criticism of Sherrington, while, as indicated by a good bibliography, he is acquainted with the literature of this vast subject. The work is a valuable contribution to human and comparative neurology.

John G. McKendrick.

Vorlesungen über technische Mechanik. By Dr. August Föppl. Vierter Band, Dynamik. Dritte, stark veränderte Auflage. Pp. viii+422. (Leipzig: B. G. Teubner, 1909.) Price 10 marks.

In this volume the vector equation of mass acceleration commonly known as Newton's laws is applied to the "law of areas," the problems of harmonic and oscillatory motion, the brachistochrone, motion of a rigid body, motion under no forces and motion of a top, vibrations of elastic bodies and equations of motion of hydrodynamics. The use of vector equations throughout and differences of notation and terminology make the treatment a little difficult for an English reader to follow; but it is clear that the author has fully realised the subject of his book to be *dynamics*, not the integration of differential equations. If exceptions exist, the most noticeable one is in the sections dealing with cycloidal motion, the whole problem of which can be solved, almost without writing down a single equation, by showing the geometric properties of the cycloid in a diagram where the author employs many formulæ. Among practical illustrations we notice the reference to Schlick's balancing of marine engines, while the reference to the Kegelbahn or skittle-ground takes our thoughts back to the Fatherland, with its pleasant afternoons spent in admiring the view, drinking beer, and listening to the heavy roll of the balls.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Beliefs and Customs of the Australian Aborigines.

IN May of last year (1908) I had the good fortune to meet the Bishop of North Queensland (Dr. Frodsham) at Liverpool, and he gave me in conversation some valuable information as to the native Australian beliefs and customs based on his personal knowledge of the aborigines. He told me that he had travelled among the Arunta as well as among various North Queensland tribes, and he asked me whether I was aware that the Australian aborigines do not believe children to be the fruit of the intercourse of the sexes. His Lordship informed me that this incredulity is not limited to the Arunta, but is shared by all the North Queensland tribes with which he is acquainted, and he added that it forms a fact which has to be reckoned with in the introduction of a higher standard of sexual morality among the aborigines, for they do not naturally accept the true explanation of conception and childbirth even after their admission into mission stations. The Bishop also referred to a form of communal or group marriage which he believes to be practised among aboriginal tribes he has visited on the western side of the Gulf of Carpentaria, but, unfortunately, I had not time to obtain particulars from him on this subject.

I pointed out to his Lordship the high scientific importance of the information which he had volunteered to me, and I requested that he would publish it in his own name. He assented; but as some time has passed without his finding leisure to draw up a full account, he has kindly authorised me to publish this brief statement, which has been submitted to him and approved by him as correct. I need not indicate to anthropologists the great interest and value of the Bishop's testimony as independently confirming and extending the observations of Messrs. Spencer and Gillen on the tribes of Central Australia. In the interest of science it is much to be desired that the Bishop, or those of his clergy who know the natives, would publish fuller information on these topics. J. G. FRAZER.

Cambridge, August 23.

A Question of Percentages.

IN NATURE of August 5 (p. 159) Mr. Cunningham asked a question as to the proper method of arriving at the mean percentage of marks obtained on papers of different values in an examination, and this has been very clearly answered by Mr. Whalley. The same question, however, arises in experimental work, particularly in agricultural and horticultural experiments, and there the answer is by no means so evident. An examiner may be supposed to have sufficient knowledge to weight his papers properly, but in an experiment no data may be available for the purpose.

Take a case where three sets of different varieties of trees are subjected to some particular treatment, and compared with three similar sets not so treated, and suppose, as an exaggerated example, that the actual measurements, say, of growth, are as follows:—

	Treated	Untreated	Diff. per cent. A	Diff. per cent. B
I.	240	120	+100	+100
II.	60	50	+ 20	+ 20
III.	4	8	− 50	−100
Sum	304	178	—	—
Mean diff.	+71	—	+ 23	+ 7

If the numbers of trees in the various sets are not the same, the results may, of course, be easily weighted to correct for this; but there are other differences for which they cannot be weighted, namely, those dependent of the differences in nature of the different varieties and of attendant circumstances beyond the control of the experimenter. The mean deduced from working each result out separately (+23) ignores all such differences, and is clearly incorrect; but that deduced from the sums of the measurements (+71) is equally so, for it ignores the difference in habit of the different varieties, and gives undue weight to the results from that variety which happens to be the most rampant grower. This difficulty has been alluded to more than once in the reports of the Woburn Experimental Fruit Farm, and the only way out of it appears to be to take the mean of the means deduced in these two ways; at any rate, it is rarely safe to draw any conclusions as to the results of experiments unless these two means agree fairly with each other.

Similar difficulties arise in interpreting the results of other experiments; with a number of analyses, for instance, in which different quantities of material were taken, the mean of the individual results assumes that none of the errors is proportional to the quantities taken, whereas a mean deduced from the sum of the quantities taken and found assumes that all the errors are directly proportional to these quantities, neither of which assumptions is correct, as a rule.

Another source of error in horticultural experiments is that the differences observed are not unfrequently of different signs, and since a *plus* difference of 50 per cent. has a very different value from a *minus* difference of 50 per cent., the algebraic sum of such differences is fallacious. This is evident from the values given above for I. and III., in which the proportions are exactly reversed, but which figure under A as differences of +100 and −50 respectively. A more correct way of calculating such differences is to take the lowest (or highest) value in each pair of plots as the standard of comparison, instead of the value in the check plot, and to affix a + or − sign to the difference, according to whether the plot under treatment has given a larger or smaller value than the untreated plot. Such differences are given under B, and correctly represent the ratios of the experimental measurements. It would be well if such a method of calculating percentage differences could receive some special designation, so that it might become recognised, for without this its use is likely to lead to misunderstanding.

SPENCER PICKERING.

The Planar Arrangement of the Planetary System.

IN your issue of July 29 your reviewer devotes some space to my paper on the origin of the planetary system (*Astronomische Nachrichten*, No. 4308), and closes by asking, "Why, for instance, on the hypothesis of capture, are the vast majority of the orbits near the plane of the ecliptic and their motion direct?" This is because our system was formed by the unsymmetrical meeting of two streams of nebulosity or by the mere gravitational settling of a single nebula of curved and unsymmetrical figure, giving a rotating cosmical vortex, or spiral nebula, but without hydrostatic pressure as imagined by Laplace. In Lick Observatory Publications, vol. viii., Plate 38, you will find an illustration of H.V. 2 Virginis, a spiral nebula of unsymmetrical figure just beginning to coil up and form a system. What will happen in the later stages of this nebula is sufficiently shown in the Lick photographs of other nebulæ given in this volume. As the mass whirls and condenses under resistance, it will necessarily retain and draw down most of the nebulosity into the plane of motion. This is exactly what has given the planar arrangement of the bodies in the solar system. In *Astronomische Nachrichten*, Nos. 4341–2, your reviewer will find a fuller explanation of the method of capture, and other papers yet to come will make the theory so clear that it need not take up more of your valuable space at present. T. J. J. SEE.

Naval Observatory, Mare Island, Cal., August 12.

The Benham Top.

MY attention has been directed to a paper in the Transactions of the Ophthalmological Society, by Mr. A. S. Taylor, entitled "Colour Phenomena due to Intermittent Stimulation with Light: Note on the Colours of Benham's Top."

It is to the conclusions in the latter part of the paper that I desire to refer, as last year, in a paper before the Physical Society (see NATURE, June 18, 1908, p. 166), I endeavoured to explain this phenomenon in a somewhat different way. The main conclusion in both theories is the same, but Mr. Taylor explains the necessary thinness of the lines as due to irradiation, whereas it appears to me to be a contrast effect. The weak illumination of the disc does not seem to warrant an assumption of irradiation.

Stewart's curves for colour vision and Burch's work on "Artificial Temporary Colour Blindness" show that the colour sensations have different rates of growth and decay. When this difference has been admitted, it is easy to explain the colours of the Benham top by the sequence of white and black divisions on the disc, the thinness of the lines being necessary to reinforce by a contrast the weak colour effect.

F. PEAKE SEXTON.

Hampton Wick.

MAN AND ANIMALS.[1]

THIS volume, of which some chapters have already appeared in the *Contemporary Review*, will be eagerly read and studied by all interested in animal psychology and the treatment of the inferior animals by man. For, mixed up with a large amount of perhaps somewhat irrelevant matter relating to the history of religions, the author has collected a vast store of information relating to the estimation or otherwise in which animals have been held by the ancient nations from Egyptian, Bhuddistic, and Græco-Roman times to the Middle Ages; while the concluding chapter deals with modern ideas on the subject.

The objects, origin, and conception of sacrifice are each treated at considerable length, while folk-lore has been largely drawn upon to illustrate the subject from all points of view. Among numerous other instances of the wide origin of such legends, we may refer to the author's account of how the Welsh story of the wolf-hound Gellert, is paralleled in other countries. The Countess appears to be a firm believer in the doctrine that the intelligence of the lower animals differs only in degree from that of their masters; and the theory that any animals are mere automatons is persistently scouted. Moreover, if we read between the lines, the author appears to be convinced that animals have souls, and are therefore immortal, although we do not find this stated in so many words. That this was the idea of the Jews in biblical times the author considers to be proved by the doctrine that "the blood is the life." If this idea of animal immortality be true, no thoughtful person can read the volume without serious misgivings and heart-searchings.

Throughout, the book is written in an attractive style, and we have read it from preface to index with real pleasure. The attractive style of the text is rendered the more interesting by the numerous excellent plates with which the volume is illustrated. Some of these do not appear, however, to be referred to in the text; and it is a pity that the author did not consult a naturalist before deciding on their titles. We find, for instance, the plate facing p. 108 (herewith reproduced), taken from an Assyrian relief in the British Museum, lettered "wild goats and young"; while in the illustration facing p. 116 we have another Assyrian sculpture, representing a god carrying a horned animal, apparently furnished with a beard, which is designated an "antelope." That the animals in the first figure are not wild goats is evident from the character of the horns of the males, the lack of a beard in that sex, and the absence of both these appendages in the females; and we have a strong suspicion that they really represent one of the larger African gazelles, such as the addra.

Assyrian Relief in the British Museum showing a troop of (?) Gazelles. From the "Place of Animals in Human Thought," where the animals are termed "wild goats."

The work, moreover, sadly wanted revision by a well-educated proof-reader. "Worser," which occurs at least twice, is not English; neither is "Quartenary," also occurring twice, correct orthography; the latter remark also applying to "camel-leopard" (p. 345). A mungoose, moreover, is not a member of the weasel tribe (p. 308), neither is it correct to term a wolf a vulpine animal. If such blemishes occurred in many books we could mention, we should pass them over without notice; the pity of it is that they mar the pages of such a thoroughly interesting volume as the one of which we now take leave.

[1] "The Place of Animals in Human Thought." By the Countess Evelyn Martinengo Cesaresco. Pp. 376; illustrated. (London: T. Fisher Unwin, 1909.) Price 12s. 6d. net.

STYLES OF THE CALENDAR.

FEW subjects are more full of pitfalls than that of the change of style and consequent alteration of dates, which therefore requires great care in its consideration. Many articles have appeared from time to time in *Notes and Queries*, and I would refer to two of my own in 9th S., vol. v., pp. 344, 461. Here I need only say that the dates given in Whitaker are correct, though it seems to me it would be better to call May 14 May Day by Julian style instead of old May Day. It is difficult always to remember that no alteration was made in the difference between the two styles in 1600, but was in 1700, 1800, and 1900. None will be made in 2000. There was an old saying about St. Barnabas's Day :—

> "Barnaby, Barnaby, Barnaby bright,
> The longest day and the shortest night."

Saints' days, &c., being kept on the same nominal day, June 11 was still St. Barnabas's Day, though what was that day in the old calendar became June 21 from 1582 to 1700, then June 22 from 1701 to 1800, June 23 from 1801 to 1900, and now June 24. But the saint's day remaining June 11, the above distich ceased to apply. George III.'s birth was announced as on May 24, but when the style was changed in 1752, his birthday became June 4, and was kept on that date during his reign. When Gregory XIII. altered the style in 1582, the count of days was changed by ten; when England adopted it in 1752 we had to change the days by eleven; in 1801 this became twelve, and in 1901 thirteen, so that we differ now from Russia and the Greek Church by that number in our dates.

The question of an alteration is again being discussed, and uniformity is so desirable that we hope Gregorian usage will be adopted, though it is not ideally perfect, and a better rule would have been to drop a leap-year at the end of each period of 128 years.[1] The late Prof. Newcomb thought that the alteration of the style was a mistake, on the ground that there was no particular object in keeping the same dates at the same seasons over very long intervals of time, and the hiatus made by the omission of days caused, as it was bound to do, great confusion. It is not always recollected that the reason why a change was so long advocated in the western Church, and at last carried out, was the supposed necessity of regulating Easter by the full moon following the vernal equinox, which was supposed to fall on March 21 at the time of the Council of Nicæa, A.D. 325, and really did so in the preceding century. To that epoch, then, everything was referred; otherwise it would have been more natural to have started when the alteration was made by which the mean calendar year was made nearly of the true length of the tropical year.

From 1500 to 1700 May Day was kept in England on the day corresponding by the season to what we should now call May 11; after 1700, until the alteration of the style in 1752, on what would be May 12 by the new reckoning. At that time, then, the dancing round the May-pole, so popular in this country, took place at nearly what is now the middle of the month. It is of interest to remember that the great May-pole in the Strand was removed, in 1717, at the instance of Sir Isaac Newton, to Wanstead, to support the Huyghens telescope of great focal length, which had been lent to Pound (the uncle of Bradley, afterwards Astronomer Royal), who made excellent use of it.

Christmas Day, of course, and all holy and saints' days, fell, after the alteration of the calendar, several days later, according to the season; ten days when Gregory XIII. decreed the change in 1582, and eleven when it was adopted in England in 1752. After 1900 the difference between the two styles became thirteen days, and old Christmas Day is marked in Whitaker and other almanacs on January 7. New Year's Day fell seven days afterwards, on the day we now call January 14; that is not marked in Whitaker, but the Russians and the Orientals generally keep it on that day, thirteen days after ours.

It is, of course, necessary to be very careful in comparing historic events (whether astronomical or otherwise) between 1582 and 1752, English dates being given in old style, and many (not all) of the Continental dates in new style.

It has been suggested to me that the following tables will be useful for reference in calendar questions.

The Gregorian calendar was arranged to start from the date of the Council of Nicæa in A.D. 325, so that the vernal equinox should henceforth be made to fall on March 21, as it was supposed to do then. Table I. gives the dates when the equinoxes and the solstices fell by the Julian style from A.D. 200 to the present century. Table II. gives the dates in Gregorian reckoning of the first day of May and the last day of October (All Hallows' Eve) for the same centuries.

TABLE I.

It will be noticed that, in the first table, as the exact times of the equinoxes and solstices vary in different years (according to the distance from leap-year), and also their local times vary in different places, the dates are for the mean, and usually apply to Europe.

AFRICAN ENTOMOLOGICAL RESEARCH COMMITTEE.

THE subjoined official announcement of the appointment of an African Entomological Research Committee will be received with much satisfaction in all quarters where the importance of a scientific basis for administrative and other official action is duly recognised. Among the advances of biological science in the last few years, none has been more remarkable than the discovery that the cause of many diseases, the nature and origin of which had hitherto escaped detection, was to be sought in the presence of parasitic micro-organisms of various kinds and qualities in the tissues of animals and plants. The part played by insects and ticks in the dissemination of these morbific parasites is now known to be of immense importance, and great efforts have already been made, not without success, to restrict the occurrence of malarial and other disorders by the systematic destruction of the insect-carriers of the organisms concerned. For this purpose it is essential to distinguish with accuracy between various closely allied species; and it is here that the work of the skilled entomologist proves its necessity. It was well remarked by Mr. A. E. Shipley, in his recent presidential address at Winnipeg to the Zoological Section of the British Association, that "a few years ago no knowledge could seem so useless to the practical man, no research more futile than that which sought to distinguish between one species of a gnat or tick and another; yet to-day they knew that that knowledge had rendered it possible to open up Africa and to cut the Panama Canal." This witness is true; and it would be difficult to point to a more complete demonstration of the fact that natural knowledge pursued for its own sake, without any direct view to future utility, will often lead to results of the most unexpected kind, and of the very highest practical importance. It is this that justifies the demand that both governments and such private individuals as have the means should do all in their power to encourage the study and pursuit of science as science, without waiting for such applications as may prove to be of commercial or political value.

When the benefits to be derived from the scientific treatment of a subject are so manifest as in the present case, even the most indifferent of public bodies can hardly afford to stand aloof; and it is to be hoped that the activity of the Colonial Office in this direction, begun under the auspices of Mr. Chamberlain, and culminating for the present in the recent action of Lord Crewe, may be taken as an indication that the Government of this country is becoming increasingly alive to the desirability of securing the cooperation of scientific authorities in administrative measures. But beyond this, the movement will deserve a still greater welcome if it helps to emphasise the importance of encouraging the pursuit of genuine science, even when no immediate prospect is offered of material results.

F. A. D.

In view of the intimate relation which is recognised as existing between certain insects and the propagation of diseases of both man and animals in tropical Africa, and of the similar relation between insects and economic plants, which is becoming more evident as settlement in the continent progresses, Lord Crewe has appointed a Scientific Committee, the object of which will be to further the study of economic entomology with special reference to Africa.

This body will be known as the African Entomological Research Committee, and Lord Cromer has consented to act as chairman. The other members of the committee are:—Lieut.-Colonel A. W. Alcock, C.I.E., F.R.S., Mr. E. E. Austen, Dr. A. G. Bagshawe, Dr. J. Rose Bradford, F.R.S., Colonel Sir David Bruce, C.B., F.R.S., Dr. S. F. Harmer, F.R.S., Dr. R. Stewart MacDougall, Sir John Macfadyean, Sir Patrick Manson, K.C.M.G., F.R.S., Mr. R. Newstead, Prof. G. F. Nuttall, F.R.S., Prof. E. B. Poulton, F.R.S., Lieut.-Colonel D. Prain, C.I.E., F.R.S., Mr. H. J. Read, C.M.G., the Hon. N. C. Rothschild, Dr. D. Sharp, F.R.S., Dr. A. E. Shipley, F.R.S., Mr. S. Stockman, Mr. F. V. Theobald, and Mr. C. Warburton. Mr. A. C. C. Parkinson, of the Colonial Office, is acting as secretary to the committee, and Mr. Guy A. K. Marshall as scientific secretary.

Arrangements are being made to despatch a trained entomologist to the east side of tropical Africa and another to the west, for the purpose of stimulating official and other residents to collect and observe noxious insects, and of affording instruction in the use of scientific methods. By this means it is hoped to obtain throughout these territories an organised body of investigators who will communicate all their collections and observations to the committee. These collections will be classified by a number of British and in some instances Continental entomologists, and named specimens will be distributed to such institutions as may require them for purposes of instruction, both at home and in Africa. The committee will also keep in touch with the work which is being done in this branch of science in Egypt and the Sudan and in South Africa. The scientific results, including all observations and experiments made by the collectors, will be published from time to time in a journal or bulletin to be issued by the committee.

It is hoped that by such organised cooperation the knowledge of these matters will be materially increased, so as to render possible the application of effective remedial measures. Offers of cordial assistance have been received from such institutions as the British Museum (Natural History), the London and Liverpool Schools of Tropical Medicine, and the leading universities, in all of which valuable work has already been done in the same direction.

THE BRITISH ASSOCIATION AT WINNIPEG.

THE Winnipeg meeting of the British Association has been a complete success. Hundreds of citizens of Winnipeg, together with representatives of science in Canada, the United States, and Great Britain, filled the Walker Theatre when the presidential address was delivered by Sir Joseph Thomson on August 25. Mr. Francis Darwin, the retiring president, was unable to be present, but he sent a letter, which was read by Prof. Carey Foster, expressing the hope that the meeting would be worthy of its distinguished president. The addresses of presidents of sections were delivered on August 26 and 27, and we are able to print two of them this week, with a summary of the lecture delivered by Dr. A. E. H. Tutton on the former date. We have been forced, however, to omit parts of Prof. Armstrong's long address to the chemical section in order to find space this week for Dr. Smith Woodward's address to the section of geology.

The *Times* correspondent at Winnipeg reports that the proposal to create a separate section of agriculture, which at present is a subsection of botany, has been rejected. On Saturday, August 29, there were various excursions to places of interest. Nearly a hundred members visited Portage la Prairie, and were conveyed in motor-cars through the wheatfields, the trip covering a distance of thirty miles. The visitors were thus given the opportunity of seeing one of the finest wheat areas in the province, and of studying modern methods of garnering the harvest. The botanical section visited Winnipeg Beach, while the members of the engineering section inspected St. Andrew's lock, now being built by the Dominion Government in order to furnish uninterrupted navigation, *via* Red River, between Winnipeg and the lake bearing the same name. In Winnipeg itself a reception was given by Lord Strathcona at his former residence at Silver Heights, and was attended by about fifteen hundred people.

The *Times* also reports that one of the tangible results of the meeting of the Association in Canada has been the purchase by Dr. Gray, the Warden of Bradfield College, Berks, and president of the section of educational science, of a ranch of 2000 acres near Calgary. A competent Canadian has been appointed superintendent, and it is Dr. Gray's intention to afford an opportunity to Bradfield boys, on the completion of their school course, to acquire practical knowledge of the farming and ranching conditions of Alberta.

Dr. T. G. Bonney, F.R.S., will be president of the Association for the meeting to be held at Sheffield next year from August 31 to September 7.

SECTION B.

CHEMISTRY.

OPENING ADDRESS (ABRIDGED) BY PROF. H. E. ARMSTRONG, PH.D., LL.D., F.R.S., PRESIDENT OF THE SECTION.

AFTER an interval only a year short of a quarter of a century, it is my privilege again to occupy the chair of this section, and that, too, under conditions of special significance. The British Association has never before sought to carry the banner of science so far west into British Dominions—never before was it so clear that the progress of humanity is linked with the progress of science by an indissoluble bond: science defined in a word being *knowledge*, not mere work nor mere lip knowledge, but systematised established knowledge, not assumed knowledge —although hypothesis often serves to guide inquiry and truth is arrived at only gradually and slowly by a series of rough approximations. Moreover, science is true knowledge *of every kind*—there is too often a tendency to give a narrow interpretation of the word. One reason probably why the term does not produce any proper effect upon the average British ear is that it is not an English word but a mere adaptation from the Latin—a language which apparently cannot be engrafted upon our Saxon tissues, although, perhaps, it may be that we have so little feeling for it because we have been allowed to learn so little else in our higher schools; monotony of diet ever favours diminutive growth. Germans, I always feel, enjoy a great advantage over us in possessing the popular word *Wissenschaft*—in calling science the *business of knowing*, the *business of gaining wisdom*, of *being wise*.

Naturally I am constrained on the present occasion to take stock of the position of our science, to draw a comparison between the condition of affairs chemical when we met in Aberdeen in 1885 and their present state. No like period of human history has been more fruitful of advance; at the same time, no period illustrates more clearly the difficulties that lie in the path of progress—because of the innate conservatism proper to human nature.

Before attempting to deal with any of the problems which concerned us at Aberdeen, I will first briefly pass the more salient features of advance in review. Few probably are aware how extraordinary is the command we now have of our subject. In 1885, in defending the tendency of chemists to devote themselves to the chemistry of carbon, I could speak of the great outcome of their labours as being the establishment of the doctrine of structure. Everything that has happened in the interval is in support of this contention. It is interesting that in a recent lecture[1] on the Physical Aspect of the Atomic Theory, the most prominent living exponent of physical theories has given a not unwelcome recognition of our right-mindedness in saying: "As time goes on it becomes increasingly difficult to resist the direct evidence for the simple view that, in many cases, chemical combination is not so much a fusion or intermingling of the combining atomic structures as rather an arrangement of them alongside one another under steady cohesive affinity, the properties of each being somewhat modified, though not essentially, by the attachment of the others; and that the space formulæ of chemistry have more than analogical significance." And again in the following passage, in which a far-reaching confession is made: "The aim of structural chemistry must go much deeper (than dynamical methods of treatment); and we have found it difficult, on the physical evidence, to gainsay the conclusion that the molecular architecture represented by stereo-chemical formulæ has a significance which passes beyond merely analogical representation and that our dynamical views must so far as possible be adapted to it." The remark made by Helmholtz in one of his letters, "that organic chemistry progresses steadily but in a manner which, from the physical standpoint, appears not to be quite rational," must be regarded as little more than a confession that he was out of his depth. When properly understood, nothing could be more rational and logical than the way in which our theory of structure has been gradually built up on an impregnable basis of fact, with the aid of the very simple conceptions of valency postulated by Frankland and Kekulé. Our security lies in the fact that the postulates of our theory have been tested in an almost infinite variety of cases and never found wanting; this is not to say they are applicable in all cases, but merely that whenever we are in a position to apply them we can do so without hesitation. Larmor refers to the habit of physicists of taking comfort in Helmholtz's remark; it will be well if instead they make themselves acquainted with our methods and with the results we have won, with a minimum of speculative effort, by the cultivation of an instinct or sense of feeling which experience shows to be an effective guide to action. Now that physical inquiry is largely chemical, now that physicists are regular excursionists into our territory, it is essential that our methods and our criteria should be understood by them. I make this remark advisedly, as it appears to me that of late years, while affecting almost to dictate a policy to us, physicists have taken less and less pains to make themselves acquainted with the subject-matter of chemistry, and especially with our methods of arriving at the root-conceptions of structure and of properties as conditioned by structure. It is a serious matter that chemistry should be so neglected by physicists and that the votaries of the two sciences should be brought so little into communion.

The central luminary of our system, let me insist, is the element carbon. The constancy of this element, the firmness of its affections and affinities, distinguishes it from all others. It is only when its attributes are understood that it is possible to frame any proper picture of the possibilities which lie before us, of the place of our science in the Cosmos. But, as Longfellow sings of the sea in his poem, "The Secret of the Sea," "Only those who brave its dangers comprehend its mystery"—only those who are truly conversant with the root-conceptions of organic chemistry are in a position to attempt the interpretation of the problems of our science as a whole or even to understand the framework upon which it is built up. And yet we continue to withhold the knowledge of the properties of carbon from students until a late period of their development; indeed, when I insisted recently that organic and inorganic chemistry should be taught as one subject to medical students,[1] I was told that it could not be; that the attempt had been made with disastrous consequences. I trust that ere long the futility of such an attitude will be generally realised.

It is remarkable how much our conceptions are now guided by geometrical considerations. The development by van 't Hoff of the Pasteur hypothesis of geometrical asymmetry has been attended with far-reaching consequences during the period under review, the completeness with which the fundamental properties of the carbon atom are symbolised by a regular tetrahedron being altogether astounding.

[1] The Wilde Lecture, 1908. By Prof. Larmor, Sec.R.S., Manchester Literary and Philosophical Society Memoirs.

[1] "The Reform of the Medical Curriculum" (*Science Progress*, January and April, 1907).

Our present conception is that the carbon atom has tetrahedral properties in the sense that it has four affinities which operate practically in the direction of the four radii proceeding from the centre towards the four solid angles of a regular tetrahedron.

More than analogical significance—to use Larmor's expression—must be accorded to this symbol on account of its remarkable accordance with the facts generally, whether derived from the study of asymmetric optically active substances or from observation of the activity of ring structures of various degrees of complexity. Nothing is more surprising than the completeness with which the vast array of facts included in organic chemistry may be ordered by reference to the tetrahedral model. In the future, when our civilisation is gone the way of all civilisations and strangers dig on the sites of our ruined cities for signs of our life, they will find the tetrahedron and the benzene hexagon among the mystic symbols which they have difficulty in interpreting; if, like the ancient Egyptians, we made our tombs records of our wisdom, such symbols would long since have acquired sacred significance and the public would probably have learnt to regard them with awe and to respect them as totems. Chemists might at least wear them on aprons in imitation of the Freemasons; perhaps no two other symbols have so great a significance—they reach into life itself.

It would seem that carbon has properties which are altogether special, the influence which it exercises upon other elements in depriving them of their activity is so remarkable. In their recent discussion of the relation of crystalline form to structure, in which valency is represented as a function of the volume sphere of influence exercised by an element, Barlow and Pope arrive at the remarkable conclusion that carbon is probably the only element the atom of which has a volume sphere of influence four times that of the hydrogen atom; although it combines with four atoms of hydrogen, silicon apparently has only half the volume sphere of influence of carbon. This may, in a measure, account for the very great dissimilarity in behaviour of the two elements, which is most pronounced in their oxides, the single atom of carbon all but dominating two atoms of oxygen in carbon dioxide (which is consequently gaseous), whilst the atom of silicon in silicon dioxide in no way eclipses the two atoms with which it is associated but leaves both charged with residual affinity which enables them to form complex collocations of remarkable fixity in the fire. At bottom the differences between organic and inorganic nature are to be regarded as very largely the expression of this difference. Ropes of sand are proverbially treacherous; yet without sand, if silica had been a gaseous substance, our world might have worn a strangely different aspect.[1]

The mineral world apparently owes its rigidity to the fact that the metals and certain other elements are so imperfectly capable of dominating oxygen that oxides generally polymerise with great readiness, giving rise to substances which do not even fuse easily. The organic, on the other hand, appears to be plastic by reason of the close approach to neutrality which is conditioned by association with carbon.

Nothing is more striking than the remarkable diversity of properties manifest both in the materials which at present we are content to call elements and in the compounds formed by their interaction; the range of variation met with in the case of the compounds of carbon with hydrogen and oxygen alone is almost infinite. We are almost compelled to attribute this diversity more to differences in the complexity and structure of the molecules than to differences in their material composition. The chemist, of necessity, must be a dreamer, knowing as he does that things are not as they seem to be. But this is not sufficiently remembered; indeed, students are systematically trained up in an atmosphere of pretence. The beginner is allowed to regard *elementary oxygen*, for example, as a colourless gas, which is generally harmless until things are presented to it in a more or less heated condition, whereat it takes umbrage and burns them up. He would regard elementary carbon as a soft black substance, which if smeared on the face of the white man makes him look like a nigger, were it not that he also learns that at times it is the hardest and whitest substance known; of organic chemistry, which alone can give him honest ideas of carbon, he is not allowed to hear, as I have said. The sting of awakening conscience is salved by the introduction of a long Greek word when he is told that the two substances, soot and diamond, are *allotropic* forms of the element carbon; nevertheless, he regards them both as elementary carbon. Gradually, perhaps, he awakens to a sense of the wrong that he has suffered at the hands of his teachers, as he realises that from no one substance can he gather what the properties of an element are, that after all the elementary substance is but an ideal —in other words, a mere concept. If appreciative, he then learns to think of the blandness of water, the sweetness of sugar, the sourness of vinegar, the causticity of soda, indeed every distinctive property of every known oxygen compound as more or less a property of, more or less conditioned by, the element oxygen; he is brought back, in fact, to the position from which Lavoisier started, as he realises that the oxygen *gas* which he inhales is not elementary oxygen; he can then perhaps appreciate the wonderful acumen which this greatest of chemical philosophers displayed when he wrote: "Nous avons donné à la base de la portion respirable de l'air le nom d'oxygène en le derivant de deux mots grecs ὀξύς, acide, γείνομαι, j'engendre, parce qu-en effet une des propriétés les plus générales de cette base est de former des acides en se combinant avec la plupart des substances. Nous appelerons donc gaz oxygène la reunion de cette base avec le calorique." We have allowed a century to pass without recognising the wonderfully accurate powers of prevision displayed by Lavoisier; what is worse, we have been so far led astray that instead of regarding oxygen as the characteristic and attractive elements in acids, hydrogen has been allowed to usurp the position: the extent to which the cult of the hydrogen ion now dominates the text-books is well known; in days to come, when the history of our times is written, it will be referred to as a remarkable example of chemical shortsightedness.

Names are needed for the elements which would serve to distinguish the ideal elementary substances from the forms in which they are known to us. No more appropriate name than oxygen could possibly be selected for the fundamental material; if the *gen* terminal could be applied to elementary materials generally, it would be an advantage; it would not be easy, however, if this were done, to devise an appropriate separate name applicable to the active constituent of air.[1]

[1] The solid model of silica which Barlow and Pope have constructed has very remarkable attributes, in that the oxygen atoms appear to be uniformly related and in intercommunication throughout its mass: so that a mass of silica, whatever its size, may almost be regarded as a single molecular complex. A similar view may be taken of the plastic metals such as those of the platinum group, gold, silver and copper. Whether when rendered brittle by association with small amounts of impurity these are resolved into simpler molecular complexes or whether the molecules merely become separated by substances which promote discontinuity and brittleness, it is impossible to say at present. The cause of hardness in mineral materials is, however, a question of no slight interest and importance. The property is strikingly exemplified in the diamond. It is difficult to understand the intense hardness of this material, on the assumption that the diamond is composed of paraffinoid carbon—that is to say, carbon with all its affinities satisfied. At present we appear to have no clue to the manner in which affinity acts in promoting the formation of such solids. But it is obvious that all solids are possessed of some degree of "surface affinity," as they not only grow when placed in solutions but determine the separation of solid from a solution at a degree of saturation which is often considerably below that at which the solution is actually saturated with the substance; and such surface affinity, moreover, is selective, as the determinative effect is exercised only upon the substance itself or substances isomorphous with it—although exception must be made in favour of water, which all surfaces appear to attract. Sir James Dewar's observations on the condensation of gases by charcoal at low temperatures afford most striking illustrations of surface affinity.

[1] In naming the inert gas in air, which he ultimately termed *azotic gas*, having proposed the name *azote* for the element, Lavoisier had in view as alternatives the terms *alcaligen* and *nitrogen*. As there was no proof that the element was a constituent of alkalies other than ammonia, he rejected the former name on the gronnd that it might convey too broad an impression; in course of time the latter is become the popular name, except in France, where motives of piety have prevailed; but the French practice has been justified by the universal use of the term *azo* in connection with many nitrogen derivatives.

Had Lavoisier realised that the alkalies and basic oxides generally owe their basicity to oxigen as much as acids and acidic oxides generally owe their acidity to oxygen—the one being oxygen tempered by metal, the other oxygen tempered by non-metal—as the number of basic oxides far outweighs the number of acidic oxides, he might well have chosen the name alcaligen rather than oxygen. The choice he made was a particularly happy one and striking evidence of his genius and sense of euphony—for oxygen is *par excellence* the acid-forming element and is most truly called *sour-stuff*, the stuff of which sour things are made—for whatever the properties of the

In 1885 I closed my address with a reference to the structure of the elements which implied that their behaviour was that of compound substances; the feeling that this is the case has long been general among chemists. Our present attitude towards this problem is a curious one and not altogether satisfactory—it is impossible to deny that we have somewhat lost sense of proportion, even if our methods have not savoured of the unscientific. The discovery of radium appears to have upset our balance—we have been carried away by the altogether mysterious and unprecedented behaviour of this weird and wondrous substance. But may we not ask: Is radium an element? Has it not been too generally, too hastily assumed that it is? Little as we know of it, does not its behaviour straightway outclass it as an element? Surely it does! Is not the established fact that an emanation proceeds from it, which in turn decomposes and gives rise to helium, a proof of its compound nature? Again, is the evidence of such a character as to justify us in asserting that uranium is the parent of radium? If it be such, must not uranium also disappear from the list of elements; must it not indeed be removed on the ground that it gives rise to uranium without any reference to its supposed relationship to radium?

The answers given to such questions must depend on our definition of an element. At present we seem to be without one.

The conception that the breakdown of radium is spontaneous and apart from all external impulse or control is also one which should be received with caution. There is reason to suppose that in all ordinary cases in which compounds undergo decomposition spontaneously, the decomposition is conditioned by an impurity; the effect, moreover, is usually cumulative. This is true of highly explosive substances, such as chloride of nitrogen and gun-cotton, for example. It might be supposed that something similar would happen in the case of radium—but apparently such is not the case; it is assumed that occasionally a molecule explodes spontaneously, not only without being incited thereto, but also without in any way affecting its neighbours.

The alternative explanation that radium in some way acts as a receiver, transforming energy frnm some external source to which ordinary substances fail to respond and being thereby stimulated to decompose, is at present out of favour, although perhaps more in accordance with its peculiar behaviour.[1]

The liberation of helium as a product of radio-active change is in itself a significant fact, in view of the possibility that helium may be an element of intense activity. Nothing in connection with the problem is more surprising, however, than the apparent production, in course of time, of a whole series of degradation products which differ greatly in stability—such behaviour is entirely without precedent and not at all becoming in elements.

No such remarkable and inspiring problem has ever before been offered for solution. We can only wonder at the results and admire the genius which some have displayed in interpreting them, Rutherford in particular. Yet outsiders may well hold judgment in suspense for the present: whilst it is permitted to workers to make use of hypothesis in every possible way in extending inquiry, the public are in no wise called upon to accept such hypothesis as fact.

But apart from the suggestion that elements may give rise to others spontaneously, we have been entertained of late with stories of elements being converted into others under the influence of the energy let loose by the breakdown of radium. There is reason, however, to suppose that the powers of radium may have been greatly overpainted; energy of almost any degree of intensity in the form of high-tension electricity is now at our disposal, and the effect which radium produces on living tissues, glass, &c., is of the same character as that effected by the Röntgen ray discharge, the only difference being that the effect is produced somewhat more rapidly; it is not to be imagined, therefore, that the discovery of radium has put any very novel intensity of power into our hands.

I pass to the consideration of the classification of the elements. The recognition of certain properties, the association of certain ideals with the several elements, is a necessary step in classifying the elements in accordance with Mendelejeff's great generalisation—or rather it may be said to be both involved in and an outcome of Mendelejeff's conception.

Until recently our difficulty was to understand the relationship of the metallic and the non-metallic elements; now we are confronted with another problem—that of the existence of inert "paraffinoid" elements. It is commonly assumed that these are monatomic, but the evidence on which this assumption is based is absolutely unconvincing, and would be generally admitted to be so were we in the habit of looking before we leapt to conclusions. Assuming that the elements are compounds, the formation of inert compounds does not appear to be out of place, in view of the existence of practically inert hydrocarbons. But, on the other hand, in view of the properties of nitrogen, which is one of the most active of substances in the monatomic state, although an inert gas in the diatomic condition, it may well be that the inertness of helium and the other members of the argon group is also simulated. Sir James Dewar's observations have shown that helium and charcoal have no inconsiderable affinity at the boiling point of the former, which is within five degrees of the absolute zero, the molecular heat of absorption (apart from that due to liquefaction) of helium at that temperature being apparently as high as about sixty calories. The proof he has also given that helium alone does not convey an electric discharge is also of significance since the passage of a discharge through it under ordinary conditions is an indication that it can be included with other substances in a conducting system. Such evidence as there is therefore points to the elements under discussion being different from the others only in the degree of stability of their molecules.

Of late years the difficulty of classifying the elements has been increased rather than diminished, not merely because of the discovery of the inert gases but also on account of the apparent impossibility of ordering the position of an element such as tellurium in accordance with its atomic weight. There appears to be little room left for doubt that the value cannot be far removed from that of iodine; it should be considerably lower. It may be pointed out that the accepted value of selenium is closer to that of bromine than would be expected if a relationship were maintained corresponding to that between chlorine and sulphur. It would seem that Mendelejeff's original conception of the elements as a simple series in which the properties are periodic functions of the atomic weights must be abandoned in favour of some more comprehensive scheme. From the chemist's point of view, it is impossible to abandon the guiding principle underlying the arrangement in family groups, which dates back to Dumas; perhaps insufficient attention has been paid in the past to the maintenance of this principle.

initial oxide of a series, as the proportion of oxygen is increased, the acidic qualities are invariably strengthened.

The choice of a terminal connoting the elementary radicles which would be applicable generally and also acceptable is very difficult. If usage do not forbid change, probably our ears will decline to allow us to be systematic. The terminal *gen* is not applicable to many present names. In the interest of euphony, exception may be taken to the adoption of *ion* as a final syllable. In English ears most of the words with this ending have an ugly sound if pronounced so as to make it significant; moreover, our object is to secure a term which is applicable to the elementary material, whatever its state; the term ion is suggestive of a particular state—a state of chemical activity; and at present there is no agreement as to the nature of an ion. The terms atom, radicle (simple and compound), ion and molecule now all have their separate meaning and value and are indispensable.

The only terminal which seems in any way likely to be generally satisfactory in use is the terminal *yl*, which is already applied to organic radicles; its use might well be extended to radicles generally.

[1] I may here put on record the opinion Lord Kelvin expressed on this question in a letter to me dated September 13, 1906:—

"Ever since, nearly four years ago, we heard of the hundred calories per hour given out by radium, I have had on my mind the question of some possible mechanism such as that which you suggest by which energy from surrounding matter (far or near) could automatically come into radium to supply the energy of the heat which it gives out. The more I think of the question the less I see of that possibility. At present I can see nothing else than that tbe energy given out is taken from a previously existing store of potential energy of repulsive force between separable constituents of radium.

"'The disintegration of the radium atom' is wantonly nonsensical. It is nonsense very misleading and mystifying to the general public, because, if what is at present called radium can be broken into parts, it is not an atom.

"'Energy of an atom' implies a thorough misunderstanding of the meaning of the word energy, which is capacity for doing work.

"I admire most sincerely and highly the energy of the workers in Radio-activity and the splendid experimental results which they have already got by resourceful and inventive experimental skill and laborious devotion. I feel sure that as things are going on we shall rapidly learn more and more of the real truth about radium."

Taking into account this principle, it is impossible to arrange a long series of elements such as the rare earths continuously in order of atomic weight, as they would be brought into every family in the table by such a procedure: the difficulty has been got over by Brauner, who has proposed to arrange a large number of the rare earths in a single vertical series under barium. Biltz has made a similar proposal.

The principle had been advocated by me previously in an article written for the "Encyclopædia Britannica."[1]

In the arrangement I have proposed, it is not only assumed that there may be as many as sixteen vertical series of elements of which the elements from hydrogen to oxygen are initial terms, some series being at present unrepresented, it is also suggested that groups of elements occur in perhaps four of these series, numbers 4, 8, 12 and 16, the largest being that of the so-called rare earths in series 8.

The principle which is assumed to be in operation is that which is so clearly manifest in the case of hydrocarbons: successive vertical series of elements correspond to successive isologous series of homologous hydrocarbons. In the case of the hydrocarbons, the passage from one isologous series to another often takes place from a term several places removed from the origin of the series—for example, from benzene, C_6H_6, which may be regarded as primarily a derivative of hexane to naphthalene, $C_{10}H_8$, which is not an immediate derivative of benzene but of butylbenzene. It is conceivable that at the genesis of the elements a process was at work corresponding to that by which a hydrocarbon such as naphthalene is derived from benzene, and by which the former then serves in turn as the point of departure for more complex hydrocarbons of other series. There is no reason, from this point of view, why progression should not take place along a particular line and that terms should exist in a series through which this line passes but below it —for example, that antimony and iodine may bear a direct linear relationship, but that tellurium, instead of being the element in the progression series in the oxygen group, is a homologue of greater weight. The same view may be taken of selenium. In this way, it would be possible to maintain selenium and tellurium in the oxygen-sulphur series, from which they cannot well be separated, whilst retaining Mendelejeff's conception of a genetic relationship along the series. The only departure involved is in assuming that instead of forming a single linear series ascending regularly in spiral progression—a series which can, as it were, be strung on a single spirally wound cord—the elements closely simulate a series of homologous isologous hydrocarbons. From this point of view, it is easy also to understand that some vertical series are unrepresented.

In discussing the chief attributes of the elements none is so difficult to deal with as that of valency, using the term in the broadest possible sense, not merely as indicative of the number of units of affinity but as including the, at present, all but incomprehensible problems of residual affinity and elementary character. I discussed the subject somewhat fully in my former address, dwelling especially on the properties of negative elements and their power of acting as linking agents; this view has met with ample confirmation in the interval, and will, I believe, be found to be of wide application in the future. I have already referred to the manner in which it is exemplified by silica.

The greatest advance in the discussion of the problems of valency in recent years is that made by Barlow and Pope, as their method of treatment is one which applies to solid substances—the correlation of structure with crystalline form which it effects promises to be of far-reaching importance.

Apart from hydrogen, carbon is the one element of certain character, always acting as a tetrad—its affinities may be only incompletely satisfied but they are always exercised, it may be supposed, even in ethenoid and similar compounds; carbon monoxide apparently is the only exception to this rule, its relative inactivity being one of the most puzzling enigmas of our science, especially as the oxide becomes one of the most active of known substances when only two atoms of hydrogen are added to it. Most other elements (non-metallic) seem to vary in valency, the valency beyond a certain minimum being dependent on the nature of the association. Of late years, attention has been directed in particular to the quadrivalency of oxygen in many of its compounds.

[1] *Cf.* Roy. Soc. Proc., 1902, vol. lxx., pp. 86–94.

The quadrivalency of sulphur in substances such as trimethylsulphonium iodide, Me_3SI, having been proved to demonstration by the production of optically active compounds of this type (Pope and Peachey), it can no longer be supposed that in such cases we are dealing with compounds in which the negative constituents of the parent molecules are conjoined, *e.g.* $MeI : SMe_2$. And yet we must contemplate the existence of such compounds as possible—in the case of nitrogen, for example, as ammonia must be supposed to form the compound $NH_3 : OH_2$ in preference to the hydroxide $NH_4.OH$, the latter being only a very minor constituent, the former the major component of the aqueous solution of the gas; hydrogen chloride, on the other hand, appears only to afford one product with ammonia, viz. $NH_4.Cl$. The existence of such differences affords clear proof in the case of the non-metallic elements other than carbon that valency is not merely a variable but also a reciprocal or dependent function.

There is no reason to suppose that hydrogen ever acts otherwise than as a simple monad; and the behaviour of the alkalies and alkaline earths in salts would seem to justify the conclusion that they have no tendency to vary in valency, were it not for the existence of well-defined non-volatile hydrides of these metals which are clearly substances of some degree of molecular complexity. Such compounds are illustrations of the difficulties which surround the subject. It has long been clear that the exhibition of the higher valency by an element is a process of a different order from that manifest when it exerts only its lower proper valency measured in terms of positive radicles such as H or C_nH_{2n+1} radicles. What that difference is we are not able at present to decide—carbon (together with silicon) differs from almost all other elements, especially in combining with hydrogen and analogous radicles to the extent of its maximum valency.

The proposition I made in 1888 (*Phil Mag.*, Series V., 25, 21) that the valency lines should, in some cases, be represented as passing through the atom, so that each is capable of acting in two directions, is the only consistent mode of expressing varying valency which has been devised, the only one, moreover, by which attention is directed to the great difference.

In many cases probably there has been a tendency to exaggerate the valency value—in the case of chlorine, for example, in assuming that it functions as a heptad in the perchlorates. In this and many other instances, it suffices to assume that the chlorine and oxygen atoms are united in a closed ring, the chlorine functioning as a triad. Some such explanation will doubtless be given of the structure of the metallic ammonias and similar compounds. The co-ordination values introduced by Werner serve only to establish certain empirical relationships and are useful for the purposes of classification. The perhaps more rational plan of dealing with such compounds suggested by Abegg has a similar value.

It is to the advantage of the hypothesis formulated by Barlow and Pope that the elements are represented as of constant valency in so far as their relative volume spheres of influence are concerned—the compound in which the higher valency is manifest being derived from that of lower valency by the opening out of the close packed arrangement and the insertion of certain new elements; but the fact that in such cases the volume is altered not in one direction alone in the crystalline structure but proportionately in all directions would seem to show that the volume sphere of atomic influence does actually change; the change is one, however, which affects all the atoms in the complex proportionately.

At present, unfortunately, our methods of treating the problems of valency are such that we cannot in any way give expression to the energy side of the phenomena.

Of late there has been talk of electrons in this connection, but what is said is little more than superficial paraphrase, in the advanced scientific slang of the day, of the ideas which have long been current. When, following Odling, we represent valency by dashes written after the elementary symbol, we give clear expression by means of a simple convention to certain ideas that are well understood by all among us who are versed in the facts; to speak of electrons and use dots instead of dashes may serve to mislead the unwary, who hang on the lips of authority, into a belief that we have arrived at an explanation of the phenomena, but those who know that we have reached only the let-it-be-granted stage and who feel that the electron is possibly but a figment of the imagination [1] will remain satisfied with a symbolic system which has served us so long and so well as a means of giving simple expression to facts which we do not pretend to explain. Not a few of us who listened to the discussion of the nature of the atom at Leicester could not but feel that the physicists knew nothing of its structure and were wildly waving hands in the air in the endeavour to grasp at an interpretation which would permit of mathematical interpretation being given to the facts. Until the credentials of the electron are placed on a higher plane of practical politics, until they are placed on a practical plane, we may well rest content with our present condition and admit frankly that our knowledge is insufficient to enable us even to venture on an explanation of valency.

In 1885 and again in 1888, I ventured to call in question the interpretation of valency which Helmholtz had given in the Faraday lecture in 1881. On the present occasion, I would insist still more emphatically on the insufficiency of the atomic charge hypothesis; especially that it affords no satisfactory explanation of variable valency and of those fine shades of difference which are manifest, especially in the case of nitrogen, when the radicle attached to the dominant element is varied. In 1885 I discussed this question with reference to the nature of electrolytes and questioned the conclusion Helmholtz arrived at that electrolytes belong to the class of typical compounds the constituents of which are united by atomic affinities, not to the class of molecular aggregates. The opinion I then ventured to give was as follows:—

"The current belief among physicists would appear to be that primarily the dissolved electrolyte—the acid or the salt—is decomposed almost exclusively. We are commonly told that sulphuric acid is added to water to *make it conduct*, but the chemist desires to know why the solution becomes conducting. It may be that in all cases the 'typical compound' is the actual electrolyte—*i.e.* the body decomposed by the electric current—*but the action only takes place when the typical compounds are conjoined and form the molecular aggregate*, for it is an undoubted fact that HCl and H_2SO_4 dissolve in water, forming 'hydrates.' This production of an 'electrolytical system' from dielectrics is, I venture to think, *the* important question for chemists to consider. I do not believe that we shall be able to state the exact conditions under which chemical change will take place until a satisfactory solution has been found."

The position is not very different now. Although the propagation of the ionic dissociation cult has assumed the form of a fine art, we are still as far as ever from agreement as to the nature of chemical change; the speculation has not helped us in the least to clarify our ideas; at most we learn that interactions are between ions, and even these, as a rule, are supposed to remain apart until they enter into the solid state. Throughout all these years I have never varied my opinion that the dissociation hypothesis is incompatible with the facts. On more than one occasion I have stated definite reasons which induce me to deny its usefulness,[2] and these arguments have never been met; in fact, there has been little but a conspiracy of silence on the part of the upholders of the creed.

A large amount of work bearing on the subject has been done, chiefly by H. Brereton Baker. Strangely enough, no proper notice of his results has been taken outside England, and even there the importance of the observations has not been sufficiently appreciated. Perhaps the most remarkable feature in the situation is that Baker himself scarcely seems to be alive to the meaning of the evidence which he has supplied; the attitude which he has displayed in his recent Wilde lecture can only be described as halting. Baker has shown, in case after case, that the occurrence of change is dependent on the presence of moisture, his greatest feat perhaps being the observation that it is possible not only to prepare nitrous anhydride in the solid and liquid states but to volatilise it unchanged if only water be excluded.

I venture to think there is only one point of view from which the problem of chemical change can be approached, that, namely, which we owe to Faraday—to which hitherto justice has in no way been done—on which I dwelt persistently in my previous address: that the forces termed chemical affinity and electricity are one and the same. In every case of chemical change there is a coincident electrical change, an electric flux; on the other hand, every case of electrical change is accompanied by chemical change, some alteration in molecular configuration is effected; the force of chemical affinity is in some way disturbed by a momentary displacement of the molecules when a current passes through a conductor. Such being the case, the conditions determinative of chemical change can only be those which permit of an electric flux. Two substances in apposition do not give rise to a current; at least three are required to determine a slope of potential. Chemical change can only take place if one of the three be an electrolyte. In all cases apparently the chemical change supervenes upon the electrical, the electrolyte being resolved into its ions, one of which at least combines coincidently with the adjacent electrode. Apparently these considerations are applicable to changes generally. And it should be added that, according to this view, the catalyst actually determines the occurrence of change.

The only other criterion which it is necessary to apply in order to decide whether change be possible in any given case is to consider if the change contemplated be one involving development of energy. It is important to remember also that a change which could not otherwise take place becomes possible when a suitable depolariser is introduced into the circuit.

The evidence that similar considerations apply to the gaseous and the liquid states cannot well be gainsaid. Before framing a theory of chemical change it is therefore necessary to formulate a definition of an electrolyte. It is doubtful if any single substance be an electrolyte; the conductivity of fused salts may well be and probably is conditioned by some admixture. Aqueous solutions of alkalies, acids and salts without exception are electrolytes. *Everything points to the fact that in such solutions the solvent and solute act reciprocally; the contention that the solute alone is active cannot be justified.* As water is altogether peculiar in its activity as a solvent and is a solvent which gives rise to conducting solutions, an explanation of its efficiency must be sought in its own special and peculiar properties.

Since 1886 this conclusion has been impressed upon me with indisputable force, and I have frequently ascribed the effect produced by the one constituent upon the other in a solution to the residual affinity of the negative elements in the two compounds which act reciprocally. It was only recently, however, that I saw my way to postulate a complete theory which would serve to account for the properties of solutions and generally that I realised how the reciprocal effect might be produced.

I would substitute for the misleading conception that liquids are comparable in their behaviour with gases the idea that the liquid state is one in which the residual affinity of the negative elements in particular always comes into play and causes the formation of molecular aggregates of various degrees of complexity; moreover, that the alteration in the properties of any given solvent by the dissolution in it of another substance is largely, and, in some cases, mainly due to a disturbance of the equilibrium natural to the solvent by an alteration in the proportion in which the several aggregates are present. The alteration in some particular property produced in *a given mass of the solvent* may, from this point of view, be taken as the measure of the activity of a substance, just as the alteration in the pressure of a particular volume is taken as the measure of the alteration produced in a gas. In the case

[1] In my opinion the experimental evidence is in no way satisfactory. It appears to me to be desirable that in studying the phenomena of electric discharge in gases and especially in vapours of complex substances, the horrible pitfalls should be taken into account with which the field of work is studded; unless every precaution to secure purity—precautions such as Baker and Dewar have taught us to use—be taken at every step, the conclusions based on all such observations must be open to grave doubt.

[2] Compare Chem. Soc. Trans. 1895, 1122; Royal Soc. Proc. 1886, xl., 268; 1902, lxx., 99; 1903, lxxii., 258; 1904, lxxiii., 537; 1906, lxxviii., 264; 1907, lxxix., 586; 1908, lxxxi., 80; *Science Progress*, April, 1909.

of non-electrolytes, if only a small amount of the solvent be withdrawn by combination with the solute, the alterations may be regarded as almost entirely due to the "mechanical" interference of the substance introduced, opportunity being given for the simpler, more attractive molecules of the solvent to exist in greater proportion because of the diminution of the chance of reuniting which is conditioned by the presence of practically inert molecules of another kind; if a more or less considerable amount of the solvent become associated with the solute the conditions become more complex, but similar considerations apply. From such a point of view a liquid is rendered more active by the addition of any soluble substance. Its vapour pressure is therefore diminished; the internal "osmotic" stresses are raised; its freezing-point is lowered.

Although it is generally admitted that water is not a uniform substance but a mixture of units of different degrees of molecular complexity, the degree of complexity and the variety of forms is probably underestimated and little or no attention has been paid to the extent to which alterations produced by dissolving substances in it may be the outcome and expression of changes in the water itself. The attempt to extend the "laws" which are applicable to the gaseous state to liquids has led us away from the truth by narrowing our conceptions. If the contention be justifiable that the alterations attending dissolution are very largely alterations in the character of the water, attention has been directed of late far too exclusively to the dissolved substance.

To give emphasis to the view, I have advocated[1] the restriction of the name *water* to the liquid mixture and have proposed that the simple molecule represented by the symbol OH_2 be termed *Hydrone.* The generalised expression

$$(H_2O)_x \rightleftarrows xOH_2$$

may be considered to be representative of the state of equilibrium in water—that is to say, of the character of the change which it undergoes when the conditions are varied either physically or by dissolving substances in it—in the sense that it pictures the resolution of the more complex into simpler forms and *vice versâ*, without taking into account the variety of molecular forms (x, x^1, x^2 . . . .) which are present.

It is probable that the agreement between "theory" and practice on which reliance has been placed, particularly in interpreting osmotic phenomena, is more often than not only apparent and fictitious, and but the outcome of counterbalancing effects which have been left out of account. We are too prone to believe in constants; we need to remember that, except perhaps in the case of the perfectly gaseous state, *constants are dependent variables.* To take an example, it is assumed that glucose and cane sugar produce like osmotic effects when used in equivalent proportions; indeed, it has been the fashion of late years to treat non-electrolytes as harmless neutrals: in point of fact they differ as much in behaviour as do electrolytes, and such a conclusion must be viewed with the gravest suspicion. Recently Dr. Eyre and I have been able to show that three substances so similar as methylic, ethylic and propylic alcohols produce effects in precipitating salts from solution which are markedly different, propylic alcohol being the most effective although the least soluble. It is clear that the precipitant does not act mainly by itself combining with and withdrawing water in direct competition with the salt; but that it promotes the *dissociation of water* by the mechanical interposition of its molecules; in fact, that the "dehydrating" powers *of the water* are enhanced owing to the increase in the proportion of simple molecules in the liquid conditioned by the presence of the solute.

The same effect is obvious when the reduction of the electric conductivity of a salt, such as potassium chloride, by equivalent quantities of the three alcohols is considered. This amounts to about 6 per cent. in the case of methylic, 12 in that of ethylic, and 17 in that of propylic alcohol; the reduction effected by glucose, however, amounts to about 27, and that effected by cane sugar to no less than 42 per cent. In these two latter cases the amount of water actually withdrawn from the solution by the sugar is probably considerable, and the "mechanical effect" of the solute is therefore exercised in a more concentrated solution—more concentrated, that is to say, than those in which the alcohols act. If, therefore, solutions of glucose and cane sugar of equivalent strength produce like osmotic effects, it is because unperceived compensating factors are at work in the solutions which in algebraic sum have the same aggregate influence.

To explain the effect produced by substances which give rise to conducting solutions when dissolved in water (acids, alkalies, and salts), it is necessary to consider the special nature of the changes which may be supposed to attend dissolution in such cases. Why, it may be asked, is an aqueous solution of hydrogen chloride a conductor, whilst that of alcohol is a non-conductor? I believe the answer to be that it is because, in the former case alone, the two components of the solution are *reciprocally distributed*; that it is because two correlative systems—

$$HCl\begin{matrix}H\\OH\end{matrix} \quad \text{and} \quad H_2O\begin{matrix}H\\Cl\end{matrix}$$

are produced which interact under the influence of the electric stress.[1] In the case of alcohol no such interchange takes place. It may be that the alcohol is hydrolated to some slight extent, but the hydrol must be less basic than hydronol; probably, like ammonia, alcohol exists in solution for the most part in the hydronated state:—

$H_2O\begin{matrix}H\\ \diagdown OH\end{matrix}$	$EtHO\begin{matrix}H\\ \diagdown OH\end{matrix}$	$EtHO{=}OH_2$
Hydronol.	Ethanol-hydrol.	Ethanol-hydrone.

Much more must be learnt of the properties of solutions before definite decisions can be arrived at with regard to such delicate and refined issues.

I would apply the interpretation here given of the nature of conducting solutions generally to the explanation of all cases of chemical change: in other words, I assume that in all cases correlative systems are present which are formed by the reciprocal distribution of the interacting substances. From this point of view the solvent is no mere medium but an active participant in the series of interchanges of which, as a rule, only the final product is noticeable.

The solution thus offered of the complex problem discussed very fully in my Address in 1885, which has ever since occupied my thoughts, will, I trust, be found to be helpful, although by no means complete in all its details.

In effect, the doctrine makes no demand which the chemist should not be able to grant forthwith, as it is generally supposed that hydrols are easily formed—to give an example, in the case of the conversion of chloral, $CCl_3.COH$, into chloraldehydrol (chloral-hydrate), $CCl_3.CH(OH)_2$. The novelty of the conception lies in supposing that the occurrence of electrolysis involves the interaction of the hydrol and its correlative and the explanation which it affords of the difference between electrolytes and non-electrolytes.

It is essentially an association theory, although it involves the dissociation of the interacting substances but never the production of separated ions. In the case of aqueous solutions the amount of the distributed substances may be taken as the measure of the activity—of the degree of ionisation, so-called. A wrong view prevails that the so-called molecular conductivities are measures of activity; they are in reality only measures of the relative activities under corresponding conditions of the substances to which they refer. The molecular conductivity of an acid is at a maximum in its weakest solutions: presumably it is then present to the maximum extent in its simplest state and in the active hydrolated state; but as a hydrolytic agent its activity is at a maximum near to the opposite end of the scale. In other words, the hydrolytic activities of a series of acids are in the order of their molecular conductivities in solutions of comparable strength, but molecular-hydrolytic and molecular-electrolytic activity run in opposite directions; the maximum electrolytic conductivity of an acid solution, which is manifest at a particular

[1] Roy. Soc. Proc. 1908, xxxi., 80; *Science Progress*, January, 1909.

[1] I would repeat the plea I put forward in 1885 that the use of the term hydrochloric acid as applied to hydrogen chloride is undesirable if not unjustifiable; the solution of the gas may be said to contain *chlorhydric acid*, $HCl(OH_2)x$. From my point of view, oxygen *is* a constituent of all acids.

degree of concentration—presumably at the point at which the two forms of the distributed materials most nearly balance—is also in no way identical with maximum molecular hydrolytic activity. On these assumptions not a few of the deductions based on the ionic dissociation hypothesis are clearly fallacious.

It has been asserted that the association hypothesis does not admit of quantitative treatment, and that therefore it is at a disadvantage; but if the quantitative meaning given to various results in accordance with the tenets of the dissociation hypothesis be more often than not one which is inadmissible, little is gained by applying the speculation quantitatively. As already remarked, the only cases in which chemical and electrolytic activity can be compared by the methods proposed are those in which the comparison is made between solutions of comparable or equivalent strength—that is to say, between compounds arranged in vertical series in the order of their activity.[1] Electrolytes are comparable in most, if not in all, their properties when the comparison is made in this way; but order of activity is one thing, actual activity another. It is in this sense, and this sense only, that we may agree with Arrhenius in his statement, "L'activité électrolytique se confond avec l'activité chimique."

The ionic dissociation hypothesis is a beautiful mare's-nest, which fails apparently to fit the facts whenever it is examined. "And the moral of *that* is," to quote the words of the classical Duchess so well known to children, "we must not use the words *ion* and *ionisation* in any speculative sense but confine their application to cases such as were contemplated by Faraday when he introduced the term ion; the conception of activity, whether electrolytic or chemical, should alone be attached to such words; no idea of actual, separate, individual existence should enter into our minds in using them: the ion is to be thought of merely as the potentially active, transferable radicle in a compound, not as a separated particle enjoying independent existence." It is so easy to speak of dissociation when it is desired to give expression to the idea; the first thing the scientific speaker or writer should guard against is ambiguity.

The subject of gaseous interchanges must not be left out of account, although it is impossible to do justice to it. Mendelejeff's contention that gaseous interchanges are usually bimolecular has been defended by Dixon and Larmor of late. But the facts must be faced. The almost inconceivable frequency of the molecular impacts must not be forgotten. The extraordinary attractive power of the hydrone molecule is also to be remembered—this would tend to promote the formation of aggregates with which the necessary third substance would every now and then form a bimolecular system—which, however, would in reality be at least trimolecular. The proportion of hydrone molecules in a dried gas has probably been under-estimated —the density of hydrone being very low (9)—as no dehydrating agent can be supposed to remove all such molecules or even nearly all; the hydrated substance must have a certain pressure of dissociation. Sir James Dewar's appears to be the only method which is in any way deserving of the epithet absolute; the results he has obtained with helium in a radiometer are strongly in favour of my view. Lastly, the gradual growth in velocity of the explosive wave up to the point of detonation as the compression becomes greater is clear indication that reduction in volume and increase of opportunity for the formation of systems of the proper degree of complexity is a matter of great consequence. Even the behaviour of cordite is significant, particularly the projection of unburnt rodlets of the material from the gun: apparently it is not decomposed by shock intramolecularly but is decomposed by heat into gases, which interact explosively.

Having dealt with the subjects of chemical change and the nature of solutions, however inadequately, I must now endeavour to justify my opening reference to the importance of the organic side of our science.

The province of organic chemistry is so vast that it may appear to be difficult to distinguish the main lines of advance from the by-paths which intersect the field of inquiry in every direction. In reality this is not the case; certain salient features stand out which must attract attention if once attention be directed to them. The efforts of the chemist to elucidate structure and to correlate structure with function have been extraordinarily successful. In the first place, as already remarked, the student of the subject now has his attention concentrated on the tetrahedron as the symbol of the *functional activity* of carbon; however numerous the compounds, he knows that certain simple rules can be laid down as applicable to all. It is established beyond question that carbon atoms have a remarkable tendency to form ring systems. The affinities of the atom seem to act almost rigidly in certain directions, which appear to be those of lines drawn from the middle point of a regular tetrahedron to its angular points. Rings containing either five or six atoms of carbon are therefore those which are most readily formed and of maximum stability; carbon atoms may and do unite in pairs, threes and fours, but compounds of this order are far less permanent than those containing either five or six atoms, as the affinities appear to meet in such a manner that they do not satisfy each other and consequently the compounds enter somewhat readily into combination with other substances. When the number of carbon atoms exceeds six, not only is there less tendency to form a ring system but the stability of the system is slight; when the number is considerable, stability is attained by the formation of complex systems, consisting of several rings conjoined (camphor, naphthalene, anthracene, &c.).

The behaviour of carbon compounds generally, in so far as this may be regarded as dependent on the condition of the carbon, is extraordinarily simple, and may be summed up in the statement that it is either paraffinoid, ethenoid or benzenoid.[1] Paraffinoid carbon is incapable of combining with other substances and but slightly attractive, so that the hydrogen atoms are by no means easily displaced from paraffinoid compounds[2]; ethenoid carbon combines readily with various substances, forming compounds of paraffinoid type; in the benzenoid state, carbon appears to combine somewhat readily with a variety of substances, but the products enjoy only an ephemeral existence and usually escape notice, as they at once break down, giving rise to benzenoid substitution derivatives, so that in this last form carbon simulates the paraffinoid state but is more active.

In earlier years our attention was concentrated on benzene and the benzenoid compounds; much was done to elucidate the structure of these hydrocarbons and of their derivatives; meanwhile these latter have proved to be of extraordinary significance technically, notably as dyestuffs, but also on account of their medicinal value, as perfumes and in photography.

The structure of benzene has been the subject of much discussion during the period under consideration. I trust I shall not be accused of parental bias if I urge that the centric[3] formula is the best expression of the *functional activity* of the hydrocarbon benzene and its immediate derivatives; the attempts which have been made of late years to resuscitate the Kekulé oscillation hypothesis in one form or another appear to me to be devoid of practical significance. Any formula which represents benzene as an ethenoid must be regarded as contrary to fact. But in considering the properties of benzenoid compounds generally, it is necessary to make use of the Kekulé conception as well as the centric expression. The model of benzene devised by Barlow and Pope subserves a somewhat different and complementary purpose, being primarily of importance

[1] Solutions of acids and alkalies have maximum conducting power at certain relatively high degrees of concentration. Hydrolytic activity also increases steadily in the case of acids as the solution becomes more concentrated; whether it attains to a maximum and whether this coincides with the conductivity maximum is uncertain at present; it is very difficult to decide this point experimentally, as the rate of change is so rapid in strong solution; moreover, the action takes another course in strong solutions, as compounds are formed by the interaction of the hydrolyte and hydrolist, so that two changes are superposed which cannot well be followed separately.

[1] A fourth condition requiring recognition is that of the carbon in acetylene; at present the acetylene compounds are so few in number, however, that this form may be left out of account.

[2] The displacement of the hydrogen associated with carbon is in all probability a secondary phenomenon; it is likely that this is true generally and that hydrogen is never merely removed or attracted away but always has its place taken by a radicle which becomes temporarily attached to the multivalent atom with which the hydrogen is associated.

[3] I have discussed this matter somewhat fully in a recent essay, with reference to the nature of amorphous carbon, in connection with the remarkable work of Sir James Dewar on the absorption of gases by charcoal at low temperatures (*Journal of the Royal Institution*).

on the geometric side in discussing the relation of form to structure.[1]

The discovery of trimethylene by Freund and the subsequent introduction of synthetical methods of preparing polymethylenes by W. H. Perkin, jun., mark the onset of a new era, opening out as they did the possibility of understanding the structure of camphor and the terpenes and other constituents of the volatile oils from plants.

Chemist after chemist had attempted in vain to solve the riddle presented by camphor. Suddenly, in a moment of inspiration, a satisfactory solution of the problem was offered by Bredt. The acceptance of the bridged ring, the special feature of the Bredt formula of camphor, marks the introduction of a new moment into organic chemistry.

The recognition of similar rings in several hydrocarbons of the terpene class, mainly in consequence of the masterly work of von Baeyer, has contributed in no slight degree to an understanding of these compounds; nevertheless, much remains to be learnt and there are many and serious difficulties to be overcome before we shall be in a position to appreciate the genetic relationship of all the substances included in the group. When the account of the work is written it will form one of the most striking and fascinating chapters in the history of our science.

Among the many names of those who have contributed to its development the first to be mentioned is that of Wallach, to whose unwearied efforts, continued during a long series of years, so much is owing. The synthetic work carried out with brilliant success in recent years by W. H. Perkin may also be referred to as of extraordinary promise but of well-nigh inconceivable difficulty.

Before leaving this chapter, reference should be made to the almost protean character of camphor, as disclosed by the work of inquirers such as Kipping, Pope, Forster, Lapworth and Lowry; no other substance has lent itself to use in quite so many directions and with such fruitful results. Special mention may be made of the demonstration which Pope has given, with the aid of the camphorsulphonic acids, that nitrogen, sulphur, selenium and tin give rise to optically active substances in all respects analogous to those furnished by carbon. The success with which Kipping's arduous labours have been crowned is also very noteworthy, taking into account the many difficulties he has overcome in preparing optically active silicon compounds. The extension of the Pasteur-van 't Hoff theory of asymmetry inferentially to all elements which are at least quadrivalent, now accomplished, is of superlative importance.

Lowry's refined observations on the conditions which determine the interconversion of isodynamic forms of some of the camphor derivatives may also be cited as of special value as a contribution to the study of metamerism and the conditions which determine chemical change generally.

Not the least interesting feature of camphor is the light thrown by its behaviour on the influence which oxygen exercises as an attractive element and on the part which spatial configuration may play in determining directions of change. It is clear that, whatever the agent, the attack is always delivered from the oxygen centre and that the direction in which the attack becomes effective depends on the position which the agent can take up relatively to the various sections of the molecule.[1]

It must be confessed that our efforts to penetrate behind the veil in the case of the higher carbohydrates—starch and cellulose in particular—have not been rewarded with success.

Moreover, though much has been done of late years to unravel the nature of the vegeto-alkaloids, substances such as quinine are still only partially deciphered and not one of the more complex alkaloids has been produced synthetically. In view of the fact that quinine is still the one effective and practically safe anti-malarial medicine, the disclosure of its constitution is much to be desired. The isolation of adrenaline from the suprarenal capsule and the discovery that this alkaloid—which is an extraordinarily active substance physiologically—plays a most important part in controlling vital processes is of supreme interest. Other glands—the pituitary gland, for example—appear to contain peculiar active substances, which are of particular consequence in regulating animal functions. The discovery of such substances affords clear proof that life is largely dependent on what may be termed chemical control.

In addition to indigo, the simpler yellow and red natural colouring-matters have now been thoroughly examined, but this class of substance still affords abundant opportunity to investigators. Kostanecki's comprehensive studies of the xanthone group may be referred to as of particular value.

Attention may be directed here to the investigation of brazilin and hæmatoxylin by W. H. Perkin and his various co-workers, not merely as being full of interest and importance as a contribution to our knowledge of the relation between colour and structure and as a brilliant example of technical skill but because of the illustration it affords of the extreme intricacy of such inquiries and of the vast amount of labour they entail. The general public probably has not the slightest conception of the difficulties which attend such research work and of its costliness.

As an investigator of vegetable colouring-matters, no one has been more assiduous or has displayed greater skill of late years than A. G. Perkin. His recent refined investigation of the colour-yielding constituents of the indigo plant is of exceptional value at the present time, although it is to be feared that it comes too late to save the situation in India. The work of the brothers Perkin, it may be pointed out, is of exceptional interest on the human side as well as from the scientific standpoint, as their enthusiasm and wonderful manipulative skill afford a striking and noteworthy example of hereditary genius.

Two substances of commanding interest which have long resisted attack—the red colouring-matter of the blood and leaf-green—are at last going the way of all things chemical, as the secret of their nature is being wrung from them. In Willstätter's skilful hands chlorophyll is proving to be by no means the fugitive material it was supposed to be; the complexity of the problem it offers, however, seems to be far beyond anything that could have been anticipated; so much greater will be the interest attaching to the final solution. The discovery that green chlorophyll is a magnesium salt is of special importance, as the first clear indication of the manner in which magnesium salts are of service to plants.

Apart from the special interest which attaches to the investigation of vegetable colouring-matters on account of their being coloured substances, such inquiries are of value as furnishing material for the discussion of the metabolic activity of plants.[2]

[1] The time is now approaching when it will be possible to extend the study of benzenoid compounds beyond the formal and superficial stage; hitherto we have been content to develop the methods of preparing such substances and to determine their number and their distinctive properties. Everything has to be learnt as to the exact character of the changes which attend their formation from the parent substance benzene and as to the exact nature of their inter-relationship. The impression produced by benzene, in my mind, is that of an eminently plastic system capable of responding to every slight change that may be impressed upon it. Nothing is more remarkable than the difference between benzene and its homologues, so obvious in the extraordinary increase in activity which attends the introduction of hydrocarbon radicles in place of one or more hydrogen atoms. But such plasticity is not characteristic of benzene only: if the properties of benzenesulphonic acid be contrasted with those of the various substituted benzenesulphonic acids, it is clear that every variation meets with some response from the sulphonic group; what is still more remarkable, if the hydrogen in the hydroxylic group in the phenolsulphonic acids be displaced by other radicles, not only does the oxygen atom to which the radicle is attached seem to respond to the change but the benzenoid system and the still more distant sulphonic system are also affected. It is well known that the physical constants are all variables in the case of benzenoid compounds. Perhaps the most remarkable confirmation of the view here advanced, however, is that afforded by the conclusion arrived at by Barlow and Pope that in the case of benzene derivatives, although the spheres of influence of the carbon and hydrogen atoms are relatively the same as in the parent compound, the spatial arrangement of the component spheres of atomic influence remaining practically unchanged, nevertheless the actual volumes of the spheres of influence of both carbon and hydrogen alter proportionally to the alteration in molecular volume. Thus they maintain that in the case of the conversion of benzene (molecular volume 77·4) into tetrabromobenzene (molecular volume 130·2), the volumes of the spheres of influence of both carbon and hydrogen expand in the ratio of 77·4 : 130·2. Such a conclusion is very noteworthy.

[2] But a note of sadness pervades the story. The effect of learning to understand Nature always appears to be that we at once brush her aside when we have wrested from her the secrets which she has so long preserved inviolate. No sooner did we learn the nature of the madder colouring-matters than we proceeded to prepare them artifically—thus putting an end to the cultivation of a valuable crop. Indigo is meeting with a like fate, a catastrophe which might well have been avoided had scientific assistance been called in at the proper time. Not content with making natural colouring-matters, we set to work to outrival the rainbow in our laboratories and the feminine world is decked with every variety of colour in consequence, although unfortunately our blends too often lack the beauty of those of truly natural origin, which rarely, if ever, offend the eye. We congratulate ourselves on our cleverness in thus imitating Nature but no idea of thrift

Even colloids are being brought into line. Studded as they are with active centres (oxygen or nitrogen atoms), they seem to be able to attract and retain hydrone molecules at their surfaces in ways which give them their peculiar glue-like attributes: as a consequence living tissue appears to be little short of animated water.

To the present generation of students, the organo-metallic compounds must have appeared to belong to the past; the discovery of methides of platinum and gold by Pope will not only serve to re-awaken interest in this group of compounds but is of primary importance as a contribution to our knowledge of the valency of these elements; the stability of the platinum derivatives is altogether astonishing.

The discovery announced in June last, at the International Congress of Chemistry, by Mond, of compounds of carbonic oxide with ruthenium and uranium is a striking and most welcome extension of his previous labours, which had placed us in possession of carbonyls of nickel, iron and cobalt. The metallic carbonyls possess altogether remarkable properties: at present, these defy explanation; nickel carbonyl in particular seems to be an exception to all rules. The complex iron carbonyls made known by Dewar and Jones also have most fascinating attributes, the variety of colours they display being specially interesting. The marked individuality of the members of the iron group as exemplified in their carbonyl derivatives is in striking contrast with the tendency they display to behave as related elements; the deeper problems of valency are clearly exposed for consideration in such peculiarities.

The discoveries of the special activity of magnesium as a synthetic agent and of the superior value of nickel as a catalyst in fixing hydrogen are other illustrations of the individuality of metallic elements. We are greatly indebted to the French chemists for the invaluable preparative methods they have based on the use of these two agents.

Although satisfactory progress has been made in almost every direction, many of the nitrogen compounds are still not properly understood. It is clear that we are as yet in no way seized with understanding of the attributes of this element as we are of those of oxygen and carbon, particularly in the case of mixed carbon-nitrogen compounds: we can make nothing of the physical data such substances afford. Nitrogen, in fact, is an extraordinary element, far more remarkable than any other; its "temper" appears to vary more than that of any other element according to the character of its associates—nothing could be more remarkable, for example, than the change in properties from ammonia, NH_3, through hydrazine, $NH_2.NH_2$, to azoimide, N_3H. No other element can be so poisonous, so immediately fatal to life. We lack a model symbolic of its functions—which means that we are unable to fathom its vagaries and reduce them to simple order.

The oximes and the diazo-compounds in particular have given rise to much dispute. Stereo-chemical formulæ have been assigned to these, but probably they have little relation with the truth; although they have been of service by supplying symbols which can be offered up at examinations, by confining attention they have served to sterilise inquiry. No better illustration could be given of the truth of the remark made by my friend the Professor that man is an idolater by nature, a fact that chemists should always bear in mind.

The compounds in question are difficult substances to handle, far too prone to undergo change without invitation —it is to be feared that many of the conclusions which have been arrived at are based on incomplete if not unsatisfactory evidence.[1] When I think of the state of our knowledge, I am reminded of the father of diazo-chemistry, Peter Griess, and of his marvellous experimental gifts; there is great need of such a man to re-investigate the whole subject.

If we inquire as to the general effect of the increase of knowledge of organic compounds, it is clear that the lessons which emerge from all modern inquiries are such as to justify Larmor's remark that our conceptions of structure must be granted more than analogical significance. Everything tends to show that function and structure are most closely connected—odour, taste, colour, physiological effect, are specific rather than general properties, each conditioned in its special variety by some special structure; we are approaching very closely to a time when it should be possible to discuss such properties with considerable confidence.

Still, it must not be forgotten that the problems they offer are all valency problems, and that the nature of valency eludes us entirely at present.

The greatest advance which chemists may pride themselves upon having made during the past decade or two remains to be considered. In 1885, I spoke as follows:— "The attention paid to the study of carbon compounds may be more than justified both by reference to the results obtained and to the nature of the work before us; the inorganic kingdom refuses any longer to yield up her secrets—new elements—except after severe compulsion; the organic kingdom, both animal and vegetable, stands ever ready before us. Little wonder, then, if problems directly bearing upon life prove the more attractive to the living. The physiologist complains that probably 95 per cent. of the solid matters of living structures are pure unknowns to us, and that the fundamental chemical changes which occur during life are entirely enshrouded in mystery. It is in order that this may no longer be the case that the study of carbon compounds is being so vigorously prosecuted. Our weapons—the knowledge of synthetical processes and of chemical function—are now rapidly being sharpened, but we are yet far from ready for the attack."

My forecast has been more than justified; indeed, the advance to be recorded is nothing short of marvellous: the great problems of vital chemistry appear now no longer to be unattainable to our intelligence—their cryptic character seems to have disappeared almost suddenly. Many have contributed in greater or less degree, but none in such measure as Emil Fischer, whose work both in the sugar group and in connection with the albuminoids must for ever rank as monumental.

It is difficult to appreciate the extent to which the practical genius of this chemist has carried us—difficult alike for those who understand the subject and those who do not; the significance of his labours is only apparent when the bearing of his results on the interpretation of vital phenomena is fully considered. In 1885 we were disputing as to the structure of substances such as glucose and galactose; now we not only are satisfied that they belong to the group of aldhexoses (aldoses) derived from normal hexane, but, taking into account the monumental discoveries of Pasteur, to which precision has been given by van 't Hoff's great generalisation, we are in a position to assign fully resolved structural formulæ not only to the natural products but to the nine other isomeric aldhexoses which Fischer has prepared artificially.

It is a striking fact that only three of the sixteen possible aldhexoses and but a single ketohexose (fructose), of which many are possible, are met with naturally. Nature is clearly most sparing, most economical, in her use of materials. And not only is this true of the hexoses, as very few of the possible lower and higher homologous carbohydrates occur in vegetable or animal materials and the condensed carbohydrates (cane sugar, starch, &c.) are all formed apparently from the hexoses and pentoses which occur naturally. The albuminoids, the alkaloids, the terpenes are also optically active substances; in other words, only a limited number of the possible forms are present. There is reason to suppose that the compounds of natural occurrence stand in close genetic connection and belong with few exceptions to the same series of enantiomorphs; in no other way is it possible to account for the occurrence of one only of the pair of enantiomorphous isomerides and for the relatively small number

possesses us: moreover, our attempts to imitate if not to undo her work are never direct but are always made with her aid, with Nature's product—coal; we are no longer content to ride on horseback but must rush through space and instead of watching the birds fly seek to emulate them but always with the aid of fuel won by Nature from the soil and air in days long past. Too much is being done in every direction to waste natural resources, too little to conserve them, too little to employ man in his proper place—as tiller of the soil. Here lies the chemist's opportunity. At no very distant date, perhaps, when petrol is exhausted, toll will be taken from the sun in the form of starch or sugar and this will be converted into alcohol.

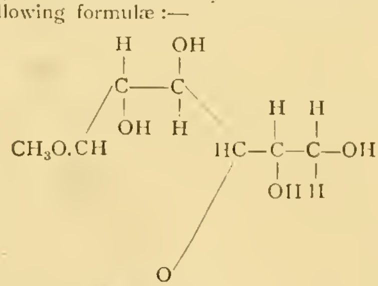
[1] Since this was written, Thiele's discovery of "Azomethane," MeN : NMe, has been announced. This is described as being, in the solid state, a distinctly coloured, very pale yellow substance. There can be little if any doubt, therefore, that, as Robertson and I have argued, the colourless so-called syn- and antidiazo-salts cannot possibly be compounds of the —N : N— or diazene type; such compounds would all be at least yellow in colour.

of compounds. Moreover, not only the sugars and most of the other products of the disintegration of the albuminoids but also the amino-acids, in like manner, are derivatives of compounds containing at most six atoms of carbon; the fats alone are of a considerably higher degree of complexity but they are probably collocations of the simpler units.

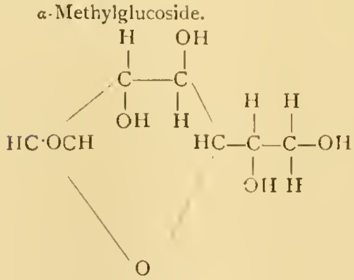
The terpenes and essential oils are mostly C_{10} derivatives; the alkaloids have complex formulæ but the units of which they are composed are simple; as all of them are optically active, it is clear that only some of the possible enantiomorphous combinations are present.

We are bound, therefore, to assume that a large proportion of the changes which occur in living organisms—which constitute vital metabolism—are directed changes. What is the nature of the directive power? We are already able to go far in explaining this, although our knowledge is mainly of analytical changes, the nature of synthetic changes being, at present, only inferentially disclosed to us.

It has long been known that under natural conditions many complex compounds such as starch, cane sugar, and other similar substances are broken down hydrolytically, not by the unassisted action of water but by the co-operation of enzymes; the effect produced by these enzymes is precisely similar to that of acids, except that all acids produce the effect, acting only with different degrees of readiness, whilst enzymes are strictly selective, a given enzyme acting only, as a rule, either on a single substance or on a series of substances similar in structure. Indisputable evidence has been obtained that the enzymes which act on the carbohydrates are intimately related in structure to the compounds which they attack, fitting them—to use the apt simile introduced by E. Fischer—much as a key fits into a good lock: the slightest alteration in the structure of the carbohydrate is sufficient to throw the enzyme out of action. The closeness of the association is well illustrated by the case of the two methylglucosides, which differ merely in the manner displayed by the following formulæ:—



α-Methylglucoside.



β-Methylglucoside.

The relative positions of the single hydrogen atom and of the hydroxyl group attached to the carbon atom are merely interchanged, but this is sufficient to render the one (the α) proof against the action of emulsin, the enzyme of the almond; the other (the β) proof against that of maltase, the enzyme present in yeast.

The enzyme may be pictured as attaching itself to a surface of the molecule, and at the same time as associated with hydrone in such a manner that this is brought to bear at the junction which undergoes disruption. The action of acids, although similar, is simpler in that the attachment is not to the molecule as a whole but only at, or near to, the junction which is resolved.

In the case of the albuminoids, the action is probably more local in character, in so far as the resolution of their polypeptide section is concerned, the same enzyme being able to effect the resolution of a considerable number of compounds.

All the peptolytes have in common the junction C.CO.N; the peptoclasts by which such substances are gradually resolved probably fit this group alone; but other enzymes are of more complex organisation, akin to that of the sucroclasts—such as arginase, for example. In principle, however, the enzymes are to be regarded as all acting alike, each as fitting some particular asymmetric centre if not the whole of the molecule which undergoes hydrolytic disruption under its influence, the asymmetric centre being that at which the cleavage is effected.

In synthetic changes the operation is reversed. It may be supposed that the separation of hydrone is determined by the circumstance that water can be formed by the interaction of this hydrone as it separates with that which is attached to the hydrolated enzyme; the formation of water, in fact, plays a great part in such changes.

The action of oxydases may be regarded from a similar point of view. The early observations of Adrian Brown on the oxidising activity of *Bacterium Xylinum*, coupled with the later work of Bertrand, afford clear proof that these enzymes are possessed of selective powers. It is conceivable that such enzymes become attached to a molecule at some one centre, and that they then deliver their attack at some more or less distant point by presenting the oxygen with which they are loosely associated at this point. It is easy, on such an assumption, to understand how ethenoid linkages may be developed in various positions in the molecule of a fatty acid.

Rosenthaler's recent observations on the formation of optically active phenyl hydroxycyano methane,

$$PhCH(OH)CN,$$

from hydrogen cyanide and benzaldehyde on shaking the solution with emulsin are, however, among the most significant yet made. I have myself confirmed his statements. The ease with which the change takes place—the manner in which the change is accelerated by the enzyme—is altogether remarkable.

Although there can be little doubt, in the case of plants and animals, that the synthetic processes do not occur spontaneously and directly between the interagents, but are for the most part at some stage or other directed or controlled, it cannot well be supposed that every asymmetric compound is the direct outcome of a controlled process; nor is it necessary to assume that such is the case. Not a few asymmetric compounds are probably but secondary products formed by the breakdown of compounds which are the products of directed synthesis.

Ehrlich's observations on the formation of the amylalcohols from the isomeric aminocaproic acids (leucines) may be referred to in this connection. Taking into account the manner in which the vegetable organism is provided with conservative powers and its tendency to retain nitrogen, in view of the peculiar structure of the members of the terpene group—especially the presence of the isopropyl group and of methyl in association with the ring in such hydrocarbons—it is highly probable that the terpenes are derived from amino-acids. A molecule of leucine, a molecule of alanine and a molecule of formaldehyde obviously provide the materials for the production of methylisopropyldihydrobenzene; it is not difficult to picture the series of changes which would lead to the formation of the hydrocarbon from such a conjunction.

The general impression produced by facts such as have been referred to is that directive influences are the paramount influences at work in building up living tissues. These come into operation, it is to be supposed, at a very early stage in the case of the plant. The initial step probably involves the electrolysis of water under the influence of solar energy and the reduction by the hydrogen thus liberated of the carbon dioxide, which is eventually converted into formaldehyde, either directly or, it may be, through the intermediation of oxalic and formic acids. The part which chlorophyll plays in this process can only be surmised: it is not improbable that reduced chlorophyll is the active reducing-agent: that chlorophyll itself is active in conditioning the resolution of water under the influence of solar energy into reduced chlorophyll and oxygen or, more probably, a labile peroxide, from which oxygen is independently split off at a subsequent stage, it may be under the influence of a so-called catalase.

Whatever the process by which the plant acquires its initial store of carbonaceous material, the formaldehyde is apparently at once made use of and, in part at least, converted into starch. The view may be taken that glucose is the primary product of condensation—that the formaldehydrol molecules become ranged against a glucose template in series of sixes, which are soldered by enzymic influence into a single molecule by the interaction of contiguous hydrogen and hydroxyl radicles along the chain.

The glucose is thereafter carried a stage higher and converted into maltose or it may be that a maltose template is effective from the beginning and that the biose is the immediate product of condensation; the conversion of maltose into starch must take place in some similar manner. The recent observation that cellobiose is a β-glucoside enables us to realise that the formation of cellulose differs from that of starch in that the glucose molecule, instead of being converted into the β-glucoside maltose, becomes changed into the correlated β-glucoside, a membrane being thus secured which can resist the diastic enzymes by which starch is attacked.

The formation of the albuminoid substances may be regarded from a similar point of view. At present, however, there is no satisfactory evidence to show at what stage nitrogen is introduced into the molecule. As the plant takes up nitrogen in the form of nitrate, not as ammonia, it is probable that the nitrate is reduced to hydroxylamine and that this, rather than ammonia, is the active synthetic agent. Formaldehyde and hydroxylamine would yield formaldoxime, which would easily pass into methylamine on reduction; the interaction of formaldoxime and formaldehydrol might give rise to a higher aldoxime which would be easily convertible into amino-acetic acid (glycine). Higher glycines might be formed from glycine by syntheses similar to those Erlenmeyer has effected; but to account for the formation of asymmetric amino-acids it is necessary to assume that the action is controlled at this stage and that the glycine is formed against a template perhaps under the influence of an enzyme.

Another conceivable mode of formation is by the fermentative degradation of glucosamine.

Until we know more of the order in which the amino-acid radicles are united in the various albuminoids and of the character of the associations other than those which are characteristic of polypeptides, we can consider the formation of albuminoids only from a very general point of view; but taking into account the very different proportions in which amino-acids and other cleavage products are formed on hydrolysing substances of different origin, it is clear that the several sections of the molecule must be differently ordered in the different proteins; again, therefore, it is necessary to assume that the formation of such substances is directed. We may picture molecule after molecule as being "brought into line" against a template and the junctions which are required to bind the whole series together as being made through the agency of the enzymic dehydrating influence before referred to.

Attention has been directed to the relatively simple way in which the hydrocarbons are constructed, that even the paraffins are not to be visualised as so many ducks strung upon a ramrod, Münchausen fashion, but as forming curls, owing to the natural set of the affinities. This probably is true of complex substances such as the proteins.

Protoplasm, in fact, may be pictured as made up of large numbers of curls, like a judge's wig—all in intercommunication through some centre, connected here and there perhaps also by lateral bonds of union. If such a point of view be accepted, it is possible to account for the occurrence in some sections of the complex series of interchanges which involve work being done upon the substances brought into interaction, the necessary energy being drawn from some other part of the complex where the interchanges involve a development of energy.

The conclusions thus arrived at may be utilised in discussing the problem of heredity. The inheritance of parental qualities, the need to assume continuity of the germ plasm and the comparative unimportance from the standpoint of heredity of somatic qualities, as well as the non-inheritance of mere environmental effects (acquired characters), are all necessary consequences of the view I have advanced.

The general similarity of structure throughout organised creation may well be conditioned primarily by properties inherent in the materials of which all living things are composed—of carbon, of oxygen, of nitrogen, of hydrogen, of phosphorus, of sulphur. At some early period, however, the possibilities became limited and directed processes became the order of the day. From that time onward the chemistry prevailing in organic nature became a far simpler chemistry than that of the laboratory; the possibilities were diminished, the certainties of a definite line of action were increased. How this came about it is impossible to say; mere accident may have led to it. Thus we may assume that some relatively simple asymmetric substance was produced by the fortuitous occurrence of a change under conditions such as obtain in our laboratories and that consequently the enantiomorphous isomeric forms of equal opposite activity were produced in equal amount. We may suppose that a pool containing such material having been dried up dust of molecular fineness was dispersed; such dust falling into other similar pools near the crystallisation point may well have conditioned the separation of only one of the two isomeric forms present in the liquid. A separation having been once effected in this manner, assuming the substance to be one which could influence its own formation, one form rather than the other might have been produced. An active substance thus generated and selected out might then become the origin of a series of asymmetric syntheses. How the complicated series of changes which constitute life may have arisen we cannot even guess at present; but when we contemplate the inherent simplicity of chemical change and bear in mind that life seems but to depend on the simultaneous occurrence of a series of changes of a somewhat diverse order, it does not appear to be beyond the bounds of possibility to arrive at a broad understanding of the method of life. Nor are we likely to be misled into thinking that we can so arrange the conditions as to control and reproduce it; the series of lucky accidents which seem to be required for arrangements of such complexity to be entered upon is so infinitely great.

It is impossible to rate chemistry at too high a value in Canada. The maintenance of the fertility of your fields, the proper utilisation of your vast mineral wealth, the purity of your food supplies [1] will depend mainly on the watchful care and skill of chemists; but the educational value of the subject may also be set very high. If properly taught in your schools, it will afford a means superior to all others, I believe, of training faculties which in these days should be developed in every responsible citizen. No other subject lends itself so effectively as a means of developing the experimental attitude of mind—the attitude of working with a clearly conceived purpose to a desired end, which is so necessary to success in these days; and if care be taken to inculcate habits of neatness and precision and of absolute truthfulness, if care be taken to teach what constitutes evidence, the moral value of such work is incalculable. But to be effective it must be done under proper conditions, systematically; the time devoted to the work must be adequate; I would even advocate that the subject be allowed to come before conventional geography and history and other unpractical subjects, assuming that the training is given in a practical way and with practical objects in view, not in the form of mere lessons learnt by rote; if taught in the form of mere didactic lessons it is as worthless as any other subject as mental discipline. Let me add that I would confine the teaching to a narrow range of problems but make it very thorough with reference to these.

[1] I should like to take this opportunity of saying that it is impossible to over-rate the public value of the great work which Dr. Wiley has undertaken in the United States in endeavouring to secure the supply of food free from deleterious ingredients. At home we certainly need some one to preach a similar crusade and to free us from doctored infants' foods and the innumerable host of medicines by which even our fair fields are disfigured.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY ARTHUR SMITH WOODWARD, LL.D., F.R.S., V.P.Z.S., SEC. G.S., KEEPER OF GEOLOGY IN THE BRITISH MUSEUM, PRESIDENT OF THE SECTION.

THE circumstances of the present meeting very clearly determine the subject of a general address to be expected from a student of extinct animals. The remarkable discoveries of fossil backboned animals made on the North American continent during the last fifty years suggest an estimate of the results achieved by the modern systematic methods of research; while the centenary celebration of the birth of Darwin makes it appropriate to consider the extent to which we may begin deducing the laws of organic evolution from the life of past ages as we now know it. Such an address must, of course, be primarily biological in character, and treat of some matters which are not ordinarily discussed by Section C. The subject, however, can only be appreciated fully by those who have some practical acquaintance with the limitations under which geologists pursue their researches, and especially by those who are accustomed to geological modes of thought.

There has been an unfortunate tendency during recent years for the majority of geologists to relinquish the study of fossils in absolute despair. More ample material for examination and more exact methods of research have altered many erroneous names which were originally used; while the admission to scientific publications of too many mere literary exercises on the so-called "law of priority" has now made it necessary to learn not one, but several names for some of the genera and species which are commonly met with. Even worse, the tentative arrangement of fossils in "genetic series" has led to the invention of a multitude of terms which often serve to give a semblance of scientific exactitude to the purest guesswork, and sometimes degenerate into a jargon which is naturally repellent to an educated mind. Nevertheless, I still hope to show that, with all these difficulties, there is so much of fundamental interest in the new work that it is worth while to make an effort to appreciate it. Geology and palæontology in the past have furnished some of the grandest possible contributions to our knowledge of the world of life; they have revealed hidden meanings which no study of the existing world could even suggest; and they have started lines of inquiry which the student of living animals and plants alone would scarcely have suspected to be profitable. The latest researches are the logical continuation of this pioneer work on a more extensive scale, and with greater precision; and I am convinced that they will continue to be as important a factor in the progress of post-Darwinian biology as were the older studies of fossils in the philosophy of Cuvier, Brongniart, and Owen.

In this connection it is necessary to combat the mistaken popular belief that the main object of studying fossils is to discover the "missing links" in the chain of life. We are told that the idea of organic evolution is not worthy of serious consideration until these links, precise in character, are forthcoming in all directions. Moreover, the critics who express this opinion are not satisfied to consider the simplest cases, such as are afforded by some of the lower grades of "shell-fish" which live together in immense numbers and have limited powers of locomotion. They demand long series of exact links between the most complex skeletal frames of the backboned animals, which have extreme powers of locomotion, are continually wandering, and are rarely preserved as complete individuals when they are buried in rock. They even expect continual discoveries of links among the rarest of all fossils, those of the higher apes and man. The geologist, on the other hand, knowing well that he must remain satisfied with a knowledge of a few scattered episodes in the history of life which are always revealed by the merest accident, marvels that the discovery of "missing links" is so constant a feature of his work. He is convinced that, if circumstances were more favourable, he would be able to satisfy the demand of the most exacting critic. He has found enough continuous series among the mollusca, for example, and so many suggestions of equally gradual series among the higher animals, that he does not hesitate to believe without further evidence in a process of descent with modification. The mere reader of books is often misled by the vagaries of nomenclature to suppose that the intervals between the links are greater than in reality; but for the actual student it is an everyday experience to find that fossils of slightly different ages which he once thought distinct are linked together by a series of forms in which it is difficult to discover the feeblest lines of demarcation. He is therefore justified in proceeding on the assumption that in all cases the life of one geological period has passed by a natural process of descent into that of the next succeeding period; and, avoiding genealogical guesswork which proves to be more and more futile, he strives to obtain a broad view of the series of changes which have occurred, to distinguish between those which denote progress and those which lead to stagnation or extinction. When the general features of organic evolution are determined in this manner, it will be much easier than it is at present to decide where missing links in any particular case are most likely to be found.

Among these general features which have been made clear by the latest systematic researches, I wish especially to emphasise the interest and significance of the persistent progress of life to a higher plane, which we observe during the successive geological periods. For I think palæontologists are now generally agreed that there is some principle underlying this progress much more fundamental than chance-variation or response to environment however much these phenomena may have contributed to certain minor adaptations. Consider the case of the backboned animals, for instance, which I happen to have had special opportunities of studying.

We are not likely ever to discover the actual ancestors of animals on the backboned plan, because they do not seem to have acquired any hard skeleton until the latter part of the Silurian period, when fossils prove them to have been typical and fully developed, though low in the backboned scale. The ingenious researches and reasoning of Dr. W. H. Gaskell, however, have suggested the possibility that these animals originated from some early relatives of the scorpions and crustaceans. It is therefore of great interest to observe that the Eurypterids and their allies, which occupy this zoological position, were most abundant during the Silurian period, were represented by species of the largest size immediately afterwards at the beginning of the Devonian, and then gradually dwindled into insignificance. In other words, there was a great outburst of Eurypterid life just at the time when backboned animals arose; and if some of the former were actually transformed into the latter, the phenomenon took place when their powers both of variation and of multiplication were at their maximum.

Fishes were already well established and distributed over perhaps the greater part of the northern hemisphere at the beginning of Devonian times; and then there began suddenly a remarkable impulse towards the production of lung-breathers, which is noticeable not only in Europe and North America, but also probably so far away as Australia. In the middle and latter part of the Devonian period, most of the true fishes had paddles, making them crawlers as much as swimmers; many of them differed from typical fishes, while agreeing with lung-breathers, in having the basis of the upper jaw fused with the skull, not suspended; and some of them exhibited both these features. Their few survivors at the present day (the Crossopterygians and Dipnoans) have also an air-bladder, which might readily become a lung. The characteristic fish-fauna of the Devonian period, therefore, made a nearer approach to the land animals than any group of fishes of later date; and it is noteworthy that in the Lower Carboniferous of Scotland—perhaps even in the Upper Devonian of North America, if footprints can be trusted—amphibians first appeared. In Upper Carboniferous times they became firmly established, and between that period and the Trias they seem to have spread all over the world; their remains having been found, indeed, in Europe, Spitsbergen, India, South Africa, North and South America, and Australia.

The Stegocephala or Labyrinthodonts, as these primitive amphibians are termed, were therefore a vigorous race; but the marsh-dwelling habits of the majority did not allow of much variation from the salamander-pattern. Only in Upper Carboniferous and Lower Permian times did some of their smaller representatives (the Microsauria) become lizard-like, or even snake-like in form and habit; and then there suddenly arose the true reptiles. Still, these reptiles did not immediately replace the Stegocephala in the economy of Nature; they remained quite secondary in importance at least until the Upper Permian, in most parts even until the dawn of the Triassic period. Then they began their flourishing career.

At this time the reptiles rapidly diverged in two directions. Some of them were almost exactly like the little Sphenodon, which still survives in some islands off New Zealand, only retaining more traces of their marsh-dwelling ancestors. The majority (the Anomodonts or Theromorphs) very quickly became so closely similar to the mammals that they can only be interpreted as indicating an intense struggle towards the attainment of the higher warm-blooded grade; and there is not much doubt that true mammals actually arose about the end of the Triassic period. Here, again, however, the new race did not immediately replace the old, or exterminate it by unequal competition. Reptiles held their own on all lands throughout the Jurassic and Cretaceous periods, and it was not until the Tertiary that mammals began to predominate.

As to the beginning of the birds, it can only be said that towards the end of the Triassic period there arose a race of small Dinosaurs of the lightest possible build, exhibiting many features suggestive of the avian skeleton; so it is probable that this higher group also originated from an intensely restless early community of reptiles, in which all the variations were more or less in the right direction for advancement.

In short, it is evident that the progress of the backboned land animals during the successive periods of geological time has not been uniform and gradual, but has proceeded in a rhythmic manner. There have been alternations of restless episodes which meant real advance, with periods of comparative stability, during which the predominant animals merely varied in response to their surroundings, or degenerated, or gradually grew to a large size. There was no transition, for instance, between the reptiles of the Cretaceous period and the mammals which immediately took their place in the succeeding Eocene period: those mammals, as we have seen, had actually originated long ages before, and had remained practically dormant in some region which we have not yet discovered, waiting to burst forth in due time. During this retirement of the higher race the reptiles themselves had enjoyed an extraordinary development and adaptation to every possible mode of life in nearly all parts of the globe. We do not understand the phenomenon—we cannot explain it; but it is as noticeable in the geological history of fishes as in that of the land animals just considered. It seems to have been first clearly observed by the distinguished American naturalist, the late Prof. Edward D. Cope, who termed the sudden fundamental advances "expression points" and saw in them a manifestation of some inscrutable inherent "bathmic force."

Perhaps the most striking feature to be noticed in each of these "expression points" is the definite establishment of some important structural character which had been imperfect or variable before, thus affording new and multiplied possibilities of adaptation to different modes of life. In the first lung-breathers (Stegocephala), for example, the indefinite paddle of the mud fishes became the definite five-toed limb; while the incomplete backbone reached completeness. Still, these animals must have been confined almost entirely to marshes, and they seem to have been all carnivorous. In the next grade, that of the reptiles, it became possible to leave the marshes; and some of them were soon adapted not only for life on hard ground or in forests, but even for flight in the air. Several also assumed a shape of body and limbs enabling them to live in the open sea. Nearly all were carnivorous at first, and most of them remained so to the end; but many of the Dinosaurs eventually became practically hoofed animals, with a sharp beak for cropping herbage, and with powerful grinding teeth. In none of these animals, however, were the toes reduced to less than three in number, and in none of them were the basal toe-bones fused together as they are in cattle and deer. It is also noteworthy that the brain in all of them remained very small and simple. In the final grade of backboned life, that of the mammals, each of the adaptive modifications just mentioned began to arise again in a more nearly perfected manner, and now survival depended not so much on an effective body as on a developing brain. The mammals began as little carnivorous or mixed-feeding animals with a small brain and five toes, and during the Tertiary period they gradually differentiated into the several familiar groups as we now known them, eventually culminating in man.

The demonstration by fossils that many animals of the same general shape and habit have originated two or three times, at two or three successive periods, from two or three continually higher grades of life, is very interesting. To have proved, for example, that flying reptiles did not pass into birds or bats, that hoofed Dinosaurs did not change into hoofed mammals, and that Ichthyosaurs did not become porpoises; and to have shown that all these later animals were mere mimics of their predecessors, originating independently from a higher yet generalised stock, is a remarkable achievement. Still more significant, however, is the discovery that towards the end of their career through geological time totally different races of animals repeatedly exhibit certain peculiar features, which can only be described as infallible marks of old age.

The growth to a relatively large size is one of these marks, as we observe in the giant Pterodactyls of the Cretaceous period, the colossal Dinosaurs of the Upper Jurassic and Cretaceous, and the large mammals of the Pleistocene and the present day. It is not, of course, all the members of a race that increase in size; some remain small until the end, and they generally survive long after the others are extinct; but it is nevertheless a common rule that the prosperous and typical representatives are successively larger and larger, as we see them in the familiar cases of the horses and elephants of the northern hemisphere, and the hoofed animals and armadillos of South America.

Another frequent mark of old age in races was first discussed and clearly pointed out by the late Prof. C. E. Beecher, of Yale. It is the tendency in all animals with skeletons to produce a superfluity of dead matter, which accumulates in the form of spines or bosses as soon as the race they represent has reached its prime and begins to be on the down-grade. Among familiar instances may be mentioned the curiously spiny Graptolites at the end of the Silurian period, the horned Pariasaurians at the beginning of the Trias, the armour-plated and horned Dinosaurs at the end of the Cretaceous, and the cattle or deer of modern Tertiary times. The latter case—that of the deer—is specially interesting, because fossils reveal practically all the stages in the gradual development of the horns or antlers, from the hornless condition of the Oligocene species, through the simply forked small antlers of the Miocene species, to the largest and most complex of all antlers seen in *Cervus sedgwicki* from the Upper Pliocene and the Irish deer (*C. giganteus*) of still later times. The growth of these excrescences, both in relative size and complication, was continual and persistent until the climax was reached and the extreme forms died out. At the same time, although the palæontologist must regard this as a natural and normal phenomenon not directly correlated with the habits of the race of animals in which it occurs, and although he does not agree with the oft-repeated statement that deer may have "perfected" their antlers through the survival of those individuals which could fight most effectively, there may nevertheless be some truth in the idea that the growths originally began where the head was subject to irritating impacts, and that they so happened to become of utility. Fossils merely prove that such skeletal outgrowths appear over and over again in the prime and approaching old age of races; they can suggest no reasons for the particular positions and shapes these outgrowths assume in each species of animal.

It appears, indeed, that when some part of an animal (whether an excrescence or a normal structure) began to grow relatively large in successive generations during geological time, it often acquired some mysterious impetus by which it continued to increase long after it had reached the serviceable limit. The unwieldy antlers of the extinct Sedgwick's deer and Irish deer just mentioned, for example, must have been impediments rather than useful weapons. The excessive enlargement of the upper canine teeth in the so-called sabre-toothed tigers (Machærodus and its allies) must also eventually have hindered rather than aided the capture and eating of prey. The curious gradual elongation of the face in the Oligocene and Miocene Mastodons, which has lately been described by Dr. Andrews, can only be regarded as another illustration of the same phenomenon. In successive generations of these animals the limbs seem to have grown continually longer, while the neck remained short, so that the head necessarily became more and more elongated to crop the vegetation on the ground. A limit of mechanical inefficiency was eventually reached, and then there survived only those members of the group in which the attenuated mandible became shortened up, leaving the modified face to act as a "proboscis." The elephants thus arose as a kind of after-thought from a group of quadrupeds that were rapidly approaching their doom.

The end of real progress in a developing race of backboned animals is also often marked by the loss of the teeth. A regular and complete set of teeth is always present at the commencement, but it frequently begins to lack successors in animals which have reached the limit of their evolution, and then it soon disappears. Tortoises, for instance, have been toothless since the Triassic period, when they had assumed all their essential features; and birds have been toothless since the end of Cretaceous times. The monotreme mammals of Australasia, which are really a survival from the Jurassic period, are also toothless. Some of the latest Ichthyosaurs and Pterodactyls were almost or quite toothless; and I have seen a jaw of an Upper Cretaceous carnivorous Dinosaur (Genyodectes) from Patagonia so completely destitute of successional teeth that it seems likely some of these land reptiles nearly arrived at the same condition.

Among fishes there is often observable still another sign of racial old age—namely, their degeneration into eel-shaped forms. The Dipnoan fishes afford a striking illustration, beginning with the normally shaped Dipterus in the Middle Devonian, and ending in the long-bodied Lepidosiren and Protopterus of the present day. The Palæozoic Acanthodian sharks, as they are traced upwards from their beginning in the Lower Devonian to their end in the Permian, also acquire a remarkable elongation of the body and a fringe-like extension of the fins. Among higher fishes, too, there are numerous instances of the same phenomenon, but in most of these the ancestors still remain undiscovered, and it would thus be tedious to discuss them.

Finally, in connection with these obvious symptoms of old age in races, it is interesting to refer to a few strange cases of the rapid disappearance of whole orders of animals, which had a practically world-wide distribution at the time when the end came. Local extinction, or the disappearance of a group of restricted geographical range, may be explained by accidents of many kinds; but contemporaneous universal extinction of widely spread groups, which are apparently not affected by any new competitors, is not so easily understood. The Dinosaurs, for instance, are known to have lived in nearly all lands until the close of the Cretaceous period; and, except perhaps in Patagonia, they were always accompanied until the end by a typically Mesozoic fauna. Their remains are abundant in the Wealden formation of Western Europe, the deposit of a river which must have drained a great continent at the beginning of the Cretaceous period; they have also been found in a corresponding formation which covers a large area in the State of Bahia, in Brazil. They occur in great numbers in the freshwater Upper Cretaceous Laramie deposits of Western North America, and also in a similar formation of equally late date in Transylvania, South-east Europe. In only two of these regions (South-east England and West North America) have any traces of mammals been found, and they are extremely rare fragments of animals as small as rats; so there is no reason to suppose that the Dinosaurs suffered in the least from any struggle with warm-blooded competitors. Even in Patagonia, where the associated mammal-remains belong to slightly larger and more modern animals, these fossils are also rare, and there is nothing to suggest competition. The race of Dinosaurs seems, therefore, to have died a natural death. The same may be said of the marine reptiles of the orders Ichthyosauria, Plesiosauria, and Mosasauria. They had a practically world-wide distribution in the seas of the Cretaceous period, and the Mosasauria especially must have been extremely abundant and flourishing. Nevertheless, at the end of Cretaceous times they disappeared everywhere, and there was absolutely nothing to take their place until the latter part of the Eocene period, when whales and porpoises began to play exactly the same part. So far as we know, the higher race never even came in contact with the lower race; the marine mammals found the seas vacant, except for a few turtles and for one curious Rhynchocephalian reptile (Champsosaurus), which did not long survive. Another illustration of the same phenomenon is probably afforded by the primitive Carnivora (the so-called Sparassodonta), which were numerous in South America in the Lower Tertiary periods. They were animals with a brain as small as that of the thylacines and dasyures which now live in Tasmania. They appear to have died out completely before they were replaced by the cats, sabre-toothed tigers, and dogs, which came down south from North America over the newly emerged isthmus of Panama at the close of the Pliocene period. At least, the remains of these old carnivores and their immigrant successors have never yet been found associated in any geological formation.

These various considerations lead me to think that there is also deep significance in the tendency towards fixity in the number and regularity (or symmetry) in the arrangement of their multiple parts, which we frequently observe in groups of animals as we trace them from their origin to their prime. It is well known that in certain of the highest and latest types of bony fishes the vertebræ and fin-rays are reduced to a fixed and practically invariable number for each family or genus, whereas there is no such fixity in the lower and earlier groups. In the earliest known Pycnodont fishes from the Lower Lias (Mesodon) the grinding teeth form an irregular cluster, while in most of the higher and later genera they are arranged in definite regular rows in a symmetrical manner. Many of the lower backboned animals have teeth with several cusps, and in some genera the number of teeth seems to be constant; but in the geological history of the successive classes the tooth-cusps never became fixed individual entities, readily traceable throughout whole groups, until the highest or mammalian grade had been attained. Moreover, it is only in the same latest grade or class that the teeth themselves can be treated as definite units, always the same in number (forty-four), except when modified by degeneration or special adaptation. In the earlier and lower land animals the number of vertebræ in the neck depends on the extent of this part, whereas in the mammal it is almost invariably seven, whatever the total length may be. Curiously constant, too, in the modern even-toed hoofed mammals is the number of nineteen vertebræ between the neck and the sacrum.

I am therefore still inclined to believe that the comparison of vital processes with certain purely physical phenomena is not altogether fanciful. Changes towards advancement and fixity which are so determinate in direction, and changes towards extinction which are so continually repeated, seem to denote some inherent property in living things, which is as definite as that of crystallisation in inorganic substances. The regular course of these changes is merely hindered and modified by a succession of checks from the environment and Natural Selection. Each separate chain of life, indeed, bears a striking resemblance to a crystal of some inorganic substance which has been disturbed by impurities during its growth, and has thus been fashioned with unequal faces, or even turned partly into a mere concretion. In the case of a crystal the inherent forces act solely on molecules of the crystalline substance itself, collecting them and striving, even in a disturbing environment, to arrange them in a fixed geometrical shape. In the case of a chain of life (or organic phylum) we may regard each successive animal as a temporary excrescence of colloid substance round the equally colloid germ-plasm which persists continuously from generation to generation. The inherent forces of this germ-plasm, therefore, act upon a consecutive series of excrescences (or animal bodies), struggling not for geometrically arranged boundaries, but towards various other symmetries, and a fixity in number of multiple parts. When the extreme has been reached, activities cease, and sooner or later the race is dead.

Such are some of the most important general results to which the study of fossils has led during recent years; and they are conclusions which every new discovery appears to make more certain. When we turn to details, however, it must be admitted that modern systematic researches are continually complicating rather than simplifying the problems we have to solve. Prof. Charles Depéret has lately written with scant respect of some of the pioneers who were content with generalities, and based their conclusions on the geological succession of certain anatomical structures rather than on a successive series of individuals and species obtained from the different layers of one geological section; but even now I do not think we can do much better than our predecessors in unravelling real genealogies. At least Prof. Depéret's genealogical table of the Lower Tertiary pig-like Anthracotheriidæ, which he publishes as an illustration of "évolution réelle," seems to me to be no more exact than several tables of other groups by previous authors which he criticises. His materials are all fragmentary, chiefly jaws and portions of skulls; they were obtained from several isolated lake-deposits, of which the relative age cannot be determined by observing the geological superposition; and they represent a group which is known to have lived over a large part of Europe, Asia, Northern Africa, and North America. There is therefore no certainty that the genera and species enumerated by Prof. Depéret actually originated one from the other in the region where he happened to find them; he has demonstrated the general trend of certain changes in the Anthracotheriidæ during geological time, but really nothing more.

Even when a group of animals seems to have been confined to one comparatively small region, where the series is not complicated by migration to and from other parts of the world, modern research still emphasises the difficulty of tracing real lines of descent. The primitive horned hoofed animals of the family Titanotheriidæ, for example, are only known from part of North America, and they seem to have originated and remained there until the end. As their fossil skeletons are abundant and well preserved, it ought to be easy to discover the exact connections of the several genera and species. Prof. Osborn has now proved, however, that the Titanotheres must have evolved in at least four distinct lines, adapted "for different local habitat, different modes of feeding, fighting, locomotion, &c., which took origin, in part at least, in the Middle or Upper Eocene." They exhibit "four distinct types in the shape and position of the horns, correlated with the structure of the nasals and frontals, and indicative of different modes of combat among the males." The ramifications of the group are indeed so numerous that the possibility of following chains of ancestors begins to appear nearly hopeless.

Among early reptiles the same difficulties are continually multiplied by the progress of discovery. About twenty years ago it began to appear likely that we should soon find the terrestrial ancestors of the Ichthyosauria in the Trias; and somewhat later a specimen from California raised hopes of obtaining them by systematic explorations in that region. During more recent years Prof. J. C. Merriam and his colleagues have actually made these explorations, and the result is that we now know from the Californian Trias a multitude of reptiles, which need more explanation than the Ichthyosauria themselves. Prof. Merriam has found some of the links predicted between Ichthyosaurs and primitive land reptiles, but he has by no means reached the beginning of the marine group; and while making these discoveries he has added greatly to the complication of the problem which he set out to solve.

Serious difficulties have also become apparent during recent years in determining exactly the origin of the mammals. For a long time after the discovery of the Anomodont or Theromorph reptiles in the Permian-Trias of South Africa, it seemed more and more probable that the mammals arose in that region. Even yet new reptiles from the Karoo formation are continually being described as making an astonishingly near approach to mammals; and, so far as the skeleton is concerned, the links between the two grades are now very numerous among South African fossils. Since these reptiles first attracted attention, however, they have gradually been found in the Permian and Trias of a large part of the world. Remains of them were first met with in India, then in North America, and next in Scotland, while during the last few years Prof. W. Amalitzky has disinterred so many nearly complete skeletons in the north of Russia that we are likely soon to learn more about them from this European country than from the South African area itself. Quite lately I have received numerous bones from a red marl in Rio Grande do Sul, Southern Brazil, which show that not merely Anomodonts, but also other characteristic Triassic land reptiles were likewise abundant in that region. We are therefore now embarrassed by the richness of the sources whence we may obtain the ancestors of mammals. Whereas some years ago it appeared sufficient to search South Africa for the solution of the problem, we are now uncertain in which direction to turn. We are still perhaps inclined to favour the South African source; but this is only because we know nothing of the Jurassic land animals of that part of the world, and we cherish a lingering hope that they may eventually prove to have included the early mammals for which we have so long sought in vain.

The mystery of the origin of the marine mammals of the order Sirenia and Cetacea appears to have been diminished by the discoveries of the Geological Survey of Egypt, Dr. Andrews and Dr. Fraas in the Eocene and Oligocene deposits of the Mokattam Hills and the Fayum. It is now clear that the Sirenians are closely related to the small primitive ancestors of the elephants; while, so far as the skull and dentition are concerned, we know nearly all the links between the early toothed whales (or Zeuglodonts) and the primitive ancestors of the Carnivora (or Creodonts). The most primitive form of Sirenian skull hitherto discovered, however, is not from Egypt, but from the other side of the world, Jamaica; and exactly the same Zeuglodonts, even with an associated sea-snake, occur so far away from Egypt as Alabama, U.S.A. The problem of the precise origin of these marine mammals is therefore not so simple as it would have appeared to be had we known only the Egyptian fossils. The progress of discovery, while revealing many most important generalities, has made it impossible to vouch for the accuracy of the details in any "genealogical tree."

Another difficulty resulting from the latest systematic researches is suggested by the extinct hoofed mammals of South America. The llamas, deer, and peccaries existing in South America at the present time are all immigrants from the northern continent; but during the greater part of the Tertiary period there lived in that country a large number of indigenous hoofed mammals, which originated quite independently of those in other regions. They seem to have begun in early Eocene times much in the same manner as those of the northern hemisphere; but as they became gradually adapted for life on hard ground, they formed groups which are very different from those with which we are familiar in our part of the world. Some of them (Proterotheriidæ) were one-toed mimics of the horses, but without the advanced type of brain, the deepened grinding teeth, the mobile neck, or the really effective wrist and ankle. Others (Toxodontidæ) made some approach towards rhinoceroses in shape and habit, even with a trace of a horn on the nose. Until their independent origin was demonstrated, these curious animals could not be understood; and it is probable that there are innumerable similar cases of parallel development of groups, by which in our ignorance we are often misled.

It would be easy to multiply instances, but I think I have now said enough to show that every advance in the study of fossils reveals more problems than it solves. During the last two decades the progress in our knowledge of the extinct backboned animals has been truly astonishing, thanks especially to the great explorations in North America, Patagonia, Egypt, Madagascar, and South Africa. Whole groups have been traced a long way towards their origin; but with them have been found a number of previously unknown groups which complicate all questions of evolution to an almost bewildering extent. Animals formerly known only by fragments are now represented by nearly complete skeletons, and several which appeared to have a restricted geographical range have now been found over a much wider area; but while this progress has been made, numerous questions have arisen as to the changing connections of certain lands and seas which previously seemed to have been almost settled. The outlook both of zoology and of geology has, therefore, been immensely widened, but the only real contribution to philosophy has been one of generalities. Some of the broad principles to which I have referred are now so clearly established that we can often predict what will be the main result of any given exploration, should it be successful in recovering skeletons. We are no longer bold enough to restore an entirely unknown extinct animal from a single bone or tooth, like the trustful Cuvierian school; but there are many kinds of bones and teeth of which we can determine the approximate geological age and probable associates, even if we have no exact knowledge of the animals to which they belong. A subject which began by providing material for wonder-books has thus been reduced to a science sufficiently precise to be of fundamental importance both to zoology and to geology; and its exactitude must necessarily increase with greater and greater rapidity as our systematic researches are more clearly guided by the experience we have already gained.

NOTES.

THE special report agreed upon by the Select Committee on the Daylight Saving Bill contains the following conclusion:—"Having regard to the great diversity of opinion existing upon the proposals of the Bill and to the grave doubts which have been expressed as to whether the objects of the measure can be attained by legislation without giving rise, in cases involving important interests, to serious inconvenience, your committee recommend that the Bill be not further proceeded with." We are glad the committee has arrived at this conclusion, which embodies the views expressed in these columns on several occasions. Most people are in favour of the principle of making the best and fullest use of daylight hours, but the compulsory alteration of the system of time-reckoning for several months of the year is quite a different matter. As we have pointed out, in engineering, building, agricultural and other industries in which it is difficult to carry on work by artificial light, the hours of labour are already adapted to the daylight hours in different seasons. Here we have the voluntary adoption of the principle of daylight saving, and we are in complete sympathy with any movement to encourage the extension of the custom to other industrial or commercial circles where earlier hours of commencing work during certain months are practicable or desirable. This can be accomplished, however, without legislation, and the committee has acted wisely in recommending that the Bill, which would make a seasonal change of time compulsory, be not carried further.

A BILL to promote the economic development of the United Kingdom and the improvement of the roads therein was introduced in the House of Commons on August 26 by the Chancellor of the Exchequer. In the explanatory memorandum of this Bill it is stated that Part i. enables the Treasury to make free grants and loans for the purpose of aiding and developing forestry, agriculture, and rural industries, the reclamation and drainage of land, the improvement of rural transport (other than roads), the construction and improvement of harbours and canals, and the development and improvement of fisheries, and for any other purpose calculated to promote the economic development of the United Kingdom. A grant or loan must be made either to or through a Government department, and all applications for grants or loans have to be referred to an advisory committee, and the recommendations of the committee considered before the grant or loan is made; but the responsibility of making the grant or loan will rest with the Treasury, who will not be bound by the recommendations of the committee. All grants and loans will be made out of a separate fund, which will be fed by (1) sums annually voted by Parliament; (2) a sum of 2,500,000*l*. charged on the Consolidated Fund and payable in five annual instalments of 500,000*l*. each in 1911, 1912, 1913, 1914, and 1915; (3) sums received by way of interest on and repayment of loans and the profits made as the result of a grant or loan in cases where the repayment of such profits is made a condition of the grant or loan. Power is given to the Board of Agriculture and Fisheries and the Department of Agriculture and Technical Instruction for Ireland to acquire land (compulsorily if necessary) for any purpose for which a grant is made to them. As the *Times* points out, this part of the Bill will permit the expenditure of money on scientific research and experimental work of a kind likely to be beneficial to agriculture. Part ii. of the Bill constitutes a Road Board for the purpose of improving the facilities for motor traffic. In addition to the power of acquiring land for the purposes of new roads proposed to be constructed by the Road Board, the Board is given power to acquire land in rural districts on either side of any such proposed road to the extent of 220 yards in depth.

DR. ALEXANDER RUSSELL has been appointed principal of Faraday House in succession to the late Mr. H. E. Harrison.

DR. T. H. BRYCE, lecturer on anatomy at Queen Margaret College, Glasgow, has been appointed Regius professor of anatomy in the University of Glasgow in succession to Prof. J. Cleland.

WE regret to see the announcement of the death, at sixty-seven years of age, of Prof. E. C. Hansen, head of the physiological department of the Carlsberg Laboratory, Copenhagen, for studies of chemistry and plant physiology, with particular reference to fermentation.

THE death is announced, at sixty-four years of age, of Dr. Radcliffe Crocker, distinguished particularly by his work on diseases of the skin. Dr. Crocker was the first president of the dermatological section of the Royal Society of Medicine, and made many valuable contributions to the literature of dermatology, among them being his "Treatise on Diseases of the Skin" and "Atlas of Diseases of the Skin."

THE twentieth annual general meeting of the Institution of Mining Engineers will be held at Newcastle-upon-Tyne on September 15. The following are among the papers to be read or discussed:—fire-damp caps and the detection of fire-damp in mines by means of safety-lamps, E. B. Whalley and W. M. Tweedie; equipment for the study of flame-caps and for miscellaneous experiments on safety-lamps, Prof. G. R. Thompson; electricity in coal mines, R. Nelson.

THE Budapest correspondent of the *Times* reports that the sixteenth International Congress of Medicine was officially opened there on August 29 by the Archduke Joseph in the name of the King of Hungary and Emperor of Austria. More than 4300 members have enrolled their names in the list, and they include a large number of eminent authorities on medicine from all parts of the world. We hope to give, in a future issue, an account of subjects of wide scientific interest and importance brought before the congress.

THE next International Congress of Mining, Metallurgy, Applied Mechanics, and Practical Geology will be held at Düsseldorf during the last week of June, 1910, under the auspices of the Rhenish-Westphalian Mining Industry. An influential committee of organisation has been formed which is charged with the making of the arrangements for the reading and discussion of papers, visits to places of technical interest, and social entertainments. Further information can be obtained in due course on application to the secretary of the Iron and Steel Institute or to the committee of organisation, Jacobistrasse, 3–5, Düsseldorf.

ON August 28 a West Indian hurricane struck the coast of north-eastern Mexico, and thence travelled inland over the States of Tamaulipas and Nuevo Leon. According to a *Times* correspondent, a deluge of rain fell for ninety-six hours, registering in all $17\frac{1}{2}$ inches, and the rivers, overflowing their banks, inundated territory estimated at 300 miles by 400 miles in area. Monterey, the capital town of Nuevo Leon, appears to have suffered most. The overflowing river swept through the lower parts of the town as a torrent half a mile, destroying life and property in its course.

IN accordance with previous announcements, arrangements have been made to hold the autumn meeting of the Iron and Steel Institute in London on September 27–30 and October 1. The programme includes the following papers:—the determination of the power consumption of reversing rolling-mills, C. A. Ablett; comparative tests of cast iron, E. Adamson; artificial magnetic oxide of iron, F. J. R. Carulla; action of air and steam on pure iron, Dr. J. Newton Friend; corrosion of iron, Dr. J. Newton Friend; uniform moisture in blast, Greville Jones; the refining of steel by electricity, Disponent E. J. Ljungberg; the fuel economy of dry blast, as indicated by calculations from empirical data, R. S. Moore; the "growth" of cast irons after repeated heatings, Prof. H. F. Rugan and Dr. H. C. H. Carpenter; the maintenance and renewal of permanent way, R. Price-Williams; the constitution of carbon-tungsten steels, T. Swinden.

THE past summer, comprised by the three months June, July, and August, was of a generally unsettled character over the whole of the British Islands; rain was of very frequent occurrence, and the days were, as a rule, decidedly cool. At Greenwich there were in all forty-one days with the temperature above 70°, of which twenty occurred in August, and there were six days with the thermometer above 80°, all of which occurred in August. Of recent years, 1903 and 1907 are the only summers as cold. The mean temperature for the whole period of three months was rather more than 2° below the average; the mean for the respective months was 55° in June, 61° in July, and 63° in August. The aggregate rainfall for the three months was 8·65 inches, of which 3·69 inches fell in June, 3·16 inches in July, and 1·80 inches in August; the total for the summer was 1·87 inches more than the average. Rain fell on forty-eight days, of which eighteen occurred in June, nineteen in July, and eleven in August. The total duration of sunshine was 502 hours, of which 106 occurred in June, 179 in July, and 217 in August. The deficiency of sunshine at Greenwich for the three months was 141 hours.

THE council of the National Museum of Wales is prepared to receive designs for a new museum at Cardiff, at a cost for the completed building of 250,000*l.*, inclusive of carving, but exclusive of decorative sculpture. A copy of a detailed statement of conditions and instructions to competing architects has reached us from Dr. W. E. Hoyle, director of the museum, and the prospect it presents is very pleasing. The museum is to afford the accommodation known to be necessary in all the various departments of a national museum, and will include the following exhibition galleries:—history and antiquities; geology and mineralogy; Welsh natural history; zoology and botany general; industries; art; children's room; aquarium. There will also be special rooms for study and reserve collections for each department. The circular of instructions states that the purpose of the building is to preserve and display articles of various kinds, not only with satisfaction to the connoisseur in each variety, but with a taste and artistic refinement likely to waken the interest of the public generally. The exhibition cases will, as a rule, stand free in the rooms and not against the walls. Designs for the building must be sent in (carriage paid) addressed to the director, National Museum of Wales, City Hall, Cardiff, on or before January 31, 1910.

THE aviation week at Rheims ended on Saturday, August 28, when several remarkable flights and achievements were accomplished. The meeting has shown that aëroplanes of various designs are able to remain in the air for two or three hours, and to attain speeds of about fifty miles an hour. The Grand Prize for the longest flight was won by Mr. Farman, with a flight of nearly 112 miles in 3h. 4m. 56·4s.; the Gordon-Bennett Cup for speed by Mr. Curtiss, who flew the two-lap twenty-kilometre course in 15m. 50·6s.; the speed prize for swiftest flight over thirty kilometres by Mr. Curtiss, who did the distance in 26m. 40·2s.; the passenger prize by Mr. Farman, who flew six miles with two passengers in 10m. 39s.; and the altitude prize by Mr. Latham, for reaching the greatest height of 155 metres. The *Morning Post* of August 28 gives the following interesting table showing the successive stages of distances achieved in aëroplane flights since the commencement of public flights in Europe:—

Date	Aëroplanist	Place	Time	Distance

SEVERAL remarkable pictures illustrate Lieut. Shackleton's account of his Antarctic expedition which he commences in the September number of *Pearson's Magazine*. The article is an interesting narrative of the origin and early work of the expedition, and may be regarded as an earnest of the detailed account to be published this autumn. We notice a few of the noteworthy points. Pack ice was sighted about 1500 miles from Lyttelton, and the journey was then continued southwards along the 178th meridian west. After passing through hundreds of tabular icebergs by means of narrow lanes, the Ross Sea was reached, and the *Nimrod* was taken along the edge of the Great Ice Barrier, the enormous cliff of ice towering high above the vessel's crow's nest. The pack ice barred the way to King Edward VII. Land, where it had been intended to winter, so the vessel steamed to McMurdo Sound, and winter quarters were established at a spot twenty miles north of the point at which the *Discovery* expedition wintered. The party which ascended Mount Erebus made valuable observations of the volcano. In the old crater, above the southern end of which rises the active cone, a number of curious mounds were seen which proved to be fumeroles. The steam from the fumeroles is converted into ice as soon as it reaches the surface of the snow plain, and the result is the production of ice mounds. The active crater of Erebus was found to be between 800 feet and 900 feet deep, with a maximum width of half a mile, and at the bottom were seen three well-like openings from which the steam is projected. The height of the volcano was found to be 13,350 feet, and immense moraines ascend the western slope to a height of fully 1000 feet above sea-level. As the adjacent sea is at least 300 fathoms deep, this indicates that when at its maximum development the ice sheet must have had a thickness of not less than 2800 feet.

IN Publication No. 60 of the Hull Museum Mr. T. Sheppard figures a fine skull of *Bison priscus* recently obtained from gravel at Kelsey Hill, Yorks.

WE have to acknowledge the receipt from Mr. B. B. Woodward of a copy of his presidential address to the Malacological Society upon the subject of Darwinism and malacology.

IN the Proceedings of the Academy of Natural Sciences of Philadelphia for May Mr. J. P. Moore describes part of a collection of polychætous annelids dredged in 1904 off southern California; a large number of new species are included in the collection.

IN the Journal of the Royal Microscopical Society Messrs. Heron-Allen and Earland continue their account of the Foraminifera found in the sand at Selsey Bill, Sussex. These include, not only recent, but also many extinct forms from various geological horizons.

IN No. 191 of the Proceedings of the American Philosophical Society are included addresses on Darwin and Darwinism delivered at a commemorative meeting held at Philadelphia on April 23. In the first of these Mr. Bryce, British Ambassador at Washington, gives interesting personal reminiscences of Darwin and of the reception accorded to the "Origin of Species" on its first appearance. Mr. G. L. Goodale and Mr. G. S. Fullerton follow on with addresses respectively devoted to the influence of Darwin on the natural and on the mental and moral sciences, while Mr. E. G. Conklin winds up with the world's debt to Darwin.

IN February last Dr. N. Annandale obtained on the Orissa coast of India a number of small more or less nearly globular organisms in the tide-wash. When placed in water their shape changed from globular to conical, and indicated that they were evidently pelagic sea-anemones, although devoid of tentacles. The mouth is conspicuous, forming a relatively long, narrow slit expanded at one end, and the whole organism presents a milky appearance, which conceals the internal organs. Externally a vinous tinge, deepening into brown at the aboral pole (which is perforated by a pore) was noticeable. As these actinians, which are apparently adult, although no gonads are visible, evidently indicate a new generic and specific type, Dr. Annandale has described them under the name *Anactinia pelagica*.

Investigator sicarius is the name proposed by Captain F. H. Stewart in vol. i., No. 4, of Memoirs of the Indian Museum for a new type of gephyrean worm of which specimens were obtained by the s.s. *Investigator* in the Gulf of Manaar and off the Arakan coast. This annelid is regarded as indicating, not only a new genus and species, but likewise a new order, which it is proposed to designate by the uncouth title of "Investigatoroidea." This order is defined as gephyreans with an anterior terminal mouth and posterior subterminal vent, and a nervous system composed of dorsal cerebral ganglia and two lateral nerve-cords. The replacement of the median ventral nerve-cord by a pair of ventro-lateral cords is not considered sufficient to bar the inclusion of the new organism in the Gephyrea.

CONSIDERABLE interest attaches to an article in the August number of the *American Naturalist*, by Prof. D. H. Campbell, on the new flora of Krakatau (Krakatoa). When the island was first visited by scientific men two months after the great eruption of 1883, the whole surface was buried under a layer of ashes and pumice averaging 90 feet in depth, and in some places reaching double this depth. A clean sweep of living organisms was thus made. Except phosphorus and nitrogen, the elements necessary for plant-life existed in the ashes. By 1886, when the island was visited by Dr. Treub from Java, a number of plants had already established themselves, slimy, blue-green algæ being of special importance in preparing the soil for higher plants. The plants in the interior were found to be quite different from those near the coast, and the preponderance of ferns was remarkable. Since 1897, when another visit was paid, the progress of the new flora has been rapid, this being especially noticeable in 1906 in the case of the forest trees, which make it evident that the island will ere long be as densely afforested as ever. Nitrogen-forming bacteria have played an important part in rendering the soil fitted for vegetation. As regards distributional agencies, there seems no doubt that the earliest plant-immigrants, such as bacteria, blue-green algæ, ferns, and mosses, were wind-borne, and the same is probably true of the first phanerogams, Compositæ, and grasses to reach the island. On the other hand, ocean-currents have probably been the chief agents in transporting seeds and fruits, those of the strand-plants being almost certainly water-borne.

AN article on the American Forest Service contributed by Mr. T. S. Woolsey to the *Indian Forester* (June and July) for the information of foresters in British India will certainly interest readers who follow the development of scientific forestry. It is mentioned that the actual administration of national forests in America by trained foresters only dates back four years, and in that time opposition has been overcome and public opinion educated by the publications which have been liberally distributed. The general nature of arrangements for timber sales is described in detail, and the outlines for working plans on national forests are indicated. Research at the experiment stations is concerned with tree and stand studies, run-off and ground-water measurements, and meteorological observations.

IN consequence of the observation that lumps of gum are occasionally exuded by the bromeliad, *Guzmannia zahnii*, an investigation of other plants belonging to the same family was undertaken by Mr. K. Boresch. It was then found that several allied plants, notably *Aechmea pineliana*, showed the same phenomenon. The gum passages are situated in the cortex of the stem; they usually originate lysigenously and the adjoining parenchymatous cells frequently grow in like thylloses; although not definitely ascertained, it seems probable that the process is pathological. Incidentally, the author traced a meristematic zone which gives rise to a thickening of the stem, as in Ruscus. The paper appears in the *Sitzungsberichte der kaiserlichen Akademie der Wissenschaften*, Vienna (vol. cxvii., part viii.).

The first portion of a study of various morphological features in the Umbelliferæ is contributed by Dr. K. Domin to the *Bulletin International* (1908), published by the Académie des Sciences de l'Empereur François Joseph I. Various interesting points are noted regarding the seedlings, *e.g.* the tubular shape of the cotyledon stalks in species of Ferula, the occurrence of so-called monocotyledonous embryos as in Bunium, and three cotyledons observed in various species of Eryngium. The formation of the tuber in such genera as Smyrnium and Bunium is traced to the hypocotyl, which also produces roots above the tuber. The most important statement refers to the stipules, which are stated to be universally present and free in all species of Hydrocotyle; Schizeilema and Huanaca possess adnate stipules, while species of Bowlesia show various modifications from an ochrea to laciniate appendages.

The chief of the U.S. Meteorological Service decided to make some important changes in the scope and character of the *Monthly Weather Review*, beginning with July 1. The data are now grouped according to natural topographic districts; for this purpose the United States has been divided into twelve climatological districts conforming to its principal drainage areas, each being under the supervision of a selected division director. The Review is to be devoted almost exclusively to the publication and discussion of climatological, river, and forecast data; special articles of a scientific nature, but not strictly climatological, will be published in the Bulletin of the Mount Weather Observatory or in separate form. The editors (Messrs. Abbe and Abbe, jun.) will prepare, as hitherto, brief notes on the progress of meteorological science throughout the world, so that the Review may still mark the development of the science, without publishing extensively the details of meteorological papers.

We have received a reprint of an article on "The Tides: their Causes and Representation," published by Mr. R. A. Harris in the June number of the *Popular Science Monthly*. The article is illustrated by useful charts showing the co-tidal lines in the different oceans.

A new rainfall map of the Balkan peninsula, compiled by Herr Franz Trzebitzky, appears in the August number of *Petermann's Mitteilungen*. The data are obtained from 380 stations, 95 in Croatia and Dalmatia, 93 in Bosnia and Herzegovina, 50 in Servia, 105 in Bulgaria, 1 in Montenegro, 12 in Turkey, and 24 in Greece. The averages are reduced to the period 1894–1905.

The *Zeitschrift* of the Berlin Gesellschaft für Erdkunde (1909, p. 361) publishes a lecture delivered before the society by Prof. Hecker on the determination of the value of gravity and its application to the problem of the distribution of mass in the earth's crust. A general outline of modern methods is given, and a summary of the most important results obtained from observation.

The *Mitteilungen* of the Vienna Geographical Society (1908, p. 150) contains a very interesting and suggestive paper by Dr. Max Müller on the graphical solution of a number of problems in "astronomical" geography. Some ten important problems are fully discussed, and methods of solution with the help of rule and compasses alone described. A final example shows how to determine the approximate latitude and longitude of a place, from two observations of the sun's altitude, using a large globe.

Prof. Hammer, discussing a paper on the forty-ninth parallel by Dr. Klotz (Journal of the Royal Astronomical Society of Canada, 1908, p. 282), deals with the determination of the boundary line between Canada and the United States west of the Lake of the Woods in a note in *Petermann's Mitteilungen* (viii., p. 188). The extraordinary difficulties inherent in the accurate laying down of a parallel of latitude are dwelt upon with great emphasis.

The director-general of the Egyptian Survey Department has issued a reprint of a technical lecture—one of a series of such lectures—by Mr. J. I. Craig, on map projections. The general principles of the subject are outlined, and examples given of projections employed for different kinds of maps. The construction of a network for a special purpose is illustrated in an extremely interesting manner by a "Mecca azimuthal" projection, which is designed to give the true bearing of Mecca from every point of the map. As the author remarks, "its usefulness in finding the direction of the *Qibla* is evident."

The June number of the *National Geographic Magazine* contains an article by Mr. Charles E. Fay on "The World's Highest Altitudes and First Ascents," which is accompanied by some remarkably beautiful illustrations. Mr. Milnor Roberts describes the Mount Rainier National Park in an article entitled "A Wonderland of Glaciers and Snow," and an interesting table, compiled by Mr. N. H. Darton, gives the highest point in each of the States. Mr. Hugh M. Smith, deputy commissioner of the U.S. Bureau of Fisheries, contributes a graphic account of "Brittany, the Land of the Sardine."

The *Journal de Physique* for August contains the address delivered by Prof. Paul Janet to the Société française de Physique in April, on the history and the present position of the question of the fundamental electrical units. After giving a brief history of the various commissions which have dealt with the subject, he gives in detail the decisions arrived at under the headings ohm, ampere, volt, and states to what extent these decisions have been adopted officially by the various Governments. He is of opinion that the action of many of these Governments in adopting particular numbers as official has been rather precipitate, and would prefer them to wait until the institution of an international electrical laboratory has permitted comparisons to be made between the electrical standards kept at the various national laboratories.

The second of a series of papers dealing with the phenomena exhibited by electric arcs between metal electrodes appears in the *American Journal of Science* for August. It is by Messrs. W. G. Cady and G. W. Vinal, and treats of the oscillations which, under certain conditions, can be produced. If an electromotive force of several hundred volts is connected through a variable resistance to an air-gap having, say, a copper kathode and an anode of any conducting material, and an arc is started, on increasing the resistance until the current falls to about 0·4 ampere the arc begins to oscillate with a frequency which in general lies between 1000 and 50,000 per second, and finally, as the resistance in series is increased, becomes a glow discharge or is extinguished. The authors explain with the aid of the volt-ampere curve the conditions which control the production of these oscillations, and give a provisional theory which covers the phenomena observed up to the present time.

ENGINEERING units of measurement form the subject of a pamphlet which has just been produced by Mr. J. Ramsay, of the Glasgow and West of Scotland Technical College. The greater part of the thirty-six pages consists of definitions of the quantities and symbols which more commonly occur in engineering, and in each case the author gives both British and metrical units, together with the connection between them. Several useful tables are given at the end. The value of the pamphlet will be appreciated when it is remembered that students of engineering in this country are compelled to use both British and metrical systems of measurement, a condition which tends to produce much mental confusion and hinders progress. While most of the author's explanations are good, we do not think that his remarks on pp. 8 and 9 regarding weight, mass, and gravitational and dynamical units of force are sufficiently clear; but few writers have succeeded in producing absolutely convincing statements when they take, as the present author does, the British gravitation unit of force as the force with which the earth attracts a pound weight at the sea-level at Greenwich, and also a unit of mass of 32·2 lb. The publishers of the pamphlet are Messrs. John Smith and Son, Glasgow, and the price is 1*s*. net.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN SEPTEMBER:—

Sept. 1. 16h. 0m. Mars in conjunction with Moon (Mars 1° 4′ S.).
2. 17h. 0m. Saturn in conjunction with Moon (Saturn 1° 14′ N.).
3. 9h. 2m. to 9h. 50m. Moon occults ξ' Ceti (mag. 4·5).
7. Maximum of Mira Ceti (mag. 3·3–8·5).
10. Saturn. Major axis of outer ring = 45·31″, Minor axis = 10·00″.
15. 12h. 5m. Minimum of Algol (β Persei).
16. 22h. 0m. Mercury at greatest elongation (26° 34′ E.).
18. 8h. 54m. Minimum of Algol (β Persei).
23. 22h. 0m. Mars at opposition to the Sun.
,, 15h. 3m. Uranus in conjunction with Moon (Uranus 2° 35′ N.).
,, 3h. 39m. to 4h. 53m. Moon occults σ Sagittarii (mag. 2·1).
28. 15h. 0m. Mars in conjunction with Moon (Mars 0° 9′ N.).
30. 0h. 0m. Saturn in conjunction with Moon (Saturn 1° 8′ N.).

THE SOUTH POLAR SPOT ON MARS.—With regard to the recent observation by M. Jonckheere, Dr. Lohse records in No. 4348 of the *Astronomische Nachrichten* (p. 61) that he observed the bright patch which has detached itself from the polar snow-cap on August 8. The position of the spot, in areographical coordinates, was:—longitude, 304·5°; latitude, −74·5°. A measure of the south polar spot gave a diameter of about 30°.

COMET 1909*b* (PERRINE, 1896 VII.).—The position of comet 1909*b*, according to the ephemeris given in No. 4348 of the *Astronomische Nachrichten*, on September 3 will be α (1910·0) = 1h. 12·9m., $\delta = +46°$ 24·8′, whilst that on September 15 will be α = 2h. 0m., $\delta = +51°$ 32·9′. Thus we see the comet is passing from Andromeda to Perseus, and on September 9 will pass about half a degree north of ν Persei; at the same time it is approaching both the earth and the sun, and is now about one magnitude brighter than when re-discovered.

THE ORBITS OF CERTAIN SPECTROSCOPIC BINARIES.—Nos. 15 and 17, vol. i., of the Publications of the Allegheny Observatory deal, respectively, with the orbits of the spectroscopic binaries π^4 Orionis and ζ^1 Lyræ. The former is discussed by Mr. R. H. Baker on the basis of thirty-six spectrograms obtained with the single-prism Mellon spectrograph. The orbit is nearly circular, the eccentricity, in the final elements, being given as 0·027 ± 0·013, and the length of the semi-major axis is 3,393,000 km.; the amplitude of the velocity-variation is 51·8 km., and the period is 9·5 days. The spectrum is of the helium type, but does not show the spectra of both components. Mr. F. C. Jordan finds, from the discussion of sixty-four plates, that the orbit of ζ^1 Lyræ is circular and the period is 4·29991 days; the amplitude of the variation is 102·48 km.

Mr. Jordan has also observed four of the stars in Taurus which Prof. Boss suggested belonged to a group having a common movement. He finds (Publication No. 16) that two of the four stars, Piazzi 234 and Bradley 716, give results in accordance with the idea that they belong to a cluster; the other two, 51 Tauri and ι Tauri, appear to have variable velocities.

THE BOLIDE OF APRIL 20 AS OBSERVED IN FRANCE.—The August number of the *Bulletin de la Société astronomique de France* contains a number of drawings and descriptions (pp. 357–61) of the remarkable meteor seen on April 20 at about 10 p.m. This meteor traversed Ursa Major, leaving behind it a train which lasted for about two minutes as a naked-eye object, according to M. Quénisset, and could be seen for five minutes with a prismatic binocular. The train moved in an east-and-west direction, and developed a condensation, which is shown by some observers as being at one side of a break in the train, and by others, M. Quénisset among them, as a bright loop. The brightness of the meteor was about equal to that of Venus at its brightest, whilst that of the train was comparable with the brightness of the Milky Way.

MATERIA MEDICA AMONG THE ZULUS.

IN the July number of the Annals of the Natal Government Museum, Father A. T. Bryant, a competent observer of native life and author of a valuable dictionary of the tribal language, has for the first time collected materials for the study of Zulu materia medica and the methods of the local medicine-man. He records some 240 Zulu plants used in medicine, giving what the people believe to be their properties and the modes in which they are administered to the patient. Here, as among other savage races, the medicine-man was a personage originally distinct from the diviner or so-called witch-doctor; but their functions tend occasionally to overlap, the medicine-man dealing largely in magic and charms, while the witch-doctor makes himself familiar with curative herbs, though his real business is to indicate or "smell out" the agency which is supposed to have caused the illness.

The Kafir medical man has no knowledge of pathology. He knows as much of anatomy as can be learned from cutting up cattle for food; but the nervous system is a complete mystery to him, and though he has observed that the blood runs through the body, he does not associate its circulation with the beating of the heart. He works by the examination of symptoms, though he is ignorant of their cause, treating paraplegia, for instance, by local applications, and not connecting its occurrence with any brain disease. His occasional successes seem to be generally due to the influence of suggestion, by exciting the feeling of confidence or imagination which summons into action the remarkable recuperative powers of the patient. In his profession medicine and magic constitute a single art, and he is called upon to combat, not only the disease which has actually shown itself in the system, but also the machinations and forms of the black art which are believed to have induced it.

Like most savages, the Zulu is unusually susceptible to new diseases, though he is hardened against those which are old. Father Bryant gives interesting details of the more common diseases and their popular treatment. He records a form of disease, believed not to be known to medical science, resulting from an intestinal parasite developing into a species of beetle. The local form of phthisis seems to be different from that of Europe, the former setting in at the bottom, the latter at the top, of the lung. The medicine-man deals largely in blood-letting, poulticing, the use of ointments, the clyster and the emetic. He knows many of our standard remedies, while of others equally accessible to him he is ignorant. Thus he uses indigenous species of Nephrodium for the relief of tape-worm, and croton as a purgative, but it is apparently from the white man that he has learned that the *Ipomoea purpurea* has qualities analogous to jalap, and though castor-oil is used for dressing hides he is not aware of its medicinal value. But he undoubtedly is acquainted with a great number of simples, mostly vegetable; and Father Bryant believes that the further investigation, and in particular the chemical examination, of many of the drugs which he names will in all probability add valuable remedies to our pharmacopœia. Dr. E. Warren, curator of the museum, promises that his department will provide all possible assistance in material and information to any competent chemist who is prepared to undertake such an inquiry.

AMERICAN INVERTEBRATES.

BULLETIN No. 63 of the United States National Museum is devoted to a monographic revision, by Mr. F. E. Blaisdell, of the beetles of the Eleodine section of the family Tenebrionidæ inhabiting the United States, Lower California, and the adjacent islands. The memoir includes 534 pages of text and thirteen plates.

In No. 2 of the Leland Stanford Junior Publications of the University of California Prof. F. M. Macfarland describes in considerable detail the anatomy of the opisthobranchiate molluscs obtained during the Brauner-Agassiz expedition to Brazil in 1899. The collection, although small, adds seven to the list of Brazilian species of the group; and since little was previously known with regard to the structure of the opisthobranchs of the district, the opportunity was taken of studying this as minutely as the amount of material permitted. A number of diagrammatic figures of the radula in different genera is given.

The feather-stars, or ophiurids, of the San Diego region form the subject of vol. vi., No. 3, of the University of California Publications in Zoology. The author, Mr. J. F. McClendon, began his investigation in the hope that a taxonomic and biological study of the local members of the group might facilitate work in which it was important to know the breeding-seasons and habitats of different species, but, unfortunately, he could not remain long enough to obtain all the data desired. It is believed, however, that the height of the breeding-season for most of the species is in the spring, although individuals full of apparently unripe eggs were taken in spring.

A number of new fossil echinoderms from the Cretaceous and Tertiary Ripley beds of Mississippi are described and figured by Mr. A. W. Slocum in vol. iv., No. 1, of the Geological Publications of the Field Museum, Chicago.

The re-arrangement of the large collection of graptolites which for many years has been in course of formation in the U.S. National Museum has afforded to Mr. R. S. Bassler the opportunity of revising the species of the dendroid group from the Niagaran Dolomite of Hamilton, Ontario, and the results of his studies are published, with a large number of illustrations, in Bulletin No. 65 of the museum.

THE SEVEN STYLES OF CRYSTAL ARCHITECTURE.[1]

THE proverbial importance of the number seven is once more illustrated in regard to the systems of symmetry exhibited by solid matter in its most perfectly organised form, the crystalline. For there are seven such systems or styles of architecture of crystals, just as there are seven distinct notes in the musical octave, and seven chemical elements in the octave or period of Newlands and Mendeléeff, the eighth or octaval note or element being but a repetition on a higher scale of the first.

A crystal appeals to us in two distinct ways, first compelling our admiration for its beautifully regular exterior shape, and next impressing us with the fact of its internal homogeneity, expressed in the cases of transparent crystals by its perfect limpidity, and the obvious similarity throughout its internal structure. As it is with human nature at its best, the external appearance is but the expression of the internal character.

The purpose of this discourse is not so much to dilate upon the seven geometrical systems of crystals as to show how they are occasioned by differences in the internal structure, and to demonstrate this internal structure in an ocular manner, unfolding at the same time some interesting phases of recent investigation.

To the Greeks, whose wonderfully perfect knowledge of geometry we are ever admiring, the cube was the emblem of perfection, for like the Holy City, lying "foursquare," described in the inimitable language of the book of Revelation, "The length and the breadth and the height of it are equal." Moreover, even when we have added that all the angles are right angles, these are not the only perfections of the cube, for they carry with them, when the internal structure is developed to its highest possibility, no fewer than twenty-two elements (thirteen axes and nine planes) of symmetry.

At the other extreme is the seventh, the triclinic, system, in which the symmetry is at its minimum, neither planes nor axes of symmetry being developed, but merely parallelism of faces, sometimes described as symmetry about a centre, and in which there are no right angles and there is no equality among adjacent edges. Between these two extremes of maximum and minimum symmetry we have the five systems known as the hexagonal, tetragonal, trigonal, rhombic, and monoclinic, possessing, respectively, 14, 10, 8, 6, and 2 elements of symmetry. All crystals do not possess the full symmetry of their system, each system being subdivisible into classes possessing a definite number of the possible elements. Altogether there are thirty-two such classes, and their definite recognition we owe to the genius of von Lang and Story Maskelyne.

The characteristic property possessed in common by all crystals is that the exterior form consists of and is defined by truly plane faces, inclined, in accordance with one of the thirty-two classes of symmetry, at specific angles which are characteristic of the substance. This has only been proved to be an absolute fact within the last few years, although asserted by Haüy so long ago as the year 1783; for the numerous cases of so-called "isomorphous" salts, the first of which were discovered by Mitscherlich in the year 1820, were for long believed to be exceptions, and until the year 1890 no actual evidence one way or the other was forthcoming. But it was eventually shown that the crystals of the members of an isomorphous series did differ, both in their angles and in all their other crystallographic and physical properties, although in the cases of the angles the differences were very small. Moreover, the differences were shown to obey a simple but very interesting law, namely, that they were functions of the atomic weight of the chemical elements of the same family group the interchange of which gives rise to the series.

All crystals possess one other obvious property, that of homogeneity, and we now know that it is the character of the homogeneous substance which determines the external form. There are no fewer than 230 different kinds of homogeneous structures, neither more nor less, the elucidation of which we owe to the independent recent labours of Schönflies, von Fedorow, and Barlow; and it is a significant fact that the whole of them fall naturally into the thirty-two classes of crystals, leaving no class unaccounted for. Of these 230 modes of regular repetition in space fourteen are the space-lattices long ago revealed to us by Bravais, and all recent investigation concurs in indicating two facts, first, that it is the space-lattice which determines the crystal system, and second that it is the arrangement of the chemical molecules which is represented by the space-lattice. Each cell of the space-lattice corresponds to a molecule. The structure is certainly not solid throughout, however, part only being matter, and the rest æther-filled space, the relative proportions and the shape of the material portion being as yet unknown. We limit ourselves, therefore, to considering each molecule as a point, and we draw the lattice as a network of three systems of parallel lines, parallel to the directions of the three principal crystal edges, analogous, according to the system of symmetry, to

[1] Summary of evening discourse delivered before the British Association at Winnipeg on August 26 by Dr. A. E. H. Tutton, F.R.S.

those of the cube. The points of intersection we consider as those representing the molecules, inasmuch as any point within the limits of the cell may equally well be taken to represent the cell and the molecule, provided the choice is analogously made throughout the structure.

It has recently been found possible to determine the relative dimensions of these molecular cells, the distances of separation of the points of the space-lattice, in those cases where we know that the structure is similar, as in isomorphous salts; and the interesting discovery has been made that the "molecular distance ratios," as these space-dimensions are called, are functions of the atomic weights of the interchangeable members of the family of chemical elements constituting the series, just as the crystal angles have been shown to be.

We are now able, moreover, to take yet one further step, for the chemical molecules are composed of atoms, and it has been indubitably shown that the atoms occupy definite positions in the crystal. For when we replace, say, the alkali metal in a sulphate or selenate by another, we observe a marked alteration in the crystal angles and the molecular distance ratio along a particular direction, this direction being the same whichever metals of the group are interchanged; whereas if we replace the sulphur by selenium, a similar kind of alteration occurs, but along a totally different direction. Now we know that the atoms are arranged in the chemical molecule in what is known to chemists as their stereometric arrangement, depending on the maximum satisfaction of their chemical affinities. Hence this important experimental fact of the occupation by the atoms of definite positions in the crystal proves, first, the homogeneous similarity of arrangement of the molecules, and, secondly, explains why we have classes or subdivisions within the systems. For it is the arrangement of the atoms within the molecule which causes the variations of the degree of symmetry, within the limits prescribed by the system and space-lattice; in other words, which determines the class.

Now obviously any one of the atoms in the molecule may be chosen to represent the latter, and the points thus chosen analogously throughout the structure will constitute the molecular space-lattice. Hence the whole structure may be considered as made up of as many interpenetrating similar space-lattices as there are atoms in the molecule. The crystal structure will thus be dependent on two factors, the space-lattice and the scheme of interpenetration of the space-lattices, the former dominating the style of architecture, the crystal system, and the latter the vagaries of the style, the crystal class. Sohncke has shown that there are sixty-five such vagaries possible, which he terms regular point systems, and these coincide with sixty-five of the 230 possible modes of partitioning space.

These are the broad, simple facts, now proved up to the hilt, which explain the majority of crystal structures, all, in fact, but a very few, of the more complicated classes of the thirty-two. For the remaining 165 ways of appropriating space all fall into a very small number of crystal classes. They are of very great interest, however, and involve an entirely new principle, that of "reflective" or "mirror-image" symmetry, enantiomorphism as it is technically termed, and include those crystals which possess the remarkable property of rotating the plane of polarised light. These are the cases the geometrical possibility of which has been accounted for by the simultaneously independent work of Schönflies, von Fedorow, and Barlow, and to which we were experimentally introduced by the discovery of the right- and left-handed varieties of tartaric acid by Pasteur. The latter has since been followed by the revelation of many similar cases of two forms of the same chemical substance, related crystallographically and structurally like a right hand to a left-hand glove, and optically differing by the direction in which they rotate a beam of plane polarised light.

With their discovery and explanation the elucidation of the seven styles of crystal architecture and their thirty-two subdivisions becomes *un fait accompli*, and although many difficult problems still confront the crystallographer, problems of vast importance to chemistry, the groundwork is now securely laid, the memorable achievement of the last twenty years. The results, moreover, are in entire accordance with the now well-proved fact that the chemical atom is composed of electronic-corpuscles. For the definite orientation of the atom and its sphere of influence within the molecule and the crystal is thereby accounted for, the motion in the solid state so frequently hitherto attributed to the atom being a myth, such motion relating, in fact, to the corpuscles within the atom.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 23.—M. Bouquet de la Grye in the chair.—The calculation of the roots of numerical equations: M. **Lémeray.** Referring to a recent paper by M. de Montessus on this subject, the author points out that he published a method on the same principle in December, 1898.—Movements from the vertical due to the attraction of the moon and sun, the earth being supposed absolutely rigid: Ch. **Lallemand.**—A poison elaborated by yeast: A. **Fernbach.** It has been recently shown by F. Hayduck that there exists in the yeast cell a substance which is toxic to yeast. The present paper contains some new observations on the same subject. A solution of the toxic substance is shown, not only to be antiseptic to yeast cells, but also to bacteria such as *B. coli* and Staphylococcus, although it has no effect on moulds. The most remarkable property of this substance is that it is volatile under reduced pressure at a temperature not above 40° C. The distillate contains no formaldehyde; further researches on the nature of this substance are in progress.—The development of the eggs of *Philine aperta* exposed to the action of radium: Jan **Tur.**

THURSDAY, SEPTEMBER 9, 1909.

A MONOGRAPH ON THE TRANSIT CIRCLE.

Les Observations méridiennes: Théorie et Pratique. By F. Boquet. Tome Premier, Instruments et Méthodes d'Observation. Pp. xi+314. Tome Second, Corrections instrumentales et Équations Personelles. Pp. iv+342+xii. (Paris: Octave Doin et Fils, 1909.) Price, 2 vols., 10 francs.

THESE two volumes comprise one of two completed sections out of a total of twenty-nine devoted to astronomy and celestial physics in a new form of scientific encyclopædia in which astronomy is only one of forty divisions. The whole work, if and when completed, should run to at least a thousand handy little volumes at a uniform price of 5 francs per volume. An index to the complete series is also promised, but it is hardly contemplated that the demand for the whole set will be very great, the idea being that each subject is to be totally distinct, so that a minimum of irrelevant matter need be purchased by any interested specialist, and that such sections as are rapidly rendered out-of-date may be quickly replaced by revised editions without necessitating alteration of the whole work.

Our purpose now, however, is to deal only with the two volumes before us, premising that the "Bibliothèque d'Astronomie et de Physique céleste," to which they belong, is under the directorship of M. Jean Mascart. It may be fairly remarked, inasmuch as the titles of the other twenty-eight sections of this "Library" are given, that it is quite possible the number will have to be augmented, as there is at present no obvious place for more than one modern investigation without straining the meaning of some of the published titles. With some 600 pages entirely devoted to meridian observations, we are at first inclined to wonder why so much space was thought necessary. But the wonder does not last long, for the pages are quite small, and the amount of detail is very great, as is only fitting in an encyclopædia. Moreover, we soon perceive that the transit-circle, though the two parts are inevitably studied separately, is the *only* instrument considered. This strikes us as an error of omission, for there is no other place for discussion of the zenith telescope in any form. There is no mention of the various forms suggested in substitution for the ordinary one, such as the fixed telescope with meridian mirror or the transit with axis view, simply rotating in bearings east and west. A very possible explanation is that these various forms are not of much account in France, but their omission seems to be a mistake.

There does not seem to be much, if anything, of consequence omitted in reference to the transit circle itself, all kinds of instrumental errors being fully and carefully dealt with, several methods of determination or correction being given in many cases. For instance, a very clear account is given of Cowell's refraction tables as used at Greenwich, while division error and eccentricity, screw value and error, pivot error, wire intervals and inclination, flexure, and so on, are treated with great fulness. The printing chronograph in various forms is naturally conspicuous, this subject being one on which M. Boquet has written more than once before. Another subject with which he has similarly shown familiarity is given an importance we do not remember to have seen before, and that is personal equation, the adequate treatment of which is especially welcome. The various physiological or psychophysiological causes of error are very carefully differentiated, and at the same time no space is wasted on the numerous devices for determining absolute personal equation in transit observations, though a long list of references is given for the use of those who care to pursue the subject.

Perhaps those whose "eye-and-ear" observations are consciously or unconsciously taken by what may be called the chronometer comparison method, as distinct from Bradley's (M. Boquet calls it "méthode de l'œil et de l'oreille par estime du temps"), will question whether their observations are so inferior as M. Boquet assumes. The use of screens also for magnitude equation is liable to meet with similar objections to those urged against the pierced cube of the Greenwich transit-circle, but in this the author is only summarising what has been done and projected. There are, in fact, very few places where he has expressed a decided personal opinion, so that we are inclined to regret that the plan of the work allowed so little scope for personality. With the reservation as to omissions to which we have alluded, we can only hope that the rest of the thousand-odd volumes will maintain the high standard of thoroughness set by M. Boquet. W. W. B.

THE HISTORY OF MECHANICS.

Lectures de Mécanique. By E. Jouguet. Première Partie: La Naissance de la Mécanique. Deuxième Partie: L'Organisation de la Mécanique. Pp. x+210 and 284. (Paris: Gauthier-Villars, 1908–9.) Price 7.50 and 10 francs.

SINCE the eventful appearance of Mach's works on mechanics and heat, much greater interest has been shown in the historical development of applied mathematics, both for its own sake and from a growing conviction that the teacher of a subject ought to know something of its actual growth and expansion, as well as the current methods of expounding it. Recent works by M. Duhem show that even in France, the birthplace and home of clear-cut analytical systems, there is an appreciation of the value of historical research and of tracing the slow formation of the leading ideas and principles of mechanics.

For several reasons M. Jouguet's book will be found a useful supplement to its predecessors. In the first place he is an engineer, so that he is in full sympathy with such men as Stevinus and Huygens and Galileo, and gives considerable attention to those who, like Reich and Andrade, propose to deduce the laws of mechanics from actual experiment. At the same time he is by no means the case-hardened empiric who ignores the claims of logic, and despises speculation. In fact, it is noteworthy, and gratifying, that he practically admits Kirchhoff's thoroughly abstract, and so to say *a priori*, presentation of dynamics to be the best extant from a critical point of view; and he is conscious of the value of a self-consistent theory which can be applied as at least a first approximation to the actual facts of experience.

Another advantage of the work is that it does not pretend to be exhaustive. By choosing definite problems (such as impact, for example) and restricting himself to the consideration of really eminent writers, the author is able to give extracts of some length from works of great interest which are not generally accessible. In some ways this is more instructive than any amount of comment can be.

M. Jouguet stops short of hydrodynamics, and only gives very brief accounts of the principles of least action and least constraint. Otherwise most of the main principles of dynamics and statics are illustrated. The chapters on internal forces are particularly interesting; so is a passage from Euler, which shows that he was vaguely conscious of the difficulties connected with the relativity of motion, and the impossibility of defining absolutely fixed axes of reference.

One reflection is almost certain to occur to the reader of these volumes, namely, that one great advance in the study of natural science has been the rejection of sham proposition about cause and effect, and adequate causes, and so on. It is distressing to find an able man like Wallis giving definitions of the most question-begging description, and stringing together such propositions as "other things being equal, a heavy body has a preference for the path by which it can sink the furthest." However, these early pioneers had a remarkable power of solving problems by elementary principles which they used without being able to express them in a proper, or even intelligible way; and the modern theories of light and electricity once more illustrate the curious paradox that theories based on the undefined and undefinable have the power, not only of simplifying our accounts of phenomena, but also of suggesting paths of discovery, and leading to larger control of the energy surrounding us.

If M. Jouguet's work reaches a second edition, he will doubtless correct "Bernouilli" to "Bernoulli." In a work of this kind it is rather irritating to find this time-honoured blunder repeated once more.

G. B. M.

ORGANIC MEMORY.

Die mnemischen Empfindungen in ihren Beziehungen zu den Originalempfindungen. By Prof. Richard Semon. Pp. xv+392. (Leipzig: W. Engelmann; London: Williams and Norgate, 1909.) Price 9 marks.

THE theory of the Mneme, propounded by Prof. Semon, has attracted the attention both of psychologists and of those naturalists who are interested in the profound problems of hereditary transmission. It is founded on the statement, which everyone is ready to admit, that a stimulus must affect the quality of living matter in such a way that the matter is not the same as it was before the stimulus acted. A permanent change, which, in a sense, may be called a memory, has been effected, or, to use the terminology invented by Semon, the action has been engraphic and the change itself is an engram. Repeated stimulation will make the engram more lasting. All stimuli then produce engrams, and the sum of the engrams of a living being is its mneme. Complex stimuli cause complex engrams, and if there is, under the action of some stimulus or other, a revivification of the complex engrams, then a condition termed ecphoria is produced, and the assemblage of engrams is ecphorized. If the new stimulus is in concord with the awakening of the complex engrams, this concord is termed by Semon homophonia, but if there is a discord, the homophonia may be restored in the case of psychical processes, by an introspective activity of the power of attention, or, in the case of a living organism, by regenerative processes acting ontogenetically, or by adaptation to the new conditions acting phylogenetically.

In this volume Prof. Semon discusses the theory with great clearness and commendable brevity, and he gives many illustrations. The theory may help to explain certain peculiar nervous conditions, as has been suggested by Dr. August Forel in his book on "Hypnotism." On the other hand, it may be of service to the naturalist in his ceaseless efforts to explain heredity, as was so forcibly put by Prof. Francis Darwin in his Dublin address to the British Association last year. Thus a stimulus may produce effects which radiate from the organised matter first affected to organised matter throughout the whole organism, either by nerve paths or by proplasmic intercellular filaments, and in this way faint engrams may be made on the matter of the reproductive elements, ova or spermatozoids. In some such way we may account for the transmission of acquired characters, a mode of thought, however, only to be ridiculed by those who hold that acquired characters are never transmitted. It may be said with much cogency that such a theory is only another method of arranging items of knowledge in one's mind; it is only an aid to memory and thought, without being a step towards an explanation. Although founded on well-known physiological facts, it rides off on the wings of the imagination, and it may be questioned if it really advances knowledge. Still, an ingenious theory is a stimulus and possibly a guide, and science is indebted to Prof. Semon for stating it in a succinct form in this interesting book.

JOHN G. MCKENDRICK.

THE PHYSICS OF THE ION.

Les Découvertes modernes en Physique. By Dr. O. Manville. Deuxième édition. Pp. iii+463. (Paris: A. Hermann et Fils, 1909.) Price 8 francs.

THE title of this work, "Les Découvertes modernes en Physique," since it is a single volume by a single author, is obviously incomplete. In effect the book is almost entirely, and might have been with great advantage entirely, confined to the relations between electricity and matter consequent upon the conception of the atomic charge and the isolation of the free negative charge as an electron. It is true that two chapters are devoted to the subject of radio-activity, concerning which we read in the preface:—

"Sur la *radioactivité de la matière* . . . nous avons dit que des généralités. Le domaine des faits dans cet ordre d'idées est si vaste et surtout si mobile, qu'il est encore très difficile de s'y orienter."

Ideas at the present time in radio-activity are more definite and well-grounded than in any other branch of physical chemistry, but it is clear the author's lack of knowledge in the recent and even the older work of the subject is responsible for his views. In subsequent editions this part of the work might be omitted. It follows, no doubt, the precedent set by Sir J. J. Thomson's well-known book on the conduction of electricity through gases; but what was natural enough when that book was written does not apply to a book published in 1909.

In the ground covered, the work does not differ materially from the one just quoted and many similar which have since appeared, but the treatment is interesting and lucid, and the critical examination and selection of the material chosen for presentation has been done impartially and well. The lack of any conspicuous originality is compensated for by clearness of exposition. In one respect, in that this is a French work dealing with a scientific movement which, if we exclude radio-activity, has proceeded mainly from this country and from Germany, the author is at an advantage, for the whole territory is surveyed in better perspective in consequence.

Both in the first part, which is of a general elementary character, and in the second, which deals for the most part with the mathematical theory of ions in physical phenomena, the author introduces his subject with an excellent account of the older work on the passage of electricity through ionised liquids before passing on to the newer ideas which followed the study of the discharge of electricity, first in high vacua and later, after the discovery of X-rays and other ionising agencies, in gases at various pressures. We are thankful for this juxtaposition of subjects which are usually regarded as independent owing to the fact that the one has been largely developed by chemists and the other by physicists; but at the same time it brings out the difficulties that arise when we seek to apply the newer views to the case of liquid electrolytes. The two subjects have surprisingly little connection with one another at the present time, and anyone who has to teach both must be painfully aware of the difficulties of harmonising them. In this book the newer work on gaseous ions and their properties, the various means of producing ionisation by kathode-rays, X-rays, flames, &c., the re-combination and diffusion of ions are discussed very thoroughly from the physical point of view along regular lines. In the second part an account of the electronic theories of metallic conduction and of magneto-optical phenomena is given, while the more metaphysical developments connected with the electronic constitution of matter, and the entanglement of ether by moving masses are properly left to the end of the two parts respectively. The book has no index, and is marred by an extraordinary number of misprints, the rectification of which occupies many pages of errata at the end.

OUR BOOK SHELF.

Problemi grafici di Trazione Ferroviaria. By P. Oppizzi. Pp. viii+204. (Milan: Ulrico Hoepli, 1909.) Price 3.50 lire.

In the preface the author tells us that although graphic methods are often used by the general mechanical engineer, they have up to now been neglected by the railway engineer. This book is intended to show how such methods may be applied to the solution of nearly all problems in connection with the working of trains on railways. In this object the author has well succeeded, and it may safely be predicted that any reader who has once used graphics in the very easy and simple manner represented in this book will never again have recourse to analytical methods. Indeed, there are cases where analysis becomes so complicated that its use by a busy engineer, even if he has the required mathematical ability, is out of the question; as an example may be cited the acceleration diagram of a train drawn by a steam locomotive. Tractive effort and resistance vary in a very complicated manner with the speed, and this, again, being the time integral of acceleration, which in turn depends on the difference between tractive effort and resistance, it is easy to see that a purely analytical treatment leads to almost hopelessly involved formulæ. Yet the author is able to solve this and many other problems by his graphics in a comparatively easy way, and with a degree of accuracy quite sufficient for practical purposes.

The book contains eight chapters, in which the following subjects are treated:—train resistance as a function of speed, weight, and type of coach and locomotive; tractive effort of locomotives of various types at various speeds, gradients, and curvature of line; speed-time-distance diagrams during acceleration; possibility of making up for lost time; running down long gradients and action of brakes; total time required for a given run; consumption of fuel or electrical energy and conditions of greatest economy; efficiency of service. In all cases the author gives numerous examples to show the application of his methods to cases which are taken from practical work, and thus even a reader whose mathematical knowledge is only elementary is able to profit by this book.

This work should prove most useful to railway engineers, and an English translation would be welcome to many. There is only one fault to find with the book, and that is the very untidy appearance of the diagrams. They have all been drawn on squared paper, the divisions being in millimetres. A page covered closely with such lines is very tiring to the eyes, and if, in addition to the multiplicity of lines, there is some writing added to the curves and the whole is reduced in rather a coarse way by photography, the effect is by no means pleasing. It would have been better if the author had omitted the millimetre divisions and retained only the lines placed a centimetre apart.

Gisbert Kapp.

General Treatise of Meteorology. Part i., Statical Meteorology. By Prof. A. Klossovsky. (In Russian.) Pp. xii+642. (Odessa, 1908.)

The complete work will comprise four parts. The two first—statical meteorology and dynamical meteorology—will not necessitate a knowledge of higher mathematics; they will form the course of meteorology properly so-called, while parts iii. and iv. will be devoted to the exposition of special questions and to the principles and use of instruments. A glance at the first volume of Klossovsky's "Meteorology" shows at once that it is the outcome of a long and useful career. In fact, the first meteorological labours of the author date from the year 1882, and from that time Klossovsky has not ceased to devote all his efforts to teaching at the Odessa University, and to the organisation and direction of the network of meteorological stations in the south of Russia.

Klossovsky's manual, far from being simply a work of compilation—the most complete of any now extant —is distinguished by its originality and by the wealth of the author's critical views. In many parts of the work we meet with pages where certain connections between meteorological data and those of other sciences are admirably described; *e.g.* at p. 179 and following pages the calorific economy of the human body is discussed. Further, original observations are met with for the first time; thus, at p. 273, the results of the actinometric observations made by Savelieff at Kiev. Again, the whole chapters devoted to solar radiation and to the study of earth temperature are interesting to read.

In no other treatise are the questions relating to underground temperature expounded in so complete a manner. The discussion of the results of the author's observations on the temperature at different depths in soil covered with grass and otherwise is especially noteworthy. On p. 334 there is a table giving for each month of the year the temperature at depths of 0·60 m. and 1·20 m. in forest and field adjoining. The forest diminishes the annual amplitude; the differences (field—forest) are $+3·0^{\circ}$ C. and $+2·7^{\circ}$ for the means of July, $-0·4^{\circ}$ at a depth of 60 cm. and $-0·2^{\circ}$ at 1·20 m. in January.

One of the characteristics of Klossovsky's work is the care with which the most recent advances have been taken into consideration; *e.g.* at p. 512 observations made in January, 1907, are noted, and at p. 606 the results of unmanned balloon ascents at Uccle up to April 11, 1907, are included. The titles of the chapters in this first volume are :—Composition of the atmosphere; physical properties; water in the atmosphere; the oceans; solar radiation; terrestrial radiation; earth temperature; increase of heat with depth; ocean temperatures; temperature of the lower strata of the atmosphere; atmospheric pressure; formation of hydrometeors; temperature and pressure in the upper atmosphere; abnormal departures. H. A.

An Introduction to the Study of Integral Equations. (Cambridge Tracts in Mathematics and Mathematical Physics.) By M. Bôcher. Pp. vi+72. (Cambridge: University Press, 1909.) Price 2*s.* 6*d.* net.

ONE main problem discussed in this tract is the following: let $f(x)$ and $K(x, \xi)$ be known functions, it is required to determine the function $u(x)$ so as to satisfy the equation

$$u(x)=f(x)+\int_a^b K(x, \xi)u(\xi)d\xi.$$

Prof. Bôcher shows, mainly after Fredholm, that under certain conditions of a very general kind, a solution exists, and may actually be put into the explicit form

$$u=f(x)+D^{-1}\int_a^b D(x, \xi)f(\xi)d\xi,$$

where D is a determinate function of a, b, and $D(x, \xi)$ a determinate function of a, b, x, ξ. That it should be possible to prove this in a simple, and at the same time rigorous manner is a good illustration of the increasing power of modern function-theory. Prof. Bôcher's exposition is very good; he begins by a heuristic discussion, which in a way resembles the ordinary method of successive approximations. Having thus been led to a certain expression as a presumptive solution, he proceeds to verify the fact that it is one.

Other workers in the same field who receive due attention are Abel, Liouville, Hilbert, Schmidt, and Volterra; and there are various subsidiary or supplementary articles of great interest.

As No. 10 of the "Cambridge Tracts in Mathematics and Mathematical Physics," Prof. Bôcher's work thoroughly helps to fulfil the object of the series; it is brief, self-contained, and stimulating, while giving sufficient reference to original sources.

The Scaly-winged. A Book on Butterflies and Moths for Beginners. By R. B. Henderson. Pp. xii+115. (London: Christophers, n.d.) Price 1*s.* net.

THE study of entomology is always extending its range, as shown by the numerous books which continue to be published especially relating to the order Lepidoptera, or butterflies and moths, which always seems to be the most popular of all, probably because many insects included in it are attractive in appearance, and easy to collect. The study is pursued systematically in several of our great public schools, and Mr. Henderson informs us in his preface that "the entomological, like most of the other sections of the Natural History Society of Rugby School, is entered by examination," and that as he did not find a suitable book for beginners to use in preparation for such an examination, he has compiled one for the purpose.

The various chapters deal with insects in general, and the Scaly-Winged in particular; metamorphosis; Psyche (imago); the Sister States (difference between butterflies and moths); bionomics: the place of Lepidoptera in the scheme of nature; the museum; appendix: note on the vision of insects; and list of some useful books for consultation, Furneaux's "Butterflies and Moths" being specially recommended. There are twenty-two useful text-illustrations of structure and apparatus, and the instructions for collecting and preservation in the chapter on the museum are particularly good.

Fossil Plants. Sixty Photographs illustrating the Flora of the Coal-measures. By E. A. Newell Arber. Pp. 75. Gowans's Nature Books, No. 21. (London: Gowans and Gray, Ltd, 1909.) Price 6*d.* net.

IT is not often that anything has been done to popularise the study of the plants of the past, a subject of which the "educated layman" is, as a rule, profoundly ignorant. This neat little volume, with its beautiful photographic illustrations of some of the most important coal-plants (club-mosses, ferns and fern-like seed-plants, horsetails, sphenophylls, and early gymnosperms) is well calculated to rouse an interest in the flora of so many million years ago. The great majority of the photographs are from casts and impressions, showing the external aspect of the fossils, and these are all admirable; we have never seen a better collection. Some of the few microphotographs of sections, illustrating the internal structure, are equally good, though in one or two cases clearer examples might have been selected. The short explanatory notes (scarcely a dozen pages in all) are, as the name of the author guarantees, thoroughly sound and up to date; they are just enough to whet the reader's appetite for more, which is all that can be expected or desired of a sixpenny nature picture-book.

LETTERS TO THE EDITOR.

The Systematic Position of Mœritherium.

PERHAPS of all the groups of mammals at present existing, no two are more dissimilar in general form than the Proboscidea and the Sirenia, but, nevertheless, the suggestion made long ago by de Blainville, that these animals are nearly related, has of late years been shown to be almost certainly correct, the discovery of early members of both groups in the Lower Tertiary beds of Egypt having to a great extent bridged the gap between the two orders. The animal that perhaps most nearly approaches the ancestral type of the two groups is Mœritherium, which, however, has hitherto been regarded as already far advanced along the proboscidean line, and if not directly ancestral to the undoubted primitive elephant Palæomastodon, at least closely related to its ancestor, and representing a stage of evolution through which it must have passed.

In an article "On the Feeding Habits of Mœritherium and Palæomastodon," published in NATURE of July 29, Prof. H. F. Osborn seems to dissent from this view to some extent, to emphasise the Sirenian characters of Mœritherium, and to regard it rather as a belated Sirenian which had not undergone the specialisation for a purely aquatic life already attained by some Sirenians contemporary with, or even earlier than, it. Prof. Osborn to a large extent bases his conclusions on peculiarities shown in some more or less conjectural restorations of the heads of Mœritherium and Palæomastodon, his chief reasons for the separation of Mœritherium from the Proboscidea being (1) the small size and high anterior position of the eyes and the high position of the ears, both said to be characteristic of the Sirenia; (2) the difference in the arrangement of the anterior teeth and mouth-parts from that found in Palæomastodon.

As to the characters of the eyes and ears, they seem to be purely adaptive, and are simply the result of the admittedly semi-aquatic habits of Mœritherium, and would not be expected to exist in purely terrestrial members of the group. The apparent height of the ears is, moreover, mainly the consequence of the small development of the occipital region of the skull compared with that found in the heavier-headed Palæomastodon. As to the arrangement of the jaws and the anterior teeth, it seems to represent exactly such a stage as a mammal with the normal Eutherian dentition would be expected to pass through before attaining the condition found in Palæomastodon. Certainly the anterior dentition of Mœritherium is quite unlike that of any known Sirenian; thus in Eosiren, a contemporary of Mœritherium, it is the first pair of upper incisors, not the second, that is enlarged, while the other incisors and the canine are already in a fair way to the complete disappearance characteristic of the later Sirenia. In the lower jaw the differences are greater still, Eosiren possessing the strongly deflected symphysis probably already partly covered with a horny plate, and in which the incisors are undergoing reduction; in Mœritherium, on the other hand, there is no deflection of the symphysis, and the first pair of incisors is small, while the second form large procumbent tusks, very similar to those found in many primitive Proboscidea. Mœritherium is further distinguished from the contemporary and even earlier Sirenians by the possession of a well-developed pelvis, which was supported by a strong sacrum composed of three fused vertebræ. The hind limb is, unfortunately, not completely known, but the femur was large and straight, being similar in many respects to that of Palæomastodon. In several other ways, also, Mœritherium differs from the Sirenia and approaches the Proboscidea; thus the position of the auditory meatus with reference to the zygomatic process of the squamosal and to the neighbouring bones is as in Palæomastodon, and quite unlike what is seen in the Sirenia. Again, the cervical vertebræ, though short, show no traces of the extreme shortening already present in Eosiren.

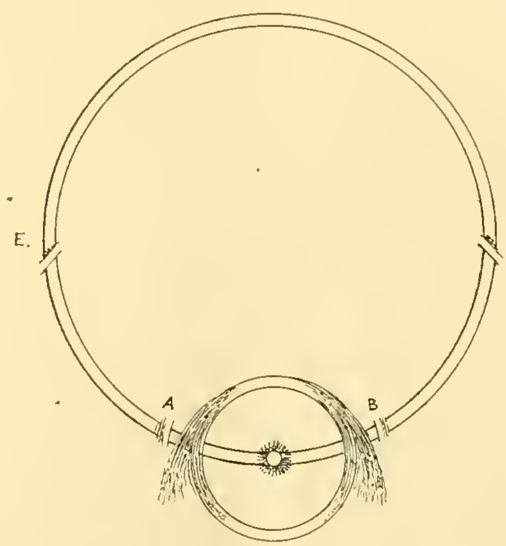
Another argument in favour of the relationship of Mœritherium to Palæomastodon is the existence of forms like *Moeritherium trigonodon* and *Palaeomastodon minor*, which, though unfortunately at present very imperfectly known, appear, both in their size and in some respects in their tooth structure, to be annectant forms.

On the whole, it seems that the weight of evidence is in favour of regarding Mœritherium as a proboscidean, though perhaps not on the direct line of ancestry of Palæomastodon, and retaining some characters of the original Proboscideo-Sirenian stock.

CHAS. W. ANDREWS.

Remarkable Halo of August 21.

THE accompanying diagram is a sketch of the Danzig phenomenon as observed at Blackpool on Saturday, August 21, between 11.45 a.m. and 0.30 p.m. There had been heavy rain and stormy winds on the previous night and in the early morning up to 10 a.m. At 11.45 a.m. thunder cloud and cumulus extended all around the horizon, but in the vicinity of the zenith, where the 22° halo and the western portion of the mock sun ring now appeared, there was no trace of cirrus or other cloud form, although a very pale milky tint might be discerned.



At noon the sky was overcast, but by 0.25 p.m. it was again clear at the zenith, and the complete phenomenon stood out very prominently, the 22° halo very vivid and brilliant with what would appear to be its arc of upper contact, the mock sun ring being very clear and of a silvery hue, and the mock suns; the two furthest from the real sun being apparently at the intersection of the mock sun ring with the 90° halo. This halo, however, was nowhere else visible.

There was nothing like an image of the sun at the N. point of the 22° halo; but this was a position of very great brilliancy, with the usual reddish colouring on the edge nearest the sun and the gradual shading off outwards to a bluish-white. The S. point was also a position of maximum brightness, though less intense than the N. point, while the E. and W. portions of the halo were fainter and untinted, but quite discernible.

The two nearer mock suns at A and B likewise could hardly be called images of the sun, but resembled the N. point of the 22° halo, as though they were the intersections in the mock sun ring of another halo, nowhere else visible, of about 33° radius. They were thus somewhat elongated, projecting slightly on either side of the ring. The two further mock suns were of a similar character, but with no colour.

Some special peculiarities seem to have been :—(1) The absence of cloud in the region of observation where the phenomenon was at its brightest. (2) The complete continuity of the mock sun ring, the portion within the 22° halo being quite distinct. (3) The fact that the arc of upper contact had its *concave* side towards the sun, and extended for more than 90° on either side of the point of contact, gradually growing more diffuse and faint. This seems to be quite a special characteristic. (4) The peculiar shape of the mock suns and the positions of the two nearer the sun. These were not on the 22° halo, but outside the arc of upper contact, as shown in the sketch, the arc bisecting the distances measured along the ring between the mock suns and the halo.

At 0.30 p.m. the sky again became overcast, nor could any trace of the phenomenon be seen afterwards. In the afternoon and evening the wind was very cold, and there was a fair amount of cloud, but on the whole it was fine and sunny. The night, however, was wet and stormy.

W. McKEON.

Man and Environment.

I AM under the impression that it is recorded somewhere that Darwin expressed the following opinion:—He considered the fact that when man appears he appears, not as a "blind" subject of his environments, but with power to determine largely, not only his own environments, but those of generations of men succeeding his own generation; and, faced by this fact, he expressed a doubt whether, when man appears, some new factor may not come into play in "natural selection" (*cf.* "The Descent of Man," 2nd ed., p. 613, lines 15 to end of paragraph). But I cannot find the reference. Could any reader of NATURE assist me?

F. C. CONSTABLE.

Wick Court, near Bristol.

THE ATTAINMENT OF THE NORTH POLE.

DURING the past week great attention has been given to the announcement on September 1 that Dr. F. A. Cook had returned from north polar regions, having reached the North Pole on April 21, 1908. The interest excited by this statement has since been increased by a message, dated September 6, received at New York from Commander Peary, reporting that he reached the pole on April 6, 1909.

Commander Peary departed for the north from Sydney, Cape Breton, on July 17, 1908, his intention being to proceed by the Smith Sound route to his winter quarters on the northern shore of Grant Land. He hoped to start for the pole with fully-loaded sledges from the "Big head" he encountered in the Polar Ocean in 1906, to the north of Grant Land, in about latitude 84° N. The last information concerning him indicated that in the middle of August last year his ship, the *Roosevelt*, was continuing her voyage northwards from Etah, the expedition's base of supplies on Smith Sound. He took sounding apparatus with him, with the intention of obtaining a line of soundings from Grant Land to the pole. When he left last year he stated that, should he reach the pole, news of his success might be expected between August 15 and September 15, and the message received on September 6 has justified his expectations.

It is difficult yet to arrive at a satisfactory opinion as to the value of the observations from which the explorers conclude that they reached the North Pole, but as both Dr. Cook and Commander Peary are responsible travellers, it must be assumed that they realise the difficulty of determining the position of the pole, and took the necessary precautions to establish the validity of their claims. We have no right to doubt their statements, but the publication of the observations at an early date is greatly to be desired, so that the matter can be placed beyond question. In the case of Commander Peary, his previous work in Arctic regions is so well known that geographers have accepted his announcement without hesitation, and a congratulatory message has been sent to him by the Royal Geographical Society. On the occasion of his previous expedition in 1906, he approached to within two hundred miles of the pole, and there was every reason to anticipate that this year he would reach the pole itself. His plans were known, and his long experience of Arctic conditions justified confidence in their successful accomplishment. There has, however, been much discussion upon Dr. Cook's journey and achievement, and as he claims to have reached the North Pole nearly a year before Commander Peary, it is of interest to give a few particulars relating to him and his expedition.

Dr. Cook is an American medical man, with varied experience of exploring work in both the Arctic and Antarctic regions. He served as surgeon on Commander Peary's second expedition to West Greenland in 1891, and was a member of the Belgian Antarctic expedition under Commander De Gerlache, which spent the Antarctic winter of 1898 drifting about on board the *Belgica* in the ice-covered seas to the southwest of Graham Land. Both in 1903 and 1906 Dr. Cook conducted expeditions to Alaska, with the object of achieving the ascent of Mount McKinley, 20,390 feet high, the loftiest mountain on the North American Continent, and after repeated failures reported that he had succeeded in reaching the summit. Two years ago it was announced that he was desirous of organising an expedition to the South Pole, and it came as a surprise to most people to learn in the autumn of 1907 that he was encamped at Etah, on the northwest coast of Greenland, and proposed to make a "dash" for the North Pole.

Briefly, Dr. Cook's story is that he left his base at Etah on February 19 of last year, accompanied only by a force of Eskimos, and dogs for pulling the sledges. The route varied slightly from that adopted by Commander Peary. Dr. Cook struck westwards across Smith Sound to Ellesmere Land, and continued westwards across that island to Nansen Sound, which separates Ellesmere Land from Axel Heiberg Land, one of the new lands discovered by the Sverdrup expedition on board the *Fram* in 1898–1902. From Cape Hubbard, the northernmost point of Axel Heiberg Land, Dr. Cook pushed out over the polar ice on March 18. Three days later the last of the supporting parties returned, and Dr. Cook continued his march to the pole with only a couple of Eskimos. Between the 84th and 85th parallels of north latitude, he sighted land to the west, but "the urgent need of rapid advance on our main mission did not permit a detour to explore the coast." This, continues Dr. Cook, in the narrative which he has supplied to the *New York Herald*, was the last sign of solid earth seen on the northward march, though, "from the 87th to the 88th parallel much surprise was caused by an indication of land ice. For two days we travelled over ice which resembled a glacial surface. . . . There was, however, no perceptible elevation, and no positive sign of land or sea." Farther north, Dr. Cook says, "signs of land were still seen every day, but they were deceptive illusions, or a mere verdict of fancy. . . . The mirages turned things topsy-turvy, inverted mountains, and queer objects even rose and fell in shrouds of mystery; but all of this was due to the atmospheric magic of the midnight sun."

Finally, to quote the words used by Dr. Cook on September 7, in a lecture to the Royal Geographical Society of Denmark:—"On April 21 my observation gave 89° 59′ 40″—that is, 20″ from the pole. We advanced the 20″ and I made another observation, and several others that day and the next. I think there is no doubt that these observations will prove that we have been on and around 90°—the North Pole." The return march was then begun. Instead of being carried by an easterly drift to the Greenland coast, the little party found themselves some distance west of Axel Heiberg Land. Continuing south to Jones Sound, they wintered in primitive fashion at Cape Sparbo, on the coast of North Devon, and subsequently made their way across to the Greenland coast, whence Dr. Cook obtained a passage to Copenhagen on board a Danish Government steamer.

Not so much the fact that Dr. Cook was unaccompanied by any white companion, as certain surprising features in the above story make it advisable to await the examination of Dr. Cook's instruments and journal of observations before his claim to have reached the pole is definitely admitted. Cape Hubbard, from which Dr. Cook pushed out into the Polar Ocean, is situated in about latitude 81° 15′ N., *i.e.* 525 geographical or rather more than 600 statute miles from the pole. To have covered this in thirty-five days Dr. Cook must have advanced northwards at an average rate of seventeen statute miles a day, making no allowance for deviations from a due north and south line. An even greater rate of travel was maintained for a longer period of time by Lieutenant Mecham on a sledge journey among the islands of Arctic Canada during the long series of the Franklin search expeditions. Nothing like such a rate of progression northwards has, however, been achieved by any previous traveller over the ice of the open polar sea. Nor is it correct to say, as Dr. Cook is reported to have said, that he was able to rely on more favourable conditions because he travelled earlier in the year than previous explorers. Dr. Nansen and Lieutenant Johansen left the *Fram* in about 84° north on March 14, 1895, and reached their farthest north in latitude 86° 5′ north on April 8, their average daily northing being thus about six miles. Captain Cagni, of the Duke of the Abruzzi's expedition, left the winter quarters of the *Stella Polare* in Teplitz Bay, Franz Josef Land, latitude 81° 47′ north, on March 11, 1900, and reached his farthest north in latitude 86° 33′ on April 25, his average daily northing having been about seven miles. In 1906 Commander Peary pushed out over the polar ice from the northern coast of Grant Land, just south of the 83rd parallel, on March 6, and reached his farthest north in latitude 87° 6′ on April 21, his average daily northing having been about six miles.

From these records it will be seen that by travelling northwards over the Polar Ocean at the rate of seventeen miles a day, Dr. Cook has far surpassed the most strenuous efforts of his predecessors. All the explorers mentioned were capable of, and did on occasion perform, journeys of twenty and more miles a day. But in advancing northward they all found themselves greatly delayed by open lanes of water and pressure ridges in the ice. Dr. Cook says very little about any difficulties of this nature, although he does on one occasion mention that "much of our hard work was lost in circuitous twists around troublesome pressure lines and high irregular fields of very old ice. The drift, too, was driving eastward with sufficient force to give some anxiety." If the conditions he encountered throughout his march were similar to those experienced by previous travellers over the Polar Ocean, it is astounding that he should have been able to travel so much faster than they.

Of course, conditions vary in different seasons and along different routes, and Dr. Cook may have been exceptionally favoured. There is no need to doubt his good faith, but for confirmation of his calculations it will be necessary to await the examination of his records. The precision with which he reports his position on April 21 would seem to show that he scarcely appreciates the difficulty of securing exact observations under the conditions as regards refraction, &c., which prevail near the pole.

However this may be, and whatever the precise point attained by Dr. Cook, there seems little doubt that he made an extended journey over the polar ice; but scientific research was not Dr. Cook's object, and his journey can possess little scientific value. He carried no sounding apparatus, and has brought back only the vaguest information about the new lands to the north-west of Greenland. The land which he did

North Polar Map. Dr. Cook's route is shown by broken lines. Commander Peary's route is not indicated, because the details are not yet available.

sight, indeed, was probably the land which Peary sighted in 1906, or some extension thereof. Further north, there is a suggestion that the party travelled over glacial ice, but Dr. Cook has nothing definite to report which indicates the existence near the pole of anything but the ice-covered Polar Ocean. Some points have still to be cleared up. In more than one report Dr. Cook is credited with stating that the land he sighted after leaving Axel Heiberg Land abounds with game; yet he did not come within several miles of the land, and, according to the *Times*, met with no game beyond Heiberg Island. If Dr. Cook reached the pole, he has given a remarkable illustration of pluck and endurance, but his journey seems likely to have a minimum of scientific value, and there is still room where he has been for a well-equipped scientific research expedition to do excellent work in studying the geographical problems of the region. A mere "dash" to the pole may awaken a certain amount of sentimental interest, and direct public attention to the traveller, but it is of no value from the scientific point of view unless exploration—physical or geographical—is carried on. Commander Peary appears to have been equipped with apparatus for taking soundings and making other observations of polar conditions, and he has telegraphed to the director of the American Museum of Natural History, New York, "I am bringing a large amount of material for the museum." The scientific importance of polar expeditions must be judged by the new knowledge obtained rather than by the determination of a mathematical point more or less accurately according to the instruments used and precautions taken. Assuming that the North Pole has been reached by one or both the explorers, the way is now clear for the scientific study of Arctic hydrography, meteorology, and many other problems of terrestrial physics without the disturbing effort to attain the highest latitude.

THE WHISKEY COMMISSION.

THE Royal Commission on Whiskey and other Potable Spirits, the final report of which has just been issued, originated out of the attempts made by various local authorities to obtain legal decisions as to what should or should not constitute brandy and whiskey. In the case of the other recognised forms of ordinary potable spirits, no acute differences of opinion appear to have arisen. When a man asked for rum or gin the legal mind representing the man in the street was content to assume that that long-suffering individual received an article of the nature, substance, and quality he demanded. As a matter of fact, the man in the street raised no difficulty even about the two forms of potable spirits which have more particularly engaged the prolonged attention of the Royal Commission. He had absolutely no interest in the touching solicitude which was displayed on his behalf by a number of professional gentlemen, who, apparently from purely altruistic motives, were determined that he should be awakened to a proper sense of the importance of knowing the origin and mode of manufacture of articles which he had hitherto been perfectly content to purchase because he was satisfied with their quality and price.

What is brandy and what is whiskey have been the occasional subjects of discussion in the public journals and in the trade organs at intervals during the past three or four years, but it has been impossible to arouse any public feeling on these momentous questions. The fact is, the agitation, such as it was, was wholly artificial. It simply originated in, and turned upon, a struggle between competing trade interests. Brandy, by use and wont, has been universally regarded as a spirit obtained by the distillation of fermented grape-juice; whiskey as a spirit obtained by the distillation of a fermented "wash" derived from some form of cereal, usually, but not invariably or wholly, malted barley. But owing to the unfortunate grape disease (Phylloxera) which, a generation ago, devastated the French vineyards, especially in the Charentes, where the particular grapes mainly employed in the manufacture of Cognac are grown, the manufacture of factitious brandy was greatly stimulated. This consisted of some form of distilled spirit—obtained usually from grain, or from beetroot molasses, or, occasionally, from potatoes, artificially flavoured with "brandy essence" and coloured with caramel. This article entered into competition, not only with the genuine product, but with a factitious brandy "drawn and made from malted corn," which has been produced for more than a couple of centuries in this country under the name of "British brandy," a term first legally sanctioned by the Spirits Acts of 1860. In due time the vineyards were re-planted, the Charente vines being grafted on American stocks, and the manufacture of Cognac by the time-honoured methods was re-established. Naturally the manufacturers contended that their product was the only legitimate brandy, and that the factitious articles were not entitled to the name of Cognac, or when sold in this country to the term brandy, unless this was qualified, as in the case of "British brandy," by some prefix which should serve to differentiate it from the product of the grape.

This, then, as regards brandy, is the *fons et origo* of the trouble. It was useless for the contending parties to appeal to our law, since, as the Commission states, there is no statutory definition of the term "brandy"; nor is there any binding judicial decision on the subject. The 148th Section of the Spirits Act of 1860, it is true, contained an implied definition of "British brandy," which would have covered the case of all factitious brandies sold in this country, whether made here or not, but this was repealed in 1880, so that there is no longer a legal definition even of "British brandy."

As regards whiskey, the cause of contention was not so much the nature of the material from which the spirit was derived, although this did to some extent enter into consideration, as the manner in which the distillation was effected. Originally all whiskey was made by means of comparatively small stills—of the type known as pot-stills—in which the fermented wort was distilled by the direct application of fire. But about the year 1831, Eneas Coffey invented and patented a form of still adapted for continuous working, in which the alcohol is driven out of the wort by means of steam, and the mixture of steam and spirit is then separated by an ingeniously contrived condensing or rectifying arrangement which enables a much "cleaner" spirit to be produced—that is, a spirit much more free from what are held to constitute the characteristic constituents of whiskey, as distinguished from plain spirit. This process not only resulted in the production of a purer form of alcohol—that is, purer in the sense commonly understood by chemists—but it was more economical in use, and consequently materially cheapened the cost of production. This, of course, made the "patent still" a formidable competitor of the "pot-still," and those who had a vested interest in the pot-still naturally complained that this interest was jeopardised by the employment of a piece of apparatus which might make alcohol, but, it was contended, did not necessarily make whiskey.

In the autumn of 1905 the Islington Borough Council was induced to bring two test cases before a London stipendiary under Section 6 of the Sale of Food and Drugs Acts, in one of which it was held that a certain publican had sold, to the prejudice of a purchaser who demanded Irish whiskey, something which was not of the nature, substance, and quality of Irish whiskey; and, in the other, that another publican had sold, to the prejudice of a purchaser who demanded Scotch whiskey, something which was not of the nature, substance, and quality of Scotch whiskey. In each case the analyst had certified that what was sold as whiskey "consisted entirely of patent-still, silent or neutral spirit," and was not, therefore, in his opinion, whiskey.

The learned magistrate ruled that patent-still spirit alone is not whiskey; and that the produce of a patent still cannot be Irish or Scotch whiskey, although made in Ireland or Scotland. He further held that

Irish whiskey was to be made from a mixture of 75 per cent. of barley malt, with 25 per cent. of barley, wheat, oats or rye, or any of them; whereas Scotch whiskey was to be made wholly from barley malt. He specifically excluded maize, which is frequently used in connection with the patent still, as a cereal from which whiskey may be made. Accordingly he convicted the defendants as having sold articles to the prejudice of the purchaser.

Attempts were made to upset the convictions by appeals to quarter sessions, but the trials proved abortive. Whiskey manufacturers took a very serious view of the position in which they were thus placed, and eventually they induced the authorities to issue a Royal Commission to determine whether, in the general interest of the consumer, or in the interest of the public health, or otherwise, it is desirable (*a*) to place restrictions upon the materials or the processes which may be used in the manufacture or preparation in the United Kingdom of Scotch whiskey, Irish whiskey, or any spirit to which the term whiskey may be applied as a trade description; (*b*) to require declarations to be made as to the materials, processes of manufacture or preparation, or age of any such spirit; (*c*) to require a minimum period during which any such spirit should be matured in bond; (*d*) to extend any requirements of the kind mentioned in (*b*) and (*c*) to any such spirit imported into the United Kingdom; and, lastly, to make the like inquiry as regards other kinds of potable spirits which are manufactured in or imported into the United Kingdom.

It should be stated that the terms of the reference relating to public health arose from the character of the evidence needed to establish the count of "prejudice to the consumer," without which it would have been impossible to have obtained a conviction under Section 6 of the Food and Drugs Acts.

The real nature of the issues to be determined was at once seen from the character of the criticisms which were passed, mainly by Irish distillers or their representatives, on the constitution of the Commission. As a fact, the *personnel* of the Commission was very carefully chosen, and every legitimate interest was adequately represented. The printed evidence proves how competent the members were to inquire into the somewhat complicated questions which were raised, and how carefully and how impartially they sifted and weighed the statements of avowedly interested witnesses. It was, of course, to be expected that their findings would not give universal satisfaction, but every fair-minded critic will admit that they have been arrived at in good faith, and are abundantly justified by the weight of the evidence.

As regards the materials to be used in the manufacture of whiskey, the commissioners find no ground for any interference with existing practice. The contention that Irish or Scotch whiskey should alone be produced from cereals actually grown in those respective countries, or even from cereals capable of being grown there, found no favour in their eyes. Of course, the contention was really aimed at the exclusion of maize, which is largely used in the manufacture of patent-still spirit. The commissioners see no valid reason for excluding maize. There is no evidence to show that it is not a perfectly wholesome material, or that the spirit derived from it is not as wholesome as that derived from any other cereal.

Nor as regards processes of manufacture, that is, modes of distillation, does any sufficient ground exist, in the opinion of the commissioners, for any interference with established procedure. To have supported Mr. Fordham's finding would have effected nothing short of a revolution in the manufacture of whiskey, inasmuch as nearly two-thirds of the potable spirits produced at the present time in Scotland and Ireland are distilled in patent stills. Moreover, spirit produced in the patent still has long been employed for blending with or diluting whiskeys distilled in other forms of still, and most of the whiskey now sold in the United Kingdom contains more or less spirit which has been obtained by the patent still. Lastly, no evidence was tendered to show that the form of still had any necessary relation to the wholesomeness of the spirit produced.

Suggestions were made to the Commission either to "standardise" the mash or to "standardise" the blend with a view of ensuring that at least a certain minimum proportion of pot-still whiskey should ultimately find its way into the whiskey as sold, but here again the commissioners saw no reason to interfere with the discretion of the blender. In their opinion "the proportion of the different whiskeys to be employed in these blends is controlled by an influence stronger than that of the law. The taste of the consumer creates the demand which ultimately controls the trade. The public purchases the whiskey that meets its taste, and the blender must satisfy that taste or lose his trade. It is not for the State to say what that taste ought to be."

The general conclusion which the commissioners came to was that "'whiskey' is a spirit obtained by distillation from a mash of cereal grains saccharified by the diastase of malt; that 'Scotch whiskey' is whiskey, as above defined, distilled in Scotland; and that 'Irish whiskey' is whiskey, as above defined, distilled in Ireland." It is difficult to see how the commissioners could have escaped reaching this luminous and oracular conclusion. At the same time, to the scoffer the whole business is eminently suggestive of one of Molière's comedies. Monsieur Jourdain would have been profoundly impressed by the strict logic and admirable lucidity of such a finding.

After this the question of brandy, as may be anticipated, presented little or no difficulty. The commissioners define brandy as a potable spirit manufactured from fermented grape-juice, and from no other materials, and that the determination of the application of the term in this country cannot be controlled by the nature of the apparatus or process used in the distillation of the spirit. They are further of opinion that the compounded spirit long recognised by the name of British brandy is entitled still to be so named and sold as "British brandy."

The limitations of space preclude any attempts to deal with the other and less important matters dealt with in this report, but the general tenor of the conclusions in respect to these is on a par with the *laissez-aller* tone which pervades the whole.

As might have been expected, the report has not been received with a unanimous chorus of approval, and the Irish distillers, in particular, have not been slow to express their dissatisfaction. But it is to be hoped that on reflection even they will be led to the conviction that the conclusions to which the commissioners have been led represent the common-sense of the question. The conflict of the stills is one more illustration of the inevitable result of what is called the "march of improvement" in which a time-honoured process has eventually to succumb, by the mere force of circumstances, to the economic pressure of a mode of manufacture based upon more rational principles. The commissioners have evidently been fully alive to this aspect of the problem which has been presented to them. At all events, they have shown themselves as not unmindful of the advice of the old merchant, who, being consulted by Colbert about what he should do in favour of trade, said, "*Laissez nous faire.*"

T.

PROF. EMIL CHRISTIAN HANSEN.

IT is with profound regret that we have to announce the death of Prof. Emil C. Hansen, director of the Carlsberg Laboratory, Copenhagen, which occurred after a brief illness on August 27. Born in 1842, he attended in his youth the art school at Copenhagen, but subsequently, between 1871 and 1876, devoted himself to the study of science at Copenhagen University. He entered the Carlsberg Institute in 1877, where he commenced his memorable researches on microbiology.

Hansen's life-work was practically confined to the study of the Saccharomycetes, but his researches in this domain of biological science stand out as a model of thoroughness. Prior to his time little was known concerning the different species of yeasts, although so early as 1857 Bail had observed that types of yeast existed giving rise to what he termed "wild fermentations." This did not, however, attract much notice among either scientific men or technologists, and even Pasteur—who must ever be regarded as the pioneer of biology as applied to the fermentation industries—regarded bacteria alone as the cause of diseases of beer. Rees, however, in 1870, had arrived at the conclusion from his experiments that brewery yeasts represent species which are quite distinct from wine yeasts, and that still other species are concerned in the secondary fermentation of beers and in so-called "wild fermentations." None of these observations were, however, convincing, and the truth only became apparent after the publication of the exact experimental data on the subject by Hansen.

In 1880, when Hansen first commenced his remarkable studies on the Saccharomycetes, biological methods of isolating micro-organisms were but little developed. The dilution method devised by Lister and employed by that observer, as well as by Naegeli and by Fitz, was the only one available, yet it was by an improved modification of this extremely tedious, not to say uncertain, method that Hansen succeeded for the first time in cultivating yeasts from a single cell. In his paper published in 1883 he described accurately six species of Saccharomycetes. The subsequent adoption by Hansen of the method of culture on a solid substratum—which had been developed by Koch—added much to the precision of his work, but he always insisted that in order to obtain absolutely pure cultures it was necessary in all cases to start from a single cell. Some might, indeed, think that he carried this injunction a little too far, in view of the results which have been obtained in the isolation of other micro-organisms by cultures from colonies; but it must be remembered that Hansen's researches were directed, not merely to the isolation of species, but of varieties.

Hansen's work consisted, however, not only in isolating distinct species of the Saccharomycetes, but he elaborated methods for their characterisation, and for this purpose he made use of film-formation, and more especially ascospore-formation, under definite conditions of temperature. By the sporulation test it is possible to detect 1/900th to 1/200th part of a wild yeast—such as a *S. Pastorianus* species—in admixture with *S. cerevisiae*. Thus the microbiologist was put in possession of a method for the quantitative as well as the qualitative analysis of yeast mixtures. Previously for the qualitative analysis of such mixtures morphological considerations alone were available, the results being rough and inconclusive, for one and the same species may under different conditions assume a different form.

Practical brewers have long known that yeasts in practice vary according to the system of fermentation adopted; it has even been suggested that a given type of yeast consists of more than one variety or race, and in this country, at all events, such a type is always associated with a certain number of cells of wild species. Whether these varieties, which seem to be the result of environment, are immutable is a moot point, and it may be pointed out that Hansen at first believed that the top-fermentation races of *S. cerevisiae* employed in this country were under no conditions convertible into bottom-fermentation races, but recently he found that the conversion was possible.

The employment of yeast grown from a single cell has met with great success in Continental bottom-fermentation breweries. Not so, however, in British breweries. One of the first to give the system a trial in this country was Dr. Horace T. Brown, who ultimately abandoned it since he was not able to obtain a satisfactory secondary fermentation; and in confirmation of Dr. Brown's results it has since been shown and fully admitted by Hansen that for the secondary fermentation of British beers, organisms other than the normal *S. cerevisiae* are needful. In this connection it should be mentioned that Schionning recently confirmed Clausen's observations that certain torulæ play an important *rôle* in bringing about the secondary fermentation and conditioning of British beers.

Few men of science since Pasteur's time can lay claim to a greater debt of gratitude from fermentation technologists all over the world than Hansen. His numerous papers are published in the *Comptes rendus* of the Carlsberg Laboratory, the *Centralblatt für Bacteriologie und Parasitenkunde*, the *Annals of Botany*, and the *Journal of the Institute of Brewing*.

ARTHUR R. LING.

NOTES.

MISS DOROTHEA BATE, already well known for her researches in the caverns of Cyprus and elsewhere, has had the good fortune to make a very remarkable and interesting discovery in a cave in Majorca. On her return home Miss Bate remarked that the cave contained only a few bones of goats, but on further examination these despised relics proved to indicate an entirely new type of an extraordinary nature—in other words, neither more nor less than a "rodent-goat." For the skull, which with certain other remains is described by its discoverer in the September number of the *Geological Magazine*, under the name of *Myotragus balearicus*, is characterised by its extreme shortness, and the presence in the front of the lower jaw of a single pair of incisor teeth, in place of the four pairs of incisors *plus* canines characteristic of ruminants generally. In all respects these incisors are rodent-like, growing from persistent pulps, having the enamel restricted to the front and outer surface, and presenting a terminal worn surface. To explain this worn facet almost seems to require the presence of a pair of upper incisors (the front of the skull is unfortunately imperfect), and if such were really the case a revision of the diagnosis of the Pecora would be rendered necessary. The cannon-bones in both limbs are remarkably short and wide, exceeding, apparently, in these respects those of the takin and white goat.

THE article by Mr. E. B. Iwan-Müller on "The Cult of the Unfit," recently noticed in these columns, has called forth a reply from Mr. Sidney Low in the *Fortnightly Review* for September. It was not to be expected that Mr. Iwan-Müller's arraignment of ill-considered sentimentalism in legislation should pass unchallenged, and Mr. Low's rejoinder, entitled "Darwinism and Politics," argues forcibly in favour of the collectivist principle as against unrestricted individual competition. Opinions will differ as to the practicability and desirability of the respective ideals of the two writers, but whatever may be the value of Mr. Low's political criticisms, they appear to miss what is the gist of his opponent's contention, viz. that the measures of statesmen should be constructed on the basis of scientific principle, and not, as is too often the case, with a haphazard disregard of natural laws and conditions. Mr. Low enlarges on the well-known fact that in some circumstances it is not the highest type that proves to be the best fitted to survive; but he appears to forget that, in spite of all counteracting influences, the net result of competition has been the evolution of forms possessing the most excellent qualities known in nature. Moreover, the struggle for life is not abolished by the association of individuals in altruistic communities. All Darwinians know this, and they also know that, as common sense teaches, there must be a limit to altruism. It is the business of scientific thinkers to determine the limit, and of politicians to shape their measures accordingly.

THE death is announced of M. L. Bouveault, assistant professor of organic chemistry at the Sorbonne, Paris, at forty-five years of age.

WE regret to see the announcement of the death of Mr. Thomas Southwell, for many years secretary, and twice president, of the Norfolk and Norwich Naturalists' Society, at the age of seventy-nine.

NEWS has reached us of the regretted death, unexpectedly, of Dr. Fritz Erk, honorary professor of meteorology in the University of Munich, and the first president of the Munich Meteorological Society.

THE Geneva correspondent of the *Times* reports that the Janssen Observatory on the summit of Mont Blanc is about to be demolished. It will be replaced by the Cabane on the Rochers Rouges. All the scientific instruments in the observatory, which was completed in 1894 under great difficulties, have been removed to the Vallot Observatory, which is at a lower altitude.

THE Scottish expedition to Spitsbergen under Dr. W. S. Bruce has arrived at Tromsö on board the steam yacht *Conqueror*, with all well on board. The expedition, which left Leith in July, is reported to have completed the survey of Prince Charles Foreland and made important geological and other investigations. An account of the constitution and proposed work of the expedition appeared in NATURE of July 15.

DR. A. DU PRÉ DENNING, for several years lecturer in experimental physics in the University of Birmingham, and principal of the Municipal Technical School, Smethwick, has been appointed by the Secretary of State for India to the newly created post of superintendent of industries and inspector of technical and industrial institutions in Bengal.

THE *Times* correspondent at Paris announces that the following members of the Bureau of Longitudes will represent France at the meeting of the International Geodetic Association to be held in London on September 21:—General Bassot, president; M. Henri Poincaré; M. Hanusse, director of hydrography in the French Ministry of Marine; M. Charles Lallemand, director-general of the French Ordnance Survey Department; and Colonel Bourgeois, chief of the surveying section of the Geographical Department of the War Office.

THE tenth meeting of the Astronomical and Astrophysical Society of America was held at the Yerkes Observatory, Williams Bay, Wisconsin, on August 18–21, Prof. E. C. Pickering, president, presiding. About sixty members, with a few guests, were in attendance, and forty papers, many of them illustrated with lantern-slides, were presented upon various topics. Reports were also made by the committee on comets and the committee on luminous meteors. The official account of the meeting, with abstracts of the papers, will be published, as usual, in *Science* a few weeks hence. The meeting was favoured with a cloudless sky, and the visitors had an opportunity for observing with the 40-inch telescope and inspecting all departments of the work of the Yerkes Observatory. The next meeting of the society will be held at the Harvard College Observatory in the latter part of August, 1910.

THE eighth International Congress of Zoology is to be held next year at Graz (Austria). As entomology plays only a subordinate part at such a congress, a movement has been started to unite entomologists in a congress entirely devoted to entomology in its various aspects, and to establish a permanent committee which may act as a central organisation in the interest of this subject. It is proposed that a congress of entomology be held every three years, about a fortnight before each triennial zoological congress, so that resolutions and conclusions of general importance could, if deemed necessary, be brought up for discussion at the ensuing zoological congress. The first International Congress of Entomology will be held on August 1–6, 1910, at Brussels, during the International Exposition which will be taking place there at that time. The subjects to be brought before the general or sectional meetings will comprise systematics, nomenclature, anatomy, physiology, psychology, ontogeny, phylogeny, œcology, mimicry, etiology, bionomy, palæontology, zoogeography, museology, medical and economic entomology. The chairman of the local committee for Great Britain is Dr. G. B. Longstaff, Highlands, Putney Heath, London, S.W.

NOTES on Cornish Crustacea, by Mr. J. Clark, form the subject of the chief article in the August number of the *Zoologist*, the author directing attention to the great richness of the coasts of Cornwall in animals of this class, even such far-off species as the gulf-weed crab being occasionally drifted into these waters.

THE July number of the *Emu* is illustrated by a very interesting plate, reproduced from a photograph, showing the feeding-grounds of the laughing kingfisher, cat-bird, and noisy pitta in the Coolabunia pine-scrubs near Kingaroy, to the south-west of Maryborough, Queensland. Near the centre of the photograph is shown a large flat stone, around which is strewn an enormous mass of shells of *Helix cunninghami*, a large species in which the shell measures more than a couple of inches in diameter. The shells of these snails are broken by the birds on the boulder, and their luscious contents eaten.

WE have received a copy of the report of the directors of the various museums in Cape Colony, namely, the South African, the Port Elizabeth, the Kimberley, the Albany, and the King William's Town Museum, for 1908. In the case of the South African Museum, Dr. Peringuey complains of the want of sufficient space in the exhibition galleries, more especially in the anthropological and ethnological department, where it has been found impossible to find room for a series of life-like models of native races recently prepared under his direction. It is interesting to note that a number of skulls and skeletons of the Hottentot races have been recently acquired by this museum.

To the *Revue scientifique* for August 21 Dr. E. Trouessart communicates an article on African big game and big-game shooting, with special reference to the effects of the latter on the numbers of the animals in the country. Several paragraphs are devoted to the facilities for hunting expeditions from Nairobi, and to the fact that by obtaining licences for his wife and servant a sportsman is able to obtain more than the permitted number of specimens of the rarer species. Despite the effects of game reserves and shooting restrictions, Dr. Trouessart is inclined to take a pessimistic view of the prospects of the big game in East Africa, and hazards the prophecy that in less than half a century it will have vanished. To quote his words:—"Avant un demi-siècle, peut-être, de tout ce gros gibier si abondant à l'heure actuelle, il ne restera plus que souvenir." Special attention is devoted to the appalling destruction of elephants which still goes on in the heart of the continent, a statement of Mr. Schillings being quoted to the effect that the number of tusks annually imported into Antwerp alone represents the slaughter of no fewer than 18,500 elephants. The inaction of France in the matter of game-protection is strongly commented upon.

THE metamorphoses of the midges and gnats of the family Chironomidæ form the subject of an article, by Dr. A. Thienemann, in the second half of vol. lxv. of *Verhandlungen des Naturhistorischen Vereins der preussischen Rheinlande und Westfalens*. The developmental history of the Trichoptera has, according to the author, been well worked out, but that of the Chironomidæ is still imperfectly known. Although the greater number of chironomid larvæ, of which the so-called blood-worms are familiar examples, inhabit fresh water, it is pointed out that many are found in various situations on land, while a few dwell in brackish, and even in salt, water. Of the land-living forms, the larvæ of some species of Camptocladius are found in the droppings of animals, those of three kinds of Ceratopogon take up their quarters in ants' nests, while others of the same genus are nourished in the resin or beneath the bark of dead branches of pines, while another is found in decaying funguses. Larvæ of another genus select damp moss as their home. Larvæ and pupæ of several genera are figured.

PART iii. of the "Treasury of Human Inheritance," which forms No. 9 of the Memoirs published by the Francis Galton Laboratory for National Eugenics, furnishes a good example of the excellent work which is being done by that institution. The subjects here dealt with from the point of view of heredity are certain pathological conditions, such as angioneurotic œdema, insanity, and deaf-mutism. There are also sections devoted to the malformations of certain organs, and to the inheritance of special kinds of mental and physical ability. Cases available for the purpose in view have been collected and tabulated with great care, the respective pedigrees being clearly shown in diagrams, and the result is a mass of material which forms a valuable addition to the data now being rapidly accumulated under the guidance of Prof. Karl Pearson. The application of the principles deduced from such investigations will present special difficulties of its own, but whatever may be the practical outcome of the movement set on foot by Sir F. Galton, there can be no question as to the importance of the study of these and similar conditions in their bearing upon the racial qualities of future generations.

A NOTE by Dr. A. C. Hof on the action of iodo-eosin as a test for free alkalis in dried plant tissues is published in the *Bio-chemical Journal*, Liverpool. The substance required is a solution in ether of the dye-acid prepared by treating an alkaline solution of iodo-eosin with excess of acid. The presence of free alkali in a vegetable tissue is indicated by the red colour due to the formation of alkaline salts. Microscopic preparations can be permanently mounted in neutral Canada balsam.

OF the articles which appear in the Journal of the Royal Horticultural Society (vol. xxxv., part i.), the most generally interesting are the hints on French gardening, chiefly on the cultivation of lettuces, contributed by Mr. C. D. Mackay, and the note on *Solanum etuberosum* provided by the editor. It is observed that plants passing under the name of *Solanum etuberosum* do produce tubers about the size of walnuts, and also show a remarkable power of resistance to the potato disease induced by *Phytophthora infestans*. The latter property has suggested the possibility of raising disease-resistant hybrids with *etuberosum* as one parent; some experiments in crossing this species, the Chilian wild potato, *Solanum Maglia*, and cultivated forms of the ordinary potato are communicated by the Rev. J. A. Paton.

As a result of some months' botanical exploration in Sardinia, Dr. Th. Herzog presents in Engler's *Botanische Jahrbücher* (vol. xlii., part iv.) an attractive sketch of the vegetation on the island, accompanied by an illustrative map. The once extensive oak forests have been much reduced by ruthless cutting; *Quercus ilex* still flourishes in less accessible situations, notably round Mt. Gennargentu, where it is accompanied by *Paeonia officinalis*; *Quercus robur* also grows in the central districts, while the cork oak, *Quercus suber*, clothes the mountains in the north. A very wide area is covered by the formation known as "mâquis," where *Pistacia lentiscus*, *Rhamnus Alaternus*, *Myrtus communis*, and *Arbutus unedo*, with species of Cistus, form the dominant species. The solitary European palm, *Chamaerops humilis*, grows in the north-west, occasionally in pure stands.

AN important article dealing with the classification of the Scitamineæ, the monocotyledonous series comprising the Zingiberaceæ, Marantaceæ, Cannaceæ, and Musaceæ, as represented in the Philippine Islands, is contributed by Mr. H. N. Ridley to the botanical series of the *Philippine Journal of Science* (vol. iv., No. 2). The area of the Philippines is much poorer in species than the Malayan region, but four genera and five-sixths of the species are endemic. Alpinia, Globba, and Amomum furnish the majority of the Zingiberaceæ; Alpinia is typically eastern Asiatic, but ranges so far as Japan and Polynesia. A feature of the genus Globba is the preponderance of white over yellow flowers, this being the reverse of what occurs in India and Malaya. The Marantaceæ are represented by three genera, but no indigenous species of Cannaceæ or Musaceæ are noted, so that there is at present no record of any species of the curious tribe Lowioideæ.

PROF. BRÜCKNER returns to the vexed question of the development of the Rhine-Rhone divide in the *Zeitschrift* of the Berlin Gesellschaft für Erdkunde (1909, p. 387). His paper is a reply to that of Herr L. von Sawicki, published in the same journal early this year (p. 7), and deals in detail with the points on which the two authors differ.

PROF. J. CVIJIĆ contributes a further important contribution to our knowledge of the geology of the Dinaric coastal region in a memoir published in the June and July numbers of *Petermann's Mitteilungen* entitled "Bildung und Dislozierung der dinarischen Rumpffläche." Few parts of the earth's surface show a more complex and varied geological history than this, and the rapidly increasing literature dealing with it has scarcely reached a stage in which a short summary of results is possible. Dr. Cvijić's paper is accompanied by maps and sections and a number of excellent characteristic photographs.

WE have received the annual report of the Survey Department of British East Africa for the financial year 1907–8, by Major G. E. Smith, R.E., director of surveys. The report is divided into three sections, trigonometrical branch, cadastral branch, and Uasingishu Rapid Allotment, and each branch shows very good progress. The trigonometrical branch having completed the preliminary astronomical observations and base measurements on the Athi plains near Nairobi last year, has been able to make rapid progress with triangulation, 7320 square miles having been completed in 1907–8, as against 1375 in 1906–7. In the cadastral branch the arrears of farm surveys have been reduced to manageable proportions, and systematic mapping should get on rapidly next season.

THE director-general of Indian observatories reports that the monsoon appeared about a week before its normal date over the Bay of Bengal, and advanced inland with the usual rapidity; the Bombay current also arrived about the normal date, but did not penetrate inland in full strength until nearly the end of June. The aggregate rainfall of June and July in the plains of India was 13 per cent. in excess of the normal, excepting in the provinces of Central India, the Central Provinces, and Mysore, where there was a deficit, especially in the latter State. Abundant monsoon rainfall is, as a rule, preceded by high pressure in South America and low pressure in the Indian Ocean. These favourable conditions were fully maintained during June and July, and the director-general infers from this fact and other data that the total amount of rainfall in August and September will exceed the average.

MUCH useful information relating to aërial navigation and the physics of the upper air is contained in the reports of scientific lectures and papers published in the weekly review of the Frankfort Aëronautical Exhibition. The number for August 14, for instance, includes (1) an illustrated account of the use of pilot balloons by Mr. H. Bongards, which show the direction and velocity of the upper wind currents. Dr. de Quervain first constructed a special theodolite by which the motion of the balloons could be easily followed in clear weather up to an altitude of 15,000 metres. At Frankfort an apparatus by Dr. Assmann is used for the purpose. (2) A preliminary report of a lecture, by Dr. Pütter, on the development of flight in the animal kingdom, in which the different muscular motions are explained. The author stated that about 62 per cent. of some 420,000 objects, including insects, birds, bats, and fishes, were endowed with some means of flight, and his views of the future development of our present flying apparatus were very promising.

THE so-called Roman amphitheatre at Charterhouse-on-Mendip, about seven miles north-west of Wells, has recently been excavated by Mr. H. St. George Gray on behalf of the Somersetshire Archæological Society. It was certainly closely connected with the extensive Roman lead-mining operations in the Mendips, which, with the remains discovered from time to time, have been fully described by Prof. Haverfield in the "Victoria County History." So far as the discovery of relics goes, the present operations were disappointing. Flint implements are numerous, and when discovered associated with Roman remains it is safe to infer that the lead-miners found them on the surface and buried them in their excavations. The arena, according to Mr. Gray, may have been used by the Roman miners for games, combats, or cock-fighting, but it is ridiculous to style it an amphitheatre of the class of the Maumbury Rings at Dorchester. In fact, the use of such a term raises, as Prof. Haverfield says, "false ideas of space and grandeur"; and he goes on to say that "we cannot decide its precise use, but it is ill-suited to form a pond or water reservoir, and the notion of a tiny amphitheatre is not wholly absurd."

CONSIDERABLE progress towards the settlement of the ever-recurring controversy regarding the origin and date of the so-called dene-holes has been made in a paper contributed to the January–June number of the Journal of the Royal Anthropological Institute by the Rev. J. W. Hayes. This contribution is somewhat lacking in lucidity and logical arrangement, but the writer has pursued the investigation in a common-sense way, and has collected a mass of facts necessary to the settlement of the problem. It is essential to know the various qualities of chalk, and the uses to which it was put in ancient and modern times. The export of the material began in pre-Roman time, and the character of it varied. It was essential for the purposes of home and foreign trade that it should be excavated in solid blocks, and the occurrence of strata of this quality accounts for the grouping of a number of pits in the same neighbourhood. It was and is raised in buckets or baskets, and difficulties of carriage suggested the construction of fresh shafts in close proximity to each other. These considerations seem to dispose of the objection that excavation for the material was only one of the objects of the construction of the dene-holes as we find them. One of the strongest reasons against the theory that they were used as granaries or hiding places lies in the fact that they contain cores of sand, which could not have arisen from attrition of the sides of the pits or from collapse of the mouths of the excavations. These cones could only have resulted from the deposit in the worked-out pits of débris from those of later construction. Mr. Hayes has collected a mass of reports from persons engaged in the chalk trade in recent times which show the methods by which the material is excavated and utilised. These raise a strong presumption that the same considerations which now influence the workers prevailed also in the British and Roman periods.

IN the *Electrician* for August 20 Mr. Morris-Airey makes a suggestion which may prove the correct explanation of the discordant results obtained when two lights of different colours are compared together by photometers of the Bunsen and of the flicker type respectively. The three groups of nerve fibres in the retina, which respond respectively to red, green, and violet light, behave, according to Mr. Morris-Airey, in different ways when the stimulus is first applied, the red group, *e.g.*, responding more quickly than the violet, so that the true degree of excitation of the nerves corresponding to a stimulus is attained by the red nerves before it is by the violet. If the speed of the flicker photometer is such that the stimulus is not applied long enough to allow the three sets of nerves to attain the proper degrees of excitation, the results of comparisons of lights of different colours will vary with the speed, and will only agree with the Bunsen results when the speed is reduced sufficiently.

ACCORDING to the July *Bulletin de la Société d'Encouragement pour l'Industrie nationale* of France, the society is in a most flourishing condition. It has 650 members and an annual income of more than 100,000 francs, part of which is derived from the Department of Agriculture of the country. The society further possesses about thirty endowments, amounting together to more than a million francs, the income from which it utilises in various ways, as, for example, in prizes to inventors who benefit industry, in assisting inventors or artisans who have come down in the world, &c., all calculated to forward the object of the society. In addition, in its monthly bulletin, which is a quarto volume of two hundred pages, it gives its members well written and illustrated articles on industrial questions of the day. In the July number, leaving out of account the shorter articles, there are reports on the breweries and distilleries of the north of France, on recent girder bridge-work, on the position of the electrical industry in France, and, lastly, forty pages of a serial article on the economic situation in Great Britain.

THE *Engineer* for August 27 comments on the reasons for the success of the French in following up new lines of research, and says that it is probably to be found in the fact that they often allow themselves to be influenced by imagination rather than by the practical aspect of the problems they are trying to solve. The remark is called forth by the interest which is being taken on the other side of the Channel in the evolution of the aëroplane, as evidenced by the meeting at Rheims. We agree with our contemporary that, not only the possession of a healthy imagination, but also unbounded enthusiasm, are qualities which go to make a good inventor. Can the fact that this country is taking so small a part in the development of aërial machines be accounted for by the absence of inventive faculties? We prefer to believe that it is rather the lack of financial support which is causing the stagnation, a lack which may be explained by the well-known desire of British manufacturers to see commercial success and profit within reach before taking up any industrial development. Given funds, there is no doubt that we have men of ability sufficient to bring this country into line with our neighbours.

THE leading article in *Engineering* for August 27 is devoted to the address of the president of the British Association. Many of the statements in the address are of particular interest to engineers, and one appeals very forcibly. Sir Joseph Thomson quotes Helmholtz as saying that often in the course of a research more thought and energy are spent in reducing a refractory piece of brass to order than in devising the method or in planning the scheme of campaign. This is exactly in accord with engineering practice. For example, in developing a certain steam turbine, the thermodynamic and kinematic questions involved occupied not a tithe of the time and thought which had to be expended on such questions as the mere form of the casing. Should it, for instance, open at a transverse joint or a longitudinal one? Would the governor fit in better at one end or at the other? These and other apparently trivial, but really very important, details absorbed the greater part of the time at the designer's disposal. The mathematician seems often to have a difficulty in appreciating this matter, but the experimental physicist is nearer akin to the engineer, and has to face many of the same problems. Both suffer from a certain apparent perversity in the materials they use, to which, however, the engineer has commonly the added burden of often wayward and intractable human nature.

MESSRS. H. F. ANGUS AND CO., 83 Wigmore Street, London, W., have submitted to us a specimen of a very useful supplementary lens which they have placed on the market for attachment to a naturalist's telescope. The telescope sent with the lens is of the usual short-focus pattern made for observing birds or other objects, and by placing the supplementary lens over the objective the instrument can be used to watch insects or similar small forms of animal life at any convenient distance down to about 20 inches, at which distance the magnification is about five diameters. The combination thus provides the naturalist with a very handy means of studying the characteristics and movements of insects, spiders, and so on at a convenient distance, and without disturbing the creatures. Similar caps can be adapted to the ordinary tourist telescope and the monocular prismatic field-glass. The attachment is inexpensive—the price being 3*s*. 6*d*. for any size or power lens required—and it certainly increases the optical capacity of any instrument with which it is used. For the observation of minute forms of animal life in the open air, and for the examination of details of objects placed beyond the distance of distinct vision in museums, the additional lens will be found a great advantage. As, however, accessory parts of instruments are often misplaced or not at hand when desired, we suggest that the attachment should be fixed upon the telescope by a band or other means which would permit the lens to be brought in front of the objective or turned away from it as desired. A simple swivel arrangement would probably enable this to be done, and the naturalist could then immediately convert his glass into an instrument for the observation of objects near or far.

OUR ASTRONOMICAL COLUMN.

CHANGES ON MARS.—Further changes in the south polar regions of Mars are recorded by M. Jarry Desloges in No. 4350 of the *Astronomische Nachrichten* (p. 95, August 25). Observations, made at the observatory installed on the Revard plateau, on August 20, 11h., showed that the Mare Cimmerium was divided obliquely by a bright band between Eridania and Electris, whilst a large gulf was distinguished on Zephyria, and numerous changes were seen to have taken place on the northern plains. Since its separation, observed on August 11–12, the bright oval region in longitude 320° has become more and more separated, and the dark regions of the planet, so pale in June and July, are changing, and becoming darker, almost daily. A greyish region seen at the eastern side of the polar cap on August 13, 2h., is diminishing rapidly, and apparently disaggregating in all directions.

THE ABSORPTION OF LIGHT IN SPACE.—A suggestion recently made by Prof. Turner, in regard to M. Tikhoff's researches on the absorption of light in interstellar space, is discussed by Mr. J. A. Parkhurst in the July number of the *Astrophysical Journal* (vol. xxx., No. 1, p. 33). Prof. Turner's suggestion was that photographs of stars should be taken using only the visual rays, and then other photographs should be taken in the same way to determine the increase of exposure necessary to get stars of a definite number of magnitudes fainter. If these photographs were more in accordance with the theoretical law connecting exposure and intensity than are those where the violet rays are not excluded, they would afford evidence that the discordance between visual and ordinary photographic magnitudes is due rather to cosmical than to photographic causes. Evidence of this nature has already been adduced by M. Tikhoff.

Mr. Parkhurst shows, however, from a number of experiments carried out at the Yerkes Observatory, that his results are contradictory to those of M. Tikhoff, and suggests that the cause of the difference lies in the instruments and plates employed; probably, in the main, in the plates and light-filters, for the same effect has been obtained by him both with a reflecting telescope and a doublet camera. Thus it would appear that the proposed experiments with photographic colour-filters would furnish no definite evidence either for or against the cosmical absorption or scattering of the violet rays.

In the same journal Mr. Paul R. Heyl also discusses the question of the apparent dispersion in space, and, whilst preferring Nordmann's monochromatic-photometry method, suggests that too great an importance has been attached to the parallax values used in measuring the dispersion; this would possibly account for the considerable differences between the values obtained by Tikhoff and Nordmann. Mr. Heyl also indicates that the objections urged by M. Lebedew against the methods are not unanswerable.

PLANETS AND THEIR SATELLITES.—In a note appearing in No. 4351 of the *Astronomische Nachrichten* (p. 97, August 27), Prof. Lowell shows that throughout the solar system there exists a remarkable parallelism between the ratios obtained by comparing the speeds of the satellites, about their primaries, with the velocities of the latter in their own orbits. A table showing the ratios for the systems of Jupiter, Saturn, Uranus, and Neptune displays relations which are too systematic to be merely fortuitous. In a brief discussion as to the effect of the calculated speeds, during the time the systems were evolving, in determining the relations between the satellites and the interplanetary particles through which they were passing, Prof. Lowell shows that the total effect of the particles on the large satellites was to retard the latter and cause them to approach the primaries. For retrograde satellites the effect was greater than for the direct, which may account for the preservation of the latter. Incidentally, this is shown to be antagonistic to the planetesimal hypothesis, wherein it is reasoned that the impact of the interplanetary particles on a direct satellite would accelerate it and thus prevent it being drawn down on to the planet; this is exactly contrary to the fact with any of the major satellites.

METEOR OBSERVATIONS.—As in previous years, organised observations of the Perseids were carried out by the members of the Belgian Astronomical Society at seven different stations, and the results are briefly reported in No. 21 of the *Gazette astronomique*. Each observing party kept watch from 10h. to 14h., each night, from August 7 to August 15, and the detailed discussion of the collected observations should provide some very useful information concerning this important shower. At Antwerp two observers recorded 492 meteors, 129 of which were of the first magnitude, or brighter, and the maximum display, both there and at Uccle, appears to have taken place on August 11; the horary numbers were 51·4 and 44·2 respectively.

Observations of the Perseids in 1908, and the Lyrids in 1909, were made at the Kasan Observatory, and the results are published in detail in No. 4350 of the *Astronomische Nachrichten*. Altogether, the paths of 132 Perseids and 59 Lyrids, with notes on their appearances and the values determined for the radiants, are given.

NEW SPECTROSCOPIC BINARIES.—No. 19, vol. i., of the Publications of the Allegheny Observatory contains the preliminary announcement that spectrograms taken with the Mellon spectrograph show the following five stars to be spectroscopic binaries:—(1) 30 H. Ursæ Majoris; range of 100 km. and period of 11·6 days. (2) B.D. + 3·2867°; 134 km. range and short period. (3) B.D. + 6·2875°; range of 80 km. (4) 25 Serpentis; range of 90 km. and a short period. (5) ι Coronæ; range 40 km., period short.

OBSERVATIONS OF PERRINE'S COMET.—Photographic observations of Perrine's comet, 1909*b*, were made at Greenwich on August 14 and 16, and at the Königstuhl Observatory on August 12, 15, and 19; on the latter date the magnitude was 15·0.

These observations show that, between the extreme dates, the ephemeris published by Prof. Kobold was nearly correct, the corrections in R.A. varying from +5s. on August 12 to −6s. on August 19; those for declination increased from −10·8′ to −14′ (*Astronomische Nachrichten*, No. 4350, p. 96).

THE BRITISH ASSOCIATION AT WINNIPEG.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY A. E. SHIPLEY, M.A.CANTAB., HON. D.SC.PRINCETON, F.R.S., PRESIDENT OF THE SECTION.

I.

Charles Darwin.

THIS is the year of centenaries. Perhaps in no other year in history were so many men born destined to impress their genius on the literature, the politics, and the science of the world as in 1809. The number of literary men who first saw the light in that *annus mirabilis* is almost too long to mention—Mark Lemon, the genial editor and one of the founders of *Punch*; "Crimean" Kinglake; John Stuart Blackie, until lately a well-known figure in Edinburgh; Monckton Milnes, the first Lord Houghton, "poet, critic, legislator, the friend of authors" and the father of Lord Crewe, who at present presides over that most important of all Government offices—that of the Colonies. One could prolong the list; and one must at least mention the names of Louis Braille, the inventor of the Braille type for the blind, of Fanny Kemble and of Elizabeth Barrett Browning, before passing on to remind you that this year is also the centenary of Tennyson, who, with Browning, formed the twin stars of poetry during the reign of Queen Victoria, and who from his intimate knowledge of natural history and his keen power of observation was essentially the poet of Darwinism. Of his life-long friend, born the same year, Edward Fitzgerald, the translator—one feels almost inclined to say author—of Omar Khayyám, and of the gifted musician Mendelssohn there is no time to speak.

On this side of the Atlantic, and yet not wholly on this side, for he spent five impressionable school years at Stoke Newington, we have that "fantastic and romantic" genius Edgar Allan Poe.[1] Later he studied at West Point, where surely he must have been as incongruous a student as James Whistler himself. We have also that kindly, humorous physician Oliver Wendell Holmes, a nature "sloping towards the southern side" as Lowell has it. Amongst many recollections of literary men I cherish none more dearly than that I once entertained him in my Cambridge and once visited him in his.

Three other names stand out. William Ewart Gladstone, that leader of men, a politician and a statesman capable more than most men at once of arousing the warmest affection of his followers and the bitterest hatred of those who went the other way. Cultured as he was and widely read, he had his limitations, and although his tenacious memory was stored with the humanities of all the ages, he was singularly devoid of any knowledge of science. If we may paraphrase the words of Lord Morley in his estimate of Gladstone's writings, we would say that his place is not in science, "nor in critical history, but elsewhere."

Abraham Lincoln, the greatest man born on this continent since the War of Independence, was some ten months older than Gladstone. Both men were great statesmen, both men were liberators; for we must not forget that in many minds the help Gladstone gave to Italy in her struggle for freedom and union remains the most enduring thing he achieved.

Yet in externals how different! One the finished, cultured product of the most aristocratic of our public schools and the most ancient of our universities, the other little read in the classics or in mediæval and ecclesiastical lore, yet deeply versed in the knowledge of men and how to sway them. Rugged, a little rough if you like, humorous and yet sad, eminently capable, a strong man, and at heart "a very perfect gentleman."

On the same day, February 12, upon which Lincoln first saw the light, was born at the "Mount," Shrewsbury, a little child destined as he grew up to alter our conceptions of organic life perhaps more profoundly than

[1] Poe lived from his eighth to his thirteenth year at the "Manor House School," Stoke Newington, at that time a village, now swallowed up by the metropolis. Poe described the place as he knew it, and his schoolmaster, Dr. Bransby, in "William Wilson."

any other man has ever altered them, and this, not only in the subjects he made his own, but in every department of human knowledge and thought.

Being as I am a member of Charles Darwin's own college, coming as I do straight from the celebration in which the whole world united to do his memory honour, it would seem meet that I should in this year of the centenary of his birth devote this address to a consideration of his life and of his work, and of such confirmation and modification of his theories as the work of the last fifty years has revealed.

As to the man, I can but quote two estimates of his character, one by a college companion who lived on terms of close intimacy with Darwin when at Christ's, the other the considered judgment of one who knew and loved and fought for Darwin in later life.

Mr. Herbert says:—

"It would be idle for me to speak of his vast intellectual powers . . . but I cannot end this cursory and rambling sketch without testifying, and I doubt not all his surviving college friends would concur with me, that he was the most genial, warm-hearted, generous, and affectionate of friends; that his sympathies were with all that was good and true; and that he had a cordial hatred for everything false, or vile, or cruel, or mean, or dishonourable. He was not only great, but preeminently good, and just, and lovable."

Prof. Huxley, speaking of his name, says:—

"They think of him who bore it as a rare combination of genius, industry, and unswerving veracity, who earned his place among the most famous men of the age by sheer native power, in the teeth of a gale of popular prejudice, and uncheered by a sign of favour or appreciation from the official fountains of honour; as one who, in spite of an acute sensitiveness to praise and blame, and notwithstanding provocations which might have excused any outbreak, kept himself clear of all envy, hatred, malice, nor dealt otherwise than fairly and justly with the unfairness and injustice which was showered upon him; while, to the end of his days, he was ready to listen with patience and respect to the most insignificant of reasonable objectors."[1]

It has been somewhat shallowly said—said, in fact, on the day of the centenary of Darwin's birth—that "we are upon very unsafe ground when we speculate upon the manner in which organic evolution has proceeded without knowing in the least what was the variable organic basis from which the whole process started." Such statements show a certain misconception, not confined to the layman, as to the scope and limitations of scientific theories in general, and to the theory of organic evolution in particular. The idea that it is fruitless to speculate about the evolution of species without determining the origin of life is based on an erroneous conception of the true nature of scientific thought and of the methods of scientific procedure. For science the world of natural phenomena is a complex of procedure going on in time, and the sole function of natural science is to construct systematic schemes forming conceptual descriptions of actually observed processes. Of ultimate origins natural science has no knowledge and can give no account. The question whether living matter is continuous or not with what we call non-living matter is certainly one to which an attempted answer falls within the scope of scientific method. If, however, the final answer should be in the affirmative, we should then know that all matter is living; but we should be no nearer to the attainment of a notion of the origin of life. No body of scientific doctrine succeeds in describing in terms of laws of succession more than some limited set of stages of a natural process; the whole process—if, indeed, it can be regarded as a whole—must for ever be beyond the reach of scientific grasp. The earliest stage to which science has succeeded in tracing back any part of a sequence of phenomena constitutes a new problem for science, and that without end. There is always an earlier stage, and to an earliest we can never attain. The questions of origins concern the theologian, the metaphysician, perhaps the poet. The fact that Darwin did not concern himself with questions as to the origin of life nor with the apparent discontinuity between living and non-living matter in no way diminishes the value of his work. The broad, philosophic mind of the great master of inductive method saw too fully the nature of the task he had set before him to hamper himself with irrelevant views as to origins.

No well-instructed person imagines that Darwin spoke either the first or the last word about organic evolution. His ideas as to the precise mode of evolution may be, and are being, modified as time goes on. This is the fate of all scientific theories; none are stationary, none are final. The development of science is a continuous process of evolution, like the world of phenomena itself. It has, however, some few landmarks which stand out exceptional and prominent. None of these is greater or will be more enduring in the history of thought than the one associated with the name of Charles Darwin.

I cannot, indeed, attempt to weigh or estimate the influence and the far-reaching import of the work which all the world has been weighing and estimating during this year, the centenary of his birth and the jubilee of the "Origin of Species." I cannot, to my intense regret, give you any personal recollections of Darwin, for though I think I once saw him in the streets of Cambridge, I have to my sorrow never been absolutely sure that this was so.

But in reading his writings and his son's most admirable Life, one attains a very vivid impression of the man. One of his dominant characteristics was simplicity—simplicity and directness. In his style he was terse, but he managed to write so that even the most abstruse problems became clear to the public. The fascination of the story he had to tell was enhanced by the direct way he told it.

One more characteristic. Darwin's views excited at the time intense opposition and in many quarters intense hatred. They were criticised from every point of view, and seldom has a writer been more violently attacked and abused. Now what seemed to me so wonderful in Darwin was that—at any rate so far as we can know—he took both criticism and abuse with mild serenity. What he wanted to do was to find the truth, and he carefully considered any criticism, and if it helped him to his goal he thanked the critic and used his new facts. He never wasted time in replying to those who fulminated against him; he passed them by and went on with his search.

In the development of the theories associated with Darwin's work the New World played a prominent part. Darwin's "Wanderjahre" were spent on this side of the Atlantic. The central doctrine of evolution through natural selection was forced upon his mind by the studies and researches he made in South America during the voyage of the *Beagle*. The numerous observations in all departments of natural science and the varied forms of life he came across in this classical journey were the bricks with which he built many of his later theories. The storm of controversy which the "Origin of Species" awoke was at least as violent in America as in Great Britain, and we must not forget the parts played by men like Hyatt, Fiske, Osborn, and many others, and above all by Asa Gray and by Brooks of Baltimore, whose recent death has robbed America of perhaps her greatest Darwinian.

It is a somewhat remarkable fact that whilst the works of Darwin stimulated an immense amount of research in biology, this research did not at first take the line he himself had traced. With some exception the leading zoological work of the end of the last century took the form of embryology, morphology, and palæontology, and such subjects as cell-lineage, "Entwickelungsmechanik"; the minute structure of protoplasm, life-histories, teratology, have occupied the minds of those who interest themselves in the problems of life. Along all these lines of research man has been seeking for the solution of that secret of nature which at the bottom of his heart he knows he will never find, and yet the pursuit of which is his one abiding interest. Had Frank Balfour lived we should, I think, have sooner returned to the broader lines of research as practised by Darwin, for it was his intention to turn himself to the physiology—using the term in its widest sense—of the lower animals. Towards the end of the nineteenth century, stimulated by Galton, Weldon began those series of measurements and observations which have culminated in the establishment, under the guidance

[1] "Life and Letters of Charles Darwin," vol. ii., 1887, p. 179.

of his friend and fellow-worker, Karl Pearson, of a great school of eugenics and statistics in London. With the beginning of the twentieth century came the re-discovery of Mendel's facts, and with that an immediate and enormous outburst of enthusiasm and of work. Mendel has placed a new instrument in the hand of the breeder, an instrument which, when he has learnt to use it, will give him a power over all domesticated animals and cultivated crops undreamt of before. We are getting a new insight into the working of heredity, and we are acquiring a new conception of the individual. The few years which have elapsed since men's attention was re-directed to the principles first enunciated by the Abbot of Brünn have seen a great school of genetics arise at Cambridge under the stimulating energy of Bateson, and an immense amount of work has also been done in France, Holland, Austria, and especially in the United States. As the work has advanced, new ideas have arisen and earlier formed ones have had to be abandoned; this must be so with every advancing science; but it has now become clear that mutations occur and exist especially in cultivated species, and that they breed true seems now to be established. In wild species also they undoubtedly occur, but whether they are so common (in uncultivated species) remains to be seen. If they are not, in my opinion a most profitable line of research would be to endeavour to determine what factor exists in cultivation which stimulates mutation.

To what extent Darwin's writings would have been modified had Mendel's work come into his hands we can never know. He carefully considered the question of mutation, or, as they called it then, saltation, and as time went on he attached less and less importance to these variations as factors in the origin of species. Ray Lankester has recently reminded us that Darwin's disciple and expounder, Huxley, "clung to a little heresy of his own as to the occurrence of evolution by saltatory variation," and there must have been frequent and prolonged discussion on the point. That "little heresy" has now become the orthodoxy of a number of eager and thoughtful workers who are at times rather aggressive in their attacks on the supporters of the old creed. "That mutations occur and exist is obvious to everyone, but that they are of frequent occurrence under purely natural conditions is," Sir William Thiselton-Dyer thinks, "unsupported by evidence." The delicate adjustment between an organism and its natural surroundings suggests that sudden change of a marked kind would lead to the extinction of the mutating individual. So far as I can understand the matter in dispute, Darwin and his followers held that evolution had proceeded by small steps, for which we may accept de Vries's term fluctuations; whilst the Mutationists hold that it has advanced by large ones, or mutations. But it is acknowledged that mutations are not all of the same magnitude, some, *e.g.* albinism, brachydactyly in man, dwarf habit or glabrousness in plants, may be large; others, *e.g.* certain differences in shade of colour or in size, are insignificant, and indeed Punnett has suggested that under the head of fluctuating variation we are dealing with two distinct phenomena. He holds that "some of the so-called fluctuations are in reality mutations, whilst others are due to environmental influence." He thinks the evidence that these latter are transmitted is slender, and later states that "Evolution takes place through the action of selection on these mutations. Where there are no mutations there can be no evolution." The disagreement about the way in which evolution has proceeded has perhaps arisen from a misunderstanding as to the nature of the two kinds of variation described respectively as mutations and fluctuations. Mutations are variations arising in the germ-cells and due to causes of which we are wholly ignorant; fluctuations are variations arising in the body or "soma" owing to the action of external conditions. The former are undoubtedly inherited, the latter are very probably not. But since mutations (using the word in this sense) may be small and may *appear* similar in character to fluctuations, it is not always possible to separate the two things by inspection alone. The whole matter is well illustrated by the work of Johannsen on beans. He found that while the beans borne by any one plant vary largely in size, yet if a large and a small bean from the same plant are sown, the mean size and variability of the beans on the plants so produced will be the same. The differences in size are presumably due to differences of condition, and are not inherited. But if two beans are sown, one from a plant with beans of large average size, and one from a bean of small average size, the bean plant the parent of which had the high average will bear larger beans than the one from the parent with small average beans. The faculty of producing a high or low mean size is congenital, is a mutation in the sense used above, and is inherited. It is no doubt unfortunate that the word mutation has been used in several different senses, for it seems to have led to most regrettable confusion and misunderstanding.

As I have said, in such a year, and in my position, I ought perhaps to have devoted the whole of this address to the more philosophical side of our subject; but, in truth, I am no philosopher, and I can only say, as Mr. Oliver Edwards, "an old fellow-collegian" of Dr. Johnson's, said to the "great lexicographer" when they met after nearly half a century of separation: "I have tried too in my time to be a philosopher, but I don't know how, cheerfulness was always breaking in."

II.

Organising Zoology.

I now turn to a subject of the greatest moment and of the greatest difficulty, and one on which there is little general consensus of opinion. The question I wish to raise is this—are the zoologists of the world setting about their task in an economic and efficient way?

We live surrounded by a disappearing fauna. Species are disappearing from the globe at a greater rate than even the most ardent mutationist claims they are appearing. To mention but a few striking cases: The European beaver has almost gone, though a few linger on around the periphery of the Continent. Norway, the lower Danube, Eastern and Arctic Russia still harbour them, and a very few are said still to inhabit the Rhine and the Rhone. The European bison is now represented by a few wild specimens in the Caucasus. The American bison is reduced, and that by the deliberate and calculated action of man, to a few herds most carefully preserved by Government; the largest of these, containing some 600 heads, is now at the National Park at Wainwright. Equally deliberate and equally calculated is the destruction of the fur-seal, which threatens soon to be complete. The Greenland sealing is almost a thing of the past. In 1860 British vessels killed 68,278 seals; in 1866, 103,578; and this went on until 1895, when the pursuit was abandoned by the British, it being no longer found to pay them, though Norwegians still continue "sealing." In 1859 19 vessels sailing from British ports killed 148 whales; in 1881 12 vessels killed 48 whales; last year 6 Dundee vessels killed but 15, and the year before that but 3. The whalers sailing from Newfoundland ports killed 1275 whales in 1904, 892 in 1905, and only 429 in 1906.

At the present time certain Norwegian whaling companies have been for the last few years actively at work in the Shetlands, and are killing off as fast as they can the common rorqual (*Balaenoptera musculatus*, L.), the lesser rorqual (*B. rostrata*), Sibbald's rorqual (*B. sibbaldi*, Gray), the cachalot (*Physeter macrocephalus*, L.), the humped-back whale (*Megaptera boops*, L.), and, when they can reach him, the Atlantic right whale (*Balaena mysticetus*, L.). These are killed primarily for their blubber, but the economy of the factories rivals that of the Chicago pork-packing industries. Nothing is wasted; the flesh is made into sausages, which are readily eaten in Central Europe, and the bones are ground up to make manure. No animal which produces but few young can withstand such persistent and organised attacks on the part of man, and I fear, before many years are passed, many species of whale will be extinct. At the present moment the two right whales seem almost on the verge of extinction, and *Balaena mysticetus* will probably go before *B. australis*. Nothing shows this more clearly than the price of whalebone, which has gone up in the last eighty-four years from 56*l.* per ton to 2100*l.* per ton, or from 12 cents a pound to 4·90 dollars, and in some years to 5·80 dollars a pound. The number of pounds on sale in the United States has dropped from 2,916,500 in 1851 to 96,600 in 1906. With the whales will disappear the whale-lice and the whole of the very interesting parasitic fauna which inhabit their vast interiors.

The disappearance of the large game from enormous tracts of country in Africa is too well known to delay us. The elephant, except where preserved in the Litzikama Forest, near Mossel Bay, and in the Addo Bush, near Port Elizabeth, is exterminated south of the Limpopo. The price of ivory, again, is a measure of the nearness of its extinction. The best pieces, which are used for billiard balls, have risen in price from 55*l.* a cwt. in 1882 to an average of 100*l.* a cwt. in 1908. The common and the brindled gnu (*Connochoetes taurinus*) are fated to follow the extinct quagga. The blesbok (*Damaliscus albifrons*), formerly found in thousands in Cape Colony, the Transvaal, and Bechuanaland, is now very rare, and seems doomed. The giraffe has long been driven out from South Africa, though it still roams over large tracts of country in East and Central Africa.

Perhaps the most striking case of the disappearance of a mammalian fauna is that presented in Western Australia. Here many districts are now said to be entirely devoid of indigenous mammals, and this depletion is in the main an affair of only the last thirty years, and many of the local extinct forms are still remembered by the older natives and colonists. Mr. Shortridge, a collector who has worked for some years in South-west and Western Australia, writes in a letter: "The entire disappearance of so many species over such large tracts of country is generally considered to be due to some epidemic perhaps brought into the land by introduced animals. It is to be noted that they have died out chiefly in the dry regions, where, except for the introduction of sheep, there has been very little alteration in the natural conditions. Rabbits, although already very numerous in the Centre and South-east, have not as yet found their way to the North-west." Amongst the mammals which have almost, if not quite, disappeared from West Australia are the banded wallaby (*Lagostrophus fasciatus*), the hare wallaby (*Lagochestes hirsutus*), the rat-kangaroos (*Potorous gilberti* and *P. platyops*). The indigenous rats and mice of Australia are disappearing even faster than the marsupials, and it seems probable that many will not be heard of again.

A very few years ago the ship employed by the company which is exploiting the phosphates of Christmas Island introduced the brown rat (*M. decumanus*) there. Within a short time the two indigenous rats first collected by Mr. C. W. Andrews, of the British Museum, named *Mus macleari* and *Mus novitatis*, were wiped out of existence. The same animal having been introduced in North America is gradually spreading, and as it spreads the native fauna of Muridæ is slowly vanishing.

To adorn our ladies' heads some of the most beautiful of birds are being systematically exterminated. In the London market alone were sold last year some 50,000 sooty terns (*Sterna fuliginosa*, *S. anaestheta*, and *S. bonata*), 20,000 specimens of the crowned pigeon (Goura) from New Guinea, their sole habitat, immense numbers of "osprey" feathers, egret and heron, and more than 50,000 birds of paradise, or more than double the number of the year before.

I have no time to continue this melancholy record, but it could be prolonged almost indefinitely.

When we reflect how greatly we treasure every scrap of knowledge we can glean about such recently extinct animals as the Rhytina—Steller's sea-cow—the dodo, the great auk, we must see that if it be impossible to check the gradual disappearance of those animals doomed to extinction, we should at least monograph them and take every care that what can be permanently kept of their structure should be kept. In respect to the recording of the habits and physical features of a disappearing race, the anthropologists are setting an example which the zoologists would do well to follow.

We are living with a disappearing fauna around us, and numerous as the museums of the world are, and skilled and painstaking as the curators of these museums are, they are both wholly inadequate to deal with the material at hand. Some dozen years ago Dr. Günther made a very careful estimate of the number of species of animals which were known in the years 1830 and 1881. I summarise his table:—

Number of Species known in the years 1830 and 1881.

	1830	1881
Mammalia	1,200	2,300
Aves	3,600	11,000
Reptilia and Batrachia ...	543	3,400
Pisces	3,500	11,000
Mollusca	11,000	33,000
Bryozoa	(40)	120
Crustacea (year 1840) ...	(1,290)	7,500
Arachnida	1,408	8,070
Myriapoda	450	1,300
Insecta	49,100	220,150
Echinodermata (1838) ...	(230)	1,843
Vermes (1838)	(372)	6,070
Cœlenterata (1834)	500	2,200
Porifera (1835)	(50) *say*	400
Protozoa (1838–44) *say* ...	(305) ,,	3,300
	73,588	311,653

Taking an average year between 1881 and the present date, but rather nearer the latter, because each year the number of newly described species becomes larger, Dr. Sharp tells me that, according to the zoological record, 12,449—let us call it 12,450—new species were described in the year 1897.

Number of new Species described in the year 1897.

Mammalia	285
Aves	105
Reptilia and Batrachia	140
Pisces	148
Mollusca	1,077
Brachiopoda	7
Bryozoa	6
Crustacea	239
Arachnida	659
Myriapoda	275
Insecta	8,364
Echinodermata	491
Vermes	294
Cœlenterata	164
Porifera	95
Protozoa	100
	12,449

This number, however, includes fossils which I do not think were included by Dr. Günther. We might deduct 450 for them if we wish to confine our attention to living animals. This leaves us 12,000. If we multiply this by 27, the number of years which have elapsed since Dr. Günther made his estimate, we find a total of 324,000. This number is possibly too large, as it makes no allowance for synonyms; still, it is a rough indication that since 1881 the number of described species has been doubled. Isolated groups, such as the mammals, treated in the same way, give us fairly similar results, so that now we may, I think, say that there are more than 600,000 described species of living animals.

It thus appears that during the fifty-one years in the middle of the last century the number of known species grew by some 238,000, giving an average increase of a little less than 5000 per annum. At the present day there are far more workers in the field than there were thirty years ago, museums have multiplied, and there are many more zoologists, and it is now estimated that the number of species annually described and named amounts to some 12,000.

The number, large as it seems, is, however, but small in comparison with the number of species collected and deposited in museums where no one has time to work them out. It is still smaller in comparison with the vast numbers of species as yet uncaptured. Dr. Sharp, in 1895, calculated that there were a quarter of a million known and described insects. This was an increase of 30,000 over Günther's figures of fifteen years before, but he states that in his opinion this quarter of a million is but one-tenth of those which exist.

With the exception of the larger Mammalia—though the Okapi warns us the exception may yet prove the rule—there is no group of animals which may not yield us new surprises—no group which we can regard as well worked out, though naturally some are better known than others. What, then, are the zoologists of the world doing to record the animal life around them? One thing of late is certainly an improvement. During last century the great zoological collections were in the main increased and augmented by the chance gifts of hunters and sportsmen, whose chief object in their expeditions was not zoology, but what is termed "sport." Many valuable gifts are still received from such sources, but it is now recognised that we must not in these matters trust to the sportsman alone. The plan of attaching trained naturalists and experts in taxidermy to an expedition avowedly meant for other purposes is good, and is well exemplified by Mr. Roosevelt's "safari" in East Africa at the present time. We may hope that we may never again see an expedition without a single trained naturalist on its staff, such as the last Stanley led across Africa. A still better plan is to send out expeditions of trained naturalists to do definite pieces of work. Such expeditions as Andrews and Foster Cooper and Osborn to the Fayum for fossils, of Cunnington and Boulenger to the same region to investigate the fauna of the lake, or Wollaston and his companions to the Ruwenzori district, yield a harvest one hundred times more abundant than the best of other schemes.

Yet even here I would plead for a little more organisation. One must not suggest too rigid a scheme, and it is to be hoped that in the future, as in the past, there will always be found wealthy men willing to devote their energies to the advancement of zoology. Such work has been done by Mr. Godman on the fauna of Central America, one of the richest regions in the world, and now, owing to his munificence, one of the best known. The stately array of volumes embodying these results is paralleled by the magnificent monographs in which the results of the Prince of Monaco's marine researches are recorded, and by the monographs of the Princeton Expedition to the Argentine, financed by one of the richest of the millionaires of the United States. We trust that such enterprises will always continue.

With regard, however, to expeditions financed from public funds which are sent out officially, it might be possible to have more international cooperation. Just as the members of the Geodetic Survey meet from time to time and determine the next step to be taken in the triangulation of the world, so it seems to me might the members of the chief museums of the world meet, say, triennially, and draw up certain thought-out plans for the exploration of the zoological world.

With regard to working out the material when collected, the existing museums of the world are too few, and their staffs are too small to deal, not only with the huge collections which are constantly pouring into their buildings, but even with the accumulated stores already housed there. In our smaller State museums it is not uncommon to find men who are responsible for the whole of the Arthropoda. Only within the last few months I have had to try to find for a Metropolitan museum a curator who was expected to be a specialist in fishes, molluscs, and arachnids. Now is it possible to expect such men, able and zealous as they are, accurately to determine species in these vast and complex groups? My own feeling is—but I fear I shall carry no one with me—that we must specialise still further. I should like to see each of the great classes of the animal kingdom assigned to one of the great museums of the world. Just as an example—which is only an example, possibly a bad one—I suggest that all the type-specimens of Amphibia be sent to one museum, say, if you like, that of Berlin or St. Petersburg; in return for this that museum should distribute to others its types of fish, birds, &c. Then, at this museum there would arise a series of specialists capable of deciding swiftly and accurately on the validity of the claims of any new species of amphibian that may be advanced. Again, a student of Amphibia, instead of wandering round the museums of the world if he wishes to study species, would find all he wants within the four walls of one building. When once the type is described and deposited, it would be the duty of the museum to distribute co-types and accurately named specimens of the same species to other museums in some recognised order. Smaller groups might be allocated to smaller museums, *e.g.* the fleas to Tring and the ticks to Cambridge—at both these places there are now specialists working out world collections of these pests. What I want is a world's Clearing-House for animals. I know I shall be told that my suggestions can never be realised, that international jealousies would prevent such a scheme being adopted, that I am proposing to fetter research. I admit the difficulties, but do not regard them as insuperable. When you recall the international Clearing Houses for the Postal and Telegraphic service, for the banking of the world, and when we reflect what private enterprise does, under the name of Lloyd's, for the shipping of the world, how it registers and describes and certifies, with a minuteness not surpassed by any maker of species, each ship in the world; how, through its signal stations and by other means, it follows the daily course of each vessel, so that at any hour of any day it can state where, in normal circumstances, that vessel is, it does not seem to me impossible to come to some understanding as to dealing with the animals of the world. Only by some such means can we hope to cope with the problem before us.

One other fruitful source of "waste of time" I will mention. That is the debatable matter of zoological nomenclature, more especially the questions of synonymy. The British Association at their last meeting passed a resolution on the proposal of Mr. G. A. Boulenger in the following sense:—

"The undersigned zoologists, whilst fully realising the justice and utility of the rule of priority in the choice of scientific names for animals, as first laid down by a committee of the British Association in 1842, wish to protest against the abuse to which it has been put as a result of the most recent codes of nomenclature, and consider that names which have had currency for a great number of years should, unless preoccupied, be retained in the sense in which they have been universally used. Considering the confusion that must result from the strict application of the rule of priority, they would welcome action leading to the adoption of a scheme by which such names as have received the sanction of general usage, and have been invariably employed by the masters of zoology in the past century, would be scheduled as unremovable."

Mr. G. A. Boulenger expressed disapproval of the extreme application of the rule of priority in zoological nomenclature on the ground that it had already produced much mischief under the pretence of arriving at ultimate uniformity. The worst feature of the abuse of this rule is not so much the bestowal of unknown names on well-known animals as the transfer of names from one to another, as in the case of Astacus, Torpedo, Holothuria, Simia, Cynocephalus, &c., so that the names which were uniformly used by Cuvier, Johannes Müller, Owen, Agassiz, Darwin, Huxley, and Gegenbaur would no longer convey any meaning; very often they would be misunderstood, and the very object for which Latin or Latinised names were introduced would be defeated.

The International Congress of Zoology takes, I believe, a somewhat sterner view, but they are engaged in drawing up a list of names which they hope will be accepted for all time. I for one am prepared to accept them, and I am prepared to go further. I would ask the International Congress if, instead of drawing up a list of single species, or perhaps in addition to it, they would draw up a list of systematic monographs, the names in which may be regarded as final. After all, modern classification began with a book, and it would take no longer, or very little longer, to sanctify a book which may contain diagnoses of hundreds of species than to sanctify the single species. The idea is due to Mr. Cyril Crossland, and he suggests—he was working at Chætopods—that such works as Claparède's "Annelides Polychètes du Golfe de Naples," Ehler's "Die Borstenwürmer," McIntosh's "Monograph of the British Annelids" be accepted. Possibly whole categories of books might be considered, such as the "*Challenger* Reports," and especially "Das Tierreich," the admirable volumes of which we owe to the enterprise of the Berlin Zoological Society. Such a scheme would certainly cause some minor injustices, but every scheme does that. The immense advantage of allowing a researcher readily to determine and give an accepted name to an animal he is investigating without waiting weary days in struggling through a vast and scattered literature for the sake of synonymy would surely far out-balance any temporary injustice.

One last phase of my subject and I have finished with what I want to say on the subject of organising zoology. In Europe the great museums of our metropolitan towns are State museums, endowed by the State, managed by the State, and in Great Britain and Ireland staffed and curated by the State; that is to say, the officials at the museums are Civil Servants. Let us consider for a moment what that means, and let us take the British Museum, which, in its entirety, is second to none in the world as an example of a State museum.

The British Museum was established by an Act of Parliament in the year 1753 (26 Geo. II. cap. xxii). This Act sanctioned the purchase of collections and library of Sir Hans Sloane, that prince of collectors, for the comparatively insignificant sum of 20,000*l*. In fact, Sir Hans left his magnificent collection of natural objects, which, twenty years before his death, amounted to just under 70,000 specimens, his library of 40,000 printed volumes and 4100 manuscripts, to the nation, on condition that 20,000*l*., about one-fourth of the estimated value of the collections, be paid to his executors. Under the above-mentioned Act 10,000*l*. were paid to each of Sir Hans Sloane's daughters, Mrs. Stanley and Lady Cadogan. The same Act provided 10,000*l*. for the purchase from the Duchess of Portland, heiress of the second Earl of Oxford, of the Harley collection of charters and manuscripts, which were then in the market, and other moneys for the purchase and repair of Montagu House, Bloomsbury, and for maintenance. The Act incorporated with the Museum the Cottonian Library at Westminster, which, by an Act of Parliament of William III.'s reign, was under the care of trustees, chief amongst whom were the Archbishop of Canterbury, the Lord Chancellor, and the Speaker; the money was raised by a lottery, and the museum was opened in January, 1759, just 150 years ago.

Now it will be noticed that at its formal birth the museum consisted of about two equal parts—on the one hand books and manuscripts, and on the other what used to be called "natural objects."

The "General Repository," as the Act of George II. called it, was placed in the hands of a body of trustees, now forty-nine in number, three of them relics of William III.—namely, the Archbishop of Canterbury, the Lord Chancellor, and the Speaker of the House of Commons, are trustees by virtue of office. These three are known as the principal trustees; there are twenty-one other trustees in virtue of their office—*e.g.* the Bishop of London, the Presidents of the Royal Society and Royal Academy, and so on—one is appointed by the Crown, nine represent the families of donors, and fifteen are co-opted. So large and unwieldy a body cannot, as a whole, transact the business of a great museum, and they have largely delegated their functions to a standing committee of the three principal trustees and fifteen annually appointed representatives.

Now the manner of appointing to the museum is this. The junior members of the staff are selected as the result of examination, and when appointed they become Civil Servants. Not a bad thing in itself, but bad for a man of science. He, through no fault of his own, becomes entangled in red tape; above all, he must not make himself a nuisance; *trop de zèle* must be avoided, his enthusiasms tend to become checked, he is perpetually observing what is called "official reticence," and he perforce spends his days in performing routine work during routine hours. No amount of skill and ability—and the staff at the museum is both skilled and able—hastens his promotion. This is a matter almost entirely of seniority. In fact, the conditions of the Civil Service are incompatible with that freedom to research in any line that proves most suggestive, and with that absence of outside control which alone makes scientific research on a large scale possible.

The appointment to the senior staff, the keepers or heads of departments, the Director of the Natural History Museum, and the chief librarian, are vested in the three chief principal trustees. This takes us back to the reign of William III. and the Cotton Library at Westminster. No doubt the then Archbishop, the then Lord Chancellor, and the then Speaker, both from propinquity and from their abilities and training, were quite the best men who could be found for this position of trust towards this library. Probably the present holders of these exalted positions—positions which they most worthily fill and which give two of them precedence after royalty in all Britain—are most fully endowed with the qualities which fit them to elect the senior staff for the library and for the collections of works of art and of antiquities at Bloomsbury. I doubt if the same eminent qualities enable them to deal equally satisfactorily with the higher posts in the Natural History Museum. If Parliament, or indeed any other body, were framing a scheme for the management of a great museum of science at the present time, I do not think it would occur to anyone that the holders of the exalted offices I have mentioned were specially fitted, either by the knowledge of the pressing scientific needs and problems of the moment or by their intimacy with the men of science of to-day, to be the most competent electoral body to choose keepers in geology, mineralogy, botany, and zoology. And, indeed, the existing arrangement has broken down. I do not know how long before Sir E. Ray Lankester's resignation of the joint posts of Director and Keeper in Zoology, in December, 1907, it became known to the trustees that that resignation was imminent, but I do know that it was talked about and written about months before that date. Yet after the resignation took effect one whole year elapsed before the trustees appointed a Keeper in Zoology; for twelve months there was no head of a department which contains collections unrivalled in the world. It took the trustees about six months longer to find a Director, and for about eighteen months the charge of this great museum of natural history was vested, under the trustees, in the Chief Librarian at Bloomsbury.

As Prof. Ronald Ross could testify, after scientific research has placed it within the power of man to exterminate so deadly a disease as malaria, the real fight begins; and the real fight is to persuade the authorities to adopt and enforce the measures which are offered them gratis. There is a case in point, if I am not misinformed, on this continent at the present time. It has been known since the time of the making of the St. Gothard Tunnel that lasting and often fatal disease is caused by a small intestinal worm, known as the tunnel-worm or hook-worm. Within the last few years Dr. Wardell Stiles has shown quite clearly that the unhappy condition of "poor white" of the Southern United States is due largely to their being affected by this hook-worm. Their bodies and their intellects are arrested in their development, and the adults amongst them are unable to understand the prophylactic measures he advocates, but the children could be taught if the proper organisation existed for teaching them. Many of the Southern States are friendly to the movement, and I know of no greater service that the central Government of the United States could confer upon the inhabitants of these southern States, in which, as is well known, President Taft takes the deepest interest, than that of detailing Dr. Stiles for several months a year to organise and control this movement. If this could be done, I believe—and I am here speaking of those things that I do know—the United States Government would confer on their own people a benefit as great as they conferred on other nations when they freed Havana of yellow fever and Panama of malaria.

In concluding this part of my address I wish to say as emphatically as I can that if science is to take its proper place in the polity of the nation we must endeavour to have men of scientific training, or at least of scientific sympathies, in the Government and also in the Government offices.

I cannot recollect the name of one single Minister trained in natural or physical science amongst the numerous members of His Majesty's Governments of the last thirty-five years. It is not so very long ago—I am glad to say that one of the actors of my little story is still with us—that Sir Joseph Hooker, then Director of the Royal Gardens at Kew, was walking through the grounds with Mr. Ayrton, President of the Board of Works, which in those days was the Government Department responsible for Kew.

They happened to run across Mr. Bentham, the great authority upon the classification of plants. Sir Joseph introduced him to the President, adding, "he works in our herbarium." "Dear me," said the President, "I hope you don't get your feet wet." Now I do not want for a moment to suggest that our present genial President of the Board of Works—whose official connection with Kew has been long severed—would not readily distinguish between an herbarium and an aquarium, but what I do wish to emphasise is that this ignorance of some of the most elementary details of scientific method exists in many of our rulers and in many of our permanent officials—not in all by any means; I know of some most notable exceptions—but in many. It is but human to distrust what we cannot understand, and it is this lack of understanding which is largely retarding progress at the present day.

III.

International Ocean Research.

As an example of international cooperation in scientific research I may take the investigations which have been going on for the last seven years in the Baltic Sea, in the North Sea, and in that greater Norwegian Sea which stretches from the western coast of Norway north to Spitsbergen and westward beyond Iceland and the Færöes. In this inquiry no fewer than ten nations—in fact, all those the shores of which touch these seas—have had a share —England, Scotland, Norway, Sweden, Finland, Russia, Germany, Denmark, Holland, and Belgium—and since most of these countries have a special steamer equipped for research and under the command of men trained in scientific methods, it has been possible to collect a mass of facts connected with the seas of Northern Europe such as has never been got together before for any similar area of the ocean.

The aim of those responsible for the scheme of work was to obtain as complete a survey as possible of the physical and biological conditions of the seas in question. They wanted to know the direction of ocean currents, both superficial and along the bottom; the variations in the degree of salinity of the water in time and in space; the nature of the sea-bottom, and whether this could be correlated with the fauna, sessile or moving, found upon it, and whether this fauna reacted on the prevalence or absence of food-fishes; the influence of depth, salinity, and temperature on the fauna; the seasonal variations and fluctuations of the small floating organisms often called the plankton; the life-history of our food-fishes, where and when they deposited their ova; what became of the ova; the distribution of the larval stages; the age at which the fish become mature, and their average length of life.

Then, again, it was hoped that much could be learned about the influence of man's activity on the sea. The relative depletion of the fish population caused by different modes of fishing; the intensity of trawling; how often does the trawl pass over the same ground in a given time? The question whether or no the seas are being over-fished, and, if so, what measures can be taken to lessen this evil, either by close time, limiting the size of fish captured, or by artificial fish-breeding. Many of these last-named problems concern the legislator as much as the man of science. The function of the latter is to provide facts upon which the administrator may act.

Such a vast task as was set out by the International Council in 1902 has necessitated an immense organisation. Some eight or ten steamers are employed making periodic voyages, under the direction of trained men of science. Enormous numbers of temperature-readings, investigations into the speed and direction of currents, and chemical analyses of sea-water have been recorded, and thousands of samples of the bottom, of the animals and plants living thereon, of fish in all stages, millions of fish ova, have been collected and accurately determined. To work up such an amount of material has occupied the attention of a large number of naturalists. Each country has at least one large laboratory devoted to this work, and their results are coordinated and generalised by the central bureau. The English part of the work was entrusted by the Lords of the Treasury to the Marine Biological Association, and has been carried out under the direction of Dr. E. J. Allen and Prof. Walter Garstang at our laboratories at Plymouth and Lowestoft.

Although all the ten countries are working upon what is, broadly speaking, a common plan, each has had its own special problems. In addition to carrying out the broad outlines of an international scheme, they have specialised along lines indicated by their own needs, and have attacked problems the solution of which affected their own special food supply. Thus Norway, where the old open fishing-boat is being replaced by the modern, decked trawler, has especially studied the cod and the saithe, the haddock and the herring, and has devoted much time and labour to the discovery of new fishing grounds, and has successfully done this along the Norse coast, in the Arctic circle, and on the banks between the Færöe Islands and Iceland. They have further established a trade in *Pandalus borealis*, allied to the prawns, which are taken in the deep waters off Norway, and are now to be bought in most fishmongers' shops in Great Britain.

In a similar way the Danes have tracked the eels as they leave the estuaries of the great rivers of Central Europe across the North Sea to the deep Atlantic off the West of Ireland, just beyond the 1000-fathom line. In these depths they spawn, and the resulting larval form, the Leptocephalus, long thought to be a separate genus, lives there for a while, until, gradually changing into an elver, it retraces by some mysterious instinct its parents' path across the ocean and regains the fresh-water rivers which those parents had left.

The English share of the investigation is limited to that part of the North Sea which lies south of the latitude of Berwick, and for the most part to the western half of these seas and to the English Channel; the latter, as we shall see, is a very important area. The work, so far as it has been specialised, deals, in the North Sea, largely with the plaice, with the food of fishes generally, and with the character of the deposits forming the sea-floor, with the creatures growing thereon. In the Channel the English worker is entirely responsible for the study of the hydrography of the water, which, entering the North Sea through the Straits of Dover, contributes greatly to its mass.

As a result of Prof. Garstang's investigations, an important spawning ground of the plaice has been located in the southern bight of the North Sea; the migration of both sexes has been traced to these grounds on the advent of the spawning season, and their return to their feeding grounds in the spring has been followed. During the spawning season it is usual to catch more males than females on the spawning grounds, possibly because at this time the female is inert and elusive, whilst the male is unusually active.

The course of the ova has been traced, chiefly by the Dutch investigators, as they drift towards the shallow fringe of coastal water, by far the greater number along the continental coast. Here the young fry grow up, and after attaining a certain size they leave the shallow coastal waters for the deeper seas off shore. Comparatively few of these, however, reach the feeding ground of the Dogger Bank, and Garstang has been able to show that by carrying the young plaice in steamers and transplanting them at the proper time on to this rich feeding ground, their rate of growth can be greatly accelerated and thus their market value largely increased, just as Dr. Petersen has done in the case of plaice on Thisted Bredning.

A few years ago there was no trustworthy method of determining the age of fish. Petersen's method of arranging the measurements of a large number of specimens in a scale according to size, when they resolved themselves into certain groups, which were considered to coincide with age-classes, has been superseded by the discovery of Reibisch, Heincke, and others, that many of the bones, the scales, and the otoliths of fishes show annual age-rings, like those found in the trunk of a tree or in the horns of cattle. By laboriously counting the rings on the otoliths of thousands of plaice, Dr. Wallace and others have been able to determine their rate of growth, and to show that some specimens attain the age of twenty-five and even twenty-nine years. Similar investigations have shown that the sexes have a different rate of growth. The age at maturity is found to differ in different regions, but in the majority of cases Wallace found that the males are sexually mature (four to five years) a year before the female is capable of spawning (five to six years). We can now correlate age with size and with weight.

The migrations of the plaice and of other fish and their rate of growth depend, amongst many other factors, upon their food supply. And the nature of the food of fishes has recently been re-investigated in the North Sea. I give some of Todd's results, which were made by the examination of some thousands of fish of thirty-one species. Of these I select three—the cod, the plaice, and the dab.

Percentages of stomachs containing various kinds of food.

Cod.

Size of fish in cm.	0–15	15–30	30–60	60+
Pisces ...	0 p.c.	11 p.c.	52 p.c.	67 p.c.
Mollusca ...	0	2	16	4
Crustacea ...	100	95	67	63
Polychæta ...	0	9	9	26

Plaice.

Size of fish in cm.	0–10	10–20	20–30	30+
Pisces ...	0 p.c.	1 p.c.	5 p.c.	5 p.c.
Mollusca ...	17	66	76	84
Crustacea ...	57	16	13	11
Polychæta ...	38	37	51	42
Echinoderma.	0	20	13	6

Dabs.

Size of fish in cm.	0–10	10–20	20–30	30+
Cœlenterata..	0 p.c.	18 p.c.	18 p.c.	20 p.c.
Echinoderma.	0	26	25	2
Polychæta ...	30	22	20	10
Crustacea ...	70	30	35	61
Mollusca ...	2	48	57	65

These tables show what, of course, was more or less known before, that as a rule the young fry live very largely, and in many cases solely, on crustacea. To a great extent the supply of suitable food dominates the movement of the young fry, for nowhere is the truth of the Frenchman's definition of life, "I eat, thou eatest, he eats," with its terrible correlative, "I am eaten, thou art eaten, he is eaten," more true than in the sea. Later in life the fishes' taste alters, and with increased size they can tackle animals the calcareous deposits of which would seem to render them highly indigestible.

Very careful investigations have been made, and are being made, by Mr. Borley and Mr. Todd as to the distribution of the fauna of the middle and southern parts of the North Sea, and its relation to the depth of water, the varying degree of salinity, and to the texture of the bottom deposits. These results, however, have not been published, but I may go so far as to say that the inquiry shows that within the area investigated the texture of the sea floor has, on the whole, more influence on the distribution of the invertebrates of the bottom fauna than has depth, and that depth in the area in question seems to have more influence than salinity.

With regard to the character of the bottom deposits, it has been found by Mr. Borley that off shore and on the gently shelving continental coast the sea bottom is of a uniform character over wide areas, though on the western side it is more patchy; and it has proved possible to divide the samples taken into some nineteen main types, each characteristic of one or more of the areas into which the region has been split up. Only one or two details of this laborious work can be mentioned. One is that the texture or degree of coarseness of the ground in various parts of the sea is such as to suggest that the distribution of the finer grades of material, the finer sands and silts, is greatly influenced by the joint action of currents and tides. It is, for instance, known that in the southern part of the North Sea the main direction of the bottom current is to the north and then to the east; and examination of the deposits shows a regular diminution in the proportion of the coarser sands, a regular increase in the proportion of finer material, as we proceed from the Straits of Dover in a north-easterly direction. A remarkable fact in this connection is the complete absence of silt from the sandy bottom west of the mouths of the great rivers Rhine and Maas. There can be no doubt that the presence of broad and shallow stretches of sand on the Continental, but not on the English, side of the North Sea is one of the factors which has determined the distribution of the small plaice, which on the Continental shores are so extraordinarily abundant, and on the English shores are relatively so scarce.

By means of bottles weighted with shot, so as to have about the same specific gravity as the surrounding sea water, Mr. G. P. Bidder has been able to trace slow currents moving over the bottom of the sea The bottles are closed, and contain a postcard in many languages offering a reward to whosoever returns the postcard, recording the latitude and longitude of the place it was trawled at, to our laboratory at Lowestoft. Attached to the neck of the bottle is a copper wire 1½ feet long. This wire trails along the bottom, the bottle itself floating about 1¼ feet above the level of the ground. Slowly as the bottles are swept along yet the distance they cover is sufficient to sharpen the free end of the wire to a needle point.

By these and by other methods it has been possible to trace the almost imperceptible but steady flow of waters along the bed of the sea. Without doubt these currents influence the distribution of the larval and young forms of all the creatures which live near the bottom, and especially influence the migration of food-fishes in their younger and less active stages, when they are swept helplessly along.

But these bottles have a double lesson to teach us: not only do they enable us to chart the slow streaming of the bottom water, but they give us to some extent a measure of the intensity of trawling in the North Sea. They have been re-fished in really surprising numbers. Commercial trawlers have re-taken them at the rate of 58 per cent. per annum. In one area these bottles cast upon the waters were re-taken, not after many days, but after very few. Out of 300, eighty-five were recovered in six weeks, and fifty out of 270 were trawled in five weeks, representing a local intensity of fishing which, if continued, would give us between 80 per cent. and 90 per cent. of recaptures in a year.

Marked fish which have been liberated and re-captured tell the same story of intensity of fishing.

The intensity of fishing as indicated by the percentage of re-captures within twelve months of liberation is shown by the following table[1]:—

Off shore	Percentage Fish under 25 cm.	Over 25 cm.
Dutch coast...	23·7	20·3
Deep water, Southern Bight	13·0	26·6
Leman Ground (liberated April and May)	18·7	17·4
Leman Ground (liberated December) ...	—	21·0
Horn Reef outer ground	33·3	23·0

Obviously, since some fish are known to have been captured but not returned to the laboratory, the method gives a minimum estimate.

By applying the same method to the marking experiments of other countries as well as our own, Garstang[2] gave the percentage recovered within twelve months of liberation of fish more than 25 cm. in length as from 4 per cent. on the Fisher Bank to 56 per cent. in the Skager Rak.

When we reflect on the chances of these marked fish dying or being eaten or losing their labels, it is surely a most remarkable fact, full of significance to the practical man, that in the North Sea marked fish of marketable size are recaptured at the rate of between 20 and 30 per cent. each year, and sometimes at a greater rate. It would seem that each square yard of the fishing grounds is swept by the trawl, not once, but again and again each year.

Mr. Borley has conducted a large series of experiments to determine the vitality of fish after they have been captured by both the beam and the otter-trawl. It was necessary to determine the degree of injury caused by the actual trawling, the raising of the trawl, and the subsequent exposure on deck. The larger fish of both sexes

[1] Garstang, "North Sea Fisheries Investigation Committee Southern Area," Report No. 1.

[2] "Provisional Report on the Natural History of the Plaice" (Committee B). *Procès verbaux*, vol. iii.

were capable of resisting the damage to a greater extent than those of smaller size, and the relative resistance of the two sexes varied at different sizes, the male showing a decline in the increase of its vigour as it approaches maturity. One factor which is very deleterious to the fish is the presence of jellyfish in the trawl; these either smother the fish or possibly sting them to death; at any rate, the mortality of the fish is enormously increased when medusæ are present in any numbers. The otter-trawl is also far more harmful than the beam-trawl, and exposure on deck to a hot sun is another constant source of death, one hour's such exposure in one series of experiments killing 99 per cent. of the smaller fish. In the ordinary commercial operation of trawling, whilst the fish are being sorted those that have no market value lie about on the deck of the vessel for at least an average period of one hour; hence it is extremely probable that when shovelled overboard practically all are dead or dying.

The work which has been done by our own special steamer has been supplemented by records carefully kept by certain selected captains of commercial trawlers, which sail from Grimsby or from Lowestoft. In this way the details of some 20,000 hauls have been examined, and their results tabulated by Miss Lee.

I have left myself no time to describe the important hydrographical investigations carried on by Mr. Mathews into salinity, temperature, &c., which show us the conflicting currents at the mouth of the English Channel and how the North Sea in its southern part is supplied with water from the Atlantic through the Channel. The curious ebb and flow of the Gulf Stream, its periodic welling up and subsidence, closely connected as they seem to be with the migrations of the herring, cod, and haddock shoals, is another most important matter of investigation.

Neither can I tell you in detail of the immense amount of work which is being done by the other countries which share in the international scheme, by the Scottish Fishery Board, the pioneer in Great Britain of this sort of research. To the west our Channel work is beginning to get into touch with the more recently established Irish Fishery Board, and with the work carried on under the direction of Prof. Herdman in the Irish seas.

The outcome of all this minute and continuous investigation will, in time, tell us whether or no the North Sea fisheries are being exploited in the most profitable way—a very important question for our country, for with a fishing fleet of 27,000 vessels, manned by 90,000 fishermen, who land 900,000 tons of fish a year, valued at 10,000,000*l.*, Great Britain takes 90 per cent. of what is caught in the North Sea. Some statistics indicate that there is a falling off. The steam trawlers in 1905 landed 25,000 tons of fish less than in 1904, and in 1904 there was a similar shortage on the total of 1903. And yet 1903 was a year in which some crisis took place; the growth of the haddocks and the number of young haddocks were far less than normal, the Norwegian cod fisheries sank to a minimum, the French statistics showed the same feature in their fisheries off Iceland. In 1903, however, there were unusually large numbers of small plaice. The polar ice-field pressed down south, and seals, cetacea, and arctic birds left their usual quarters, and came south in some cases so far as Shetland. The gigantic climatic changes indicated by the above undoubtedly disturbed for a time the rate of increase and the rate of growth of the fish population of the North Sea, but they soon returned to their normal state. Compared with such mighty influences the fishing activity of man seems almost negligible, and Dr. Hjort for one thinks that "the productiveness of fish" "may be regarded as independent of the interference or fisheries of man." I am not sure that this is so. Taking large areas and all fish into consideration, it may be true; especially it would seem to be so of some species, such as the herring, the saithe, and the cod; but in certain areas and with certain fish, such as the sole and the plaice, man's activity has undoubtedly decreased the number.

Although the researches of the last few years have immensely increased our knowledge of what is going on in the sea, they have, like an ever-widening circle, but increased the number of problems which await solution. It is earnestly to be hoped that the work may go on on at least its present basis. The business man, always on the outlook for a dividend, has sometimes complained that some of our inquiries do not seem to him practical, but he must have patience and faith. A few years ago no knowledge could seem so useless to the practical man, no research more futile than that which sought to distinguish between one species of a gnat or tick and another; yet to-day we know that this knowledge has rendered it possible to open up Africa and to cut the Panama Canal.

And here, if I may quote the words of the author of the Maccabees:

"And here will I make an end."

"And if I have done well, as is fitting the story, it is that which I desired; and if slenderly and meanly, it is that which I could attain unto. . . . And as wine mingled with water is pleasant and delighteth the taste: even so speech, finely framed, delighteth the ears of them that read the story."

"And here shall be an end."

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY COLONEL SIR DUNCAN JOHNSTON, K.C.M.G., C.B., R.E., F.R.G.S., F.G.S., PRESIDENT OF THE SECTION.

It has been usual for Presidents of this Section to make some allusion in their addresses to the principal matters of geographical interest which have occurred during the preceding year, and I propose to follow this custom before proceeding with the rest of my address, which would hardly be complete without some allusion to the great geographical achievements of the past year.

I doubt if there has ever been a year in which more important additions to geographical knowledge have been made than those resulting from the journeys of Dr. Sven Hedin, Dr. Stein and Lieut. Shackleton.

Dr. Sven Hedin's previous explorations had deservedly gained him such a high reputation as an explorer that it seemed almost impossible for him to increase it, yet his recent expedition in Tibet, extending over two years, has enhanced his already great reputation.

Refused permission to enter Tibet from India, he was not to be deterred. Travelling round to Leh and making that place his starting point, he entered Tibet and traversed in various directions a considerable tract, previously unexplored, of that country, making a good reconnaissance survey of the country he passed through.

A large part of his journey was through a bleak and inhospitable region, where he encountered intense cold and very great privations. At one time he went for eighty-three days without meeting a living soul, and the cold and hardships were such that out of ninety-seven ponies and mules with which he started only six came through. Yet in the following year, in the depth of winter, Dr. Sven Hedin again traversed this terrible country. In doing so he ran imminent risk of starvation, as his last sheep was killed a considerable time before he got through to country where he could obtain fresh supplies.

Dr. Sven Hedin's tact and resource were as great as his fortitude and courage. He made friends wherever he went, and, although the Tibetan Government sent orders over and over again that he should be turned back, he succeeded in spending two years in exploring the country, maintaining the most friendly relations with the Government officials and others whom he met. Besides exploring and surveying a large tract of previously unexplored country, he investigated the sources of the Brahmaputra, the Indus, and the Sutlej, and in the course of his journeys he accumulated a mass of geographical and other scientific information.

Next comes Dr. Stein's expedition to Chinese Turkestan, by which he has made a most noteworthy contribution to geographical knowledge and antiquarian research.

Dr. Stein, accompanied by that capable surveyor Rai Ram Singh, who was later on relieved by that equally skilful and energetic surveyor Rai Sahib Lal Singh, travelled from India *viâ* Chitral and Kashgar. He commenced survey work in the eastern part of the Mustagh-ata range, and carried it along the Kun Lun Mountains, skirting the southern side of the Takla Makan Desert and the Lob Nor Desert to Suchou and Kan-chou. He surveyed a large area of the mountainous region lying westward of Kan-chou, then crossing the desert from Anshi to Hami he returned north of the Tarim River, skirting the southern slopes of the Tian Shan range, to Kashgar. During this very long journey Dr. Stein came across the ancient frontier wall, built about the second century B.C. He traced it west of Suchou, until lost in the desert, for some 250 miles, and he made various incursions into and across the desert, making discoveries of the greatest antiquarian interest.

After his return to Kashgar he surveyed the last unexplored portion of the Kun Lun Mountains and the country containing the sources of the Khotan or Yurungkash River, which proved to be flanked on the south by a magnificent range of snowy peaks rising to more than 23,000 feet; thence passing the sources of the Keriya River he skirted the southern slopes of this snowy range and finished by connecting this survey with that to the north of this range. The privations and hardships undergone by Dr. Stein and his party were very great, and, just as he completed his last bit of survey, he was unfortunate enough to get his foot badly frost-bitten, and had to hasten to more civilised parts for medical treatment.

Dr. Stein, during his expedition, displayed all the best qualities of an explorer—enthusiasm, determination, skill, and tact. The modest account he has so far given us of his travels, which gives a mere outline of his work, shows that the geographical as well as the archæological results of his expedition are of the greatest value.

The last completed exploration I propose to mention is Lieut. Shackleton's great journey in the Antarctic Circle, which has raised him to a high position among the gallant explorers of the Polar regions.

Lieut. Shackleton personally arranged and supervised all arrangements for the expedition, his experience in the British Antarctic expedition under Captain Scott standing him in good stead.

Having landed in McMurdo Sound, a party consisting of Lieut. Adams, Prof. David, and others ascended Mount Erebus, which is more than 13,000 feet high, all above snow-level.

Later on Lieut. Shackleton and a sledge-party set off southward, and after an arduous journey succeeded in reaching 88° 33′ south latitude, more than six degrees nearer the Pole than any previous explorer. His party travelled altogether about 1700 miles, including relays, in 126 days, a splendid performance in a rough and difficult country under very trying climatic conditions. Soon after passing 83° 33′ south latitude they lost their last pony, and from this point they had to drag their sledges themselves, although their journey involved the ascent of a plateau 10,000 feet high. They only turned back when their diminishing stock of provisions rendered it imperatively necessary to do so. They were for a considerable time on short rations, and found several times that they had expended their food supplies before reaching their next depôt. Had they missed one of these depôts—no unlikely contingency in such a country—they must have perished by starvation. Altogether the sledge journey was a great feat of pluck and endurance.

Lastly, Lieut. Shackleton's colleague, Prof. David, with others, made a sledge journey to the north-west, reaching the South Magnetic Pole. A good deal of triangulation was carried out, many geological specimens were collected and much scientific information was obtained.

Whether we consider Lieut. Shackleton's skill and energy in organising the expedition, the courage and determination displayed in carrying it out, or the results obtained, his expedition will stand out as one of the greatest of the many great efforts to reach the Poles, and as a British expedition it is one that specially appeals to us.

At first sight it would seem that these great journeys belie the opinion so often expressed of late years that the days of the explorer are numbered, and that in future geographers will have to deal with surveys rather than exploration; but, in fact, these splendid achievements only strengthen this opinion. These explorers have considerably reduced the comparatively small area still unexplored, and other expeditions are helping to diminish the unexplored area.

Among those which are in progress I may mention the following:—Colonel Kozlof's expedition to Mongolia, which has already visited Kuku Nor and which is exploring the upper course of the Huang Ho and other parts of Mongolia. Lieut. Boyd Alexander is exploring in West Africa. The Duke of the Abruzzi is investigating part of the mountainous region across our Indian frontier; Dr. Longstaff is exploring another part of that mountain system; Captain R. E. Peary, U.S.A., and Captain E. Mikkelsen are leading expeditions in different parts of the Arctic regions, and M. Charcot is exploring in the Antarctic Circle. Lastly, an important British expedition will start before long to explore part of the Island of New Guinea, one of the largest still unexplored land areas. There are other expeditions, either in progress or projected, too numerous to mention.

The best modern explorers are not now content with exploration or even with a rough route traverse and an occasional observation for latitude; they either themselves make careful reconnaissance surveys of the country adjoining their route or they are accompanied by trained surveyors, who make such surveys.

Again, every year the area surveyed on correct scientific principles is extended. The interesting address of my predecessor, Major Hills, will have told you what is being done in this way in the British Crown colonies. In the British self-governing colonies and in the colonies and dependencies of other Powers the area of regular survey is being continually extended, and in more remote regions surveys are being carried out by Boundary Commissions or for railways or other purposes. Along with the increasing appreciation of the value of geography which has taken place of late years, there has been an increasing recognition of the need for regular surveys, and it is probable that the next generation will find that not only is no considerable area of the earth's surface unexplored, but that the area not yet surveyed at least geographically, or for which a regular survey has not been projected, is getting limited.

I propose in the rest of my address to deal with the regular survey and mapping of new areas, and to discuss various questions connected therewith; if I am right in believing that large areas will be regularly surveyed in the near future, such questions merit careful consideration. I shall state on these points the practice of some of the great national surveys, because their experience seems the best guide for future work; but I recognise that methods suitable for rich and populous countries, such as Germany, France, or Great Britain, may be too costly for many countries and provinces the survey of which has still to be made, and mention will be made of less expensive methods which are likely to be much in demand in future.

It would be difficult to say anything new on the subject I propose to deal with, and I lay no claim to do so, still less do I wish to dogmatise as to the best methods. When I express opinions I shall also state the practice of some of the principal surveys of the world, and my hearers having weighed the matter can accept my opinions or not according to their judgment. In either case my object will have been attained if careful consideration is given to the points raised.

Maps may be roughly divided into three classes:—

(1) Geographical maps—*i.e.* those on very small scales.

(2) Topographical maps. The dividing line between these and geographical maps is not very clearly defined. For the purpose of this address maps between the scales of 4 miles to the inch and $\frac{1}{25000}$ scale will be considered as topographical.

(3) Cadastral maps—*i.e.* maps on large scales mainly for property purposes.

As the time at my disposal will not admit of my discussing all three classes of maps, and as I have on a previous occasion read a paper to this Association on "Cadastral Surveying," I propose to limit my remarks to topographical surveys and maps.

In most of the older countries topographical surveys have originally been made to meet military needs, and as a rule they are carried out under military supervision.

In order that they may be useful in case of war such surveys must have been made before war breaks out. The use, however, of topographical maps is not limited to military purposes; on the contrary, they have invariably proved of great value for civil requirements. In one respect they are more useful for civil than for military purposes, as a state of war occurs rarely, and hence while the maps are only occasionally used in connection with war, they are constantly used in connection with civil administration and with public and private business of all kinds. The topographical maps of the Ordnance Survey, prepared originally solely for military requirements, have proved extremely useful for civil purposes. Directly or indirectly all the numerous maps prepared by the trade in Great Britain for civil use are based on them. I believe the experience of all other countries is similar to that of the Ordnance Survey. In most countries in which land is of any value, a cadastral survey for land transfer purposes is needed, as well as a topographical survey. In some cases indeed, the need for a property survey has first made itself felt; thus in the Transvaal and in the Cape Colony, neither of which yet has a topographical survey, there has for many years been a Government Survey Department for making property surveys. The question arises whether there should be two separate surveys, one for topographical and one for cadastral maps, or whether there should be only one survey, the topographical maps being prepared by reducing the cadastral survey. Incidentally the further question arises whether, if two separate surveys are made, they should be under one head.

In most countries—the Ordnance Survey of the United Kingdom being an exception—not only are entirely separate surveys made for these two classes of maps, but these surveys are generally under different departments. In some cases the cadastral surveys are isolated farm surveys, showing little detail except property boundaries. Such surveys would, of course, not answer as a basis for topographical maps. In other cases, however, the cadastral surveys show all necessary detail except ground forms, which can be added by a separate survey. The only cadastral survey, so far as I know, which shows ground forms is the Ordnance Survey, the 6-inch maps of which are contoured.

A difficulty in the way of utilising the cadastral survey for the smaller scale maps arises from the fact that a cadastral survey is, from its large size, much slower than a topographical survey. It is often found advisable to take up the survey of the former somewhat irregularly, while it is important for the proper progress of the latter that it should be taken up regularly and methodically. The Ordnance Survey 1-inch map has, since 1824, not had a separate survey of its own, but has been based on the cadastral survey. Ordnance Survey experience has shown that the delays in completing the topographical map, due to this course, have been much greater than one would have expected, and that there are grave disadvantages in having the scale of survey very much larger than that of the finished map. These objections do not apply, or can be overcome, if the cadastral survey of any locality is completed before the topographical map is taken up. This is a condition not likely to be often fulfilled in the case of future topographical surveys. I advocate therefore that, following the general practice, there should be entirely separate topographical and cadastral surveys. I should advocate this even where it is essential to keep the expense as low as possible. More economy would probably result from the adoption of a fairly small scale for the topographical map, from curtailing the small detail to be shown on it, and from showing on the cadastral maps only such detail as is needed for property purposes, than would result from making one survey do for both classes of maps.

On the other hand I consider that, even when separate surveys are made for the two classes of maps, it is advantageous that both should be made under the same head. The more usual course is, however, to have the two surveys independent, and in some cases local circumstances may make the course I advocate inadvisable.

Triangulation.

The first preliminary to any survey should be a triangulation. It is the most satisfactory course, and the best economy in the long run, to carry out with the greatest accuracy possible the primary triangulation on which the survey is to be based. Such a triangulation will remain good for a very long period. For example, the primary triangulation of the Ordnance Survey was commenced in 1791; while some doubts have been expressed whether it is accurate enough to combine with other more recent work for the purpose of investigating the figure of the earth, no one has questioned that even the earliest part of this triangulation is amply accurate enough for map-making purposes.

On the other hand I do not advocate carrying out a primary triangulation until arrangements have been made for basing a survey on it. In South Africa an excellent and very accurate primary triangulation has been carried out. This triangulation was undertaken largely no doubt for scientific purposes. While answering its purpose in that respect it has so far had no surveys of any great extent based on it. An accurate triangulation is now a much quicker and less expensive operation than it used to be. The introduction of Invar tapes and wires has largely expedited and simplified the accurate measurement of base lines, while the improvements effected in theodolites enable equal or greater accuracy to be obtained with the comparatively small and handy instruments now made than could be got formerly with large and cumbrous instruments, such as the 36-inch theodolites, with which most of the primary triangulation of Great Britain and Ireland was carried out. Unless observations are rendered difficult by numerous buildings, by trees or by a hazy or smoky atmosphere, a good primary triangulation should not now be very expensive. It is usual to base on the primary triangulation a minor triangulation of several orders, the object being to have an accurate framework of trigonometrical points on which to base the survey. If it is important to keep the expense low, the trigonometrical points may be rather far apart, intermediate points being fixed by plane table; but it should be remembered that it is the truest economy to make the best triangulation which funds admit of. In forests or in wooded and rather flat country, where triangulation would be very expensive, lines of traverse made with every possible accuracy, and starting and closing on trigonometrical points, may be used instead of minor triangulation.

Detail Survey.

Provided the detail survey is based on triangulation, it may be made by any recognised method. Plane tabling is now almost universally resorted to, and is probably as cheap and convenient as any other method. The vertical heights of the trigonometrical points will have been fixed by vertical angles with reference to some datum. The height of intermediate points can be fixed by clinometer lines, especially down spurs and valleys, and even by aneroid, and from these heights the contour lines can be sketched in. Altitudes can be more accurately fixed by spirit-levelling, but this is an expensive method not likely to be much used in the case of topographical surveys. It is possible that in exceptional cases photographic surveying may be resorted to with advantage, and undoubtedly photographic methods sometimes enable work to be done which would not otherwise be feasible. The photographic method suggested by Captain F. V. Thompson, R.E., is an advance on previous methods. In Canada, I understand that a good deal of photographic surveying has been done, and presumably the conditions in Canada have been found suitable for this method. It has been little used elsewhere.

Scale of Map.

The next point for consideration is the scale on which the map is to be published, and it is an important one. Speaking generally, the cost increases with the scale, and cost is therefore one of the main determining considerations. The physical and artificial character of the country, the amount of detail it may be decided to show on the map, the method adopted for representing hills and other detail, and the method of reproduction to be used, all affect the question.

Clearness and legibility are among the first essentials of a good map, and it is desirable that the scale should be such that all detail it may be decided to show on the map can be inserted without overcrowding, or conversely, if the scale is fixed, the amount of detail and method of showing it should be such as to avoid the common fault of overcrowding the map.

In populous countries, such as Belgium, France, and Germany, where buildings, roads, railways, &c., are numerous, a larger scale is, *caeteris paribus*, desirable, than in less populous countries.

All important detail such as roads, railways, canals, forests, woods, &c., should appear on the map, as should the more important names, but it is a matter for consideration how far minor detail such as orchards, marshes, rough pasture, state of cultivation, &c., should be inserted on the map, and to what extent the less important names should be omitted.

In hilly country hachures and contours, especially if in black, tend to obscure the detail and names, and the smaller the scale the greater this tendency.

Methods of reproduction will be dealt with later, but I may here say that more detail and names can be shown clearly on a given scale if the map is engraved on copper than if reproduced in any other way. The scales adopted by different countries vary very much—I give below the scales adopted by some of the principal surveys.

$\frac{1}{25000}$ scale—Switzerland (the more populous parts), Prussia, Baden, Saxony, Bavaria, and Würtemberg (these German maps, although called maps of position, are practically topographical).

$\frac{1}{40000}$ scale—Belgium and Denmark.

$\frac{1}{50000}$ scale—France (the new topographical map), Algeria, Tunis, Holland, Japan, Spain, Switzerland (the less populous parts).

$\frac{1}{62500}$ scale—the United States (the more populous parts).

$\frac{1}{63360}$ scale (1 inch to a mile)—Great Britain and Ireland, and Canada.

$\frac{1}{75000}$ scale—the Austrian Empire.

$\frac{1}{80000}$ scale—the old staff map of France.

$\frac{1}{100000}$ scale—the German Empire, Italy, Norway, Portugal, Sweden, and Switzerland (Dufour atlas).

$\frac{1}{125000}$ scale—the United States (the less populous parts).

$\frac{1}{126000}$ scale—Russia.

$\frac{1}{250000}$ scale—the United States (barren districts).

The introduction of cycles, motors, and other rapid means of locomotion has led to a demand for a scale which will show a considerable tract of country on a sheet of moderate size. If the standard map is already on rather a large scale, this demand is best met by publishing a reduction of the standard map. This course is followed by Great Britain and Ireland and by Canada, the 1-inch map of which is reduced to and published on the ½-inch scale; but if only one scale is used a compromise must be arrived at which will meet the reasonable requirements of rapid locomotion, as well as the other essentials of a topographical map.

If I may venture an opinion in a matter in which practice varies so much, it is that for countries using British measures in which, owing to dense population, the detail is close the 1-inch scale ($\frac{1}{63360}$) is a very good one, and that for more open parts the ½-inch scale may with advantage be adopted. For countries using metrical measures I should advocate $\frac{1}{62500}$ and $\frac{1}{125000}$ respectively. These scales do not differ largely from those adopted by most of the principal countries, the majority of which use scales between $\frac{1}{50000}$ and $\frac{1}{100000}$ for fairly close countries.

Where it is important to keep the cost down I should advocate a half-inch to the mile or a $\frac{1}{125000}$ scale. All except the most closely populated country can be shown clearly on such scales provided the maps do not show too many names or too much small detail.

The United States have scales of $\frac{1}{62500}$, $\frac{1}{125000}$, and $\frac{1}{250000}$, the general closeness of detail in any area determining which of these three scales is adopted. This arrangement is a good one, and would be still better if the areas published on the $\frac{1}{62500}$ scale were also reduced to and published on the $\frac{1}{125000}$ scale, and if the whole country were published on the $\frac{1}{250000}$ scale. The principle here advocated of having each scale so far as possible complete for the whole country has been carried out by Great Britain, where the whole country, except some uncultivated areas, is published on the 25-inch ($\frac{1}{2500}$) scale, and the whole country on the 6-inch, the 1-inch, the ½-inch, the ¼-inch, and other smaller scales.

Scale of Field Survey.

It is usual to make the field survey for small scale maps on a larger scale than that on which the map is to be published with the view of securing greater accuracy of detail, but this should not be overdone. If the field survey is on too large a scale it entails needless expense, also when the surveyor is working on too large a scale he is apt not to realise the effect of reduction on his survey, and is likely to survey so much detail as to overcrowd the map, thus increasing the cost of the work and injuring the map.

When the map is reproduced by photographic methods the fair drawing is usually on a larger scale than the finished map, so as to get finer results on reduction; but in this case also, for somewhat similar reasons to those stated above, there are limits to the amount of reduction which can be made with advantage.

In these respects the practice of different countries varies considerably.

In Austria the field survey is on the $\frac{1}{25000}$ scale; this is reduced to and drawn on the $\frac{1}{60000}$ scale, and this drawing is reproduced by heliogravure on the $\frac{1}{75000}$ scale.

In France the field survey is on the $\frac{1}{10000}$ or $\frac{1}{20000}$ scale. The survey is reduced to and drawn on the $\frac{1}{40000}$ scale. In Algeria and Tunis, both field survey and drawing are on the $\frac{1}{40000}$ scale. In all cases the French maps are now reproduced by heliogravure on the $\frac{1}{50000}$ scale from the $\frac{1}{40000}$-scale drawings.

In Germany the field survey is on the $\frac{1}{25000}$ scale. This is reduced to the $\frac{1}{100000}$, on which scale the maps are engraved on copper.

In Great Britain the 1-inch map is based on the 25-inch and 6-inch survey. These were reduced, and a fair drawing was made on the 2-inch scale in a manner suitable for reduction to the 1-inch scale—*i.e.* the detail lettering, &c., were drawn so that when reduced to the 1-inch scale they should be in proper proportion. This drawing was reduced and printed by heliozincography on the 1-inch scale, and from these prints was engraved on copper.

In America the field surveys are on the scales of $\frac{1}{45000}$, $\frac{1}{90000}$, and $\frac{1}{192000}$ for the $\frac{1}{62500}$, the $\frac{1}{125000}$, and the $\frac{1}{250000}$-scale maps respectively. The drawings, on the same scale as the field survey, are reduced by photography and engraved on copper.

I consider that the best results are obtained when the field survey is made on double the scale of the finished map; that if reproduction is to be by engraving, the fair drawing should be on the same scale as the finished map; that if, on the other hand, reproduction is to be by photographic methods, the fair drawing should be on the same scale as the survey, *i.e.* double that of the finished map. The reduction I advocate should conduce to accuracy of detail and, if reproduced photographically, to fineness of detail, while it is not so great that the surveyor and draughtsman should be unable to realise the effect of reduction.

Detail.

The need of considering the amount of detail, &c., to be shown is not always sufficiently realised. The way in which detail is to be represented also needs consideration, as on small scale maps much detail has to be represented conventionally.

Railways have to be shown conventionally, and should be so marked that they catch the eye without being too heavy.

Roads also should be clearly marked. Where different classes of roads exist they should be distinctively shown, main roads being more prominent than others. It is important to know what roads are fit for fast wheeled traffic in all weathers, and which are fit only for slow traffic. The exact classification of roads must depend on the conditions obtaining in the country. The most elaborate classification is that shown on the French maps, and next that shown on the maps of Great Britain. Provided that important distinctions are represented, the simpler the classification the better.

Forests, woods, marshes, and in some cases pasture, rough pasture, orchards, vineyards, gardens, &c., are shown by conventional signs. While forests, woods, and marshes should certainly be distinguished on the maps, I incline to the opinion that the state of cultivation is better omitted, and that the less small detail shown the better. Such small detail increases the cost and often overcrowds the map. The German $\frac{1}{100000}$ scale shows much small detail, and although the maps are beautifully and delicately engraved on copper, the detail is rather crowded on some sheets. The French Carte Vicinale is, in my opinion, rather crowded with names.

The most difficult question, and that on which opinions differ most, is the method of representing ground forms. Methods which answer well on steep ground are less satisfactory on gentle slopes, and *vice versâ*, and each method is open to some objection.

Ground forms may be indicated by contours, hill shading in stipple, vertical hachures, horizontal hachures, the layer system, or by a combination of some of these.

Ground forms are represented by contours on the $\frac{1}{25000}$-scale maps of the German States, the Swiss Siegfried Atlas, the maps of the United States, the 1-inch map of Canada, the $\frac{1}{40000}$-scale map of Denmark, and the maps of Japan. Where the slopes are steep the contours give almost the effect of hill-shading. Some of these maps give a very good representation of the ground, the best being those in which the contours are in colour.

Hill features are shown by stipple shading on the French Carte Vicinale and the Ordnance Survey four-mile map. In mountainous country stipple shading gives a good pictorial representation of the ground, but it fails in flatter country, and it is often difficult to tell from it which way slopes run.

The Swiss Dufour Atlas ($\frac{1}{100000}$ scale) is a good example of vertical hachuring, as are some of the German $\frac{1}{100000}$-scale maps. Vertical hachures are also used on the Austrian and Swedish maps, and in conjunction with contours on the maps of several other countries.

Vertical hachures when well executed give an artistic and graphic representation of the hills. In the Swiss and British maps the pictorial effect is enhanced by assuming a light from the left-hand top corner. In steep ground, especially when the hachures are in black, these are apt to obscure detail and names. I think hachures are better when printed in colour, but many will disagree with me on this point.

Horizontal hachuring, while having some advantages, is less effective and is little used.

The system generally known as the layer system has been used in Great Britain by the well-known Scotch firm of J. Bartholomew and Co., has recently been adopted by the Ordnance Survey for its $\frac{1}{2}$-inch maps, and is used in the $\frac{1}{2}$-inch maps of Canada. It consists in indicating by various shades of colour the area lying between certain contours; thus one shade may be given to all ground below the 50-feet contour, another shade to ground between the 50-feet and 100-feet contour, and so on. This system gives a general indication of ground form and enables the contour lines to be followed more easily. Its shades of colour enable the eye to pick out more easily all land lying at about the same level. It is most effective in ground with a small range of vertical height, as the vertical depth of layers can then be small and the distinction in colour between successive layers marked. In hilly ground the depth of the layer must be increased, which means that many ground features are ignored on the map, or the number of layers on the map must be large, in which case the distinction in shade between successive layers will be less marked. This method is popular in Great Britain, and enables those who are not versed in reading contours and hachures to realise something of the nature of the ground forms.

A combination of these methods has been used as follows:—

France on her $\frac{1}{50000}$-scale maps shows ground forms by contour lines and stipple shading. This gives a very fair representation of the ground, but where the contours are very close together the effect of the coloured contours on the stipple is not pleasant. Nor does the stipple always look well when it falls on colour.

The German coloured $\frac{1}{100000}$-scale map, the Italian $\frac{1}{100000}$, and the British 1-inch show both contours and vertical hachures.

The Norwegian $\frac{1}{100000}$-scale map shows the features by contours, vertical hachures and shading.

The new British $\frac{1}{2}$-inch scale map has both contours, layers and stipple shading.

Opinions differ so much on this subject, and there is so much to be said for and against each method, that I will confine myself to the opinion that contours reasonably close together should form the principal feature of any method of representing ground forms; that contours by themselves give a very fair representation of the ground; that vertical hachures, if printed so as not to obscure the detail and names, or stipple shading when there is not too much colour on the maps, increase the pictorial effect and are useful additions to contours; that ground forms should preferably be in colour, and that where hachures or stipple are used as well as contours both should be in the same colour.

The German coloured $\frac{1}{100000}$-scale map (brown hachures and contours), the British 1-inch scale copper-plate printed map (brown hachures and black contours), the British 1-inch coloured map (brown hachures and red contours), and the French $\frac{1}{50000}$-scale (grey stipple and brown contours), all give a good representation of the ground, and there are other maps which might be named almost, if not quite, as good.

Vertical Interval of Contours.

The vertical interval between contours should depend partly on the scale, partly on the steepness of the ground. Practice varies considerably in this matter.

The $\frac{1}{25000}$-scale maps of Switzerland and of Germany, except Prussia, are contoured at 10-metre intervals.

The $\frac{1}{50000}$-scale maps of France are contoured at 10-metre intervals.

The $\frac{1}{50000}$-scale maps of Japan and Spain are contoured at 20-metre intervals.

On the Swiss $\frac{1}{50000}$ scale contours are 30 metres apart.

On the United States $\frac{1}{62500}$ scale the contour interval varies from 20 to 100 feet.

On the British 1-inch map there are contours at 50 feet, at every 100 feet up to 1000 feet, and thence at 250-feet intervals.

On the Canadian 1-inch and $\frac{1}{2}$-inch maps the contour interval is only 25 feet, but the sheets published have been in ground with only moderate elevations.

On the German $\frac{1}{100000}$-scale the contour interval is 50 metres.

I consider that if the contours are printed in colour the vertical interval may with advantage be such that on steep ground the contours are reasonably close together, every fourth or fifth contour being printed heavier so as to be more easily followed. If the contours are in black they cannot with advantage be so close.

It is, in my opinion, best if the contour interval is uniform all over a country. Failing this, it seems desirable that it should be uniform over considerable areas and at least throughout a sheet; but this view is not universally held. I do not like the varying interval adopted by the Ordnance Survey. The contours on the Ordnance Survey maps are surveyed with great accuracy and at great expense. For topographical maps much cheaper and more rapid methods will suffice.

Cartography.

I have, with a view to clearness, kept the question of the method of reproduction separate, but it has a bearing on some of the points already considered. Thus the fine engraving of the German $\frac{1}{100000}$-scale map enables an amount of small detail and ornament to be shown on that map which could not have been clearly shown if any other method of reproduction had been used.

The older maps were generally engraved on copper, or sometimes on stone, and printed in black and white. Subsequently photographic methods, such as the photogravure of the Austrian and the more recent $\frac{1}{50000}$-scale French maps, were used, and colour printing is now largely resorted to.

In some cases the colour-plates are prepared by engraving on copper, stone, or zinc. The maps of the United States and Switzerland are engraved on copper. In other cases, for instance, the 1-inch Ordnance Survey, colour-plates are prepared on stone by transfers and offsets from the engraved copper plate. In other cases—*e.g.* the $\frac{1}{80000}$-scale map of France—the colour-plates are prepared by photographic methods.

For clearness, delicacy of outline, and artistic effect nothing equals engraving on copper. It forms also the best basis for colour-printing. Unfortunately it is very slow and costly.

Engraving on stone is quicker and less expensive than copper engraving. It is inferior in delicacy to the latter, but some of the best stone engraving is very good.

Photographic methods are the most rapid and the cheapest, and with care give very fair results. As good examples I may quote the $\frac{1}{75000}$-scale maps of Austria, prepared by heliogravure, and the 6-inch maps of the Ordnance Survey, prepared by heliozincography, both black and white maps.

Of colour-printed maps I may instance the new $\frac{1}{50000}$-scale map of France prepared by heliogravure, and the $\frac{1}{2}$-inch Ordnance Survey map hitherto prepared by photo-etching, although I understand that in future the outline will be engraved on copper.

When rapid reproduction and moderate cost are desired I do not hesitate to recommend photographic methods which, although not so good as engraving, give, when carefully executed, reasonably good results.

Opinions differ as to the extent to which colour should be used, the modern tendency being to use it very freely. I can hardly be accused of prejudice against colour, as during my tenure of office at the Ordnance Survey colour-printing was largely developed, but I think it is often overdone. I consider that a moderate amount of colour is a great improvement to a map. Ground forms, however indicated, can, in my opinion, be better shown by colour than in black; it is advantageous also to distinguish water by colour, to give prominence to main roads by colouring them, and to colour woods and forests, but I do not advocate going much beyond this. It is difficult to choose colours which are suitable, distinctive, and harmonious, and the more numerous the colours used the greater the difficulty of doing so.

Colour-printing introduces possible sources of error. Colour maps are based on a drawing on which all detail to appear on the map is shown. A plate is prepared for each colour on which there should be only such detail as shall be printed in its particular colour. In preparing this plate there is a risk that detail which should appear may be omitted, or that detail be inserted which should be on another plate, or that the detail may be slightly out of position. Again, owing to change of temperature and to the varying amount of moisture in the air, paper contracts or expands. Registration can rarely be mathematically correct, and with every care may sometimes be appreciably out. While with care errors such as I have indicated can be minimised so as not appreciably to affect the map, it is difficult to ensure that they should be altogether absent.

To recapitulate my views, I advocate for a topographical map a scale between $\frac{1}{62500}$ and $\frac{1}{126720}$ ($\frac{1}{2}$ inch to a mile), according to circumstances. The scale of survey to be double that of the finished map; ground forms to be shown by contours reasonably close together, the exact interval depending on the scale of the map and the nature of the country, also, if funds are available, by vertical hachures; both contours and hachures, if shown, to be in colour, the same colour being used for both. If considerations of time and cost do not admit of reproduction by engraving on copper, the map to be reproduced by some photographic method and printed in not more than five colours. I put forward these opinions rather as a basis for consideration than as having special weight in themselves. With the increasing recognition of the importance of geography an increasing demand for maps is sure to come, and good maps can only be satisfactorily designed after considering the points here discussed.

It is not yet, I think, generally recognised that a really good topographical map, based on triangulation, may be produced on a scale of about $\frac{1}{2}$ inch to the mile at very moderate expense if unimportant detail is left out and survey and reproduction carried out as economically as possible. Such a survey has recently been carried out in the Orange River Colony, a country mainly agricultural with generally poor land. There must be few parts, other than barren and mountainous regions, under settled government where such a survey would not be of value. I believe that in future still further economy in surveying and mapping will be attained, and this will stimulate the undertaking of fresh surveys.

Meeting, as we are privileged to do this year, in Canada, I should like to say a few words on the surveying and mapping of the Dominion. Until recently the only maps published have been on very small scales and have shown no ground forms. During the last few years, however, a regular topographical survey has been undertaken by the Militia Department. I am glad that for this topographical survey the scales of 1 inch and $\frac{1}{2}$ inch to the mile, both standard scales in Great Britain and Ireland, have been adopted. They are, in my opinion, suitable scales for Canada, and it is to be hoped that for any new mapping within the British Empire these or similar scales may be adopted as they have been in many parts. Uniformity in scales is very desirable.

Without committing myself to praise in every respect of the maps prepared by the Militia Department, I may say that they appear to me excellent, well-executed maps. Not many sheets have yet been issued, and they are probably not yet well known even in Canada; but I have little doubt that when known their value will be appreciated, and that the area mapped will be rapidly extended. There are no doubt large areas in Canada for which a smaller scale than 1 inch will suffice, but there can be few, except waste and barren regions, for which maps on some scale will not be needed. To a country like Canada, which has made wonderful progress already, and which has a great future before it, adequate mapping must be of importance, specially so in view of the vast area of the country. I have misread the character of the Canadian people if they will be content with any except first-rate maps for the whole settled area of the Dominion.

I should like to have said a few words on the aid which good maps give to geographical education, but my address is already too long. I will only say that while good maps and geographical education are of use to all countries, they are of special value to the British Empire, the different parts of which are geographically so scattered, but which are so closely bound together by common ties of kinship, interest, sentiment, and loyalty.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE issues of the *Lancet* for August 28 and *British Medical Journal* for September 4 are "educational" numbers, and give full information for those desirous of entering the medical profession and of the various services with medical officers attached.

A NEW mathematical professorship has been created, we learn from the *Revue scientifique*, in the University of Paris with the title of the Chair of the Theory of Functions. Prof. E. Borel has been appointed to the new post, which brings the number of mathematical professors in the University up to twelve.

A CIRCULAR from Principal Miers announces that an Appointments Board has been constituted by the University of London. The terms of reference to the Board are "to assist graduates and students of the University in obtaining appointments, and to coordinate and supplement the work done by the schools and institutions of the University with this object." The aim is to encourage the selection of university men for all posts in the work of which the possession of a university training on scientific methods is an advantage. The Board wishes to assist graduates to find employment, and to assist employers to find, in the university ranks, suitable men for vacancies.

AMONG the names of the distinguished persons upon whom the University of Birmingham has decided to confer the honorary degree of Doctor of Laws by way of commemorating the recent Royal visit, we notice the following:—Mr. W. N. Atkinson, H.M. Superintendent Inspector of Mines, South Wales; the president of the Royal College of Surgeons; Sir William Crookes, F.R.S.; Mr. Maurice P. Fitzmaurice, C.M.G., chief engineer to the London County Council; Sir Archibald Geikie, K.C.B., P.R.S.; Mr. Haldane, F.R.S.; Dr. J. S. Haldane, F.R.S., reader in physiology at the University of Oxford; Sir A. B. W. Kennedy, F.R.S.; Sir Joseph Larmor, F.R.S., Lucasian professor of mathematics in the University of Cambridge; Sir R. D. Powell; Sir William Ramsay, K.C.B., F.R.S.; Lord Rayleigh, F.R.S.; Prof. E. Rutherford, F.R.S., professor of physics in the University of Manchester; Prof. Silvanus P. Thompson, F.R.S.; Dr. W. A. Tilden, F.R.S.; Sir J. J. Thomson, F.R.S.; Mr. C. S. Tomes, F.R.S.; Dr. T. Herbert Warren, Vice-Chancellor of Oxford University; and Dr. B. C. A. Windle, F.R.S., president of Queen's College, Cork. The degrees are to be conferred on October 20.

THE calendar for the session 1909–10 of the Manchester Municipal School of Technology shows how thoroughly the education committee of the city has, by the courses of instruction sanctioned in the school, met the requirements of the industries of south-east Lancashire, of which Manchester is the commercial centre. A prefatory statement to the calendar points out that the object of the school is to provide instruction and training in the principles of science in their application to the industrial arts, with the view of a right understanding of the foundations upon which these arts rest, and to promote their effective development. The essential aim of the instruction is the training of faculty through a systematic course of sound theoretical study, and the development of resourcefulness and habits of self-reliance by means of an exact, thorough, and progressive course of laboratory and shop work, so as to prepare the student after due experience for positions of responsibility. Courses of three years' duration have been arranged, for day students of sixteen years of age and upwards, in each of the following branches of technology:—mechanical engineering; electrical engineering and technical physics; municipal and sanitary engineering; applied chemistry in each of the six aspects—general chemical technology, chemistry of textiles, manufacture of paper, metallurgy and assaying, brewing, and electrochemistry; manufacture of textiles; photography and the printing crafts; and architecture and the building trades. It is interesting, in view of the distinguished success with which the work of the school has been crowned, to direct attention to the fact that the subcommittee which administers the school consists of three classes of members, viz. representatives from the city council, members representative of educational and other institutions of various grades, and co-opted members consisting of men distinguished in the district for their knowledge of manufactures or science.

ATTENTION has often been directed in these columns to the amount of State aid provided for the purposes of university and other higher education in this country. It has been pointed out repeatedly that the financial assistance forthcoming from the Treasury in this direction compares very unfavourably with the sums of money provided for similar purposes by the Governments of other great countries. An examination of the Civil Services Estimates for the past eleven years shows, however, that there has been a steady increase year by year in the annual amounts voted by Parliament for higher education. The total amount for this purpose for the financial year 1899–1900 was 108,338*l.*, made up as follows:—universities and university colleges of Great Britain, 85,000*l.*; the Royal College of Science, London, 18,388*l.*; and Queen's Colleges in Ireland, 4950*l.* In 1905–6 the total amount had increased to 201,773*l.*, allocated thus:—universities and university colleges of Great Britain, 174,000*l.*; the Royal College of Science, London, 22,723*l.*; and the Queen's Colleges in Ireland, 5050*l.* For the present year the total amount has grown to 215,700*l.*, the items under the respective headings being 191,000*l.*, 20,000*l.*, and 4700*l.* The grant in aid of *Scottish* universities (included under Great Britain) is 42,000*l.*, which is in addition to an annual sum of 30,000*l.* payable to these universities from the Local Taxation (Scottish) Account. The local education authorities in England and Wales give grants amounting to about 100,000*l.* annually to universities and university colleges. It may be said, therefore, that roughly the State grants in aid of universities and colleges in Great Britain amount now to nearly 220,000*l.* annually, and the local taxation grants to about 130,000*l.*, making an annual sum of about 350,000*l.* It is instructive to point out in connection with the amount thus arrived at that the total for grants in respect of public elementary schools in England and Wales in connection with the Board of Education amounts for the present year to 11,162,405*l.*, and that 555,000*l.* is paid for the training of teachers, 791,800*l.* to secondary schools, and 537,505*l.* in connection with technical institutions, schools of art, and evening schools.

IN an article on the position of higher education published in the issue of NATURE for July 22 (vol. lxxxi., p. 113), attention was directed to an article by Prof. Guido H. Marx on the remarkable growth and spread of interest in higher education in various countries. The opportunity was taken on that occasion to point out that Prof. Marx's figures, so far as the numbers of students in institutions of university standing in Great Britain are concerned, were not quite trustworthy. Referring to this article by Prof. G. H. Marx, Prof. B. Menschutkin, of St. Petersburg, writes to correct the statistics given in respect of Russia. He says:—"The statistics with regard to Russia (23,000 students) are very antiquated. This number of students was reached some fifteen years ago, but at present the students of the higher colleges number at least about 77,000, as can be seen from the following data, showing how many students there were in the different institutions in 1908 (in some cases, as for St. Petersburg, the numbers refer to the present year):—

St. Petersburg (University 9800, Academy of Law 350, Philological Institute 150, Medical Academy 800, Technological Institute 2000, Polytechnik Institute 4200, Institute of Ways of Communication 1200, Institute for Engineers 700, Electrotechnical Institute 650, Mining Institute 650, Institute of Forestry 550, the three higher colleges for women 6000, Lyceum and three Military and two Nautical Academies 1200, Academy of Theology 300), 28,550; *Moscow* (University 9000, Institute of Oriental Languages 150, Academy of Theology 200, Technical Institute 2500, Agricultural Institute 850, Engineering Institute 550), 13,250; *Kharkov* (University 5300, Technological Institute 1200, Veterinary Institute 500), 7000; *Kiev* (University 3200, Academy of Theology 200, Polytechnic Institute 2500), 5900; *Kazan* (University 3000, Academy of Theology 170, Veterinary Institute 430), 3600; *Tomsk* (University 800, Technological Institute 1900), 2700; *Warsaw* (University and Polytechnic Institute), 1500; *Odessa* (University), 3300; *Novocherkask* (Polytechnic Institute), 700; *Yuryev* (Dorpat) (University 3000, Veterinary Institute 350), 3350; *Helsingfors* (University 2400, Technical College 350), 2750; *Riga* (Polytechnicum), 1700; *Novaya Alexandria* (Agricultural Institute), 400; *Yaroslavl* (Lyceum), 1050; *Yekaterinoslav* (Mining Institute), 500; *Nĕžin* (Philological Institute), 150; *Saratov* (University, established this year), 200; *Vladivostok* (Institute of Oriental Languages), 300. The total number is therefore 76,900. There are also many *private* higher colleges in different towns, the number of students of which it was impossible to ascertain; it is surmised that this number is about 20,000."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 30.—M. Bouchard in the chair.—The improvement of the theory of partial equations of the first order: N. **Saltykow**.—A demonstration of the phase rule: M. **Boulouch**. A criticism of the demonstration of the phase rule by M. Müller, in which thermodynamical considerations are excluded. The author regards some of M. Müller's assumptions as unjustifiable.—The hydrolytic dissociation of bismuth iodide: René **Dubrisay**. The effects of temperature and dilution have been studied. Two oxyiodides have been shown to exist, the red compound being BiOI; the second black oxyiodide gives a ratio of bismuth to iodine corresponding to $Bi_2O_3 : 5HI$.—A simplified method and apparatus for determining the calorific power of gaseous combustibles: P. **Lemoult**. The method is based on the fact that the combustion of molecular proportions of hydrogen and oxygen or carbon monoxide and oxygen gives nearly the same heat evolution, and after absorption of carbon dioxide formed in the latter case, the contractions are the same. If carbon monoxide, hydrogen and methane are present, the contraction (*a*) after combustion and absorption of CO_2 is measured, and also the oxygen consumed (*b*). The approximate calorific value is $P=0{\cdot}914a+3{\cdot}405b$.—The pseudopolychroïsm of sphærolites: Paul **Gaubert**.—The extension and retrogression of the virgin forest of tropical Africa: Aug. **Chevalier**.—The Mesoplodon of la-Hougue (November 2, 1908): R. **Anthony**.—The proof of experimental ammoniuria in epilepsy: J. E. **Florence** and P. **Clément**. Ammonium acetate, administered in 4-gram to 6-gram doses, is in healthy individuals excreted mainly as urea. In epileptics under the influence of bromides the method of elimination is similar; in epileptics not under bromide treatment a marked elimination of ammonia coincides with the very frequent attacks.—Alcoholic fermentation in presence of sulphurous acid: P. **Martinand**.—The specificity of oxydases: J. **Wolff**.

NEW SOUTH WALES.

Royal Society, June 2.—Mr. H. D. Walsh, president, in the chair.—A pitchblende probably occurring in New South Wales: T. H. **Laby**.—The viscosity of water: R. **Hosking**.—A contribution to the experimental study of the large ions in the air: S. G. **Lusby**.—The mobility of the large ions in the air: Prof. J. A. **Pollock**.—"Lope de Vega": L. **Hargrave**.—Note on the determination of the free acid in superphosphates: F. B. **Guthrie** and A. A. **Ramsay**.

July 7.—Mr. H. D. Walsh, president, in the chair.—Description of a new hæmoprotozoa from birds in N.S. Wales: Dr. J. B. **Cleland** and T. H. **Johnston**.—A new melanin-producing hæmatozoon from an Australian tortoise: T. H. **Johnston** and Dr. J. B. **Cleland**.—A new reptilian cestode: T. H. **Johnston**.—The discrepancy between the results obtained by experiments in manuring, &c., in pots and in the field: L. **Cohen**.

Linnean Society, July 28.—Mr. C. Hedley, president, in the chair.—New Australian Lepidoptera belonging to the family Noctuidæ: Dr. A. J. **Turner**. One genus, and twenty-five species referable to twenty-two genera, are described as new, and new habitats are recorded for a number of species previously known.—Notes from the botanic gardens, No. 14: J. H. **Maiden** and E. **Betche**. Three species, referable to the genera Halorrhagis, Bæckea, and Olearia, are described as new; *Rutidosis leiolepsis*, F. v. M., *Ageratum conyzoides*, L., *Prunella vulgaris*, L., var. *laciniata*, Benth., *Gleichenia flagellaris*, Spreng., *Angiopteris erecta*, Hoffm., and *Cassytha filiformis*, L., are recorded as new for New South Wales; it is suggested that *Acacia Dorothea*, Maiden, should be transferred from the Uninerves to the Julifloræ; and notes on, or new records for, certain rare or interesting plants are appended.—Studies of the life-histories of Australian Odonata. No. 2. The life-history of *Diphlebia lestoïdes*, Selys: R. J. **Tillyard**. The genus Diphlebia contains the only Australian representatives of the family Calopterygidæ. The discovery of the larva is of great importance to ontogenists. The ova were found in the tissue of water-weed one foot below water, the female having deposited them by descending the reed under protection of an air-film. Larvæ were successfully hatched out in October, and some of them were kept until March. In November four exuviæ were found clinging to rocks in the stream-bed of the Rodriguez Pass, at Blackheath. The larva is of most remarkable form, quite unlike any other calopterygid larva known, and having some points in common with agrionid larvæ. It must be regarded, not as a synthetic type, but as a highly specialised and successful development from the main calopterygid stock, such development having taken place on lines parallel to that of the agrionid type.—Some hæmogregarines from Australian reptiles: T. H. **Johnston**. Four Australian species of Hæmogregarina have been described. Three additional species, from snakes or from a tortoise (Chelodina), are described as new, and some observations on *H. shattocki*, Samb. and Seligm., are offered.—The influence of the dilution of serum upon the phagocytic index: Dr. R. **Greig-Smith**. Several factors have each an influence in modifying the nature of the curve representing the opsonic and phagocytic effects obtained upon progressively diluting normal serum. It would be possible to obtain the phagocytic indices so that their ratios lie upon a straight line, by using a 1·0 per cent. to 1·1 per cent. solution of sodium chloride for making the dilutions and suspensions. With weaker strengths of normal saline the curve rises above, and with increased strengths it falls below, the straight line. The thickness of the bacterial suspension, the nature of the phagocytes, and the time of incubation influence the results, and have to be taken into account.

THURSDAY, SEPTEMBER 16, 1909.

PRINCIPLES OF IGNEOUS PETROLOGY.

The Natural History of Igneous Rocks. By A. Harker, F.R.S. Pp. xvi+384. (London: Methuen, 1909.) Price 12s. 6d. net.

FOR some time the need of a text-book of general petrology in English has been acutely felt, owing to the rapid progress which the science has made in theoretical subjects and the inaccessibility of many of the original memoirs to students and teachers. Most text-books treat the subject from a purely descriptive point of view, and the speculative developments are kept in the background. In fact the literature of descriptive petrology is now so large that an attempt to extract the general conclusions to be deduced from the observations becomes of greater importance than merely to add to the number of ascertained facts. In a book of about four hundred pages Mr. Harker endeavours to meet this demand, and has covered so wide a range and compressed so much information into this brief space that he has achieved a very large measure of success.

The work is confined to the investigation of the principles of igneous petrology, and the metamorphic and sedimentary rocks are excluded from its scope. The title fairly expresses the aims of the book; it is an attempt to treat of igneous rocks in the manner of natural history, taking account not only of their minute anatomy and structure, but also of their distribution, their range in time, and their genetic associations. Of late years there has been a plethora of unnatural systems of petrology, based on purely arbitrary lines. On the best known of these (the "quantitative classification") the author passes severe judgment, and returns to the broader treatment followed by Rosenbusch, Brögger, Judd, and Teall. That combination of geological reasoning with petrological analysis which has always characterised the English school of petrologists finds able expression in the pages of this treatise.

The geographical distribution of recent volcanic rocks is considered in the introductory chapters, and the remarkable association of "Atlantic" and "Pacific" rock types with certain classes of tectonic developments is made the foundation of an appeal for a natural classification. Undoubtedly the facts are most impressive, though we are entirely in the dark regarding their causes; and they afford the clearest indication that in time we shall be in possession of natural systems of petrography. We learn incidentally that the first sketch of this grouping was presented by Mr. Harker, though it has become more generally known through the treatment of Dr. Prior and Prof. Becke. The Tertiary volcanic rocks of the Inner Hebrides are placed among the Pacific types, a conclusion by no means easy to accept, and one which may need to be revised at some future date.

The application of physical chemistry to the crystallisation of magmas is taken up in considerable detail. This part of the book is practically a summary of Prof. Vogt's papers, and leaves nothing to be desired in lucidity of exposition and accuracy of statement. For students it will be of the greatest value, as the original memoirs are loaded with detail, and much too voluminous for their use, and no satisfactory account of them has hitherto appeared in English. We must confess, however, to a certain feeling of disappointment in reading them, a sense of incompleteness. The *a priori* principles are laid down in a very satisfactory fashion, but the applicability of these principles to the actual concrete facts of rock structure and history, which we had a right to expect from a geologist of Mr. Harker's wide experience, is dismissed with scant treatment. The difficulty of interpreting the history of crystallisation in the commonest rocks in terms of the theoretical principles laid down is sure to face the student at an early stage in his studies. We miss in particular any reference to the work of Schreinemaker, who has proved by analytical investigations that in a solution of three minerals in one another, of which two can form mixed crystals, while the third is independent, there are many possible schemes of crystallisation; one mineral may separate out completely at an early stage, and the crystallisation of any substance may be interrupted or repeated. If there are more components, or if we allow for the influence of dissolved gases in the magma, the problem becomes much more complicated; but it is a relief to find that as the theory is better understood the discrepancies between it and the observed facts seem to diminish.

The subject of "hybridism," or mixed rocks, is discussed in a brief chapter, which sums up in admirable fashion the results of the author's work in this difficult field. He takes a middle position between the schools of petrology which deny that igneous rocks dissolve sediments or older rocks with which they come into contact, and those which hold that such processes go on on a large scale, and that many rocks generally regarded as of normal types are thus produced. Mr. Harker's field work enables him to speak on this subject with great authority, and his conclusions are so moderate and so firmly based on sound evidence that he carries us with him in all that he says. There is also a chapter on magmatic differentiation, a subject on which it does not seem possible to say anything that is new, and a very interesting account of the mutual relations of associated igneous rocks which, in our opinion, is the best in the volume. The curves drawn on a very simple graphic system show the variation in the components of allied rock types, and are convincing that some general principles must underlie the facts, though as yet we have been unable to grasp them. The final chapter on classification is unexpectedly brief, and contains an admission that existing systems are merely temporary stop-gaps, and a satisfactory classification must traverse the lines of all current groupings, and will require an entirely new nomenclature. To us this appears unduly pessimistic, and we believe rather that in petrology as in other sciences the future will be the child of the past, and that real progress will not involve the demolition of the older systems, but will include them while giving them a sounder basis to rest upon. The book contains two beautiful photographic plates of active volcanoes, and a large number of useful illustrations; in print, paper, and binding it will meet the approval of every book-lover. J. S. F.

A POPULAR MAMMAL BOOK.

Wild Beasts of the World. By Frank Finn. Pp. viii+188; illustrated. (London and Edinburgh: T. C. and E. C. Jack, 1908–9.) Price 17*s.* net.

THE favourable opinion we formed of Mr. Finn's work when the first part was noticed last year in NATURE we are pleased to be able to endorse now that the complete volume is before us. The book is confessedly a thoroughly popular one, and, therefore, ought to be judged solely from that standard; and from that point of view it may be pronounced a decided success. The author's style of writing is bright and attractive; and in the main his descriptions appear correct and up to date. Mr. Finn has not overloaded his text with names of naturalists and observers about whom the public knows little or nothing; and he has, in our opinion for the most part rightly, altogether ignored subspecies. As regards nomenclature, the author will have nothing to do with modern innovations and changes, and we accordingly find the baboons (and not the flying-lemur) appearing under their old title of Cynocephalus, and the fox as *Canis vulpes.* The fact that such names still dominate in popular literature suggests that they should not, as is now too much the fashion, be ignored in our museums, which are primarily popular institutions.

Mr. Finn appears to take as his texts the hundred mammals represented in the coloured plates, as the descriptions of all these are printed in larger type than is conceded to many of the others noticed. Personally we are not enamoured of this plan, as it suggests that the species to which large type is accorded are of more importance than the rest; but this point is not one affecting the character of the work as a whole.

The coloured plates form, of course, the characteristic of the volume which will appeal most strongly to the general public; and for these illustrations—the only ones in the book—we have in the main nothing but commendation, although some appear rather too brilliantly coloured. A few, moreover, do not indicate important details—notably the one of the hamster, in which the dorsal gland-patch is not shown. The one serious error in the illustrations occurs in part xii., where the plate lettered Marco Polo's wild sheep really represents the true argali (*Ovis ammon*); and there is no excuse for this, as the figures, if we mistake not, have been drawn from the mounted specimens in the British Museum. Nor is this all, for, whereas the figure in the foreground depicts, as we have said, the true Altai argali, the one in the middle distance is taken from its Tian Shan representative. In the concluding part we notice that the plate of the platypus shows the web of the forefoot fully extended when the animal is on land, in place of being folded beneath the palm, as it must be in order that the creature should get a foothold.

Misprints and other errors in the text appear to be few, but we notice on p. 47 *Mipsiprymnus* for *hypsiprymnus.* In the account of the Derbian eland no mention is made of the fact that the species occurs in the Bahr el Ghazal; while the occurrence of the water-chevrotain in East Central Africa is ignored. The old error as to female takin-horns differing in form from those of the male is also repeated.

Most of these are, however, but trifling errors, which detract but little from a work worthy in the main of high praise. R. L.

APPLIED MECHANICS.

(1) *Applied Mechanics for Engineers.* A Text-book for Engineering Students. By E. L. Hancock. Pp. xi+385. (New York: The Macmillan Co., 1909; London: Macmillan and Co., Ltd.) Price 8*s.* 6*d.* net.

(2) *Machines—Outils, Outillage, Vérificateurs.* By P. Gorgeu. Pp. 232. (Paris: Gauthier-Villars, 1909.) Price 7 francs, 50 centimes.

(1) THIS book is intended to be a text-book for engineering students during the first year of their course, and the examples selected to illustrate the principles discussed are, therefore, mainly such as are likely to be met with in practical engineering work. To facilitate the working out of the numerical problems, of which there are nearly 300 scattered through the book, the author has printed in the form of five appendices a series of tables including hyperbolic functions, logarithms of numbers, trigonometrical functions, squares, cubes, square roots, conversion tables, &c.; it is very problematic as to how often such tables incorporated in a text-book are of use to the student—it is much more convenient for him to have a small thin book of mathematical tables, and there are several such books now available, which he can carry about with him in his pocket, and refer to whenever calculations have to be made.

Two very complete chapters are those devoted to centre of gravity and moment of inertia; the application of Simpson's rule to the finding of the area and centre of gravity of rail and similar sections is fully discussed, and the whole subject of the determination of moments of inertia of various standard sections is treated very fully, both by analytical and graphical methods: this is a matter of considerable interest to engineers engaged in structural design work. Another chapter which will be found of use by the engineer in practice as well as by the young student is that dealing with the dynamics of machinery: after dealing with such usual problems as those of the flywheel and connecting-rod in a reciprocating engine, a number of sections is devoted to the gyroscope, and to its application to the mono-rail and similar devices.

The last chapter in the book treats of impact in a more satisfactory manner than is usually the case in text-books on mechanics. The book is certain to prove a useful one to all those who are engaged in teaching the subject of mechanics to engineering students, and the number of well-selected examples makes it a particularly satisfactory book for the student himself. Many young engineers are far away from help in matters of this nature, and have to depend upon their own resources—it is essential in such a case that they should have a large number of practical problems to work through in order to familiarise themselves with the principles underlying each branch of the subject.

(2) This book has been written specially for artillery officers detailed for duty in ordnance factories; it is copiously illustrated, and special attention has been given to the relative advantages and disadvantages of different types of machine tools, and to different methods of transmitting motion to the tools.

The first section is devoted to such details as the transmission of motion from one shaft to another by belting and gearing, quick return motions, cams, sliding pairs, turning pairs, and screw pairs, and in each case brief notes are given as to the important points to which attention should be paid in order to secure good results and to maintain all working parts in good order.

The second section deals with all the more important machine tools which are to be found in a modern workshop; in each case a regular order of treatment is followed—first the parts exterior to the machine itself and transmitting motion to it are discussed, and then in order the links in the machine receiving this motion, the links of the machine transmitting movement to the work, the links of the machine transmitting movement to the cutting tool, and lastly any other specialised link, and the frame. This is a method of treatment suitable not only for the non-technical student, but also for students who are just beginning the study of machines and machine tools, and the illustrations, which form a special feature of the book, are so arranged that the reader has no difficulty in finding at once in any of the figures the link of the machine which is described in any particular paragraph of the written description of the machine.

The third section deals with the cutting tools used in the various types of machine tools, methods of tempering, angles for the cutting edge for different classes of work, methods of lubrication, and speed of cutting are all discussed in detail, and a few paragraphs are devoted to the employment of the new high-speed steels.

In view of the fact that interchangeability of parts is now so important in all cases where large numbers of similar machines are constructed, the fourth section is entirely given up to an account of the construction and use of various types of gauges, with a series of useful notes on the precautions which must be adopted to ensure that their employment shall secure the desired result. The book should be consulted by all those who are engaged in the design of machine tools.

T. H. B.

A BELGIAN BOTANIST.

Notice sur Léo Errera. By L. Fredericq and J. Massart. Pp. 153. (Bruxelles: H. Lamertin; London: Williams and Norgate, 1908.)

Recueil d'Œuvres de Léo Errera. Vols. i. and ii. Botanique générale. Pp. iv+318 and v+341. Vol. iii. Mélanges Vers et Prose. Pp. xiv+222. (Bruxelles: H. Lamertin; London: Williams and Norgate, 1908–9.)

It would be difficult to overestimate the influence of the two great German professors, Anton De Bary and Julius Sachs, on the progress of botany. At a time when many fundamental ideas were only beginning to take shape, these advanced workers and leaders of thought attracted a succession of brilliant students from many European countries, who absorbed in Strassburg and Würzburg the doctrines and inspirations of their masters, and eventually spread abroad the new theories and conceptions that are now regarded as the foundations of botanical science. Amongst this band of eager students was the Belgian, Léo Errera, who entered first De Bary's laboratory in 1897, and subsequently sought further experience under the tutelage of Sachs. Two important results can be traced to these courses of foreign study. In the first place, intercourse with such gifted teachers and with brilliant colleagues helped to stimulate the energies of an already keen enthusiast, and to pave the way for future friendships and associations. In the second place, his interests were diverted from systematic to chemico-physiological botany, which became one of the chief lines of research at the University of Brussels.

The first of his primary contributions to science was the paper on glycogen in the Mucorineæ; this was the outcome of research in De Bary and Hoppe-Seyler's laboratories, and required a profound knowledge of the two sciences of botany and chemistry. It was followed by other papers on the same and other physiological subjects published by himself or his students. Prof. Errera was also well versed in mathematics and physics, evidence of which is furnished by the course of molecular physiology prepared for his advanced students. The researches connected with glycogen and the localisation of alkaloids, the papers on the application of physical chemistry to the elementary phenomena of cells, the relations of flowers and insects, and the defensive structures of plants, may be regarded as his chief contributions to botany.

As a professor, Errera took the keenest interest in his students, and spared no pains to stimulate their energies towards the acquirement of knowledge and the prosecution of research. At the time when practical courses were not yet customary he initiated a course which was first held in two small rooms in the gardens, and later in a more spacious laboratory provided at his own expense in a neighbouring building. The biography compiled by two of his former students bears testimony to the enthusiasm he inspired, and provides a realistic picture of his varied talents. He was an accomplished linguist, an excellent lecturer, and an entertaining companion.

The papers on general botany collected in the two volumes noted above are of a popular nature, as his more technical contributions have been published in the *Recueil de l'Institut botanique de l'Université de Bruxelles.* The first is a letter describing the vegetation in the neighbourhood of Nice, written when he was sixteen years old. The article on the structure and methods of fertilisation of flowers appeared four years later; it was inspired by Charles Darwin's work, and the introductory quotation from the "Origin of Species," taken in conjunction with his essay on Darwinism, is worth reproducing:—"Whoever is led to believe that species are mutable will do good service by conscientiously expressing his convictions." The article is, to a large extent, an account of contemporary investigation, but includes original notes on the oxlip and the genus Pentstemon. The essay entitled "Une Leçon élémentaire sur le Darwinisme" was revised in 1903, after the publication of de Vries's book. Errera fully accepts the mutation theory, regarding it as an amplification, and not a contradiction, of the selection theory. The references in this paper to Dr. Scott's work on Cheirostrobus and the joint communication by Drs. Scott and Oliver on Lagenostoma will serve to indicate how the author incorporated the very latest results into his teaching.

The most interesting part of the third volume, containing miscellaneous verse and prose, will be found in the collection of extracts and aphorisms. Here is an epigram that will be appreciated by philosophers generally:—"La vérité est sur une courbe dont notre ésprit suit eternellement l'asymptote." The authors of the biography are to be congratulated on presenting such an interesting account of the brilliant alumnus of Brussels University. The papers are worthy of consultation, not alone for the facts contained, but also for style and arrangement.

OUR BOOK SHELF.

An Atlas of Skiagrams, illustrating the Development of the Teeth, with Explanatory Text. By Dr. J. Symington, F.R.S., and Dr. J. C. Rankin. Pp. 47; pl. xii. (London: Longmans, Green and Co., 1908.) Price 10s. 6d. net.

THE difficulty of cutting sections comprising both soft and highly calcified parts without causing displacements, and the further trouble of piecing together the disposition of parts in a large number of serial sections so as to reconstruct a model in the solid, gives to skiagrams an especial value, as being a representation of the relations of the developing teeth to one another and to the jaws which is beyond suspicion of disturbance. Certain difficulties arising from the teeth being disposed in an arch were very successfully met by the authors, who resorted to tipping the back of the skull upwards to a uniform extent in all cases, namely, raising the back about 30 degrees, and by this method the shadows of the front teeth were separately projected and the overlapping of the shadows to a great extent avoided. The skulls used were divided into halves, and the right and left sides both presented in nearly every case where the skulls used were more than seven years of age; but in the younger ones, no difference being found between the two sides, only one is presented.

The ages of the subjects used range from birth to adult life, and twenty-three skiagrams are given which illustrate the calcification of the temporary teeth and their change to the successional set; amongst other points clearly shown, the extent of calcification in each tooth, at each age, a point sometimes of medicolegal importance, is well seen. Some points in the relation of the growth of the jaws to the development of the teeth can be advantageously studied in these skiagrams, as well as the relation of the developing teeth to the antrum. Inasmuch, however, as the walls of the antrum cannot always be very clearly traced in the midst of shadows cast by other parts of the upper jaws, the anatomy of the antrum is also illustrated by drawings made subsequently from the same specimens, the technique adopted being to harden the tissues in formol, and then to chip away as much of the bone as could be removed without destroying all support. The lining membrane so treated becomes sufficiently firm to stand alone and retain its shape, and the dissections made were carefully drawn. These figures include also the accessory sinuses. The authors may be congratulated upon having produced an atlas which is of the greatest service in adding to the accuracy of our knowledge of the development of the teeth and of their relations to the parts about them.

Mineralogie und Geologie für schweizerische Mittelschulen. By Dr. Hans Frey. Dritte Auflage. Pp. iv+234. (Vienna: F. Tempsky; Leipzig: G. Freytag, 1909.) Price 2.75 marks.

THIS work, which has evidently been successful, is of the type commonly used in German-speaking schools, and makes no special appeal to the beginner's interest in field-observation, or to the splendid object-lessons ranged around him in his native land of Switzerland. A number of Swiss illustrations are, however, inserted, and the passages on mountain-building and the Alpine lakes embody considerations raised in recent times. To a British mind the mineralogical section will seem to contain far too much in a small compass, if the course is to be gone through systematically before the pupil enters on his collegiate years. It occupies half the book, and is followed by a petrographic chapter, which similarly bears traces of having been brought somewhat hesitatingly towards modern modes of statement and classification.

The section on historical geology, perhaps in accordance with a settled syllabus, is limited to thirty-four pages, and the illustrations of fossils are given without any explanation as to the nature of the organisms. In these circumstances, the generic and specific names are worse than useless; they need, moreover, some revision and press correction. A great opportunity still remains for making the mineralogy and geology of Switzerland serve as an introduction to these sciences, and for letting the land itself speak to the pupil, before he becomes entangled in the strings of facts which are supposed to be inseparable from a scientific education. G. A. J. C.

Gilbert White and Selborne. By Henry C. Shelley. Illustrated from photographs by the author. Pp. xvi+226. (London: T. Werner Laurie, 1909.) Price 6s. net.

THIS little book is not badly done so far as it goes, but there is nothing in it that has not often been said before; the photographs are good, but of quite familiar objects. The one innovation consists in eking out a volume offered at six shillings by "Cameos from the Natural History of Selborne," which occupy fifty of these meagre pages: a serious literary blunder, to use a mild word. The six shillings might be much better spent in the purchase of an edition of the famous book, which is much talked of but probably little read.

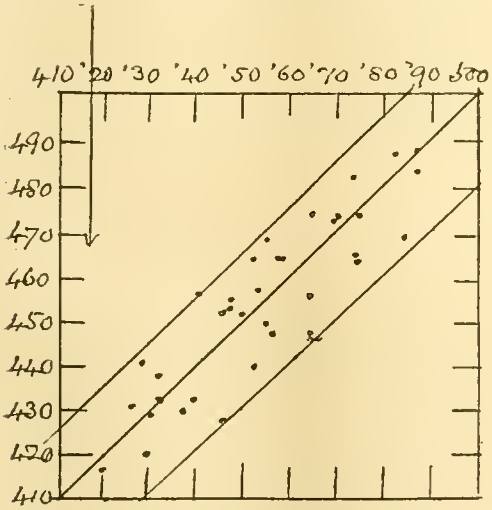
LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Summer Season of 1909.

IN endeavouring to estimate the character of a coming season, the following method is, I think, often serviceable. Let us take, as a concrete case, the annual numbers of very hot days at Greenwich (80° or more) from 1841 to 1908. Add these in the thirty years ending 1870, 1871, 1872, &c. Then compare each sum with the next by the dot method; where each dot represents one value by the horizontal scale, and the next by the vertical. A line may be drawn connecting points of intersection of lines (horizontal and vertical) from equal numbers in the two scales, and two others roughly parallel with it (as shown).

Now the last value, previous to this summer—the sum, that is, of the thirty years ending 1908—is 417. Find this in the horizontal scale, and consider where the next dot is likely to go. It would hardly be higher than (say) the level of 433. Now we know the numbers of those days in twenty-nine out of the thirty summers ending 1909; their sum is 416. Deducting 416 from 433 leaves 17; and we infer that this season would probably not have more than seventeen of those hot days (which is only two more than the average). The season has, so far, proved a very cool one (August 4). This method is obviously capable of wide application.



A similar conclusion seems to be arrived at by a comparison of Greenwich and Rothesay weather. It appears (whatever the explanation) that when the year's rainfall at Rothesay has exceeded 55 inches (last year had 56), the following summer at Greenwich has never been very warm. We may tabulate the cases (eleven in number, 1841–1907) as follows:—

	Rothesay Rf. in.	Greenwich days with 80° or more following summer	Relation to av. (15)
(1) 1872	70·2	16	+ 1
(2) 1877	68·6	11	− 4
(3) 1841	65·9	17	+ 2
(4) 1903	61·6	16	+ 1
(5) 1882	59·6	7	− 8
(6) 1862	59·5	13	− 2
(7) 1866	58·7	9	− 6
(8) 1907	58·5	8	− 7
(9) 1868	57·2	14	− 1
(10) 1861	56·3	1	− 14
(11) 1906	56·3	2	− 13
		Av. 10·4	

That is, eight cool summers, three slightly warm, and the hottest with seventeen of those days. It seemed not unreasonable to apply this "rule-of-thumb" (if it is to be so called) to the present season, following on a Rothesay year, which would fall to be added to the above list.

Once more; the summer season of 1879 is well remembered as a singularly cold one. There were only thirty days with 70° or more, and one with 80° or more (the averages being 77 and 15 respectively); and now, at thirty years' interval, we have another very cold summer.

Suppose we compare each summer with the thirtieth after, in respect of those very hot days (80° or more). We can carry the comparison obviously up to 1878 (that year compared with 1908).

It would appear that, in the case of very cold and very warm summers, there is some tendency for the thirtieth after to be of like sign in relation to the average.

Thus the six coldest, in ascending order (0 to 6 hot days), are 1860, 1862, 1841, 1853, 1855, 1845; in each case but one the thirtieth season after was cold, and that one was average.

The six hottest, in descending order (40 to 27 hot days), are 1868, 1857, 1859, 1846, 1876, 1870; in each case but one (again average) the thirtieth season after was hot. The season of 1909 seems likely to conform to this.

ALEX. B. MACDOWALL.

P.S. (September 13).—There have been, so far, nine of those very hot days (three in May, six in August), which is probably the year's total, or near it.

A New Mineral from a Gold-washing Locality in the Ural Mountains.

SOME time ago I acquired through a friend two small glass tubes, together containing about 5 grams of a bright greyish-yellow crystalline powder.

The manager of the gold workings in question noticed several years ago in his troughs minute quantities of the dust referred to, and commenced to collect it, but in spite of the greatest care he was not able to find more than about 10 grams during the subsequent years.

The separation of the dust has been made easier through the specific gravity of the microscopic crystals being =9. Various analyses made proved the dust to consist of about 98·5 per cent. tantalum and about 1·5 per cent. niobium, with 0·001 per cent. manganese. We have therefore a new mineral, namely, native tantalum.

During the last six months no more traces of the mineral have been found, notwithstanding the greatest possible care taken to find more. It seems to have been here an instance of an isolated formation, but it is not impossible that the same mineral may be found elsewhere, associated with gold and platinum, but is overlooked owing to the small quantity and the fact that it has a lower specific gravity than gold or platinum.

Perhaps this information may be of interest to those associated with gold or platinum workings, and may induce them to look out for this new mineral, when it is not improbable there may be found other native metals as well.

Newcastle-upon-Tyne. P. WALTHER.

The Benham Top.

IN confirmation of Mr. F. Peake Sexton's contention in NATURE of September 2 (p. 275), that irradiation plays no appreciable part in the necessity for thin lines on the Benham top, I may add that the colours are equally well seen when the top is viewed (1) through a narrow diaphragm held close to the eye; (2) through a magnifying lens; (3) in the monochromatic light of the sodium flame.

My only objection to Mr. Sexton's theory was at first the brilliancy of the colours in the light of the sodium flame, but this difficulty at once disappeared when Mr. Sexton pointed out that though blue objects cannot be seen as such in that light (because there are no blue rays present for them to reflect), it by no means follows that the nerve centre for blue cannot be stimulated by the light of a sodium flame. It will be seen, on reflection, that quite different phenomena are involved in the two cases, and, this understood, there seems to be no difficulty in accepting Mr. Peake Sexton's theory, which is substantially similar to that of Prof. Liveing, made at the time the top first appeared, though Prof. Liveing did not seem to realise that the case of the sodium flame presented no real difficulty, and he suggested that the colours seen in that light were due to the fact that it is not absolutely monochromatic—a quite unnecessary contention.

Colchester, September 8. CHARLES E. BENHAM.

THE APPROACHING OPPOSITION OF MARS.

THE planet Mars is now a conspicuous object in the evening sky, its ruddy, brilliant disc appearing just below the great square of Pegasus, and astronomers the world over are once more seizing the opportunities presented by a favourable opposition for the further solution of the Martian enigma. The actual opposition will not take place until September 23d. 22h., or 10 a.m. on September 24, civil date.

FIG. 1.

As Prof. Lowell says in his classical memoir on Mars, "Study of Mars at one opposition is material to its study at the next. . . . At any one opposition we may scan Mars but for a few months through only a fraction of its circuit round the sun." Therefore, no opportunities may be missed by the students of the ruddy planet, whenever, and under whatever conditions, an opposition takes place. But only at one opposition in every seven, or about once every fifteen years, are the conditions so favourable as at present; Figs. 1 and 2 show this diagrammatically. The orbits of the earth and Mars are drawn to scale, but as eccentric circles, and from Fig. 1 it will be seen that the opposition of this month will be, as regards the distance separating the two planets, the most favourable we have experienced since 1892. Owing to the eccentricity of the planet's orbit, the distance between the earth and Mars, when at an opposition, may range from 61,000,000 to 35,000,000 miles, the corresponding range of the apparent diameter being 13″ to 25″. The most favourable oppositions occur when Mars is near its perihelion (Π, Figs. 1 and 2), with the earth near its aphelion (α), point. The ideal condition would be for opposition to take place about the last week in August, whilst the most unfavourable conditions would obtain if it occurred about the third week in February; thus the opposition of 1877 was the most favourable during last century, except that of 1845, whilst that of 1901, February 21, was about as unfavourable as is possible.

The advantage of proximity was well illustrated in 1877, when Asaph Hall discovered the two Laputan satellites, and Schiaparelli first observed the much-discussed *canali*.

On September 23, when at opposition, Mars will be about 36·4 million miles from the earth, but the nearest approach of the two bodies will take place on September 18, when the distance separating them (E_2–M_2, Fig. 2) will be about 160,000 miles less. After the opposition, as the planet lags behind the earth, as shown in Fig. 2, the distance will continue to increase, and the apparent diameter of the planet will, of course, decrease, as shown by the circles drawn on the right of the diagram. These circles show the relative apparent diameter of the planet on August 13, when Mars is at perihelion, on September 18, when at least distance from the earth, and on November 1, when a substantial increase in the distance separating the two bodies will have taken place. The following are the apparent diameters of the planet at different epochs during the present opposition:—September 1, 22·8″; September 18, 24″; September 23

FIG. 2.

(opposition), 23·9″; October 1, 23·3″; November 1, 17·8″; December 1, 12·7″. This means that on September 18, an observer using a power of ×80 would see Mars on the same scale as a naked-eye observer sees the moon; the conditions of "seeing" would be worse. Taking another illustration, a land area of about the size of Ireland would, roughly speaking, appear as a spot of 1·3″ diameter, or a little longer than 1/1500th of the apparent diameter of the full moon.

Whilst the distance of the planet is an important factor in determining the value of the observing conditions at an opposition, it is by no means the sole factor; the altitude of the planet above the horizon makes or mars the conditions for the users of large instruments searching for minute detail. Thus, although the opposition of 1892 produced a more favourable distance-condition than that of 1894 (see Fig. 1), the observing conditions at the latter were not inferior, because of the higher culmination of the planet. At the present opposition, the declination of Mars is 4° S., and this means that for observers in our latitude (51° 30′) the meridian altitude will not exceed 35°; but this is a great improvement on the conditions in 1907, when the corresponding altitude was only 10°, and when, even from Flagstaff, Prof. Lowell found it desirable to send an expedition to the Andes for the observation of the planet. During the present opposition the meridian altitude at Flagstaff will be more than 50°.

As at all favourable oppositions, taking place about August, the south pole of Mars is now tilted earthwards, the earth, at the date of opposition, being about 20° below the plane of the planet's equator. Therefore the southern hemisphere will be observed, and as the summer solstice of this hemisphere, as shown in Fig. 2, occurs but a few days before opposition, the southern snowcap is in the process of dissolution, and changes due to the melting of the snow are taking place. Already such phenomena have been recorded by MM. Desloges and Jonckheere, among others. As the rotation-periods of the earth and Mars are approximately equal, the same regions can be observed on consecutive nights. On September 19 the Syrtis Major region will be in view, and on September 27 the region of the Mare Cimmerium.

Probably at no opposition since the time that Fontana suspected markings on the ruddy planet, in 1636, has the status of areographers been so critical as at the present juncture. Thanks to the persistent labours and unswerving faith of a few observers, of whom Prof. Lowell is the foremost, the question as to the subjective reality of the *canali* discovered by Schiaparelli in 1877 may be considered as settled. Whether one follows Prof. Lowell's lead in the matter of "artificial, irrigating waterways" or not, there can remain but little, if any, doubt that these long, straight channels do exist. In describing his observations, made at Trincomali, Ceylon, during the unfavourable opposition of 1903 (see Fig. 1), when the apparent diameter of the planet was but 14·6″, the late Major Molesworth said[1]:—"Personally, I am quite convinced of the reality of the great majority of the so-called canals: I think I could convince the most sceptical on this point if they could only have spent an hour or two at my telescope on some of the perfect nights in March and April this year." Major Molesworth used a 12¾-inch Calver reflector, with a power of 450. Numerous observers, and the Flagstaff photographs, have also testified as to the gemination of these features. Not only do these canals exist, but, in the opinion of many experienced observers, they also suffer changes which show a dependence on the seasonal changes of the planet.

Having settled the existence of the "canals," it became necessary to account for the changes, and, in one essential, this question remained more or less open until the opposition of 1907. With regard to the polar caps, Herschel's observations enforced the natural conclusion that their changes were due to the accumulation and dissipation of "snow" as the Martian winters waxed and waned. This coincidence of snowcap and season was not to be denied, and in the Martian spring, at the opposition of 1892, Prof. W. H. Pickering observed the disappearance of some 1,600,000 square miles of the southern snowcap, an area about the size of India, in a period of thirty-three days. But there still remained the one essential factor, that was the proof that this "snow" was really frozen water; that the Martian atmosphere contained water-vapour sufficient to produce these effects. On this point the different observers were at issue.

Beer and Mädler, during 1830–9, found that occasionally certain permanent features of the planet's landscape were blurred, as though by passing cloud and mist. During the favourable opposition of 1862, Lockyer's observations led to the definite conclusion that "the daily—nay, *hourly*—changes in the detail and in the tones of the different parts of the planet"[1] were caused by the transit of clouds over the various features.

"Clouds and mists" and "polar snows" inevitably suggest to the terrestrian the presence of water, hence a *raison d'être* for the canals, and the spectroscopic evidence adduced by Huggins and Vogel went to confirm the suggestion. But with the spectroscopic equipment of the Lick Observatory at their disposal, Campbell and Keeler could find no evidence for water-vapour in the planet's atmosphere, and the critics of a "terrestrial" Mars suggested that the snowcaps might be caused by the solidification and deposition of some other compound, such as carbon dioxide.

However, the spectrograms obtained by Mr. Slipher at the last opposition, 1907, afford, according to our present view, incontrovertible evidence that the atmosphere of Mars does contain a detectable quantity of water-vapour (see NATURE, vol. lxxvii., p. 442, March 12, 1908). Prof. Very estimates that at the time the spectrograms were taken, the Martian atmosphere contained sufficient precipitable water to give an average layer 14 mm. deep, or about one-third or one-fourth that in the earth's atmosphere. Nor is water-vapour the only familiar atmospheric constituent which has been shown to be present by the Lowell Observatory spectra. When Mr. Slipher described[2] the 1907 spectra, he explained the difficulty of detecting the free oxygen constituent of the Martian atmosphere, viz., the probable relatively slight increase in intensity, of the oxygen bands, produced by adding the absorption of a thin (Martian) atmosphere to that of a dense (terrestrial) atmosphere, but expressed the opinion that "its detection need not be considered impossible."

A recent message from the Kiel Centralstelle, dated September 10, informs us that Prof. Very's measures of the Lowell Observatory spectrograms—which show the spectra of the moon and Mars photographed side by side when the respective objects are at equal altitudes—show that oxygen is present in the atmosphere of Mars; the relative intensification of the oxygen band *b*, in the planet's spectrum, is stated to be eight times the probable error of the measures. Therefore, although the details are yet to come, it appears fairly

[1] Monthly Notices, vol. lxv., No. 8, p. 839, 1905.

[1] Memoirs R.A.S., vol. xxxii., p. 179, 1863.

[2] *Astrophysical Journal*, vol. xxviii., p. 404, 1908.

safe to assume that not only water-vapour, but oxygen also, exists in the Martian atmosphere.

Thus we arrive at the present opposition with the knowledge that a familiar compound, capable of forming snowcaps, of filling canals, and of being pumped in order to irrigate the pastures of a thirsty landscape, exists on Mars, and is accompanied by that element which we terrestrians look upon as another essential for the existence of animal life; and crucial difficulties in the "habitability" theory have been removed. Close, persistent, and world-wide scrutiny, at this favourable epoch, should lead to further elucidation of the enigma, and enable us to "reconstruct" a being and a vegetation capable of existing there.

An idea which has caught the popular fancy is that of signalling to Mars, but as the earth, from the planet, would be in the glare of the sun and would subtend, even at the impossible moment of opposition, an angle of less than 50″—of the same order as the apparent diameter of Jupiter at his recent opposition—to say nothing of the questionable transparency of our thicker atmosphere, this problem has not yet entered the province of practical astronomy.

WILLIAM E. ROLSTON.

POLAR EXPEDITIONS AND OBSERVATIONS.

THE position and prospects of polar exploration have been given great attention in the daily Press during the last few days. No precise information as to Dr. Cook's journey to the North Pole has yet been published, but the general narrative of Commander Peary's expedition leaves little room for doubt that Commander Peary reached the neighbourhood of the pole, and probably the pole itself, though an element of uncertainty must exist until his observations for latitude are examined critically. The Berlin correspondent of the *Times* reports that an executive committee for a Zeppelin polar expedition has been formed, the object of the expedition being defined as "the scientific investigation by means of the dirigible airship of the unknown Polar Arctic Sea and the development of the dirigible airship for the carrying out of scientific labours." Announcement has also just been made that a British Antarctic expedition will start next August under Captain R. F. Scott, who commanded the National Antarctic Expedition of 1900–4, with the object of reaching the South Pole.

As all the world knows, Mr. Shackleton's record of this year has given Great Britain the premier position in Antarctic exploration, and an earnest desire is felt by British explorers to place to the credit of this country the feat of first reaching the South Pole. McMurdo Sound has in the past been used as the base for British South Polar expeditions, but it is proposed on the next journey to establish a second base in King Edward VII. Land, 400 miles to the east of McMurdo Sound. The track to the pole from the new base may be expected to include phases similar to those met with in travelling from McMurdo Sound, but it is anticipated it will continue longer on the sea-level, meet the mountains nearer the pole, and consequently leave a shorter journey on the high inland plateau. The distance to be covered is in all some 1500 miles, for which 150 days are available. The plan for the journey to the pole from King Edward VII. Land includes the use of three means of sledge traction: ponies, a dog team with a relay of men, and motor sledges.

The scientific objects of Captain Scott's expedition are stated to be as follows:—(1) Geographical.—To explore King Edward VII. Land, to throw further light on the nature and extent of the great Barrier ice formation, and to continue the survey of the high mountainous region of Victoria Land. (2) Geological.—To examine the entirely unknown region of King Edward VII. Land and continue the survey of the rocks of Victoria Land. (3) Meteorological.—To obtain synchronous observations at two fixed stations, as well as the weather records of sledge journeys. (4) Magnetic.—To duplicate the records of the elements made by the *Discovery* expedition with magnetographs. The comparison should throw most important light on secular changes. (5) Miscellaneous.—In addition, attention will be paid to the study of marine biology at both stations and in the ship, and the examination of physical phenomena will be continued.

It is estimated that an expedition of the kind projected will cost at least 40,000*l*., and towards this sum considerable amounts have been given already. An appeal has been made to the public, and it is hoped that no difficulty will be experienced in raising the necessary money for the accomplishment of what will in any case include valuable scientific work.

The full narrative of Commander Peary's expedition to the North Pole appeared in the *Times* of September 11 and 13, and occupied six columns. By permission of the editor we are able to give a summary of this account of the journey and the observations made. The expedition left Etah, Greenland, on August 18, 1908, in the *Roosevelt*, having on board 22 Eskimo men, 17 women, 236 dogs, and about 40 walrus. Cape Sheridan was reached on September 5 and winter quarters were established there. Sledge loads of supplies were then taken to Cape Belknap, Porter Bay and other stages up to Cape Columbia, where Prof. McMillan obtained a month of tidal observations during November and December. Tidal and meteorological observations were also made at Cape Bryant, and explorations were carried on.

The expedition started for the north from Cape Columbia in several divisions at the end of February of this year. Latitude 83° 20′ was passed on March 2, and on March 5 "the sun, red and shaped like a football by refraction, just raised itself above the horizon for a few minutes and then disappeared again." The lead, or creek of open water, which was then reached, prevented further movement until March 11, when it was frozen and a start became practicable. The depth of the lead was determined by soundings to be 110 fathoms. On March 14 the lead had been passed, and the temperature was $-58°$ (?) F. Two days later Prof. McMillan had to be sent back to Cape Columbia at once on account of frostbite. "Sounding gave a depth of 825 fathoms. We were over the Continental Shelf, and as I had surmised, the successive leads crossed in the fifth and sixth marches composed the big lead and marked the Continental Shelf."

By an admirable system of advance, main and supporting parties, the expedition moved rapidly north, covering no fewer than fifty minutes of latitude (about 57 miles) in three marches. The fourth supporting party started on the back trail from about latitude 88°, and on April 2 Commander Peary, with his party of Eskimos, moved towards the pole.

In a march of about ten hours the party travelled twenty-five miles and was well beyond the 88th parallel, "with the sun now practically horizontal." Several long marches were accomplished, and one of forty miles in twelve hours. In four days, two degrees of latitude were covered, that is, a distance of about 138 miles. On the last stage of the journey Commander Peary's only companion was an Eskimo. An observation made on April 6 showed that the latitude was 89° 57′, so that the pole had been practically reached. Thirty hours were spent in making observations there and ten miles beyond the camp, and in taking photographs. No land could be seen. The minimum temperature recorded during the thirty hours was -33° and the maximum -12° (?) F. A sounding was made five miles from the camp, but bottom was not touched at 1500 fathoms. The party returned to Cape Columbia on April 23, and to the *Roosevelt* four days later. On July 18 the ship left Cape Sheridan and arrived in Indian Harbour on September 6.

The record of the expedition is a triumph for good organisation and persistent endeavour, and though details of the scientific observations are not yet available, the narrative gives good reason for believing that, so far as the time permitted, some valuable work was accomplished. Commander Peary states that Prof. Marvin and Prof. McMillan both secured numerous observations of tidal and meteorological conditions, as well as other data of scientific interest, while Dr. Goodsell gave special attention to microscopic work.

Commander Peary's achievement has rendered unnecessary any further expedition to reach the North Pole, so that attention may now be concentrated upon systematic scientific work in the region of which a preliminary view has just been taken. Whatever may be the ultimate decision as to relative claims to have been the first to reach the pole, there can be no doubt that the work carried on by the members of Commander Peary's expedition will be of greater value to science than mere observations of latitude taken during a "dash" to the pole. The success of the expedition is associated, however, with a fatal mishap to one of the scientific members. Prof. R. G. Marvin, of Cornell University, was drowned on April 10, forty-five miles north of Cape Columbia, while returning from latitude 86° N. in command of a supporting party. Prof. Marvin was only thirty years of age, and his death has caused great regret.

Though Commander Peary refers in his narrative to observations for latitude made at various points, no particulars are given, but that may be because the narrative was written for the general public. The explorer has had a unique experience in Arctic regions, and when his observations are published they will, it is hoped, show that the instruments used and corrections applied enabled him to determine position with reasonable accuracy. The determination of latitude by observations of the sun is, however, very difficult in latitudes near the poles. Without suggesting that Commander Peary's results may be found to require correction, it is of interest to indicate the conditions of observation in polar regions and the instruments used by some explorers.

LATITUDE OBSERVATIONS IN POLAR REGIONS.

To an explorer situated at one of the poles of the earth, the stars and all other heavenly bodies appear to pass round him in circles parallel to the horizon once in twenty-four hours, and the altitude of any one star is the same at whatever time it might be taken, provided the atmospheric conditions remain unchanged. If an explorer could be at either pole during the winter months, the best proof he could have that he had really reached 90° latitude would be by observations of stars. Should he be able to measure the altitude of a star with a theodolite or sextant and artificial horizon, at not less than 35° above the horizon, and repeat his measurement at regular intervals, say, of three hours, during one complete rotation of the earth, and find the altitude to be the same at every observation, he would certainly be at an extremity of the earth's axis. Should time be pressing, instead of this somewhat lengthy operation he could take observations of different stars one after the other around the horizon, and then if, after applying corrections for refraction and instrumental errors, he found in each case the altitude to be the same as the declination of the star given in the Nautical Almanac or similar publication, he could conclude that he was exactly on a pole of the earth. The former of these two would be the more satisfactory method, because effects of refraction, which is very uncertain in high latitudes, would be eliminated.

But it is usually daylight when the explorer reaches his highest latitude, and the stars are not visible, so here is a practical difficulty in the way of either of these methods. Still, much the same plan could be followed with the sun. If an explorer is exactly at the pole the sun will pass round him in a circle in twenty-four hours, and the only change in its altitude will be due to the change in declination, which is given in the Nautical Almanac for every hour. Should it be found, then, during a series of observations of the sun extending throughout twenty-four hours, or over a number of hours, that the observations changed just the amount of the sun's change in declination for every hour, the only place where the observer could be would be at the pole.

If, instead of the altitude remaining the same, it should, during one rotation of the earth, be found to decrease for twelve hours and then increase for the other twelve, or *vice versa*, it is clear that the latitude would not be 90°, but its value could easily be computed from the observations.

As regards observations for time taken at or near the poles, the ordinary method of taking sets of altitude of east and west stars fails altogether, for the simple reason that the altitude remains practically the same at all times, and it is impossible to state the *exact* instant of time corresponding to a certain altitude. The only satisfactory method of rating a chronometer would be by taking transits of the sun or stars by a theodolite firmly fixed and left in position on a stand. Since all the meridians converge at the poles, there can be no difference of longitude, and another remarkable fact would be that an observer exactly over the North Pole would be facing south whichever way he turned, and this would interfere with his ordinary idea of bearings considerably.

There can be no doubt that the best instrument to take for accurate observations at or near a pole is a good transit theodolite, and altitudes below 30° or so should, if possible, be avoided. With a sextant and artificial horizon, a low altitude, such as 10° or 11° or below, is very satisfactory. In the first place, it is extremely difficult to make a contact at all, and then the image in the artificial horizon is usually greatly distorted, specially when a glass plate artificial horizon is used, silvered only on the back. But whether the observations are taken with a theodolite or sextant and artificial horizon, it is naturally impossible to expect any result that can be depended on unless a solid foundation exists upon which to level up the theodolite or place the artificial horizon.

To take advantage of the best conditions of the ice and ensure a safe return, a polar explorer endeavours to reach his highest latitude at an early date when the sun's declination is only a few degrees. Thus it was April 7, 1895, when Dr. Nansen arrived at 86° 12·3′ N., and April 25, 1900, when Captain Cagni, of the Duke of the Abruzzi's expedition, reached latitude 86° 34′ N., his farthest north; whilst the two explorers whose names are just now so prominent both announce that they discovered the North Pole in this month.

Although doubtless unavoidable for the reasons stated, these comparatively early dates of reaching high latitudes have great disadvantages so far as observations are concerned. The stars have disappeared, to be seen no more for five or six months, and the sun is so near the horizon, owing to its low declination, that the meridian altitude, upon the measurement of which the latitude usually depends, is not high enough to give a satisfactory result, owing to the uncertainties of the refraction correction, and, if a sextant and artificial horizon are used, to the great difficulty in making the observation at such a low altitude, and unavoidable distortion of the sun's image. For good results it is a maxim with geographical surveyors that no altitude should be taken that is less than 25° or 30°.

A meridian altitude of the sun only a little above 6°, which is what would be observed at the poles on April 6, or between 11° and 12°, which would be the amount for April 21, would not be likely to furnish a very exact latitude, even if taken with a first-rate instrument under favourable climatic conditions, much less so when these are not favourable and when the observations are made with the small portable instruments which alone can be carried by the explorer on a rapid dash to the pole, when every ounce of weight is a serious consideration.

Dr. Nansen, after leaving the *Fram*, took with him on his famous sledge journey a small altazimuth, with 4-inch circles, and a pocket sextant with an arc of $1\frac{3}{4}$ inches radius, both of which, by means of verniers, read to single minutes. It was with the pocket sextant, however, that his farthest north latitude observation was made, using the natural horizon, and he admits that the result cannot be depended upon to a minute or two

Captain Cagni observed with a sextant, and in referring to his farthest north latitude, which depended upon an altitude of about 12°, states that he used both the artificial horizon and the natural horizon, which latter was very distinct.

Coming now to the Antarctic regions, Captain Scott's expedition was well provided with instruments, but his highest latitudes on the southern journey were taken with a small theodolite. In the case of this expedition, the dates when the high latitudes were reached were later on in the summer, so that the sun's southern declination, and consequently its meridian altitude, was higher.

This same remark also applies to Mr. Shackleton's recent expedition, for on January 3, when the last observation on his long journey to the south was made, the sun's meridian altitude was about 25° 33′, which resulted in a latitude of 87° 22′, the further distance travelled south of this depending for its measurement chiefly on the sledgeometer, which throughout the journey had been found to agree well with the latitudes observed. On his journey Mr. Shackleton used a 3-inch transit theodolite, reading to single minutes, and the adjustment of which had been thoroughly tested. He also had the advantage of observing on *terra firma* instead of moving ice, so altogether his resulting latitudes doubtless compare very favourably, as regards accuracy, with those of other polar explorers.

As regards the effect of extreme cold on the refraction correction of the altitude, it may be interesting to note that, for an altitude of 11°, there is a difference of just above 1′ for a change of temperature from +50° to −60° F.

Sextant observations taken with a glass plate artificial on moving ice would be most untrustworthy, for, in addition to the probable sources of error already referred to, there may be slow oscillations of the water, tidal or other, that may affect the level of the reflecting surface considerably.

CHEMISTRY IN THE SERVICE OF THE STATE.

IT is generally known in chemical circles that Sir Edward Thorpe is relinquishing the post of principal chemist at the Government laboratory, which he has so ably held for the last fifteen years. In the closing paragraphs of the present report[1] he notes that it is the last document of the kind he will have the honour of submitting to the Treasury, and takes the opportunity of directing attention to the great increase which has occurred in the work of the laboratory during the period in question. It appears that the number of samples examined yearly is now more than double what it was fifteen years ago, the actual figures being 76,513 in the year 1894, and 176,935 in 1908–9.

Naturally there is not much of strictly scientific importance to be found in the record of an establishment devoted to "the daily round, the common task" of acting as chemical Abigail to all and sundry Government offices. Yet in its applications of chemical science to civic requirements Sir Edward's department touches the public welfare at many points; and in illustration of this some gleanings from the pages before us are not without interest. For statistics, in which the report abounds, the reader may be referred to the publication itself.

The business of the laboratory is subdivided into three main classes. Articles examined for the two great revenue departments, Customs and Excise, form by far the largest number of samples. A considerable amount of work, however, is submitted by other branches of the executive, especially the Board of Agriculture, the India Office, the Admiralty, the Board of Trade, and the Office of Works. Finally, samples, relatively few in number, but important as being objects of dispute in legal proceedings, are referred to the laboratory for examination under the provisions of the Sale of Food and Drugs Act and the Fertilisers and Feeding Stuffs Act.

In its *rôle* of revenue chemist, the laboratory is required to hold the balance fairly between the Exchequer on the one hand and the maker or importer of taxable commodities on the other. Alcoholic liquors, sugar, tobacco, tea, coffee, and chicory naturally furnish the greater number of samples for analysis, since they are the chief dutiable articles in this country. But in safeguarding the revenue derived from these products it is also necessary to analyse numerous other articles; thus the principal chemist remarks that "the duty on chicory involves the examination of many substances botanically allied to it, such as dandelion and burdock roots." Genuine cider, again, is not liable to import duty, but samples are analysed nevertheless; for "if evidence is found that spirit has been added," the cider comes under the tariff as a preparation containing spirit, and is taxed accordingly. It is noted that a large proportion —more than 13 per cent.—of certain beverages sold as temperance drinks contained an excess of alcohol, the quantity ranging from 3 to 11 per cent. of proof spirit.

Among other miscellaneous matters, an investigation into the character of the spirits usually sold to the labouring populace was undertaken. Such phrases as "adulterated, maddening liquor" are common in the mouth of the well-meaning but uninformed temperance enthusiast. The results of an impartial inquiry, however, lend no support to the charge of adulteration. Samples of whiskey, gin, rum, and brandy were purchased in the ordinary way

[1] Report of the Principal Chemist upon the work of the Government Laboratory for the Year ended March 31, 1909. Cd. 4771. Price 3*d*.

at public-house bars and retail counters in working-class neighbourhoods of London and the principal towns of the United Kingdom, as well as from the booths at fairs and markets in West of Ireland districts. "There was no evidence of any deleterious substance or adulteration of any kind," remarks the principal chemist.

The work done for "other Government departments" covered a very wide range of products. From gold-braid to African coinage; from cordite-jelly to poisoned trout, almost every conceivable variety of article was submitted for analysis. There is an account of feeding-stuffs sold by a firm of millers, and found to consist wholly of sawdust and gypsum; wherefore the millers were mulcted in heavy penalties. There is a story of "a firm of traders doing a considerable business" who were found practising extensive frauds with postage stamps. "Proof of the fraud was given by one of the chemists of the department, first at the Mansion House, and afterwards at the Old Bailey, where the accused persons were duly convicted and sentenced."

Glimpses of tragedy also appear here and there. Thus we read about the analysis of the air from an underground chamber in which a post-office employé had been asphyxiated; and about the examination of a paint which gave off certain fumes, and apparently brought about, indirectly, the electrocution of a workman.

Foodstuffs, of course, figure largely in the report. As regards imported butter, it would appear that the legal proceedings taken three or four years ago have had a beneficial effect in eliminating much of the adulteration that was then practised. A similar result is also recorded in respect of preservatives in cream.

The foregoing are a few examples indicating the nature of the year's work, though not altogether its scope. Questions of brewing and distilling, the use of duty-free alcohol in manufactures, the purity of tobacco, the sale of patent medicines, the efficacy of sheep-dips, the trustworthiness of disinfectants, the materials used in dangerous industries, water supply, and many similar matters were also dealt with, and are duly chronicled in the report.

In relinquishing his post, Sir Edward Thorpe can look back upon fifteen years of eminently useful service to the State. Large and conflicting interests are involved in the duties of his department; and to have held the scales evenly between the claims of the public services on the one hand, and the various sections of the trading community on the other, is no mean achievement. One question, however, suggests itself at this juncture. Is it any longer of public utility to retain the present grouping of what are really several laboratories under one head? Looking at what is done in other countries, should not the Board of Agriculture, for example, have its own separate chemical establishment, with a freer hand for investigation and development than is readily practicable under the present conditions?

SECTION G.

ENGINEERING.

OPENING ADDRESS BY SIR W. H. WHITE, K.C.B., SC.D., LL.D., F.R.S., PRESIDENT OF THE SECTION.

ON the present occasion, when the meetings of the British Association for the Advancement of Science are held in the heart of this great Dominion, it is natural that the proceedings of Section G (Engineering) should be largely concerned with the consideration of great engineering enterprises by means of which the resources of Canada have been and are being developed and the needs of its rapidly increasing population met. It will not be inappropriate, therefore, if the Presidential Address is mainly devoted to an illustration of the close connection which exists between the work of civil engineers and the foundation as well as the development of British Colonies and Dominions beyond the seas.

British colonies and possessions have started from the sea-front and have gradually pushed inland. Apart from maritime enterprise, therefore, and the possession of shipping, the British Empire could never have been created. An old English toast, once familiar, but which has of late years unfortunately fallen into comparative desuetude, wished success to "Ships, Colonies and Commerce." A great truth lies behind the phrase: these three interests are interdependent, and their prosperity means much for both the Mother Country and its offspring. As colonies have been multiplied, their resources developed, and their populations increased, over-sea commerce between them and the Mother Country has been enlarged; greater demands have been made upon shipping for the over-sea transport of passengers, produce and manufactures; there has been a growing necessity for free and uninterrupted communication between widely scattered portions of the Empire, the maintenance of which has depended primarily and still depends on the possession of a supreme war-fleet, under the protection of which peaceful operations of the mercantile marine can proceed in safety, unchecked by foreign interference, but ever ready to meet foreign competition.

Now that our colonies have become the homes of new nations it is as true as ever that the maintenance of British supremacy at sea in both the mercantile marine and the war-fleet is essential to the continued existence and prosperity of the Empire. The trackless ocean supplies the cheapest and most convenient means of transport and intercommunication; continuous improvements in shipbuilding and marine engineering have abridged distances and given to sea-passages a regularity and certainty formerly unknown. It is a literal fact that in the British Empire the "seas but join the nations they divide." Every triumph of engineering draws closer the links which bind together its several parts. Greater facilities for frequent and rapid interchange of information of what is happening in all sections of the Empire and of knowing each other better should lead, and have led, to increased sympathy and a fuller realisation of common interest in all that affects the well-being of the Empire. Within the last few years the events of the Boer War have given remarkable proofs of the practical interest of the colonies in Imperial concerns and their readiness to share its burdens. The present year will always be remembered as that in which generous offers of assistance from the colonies in the task of strengthening the Royal Navy at a critical period have led to a conference the labours of which should produce important practical results and make our future secure. Organised cooperation between the Mother Country and the Dominions beyond the seas in the maintenance of an Imperial Navy adequate for the protection of vital interests is essential to that security; and, at last, there is a prospect that this end will be attained.

While claiming for the shipbuilder and marine engineer an important place in the creation and maintenance of the Empire, it is recognised that the work of other branches of civil engineering has been equally important. The profession of the civil engineer was described in the Charter granted to the parent institution in 1828 as "the art of directing the Great Sources of Power in Nature for the use and convenience of man; as the means of production and of traffic in States both for internal and external trade, as applied in the construction of roads, bridges, aqueducts, canals, river navigation and docks, for internal intercourse and exchange; and in the construction of ports, harbours, moles, breakwaters and lighthouses; and in the art of navigation by artificial power for the purposes of commerce; and in the construction and adaptation of machinery and in the drainage of cities and towns." Since this description was penned there have been great and unforeseen developments in many directions, including those relating to improvements in the use of steam, the generation and practical applications of electrical power, the manufacture and extended employment of steel. The main ideas expressed eighty years ago, however, still remain applicable to the beneficent work of the civil engineer. His skill and enterprise, backed by adequate financial provision, are continuously being applied to improve and extend means of production, internal and external means of communication, inland and over-sea navigation, the use of mechanical power and appliances, the acceleration and cheapening of transport, the development and utilisation of natural resources, and the direction of the sources of power in nature for the use and convenience of man. One of the chief fields of engineering operations at the present time is to be found in the Dominion of Canada, the governing authorities of which have appreciated the fact that bold enterprise and generous financial provision for the execution of great engineering works are essential to the progress and prosperity of the country. Its vast extent, its magnificent lakes and rivers, its agricultural and mineral riches, its forests, its unrivalled water-power, and many other potential sources of future wealth and progress, furnish exceptional incentives and opportunities to the engineer. From an early period in the history of Canada this fact has been realised, and attempts have been made to utilise natural advantages; while the same policy has been energetically adopted since the Dominion was established forty-two years ago. It is impossible in this Address even to enumerate the great engineering works which have been accomplished or are in process of execution; and it might be thought impertinent if the attempt were made by one who has only an outside knowledge of the facts. On the other hand, it may be of interest to illustrate by means of Canadian examples the truth of the general statement that civil engineering has exercised and must continue to exercise great influence upon the well-being and development of the British Empire.

By the kindness of the High Commissioner of Canada, Lord Strathcona—who has himself done so much for the development of the Dominion, including a great part in the construction of the Canadian Pacific Railway—the writer has been favoured with official reports and statistics bearing on the subject. These have been freely used in the statement which follows.

The subject is so extensive and the time available for this Address so short that it will be necessary to omit detailed reference to important applications of engineering which are necessarily made, under modern conditions, in all great centres of population. Amongst these may be mentioned building construction, sanitation, water supply, heating, lighting, telegraphy, telephony, tramways, electric generating stations and their plant, and gas manufacture. No attempt will be made to deal with the important assistance given by engineers to the operations of agriculture, mining and manufacture, or to the utilisation of the splendid forests of the Dominion, although the demands for machinery and mechanical power are in these respects exceptionally great, owing to the sparseness of the population and the magnitude of the work to be done. Notwithstanding the large immigration and rapid increase of population, these demands will certainly continue and will probably become greater as the area under cultivation is increased, as manufactures are developed, and the natural resources of the country more largely utilised. The example of the United States places this anticipation beyond doubt, and demonstrates the great part which the engineer must continue to play in the development of Canada.

Even when the limitations described have been imposed upon the scope of this Address, the field to be traversed is a wide one: and without further preface an endeavour will be made to describe a few of the most important services which the engineer has already rendered to the Dominion and will render in the immediate future.

Railways.

It has well been said that the great problem of to-day in Canada is that of providing ample and cheap transport for her agricultural, mineral, and forest products from the interior to the sea, and so to the markets of the world. Important as inland navigation may be as an aid to this enterprise, it cannot possibly compare with railway development in actual and potential results. Apart from that development the one united Dominion must have remained a dream; thanks to the rapid and efficient intercommunication furnished by railways, widely scattered provinces are knit together in friendly and helpful union, literally by "bonds of steel" which stretch from the Atlantic to the Pacific, and reach farther and farther north each year. Regions which would otherwise have remained inaccessible and unproductive have been turned into new provinces, the fertility and future development of which it is not easy to forecast, and practically impossible to exaggerate.

In this department successive administrations (both Federal and provincial) have realised the facts and possibilities of the position, and have given substantial assistance to private enterprise in the execution of great engineering works. Progress in railway development has been remarkable since Federation was accomplished forty-two years ago. During the preceding thirty years the total railway mileage in operation had been raised to 2278 miles; in 1887 it was 12,184 miles; in 1897, 16,550 miles; in 1907, 22,452 miles. The number of miles of railway actually under construction in 1907 was officially estimated at 3000, exclusive of lines projected but not yet under contract. In 1906, when the lines in operation were 21,353 miles, it was estimated by competent authorities that the railways under construction, and projects for extensions likely to be carried into effect in the immediate future, reached a total of at least 10,000 miles, while probable further extensions of about 3500 miles were under consideration. Further, it was estimated that the capital expenditure required to complete these schemes would be about 60 millions sterling. These figures may need amendment, but there are others representing ascertained facts which equally well illustrate the magnitude of the railway interests of the Dominion.[1] The total capital invested in Canadian railways in 1907 was officially reported to be about 234,390,000*l.*; the aid given to railways up to that date by Dominion and Provincial Governments, and by municipalities, considerably exceeded 36,000,000*l.* sterling in money; the land grants from the Dominion Government approached 32 million acres, while the Provincial Governments of Quebec, British Columbia, New Brunswick, and Nova Scotia had granted about 20½ million acres. The Governments have also guaranteed the bonds of railway companies to the extent of many millions of dollars. The capitalisation per mile of railway lines owned by the Governments (amounting to 1890 miles) is reported as being 11,400*l.*; this is practically the same amount as that for Indian railways, that for the United States being 13,600*l.*, and for New South Wales and Victoria about 12,600*l.* For British railways the figure given is 54,700*l.* per mile. The freight carried by Canadian railways in 1907 amounted to nearly 63,900,000 tons (of 2000 lb.), which included about 14,000,000 tons of coal and coke, nearly 4,500,000 tons of ores and minerals, 10,250,000 tons of lumber and other forest products, nearly 7,900,000 tons of manufactures, and 2,309,000 tons of merchandise. In 1875, when 4800 miles of railway were in operation, the corresponding freight-tonnage was 5,670,000 tons; so that while the length of railway increased nearly 4·7 times, the tonnage increased nearly 11·3 times. During the same period passengers increased from 5,190,000 to 32,137,000. For twenty-eight railways making returns the average revenue per passenger per mile was 2·232 cents, and for the four principal railways was 2·07 cents. For freight fifty-nine railways showed an average rate of 2·328 cents per ton-mile, and for the five principal railways it was 0·702 cent per ton-mile. The average distance travelled by a passenger was 64 miles, the corresponding figure for the United States being 30·3 miles. The average distance a ton of freight was hauled was 183 miles, as against 132 miles for the United States. In Canada, as the official reporter remarks, there is a small amount of suburban railway traffic and a low density of population. The following table is taken from the official Canadian Railway Statistics for 1907:—

	For each mile of Railway	
	Population	Square miles of Territory
United States	381	13·61
United Kingdom	1,821	5·29
France	1,590	8·46
New South Wales	686	146·09
New Zealand	358	43·42
Victoria	360	25·89
India	10,119	61·09
Canada	289	161·8

Canada has therefore the highest mileage measured against population, and the lowest against territory.

The earliest great railway system of Canada, the Grand Trunk, had its beginnings in 1845; in 1907 it was working about 3600 miles within the Dominion. In association with the Government it is now engaged on the construction of the Grand Trunk Pacific Line, which will cross the Continent wholly in Canadian territory, and have a length of 3600 miles, exclusive of branches.

The story of the Canadian Pacific Railway is well known, and need not be repeated; the influence which its existence and working have had upon the prosperity of the Dominion has been enormous and beneficial since its opening in 1885, and experience of its effect has led to the promotion of other Trans-Continental lines. In June, 1907, the total length in operation was nearly 9000 miles, and the company owned in addition great lines of steamships employed on Atlantic and Pacific services.

The Canadian Northern Railway system represents one of the most striking examples of recent railway development in the Dominion. In 1907 it was working nearly 2600 miles in the North-Western provinces, about 150 miles in Ontario, 500 miles in the Province of Quebec, and 430 miles in Nova Scotia and Cape Breton, making a total of nearly 3700 miles. In 1908 its mileage on the main system was reported to have increased to nearly 3400 miles, and the total length in operation had become 4800 miles. The North-Western Provinces have given substantial assistance to this great system, and its promoters are said to aim at a complete Trans-Continental route, as well as the development of railway communication to Hudson's Bay and the establishment of a line of steamships therefrom to Great Britain.

Besides these three great railway organisations, which in 1907 controlled about 75 per cent. of the mileage in operation, there are a large number of smaller companies, making up a total of about 80. Their total earnings in 1907 amounted to 29,350,000*l.*, the total working expenses being 20,750,000*l.* Earnings from freight service were (in round figures) 19,000,000*l.*; from passenger service, 7,837,000*l.*; from express services, 655,000*l.*; from mails, 325,000*l.*, the balance coming from miscellaneous items. The total number of persons employed by the railways was 124,000; their salaries and wages amounted to 11,750,000*l.* It was officially estimated that if to the railway employees were added persons employed in factories for rolling stock and railway materials, as well as those engaged in the casual service and shipping, with an allowance for their families, "quite 25 per cent. of the population win their daily bread from the carrying trade" of the Dominion.

The equipment of the Canadian railways in 1907 included 3504 locomotives, 3642 passenger cars, and 113,514 freight cars. In the opinion of the official reporter on railway statistics, based chiefly on a comparison of the proportion of rolling stock to mileage in Canada and the United States, a considerable increase of rolling stock is required, and there is a possibility of greater efficiency being obtained in the utilisation of existing freight cars. The manufacturing resources of the Dominion are declared to be fully capable of meeting all requirements, as in 1907 they produced 227 locomotives, 397 passenger cars, and 13,350

[1] Most of these statistics are taken from the valuable Report for 1907, presented to the Minister of Railways and Canals by Mr. Butler, Deputy Minister and Chief Engineer of the Department.

freight cars. A reduction of grades and curvatures has been carried out on the principal railways in recent years, and this has permitted the hauling of heavier loads. It is estimated that in 1907 the average earnings per ton of freight hauled were 1·472 dollars, and the average earnings per passenger carried were 1·219 dollars. The earnings per train mile were 1·953 dollars, and the working expenses 1·381 dollars. The total earnings per mile of railway were 6535·64 dollars, and the working expenses were 4620·9 dollars. The working expenses were divided as follows in the official report:—

	Per cent.
Maintenance of way and structures ...	20·13
,, ,, equipment ...	20·88
Conducting transportation ...	55·25
General expenses ...	3·74

Allowing two cords of wood fuel to be equal to one ton, 5,609,000 tons of fuel—of which 5,578,000 tons were coal—were consumed by Canadian railway locomotives in 1907 in running 100,155,000 miles. The total cost was about 3,027,500*l.*, equal to 14·59 per cent. of the working expenses.

From this brief summary of facts some idea may be gained of the rapid development of Canadian railways, their immense capital value and traffic, and the remarkable influence they have had upon the progress and population of the Dominion. It is a matter for satisfaction that British capital and engineering skill have contributed in no small measure to produce this development, and it may be hoped that in the future they may render even greater service.

Inland Navigation.

The most important system of inland navigation which Canada possesses is primarily due to the existence of the Great Lakes and the St. Lawrence River; but the utilisation of these natural advantages and the construction of a continuous navigable channel from the sea to the head of Lake Superior is due to the work of engineers. The importance of such a navigable waterway leading to the heart of the Dominion was recognised long ago by the Government. The first canal is said to have been opened in 1821, and from that time onwards the canal system has been developed, but the greatest progress has been made during the last forty years under successive Administrations. Up to March 31, 1907, the capital expenditure on Canadian canals, exclusive of outlay by the Imperial Government, has approached 18,350,000*l.* sterling, of which more than ten millions have been spent on enlargements. Besides minor canal systems, many of which are important, a great "trunk system" of water-transit has been created from Montreal to Port Arthur, at the head of Lake Superior, this all-water route being nearly 1300 miles in length, having a minimum depth of water of 14 feet and effecting a total vertical rise of about 600 feet from tidal water in the St. Lawrence to Lake Superior. In order to effect this rise forty-nine locks are provided, most of which are 270 feet long and 45 feet wide, enabling vessels 255 feet long to be accommodated. Out of the total length of more than 1200 miles, only 73½ miles consist of artificial channels. The Welland Canal, connecting Lakes Erie and Ontario—with a total rise from lake to lake of 327 feet, effected in twenty-five locks—is 26¾ miles long. This canal dates from 1824; its enlargement to present dimensions was begun in 1872, and occupied fifteen years; the total expenditure on the canal has been nearly five and a half millions sterling. Another important section of the waterway is the Sault Ste. Marie Canal—about 6000 feet in length and from 142 to 150 feet wide between the pier-ends, with a lock 900 feet long, 60 feet wide, having 20¼ feet of water over the sills. The difference of level between Lakes Superior and Huron is 18 feet. Commenced in 1888, the Sault Ste. Marie Canal was opened for traffic in 1895, the cost being about 930,000*l.* Like its predecessor on the United States side of St. Mary's River—the so-called "Soo" Canal affords *free passage* for the ships of both countries. In 1898 about two and three-quarter millions represented the tonnage of vessels passing through the Canadian Canal, and of this total about 403,000 tons was in Canadian vessels. In 1907 the total tonnage had risen to 12,176,000 tons, of which 2,288,000 was in Canadian vessels. The Soulanges Canal is fourteen miles long, with a rise of 84 feet effected in four locks. Commenced in 1892, it was opened for traffic in 1899, and cost nearly 1,400,000*l.* The Lachine Canal was commenced in 1821, enlarged in 1843 and 1873, and, as completed in 1901, is 8½ miles long, has 45 feet rise, effected in five locks, and has cost from first to last about 2,300,000*l.*

In the construction of this great waterway many difficult engineering problems have been solved, and every modern improvement has been introduced; electricity has been utilised in its equipment, both for power and lighting, so that navigation can proceed by night as well as by day. For the years 1903–7 the canals were declared *free of tolls*; but it is estimated officially that if tolls on the ordinary scale had been collected the revenue for 1907 would have exceeded 91,000*l.* In these five years the water-borne traffic of the Dominion increased from 9,204,000 tons in 1903 to 20,544,000 tons in 1907; in the same period the increase in Canadian railway traffic was from 47,373,000 tons to 63,866,000 tons. The official reporter justly remarks that "these results are exceedingly encouraging."

It was recognised long ago that the utilisation of the waterways of Canada from the Great Lakes to the sea would yield considerable advantages by facilitating cheap transport of agricultural products of the fertile regions from the great North-West, but the Canadian portions of that territory were then regarded as "a great lone land." Subsequent developments of the corn-growing regions of Canada have emphasised the value of the water route and its great potentialities. In his "History of Merchant Shipping" (published 1876) Lindsay dwelt upon this point, and foresaw that if the waterways of Canada were made continuously navigable a struggle for supremacy in oversea trade must arise between New York and the Canadian ports of Montreal and Quebec. This struggle is now in full force, so far as the grain trade is concerned, and it is likely to grow keener. The quantity of grain passed down the whole length of the St. Lawrence navigation to Montreal increased from about 450,000 tons in 1906 to 685,000 tons in 1907, while the quantity carried to Montreal by the Canadian Pacific Railway was about 387,000 tons for 1906 and 384,000 tons for 1907. On the other hand, the quantity carried by canals in the United States to New York fell from 294,500 tons in 1906 to 230,800 tons in 1907.

An important addition to the Canadian canal system has been proposed, and its execution will probably be undertaken when great works now in progress have been completed. This route extends from Georgian Bay on Lake Huron to the St. Lawrence, and would utilise Lake Nipissing as well as the French and Ottawa rivers. The distance to be traversed would be 450 miles, less than that of the present all-water route. On the basis of careful surveys it has been estimated that a canal having 20 feet depth of water could be constructed at a cost of twelve millions sterling, upon which capital a reasonable dividend could be paid, even if the charges made for transport were one-third less than the lowest rates of freight possible on United States routes to New York. It would, of course, be most advantageous to have the available depth of water increased from 14 to 20 feet, thus making possible the employment of larger and deeper draught vessels between the Lakes and Montreal. Considerable economies in the ratio of working expenses to freight earnings would be effected, break of bulk in transit to the sea would be avoided, and the cost of transport greatly reduced.

The magnitude of the grain trade and its growth may be illustrated by the following figures for recent years:—In 1897 the grain cargoes passed down the Welland Canal to the ports of Kingston and Prescott numbered 377, and represented 515,000 tons; for 1907 the corresponding figures were 518 cargoes, weighing 841,000 tons. As to the elevators and mechanical appliances for handling economically these huge quantities of grain, nothing can be said here, although they involve the solution of many difficult engineering problems and have been greatly simplified and improved as experience has been gained.

The bulk of the canal traffic, of course, moves eastwards and outwards from the interior provinces. For example, of the total quantity of freight (1,604,321 tons) passed through the whole length of the Welland Canal in 1907, about 75 per cent. moved eastwards, and more than 62 per cent. of the 2,100,000 tons which passed through the St. Lawrence canals moved in the same direction.

Shipping on the Great Lakes.

Canadian shipping and shipbuilding on the Lakes have made considerable progress in recent years, although they do not rival those of the United States. According to authoritative statements there were not twenty Canadian steamers engaged in the transport of grain fifteen years ago; only three of these were steel-built, and the largest carried only 90,000 bushels. The total carrying capacity of Canadian grain-carriers at the present time has been estimated at ten million bushels, and the capital invested in the fleet is said to be about three millions sterling. Between the harvest and the close of navigation in winter it is estimated that no fewer than sixty million bushels of grain can be moved from port to port in Canadian steamers.

Many special engineering features have been introduced into the structures and equipment of these Lake grain-carriers. They are really huge steel barges of full form, of uniform cross-section for a considerable portion of their length; and they possess enormous cargo capacity, moderate engine power and speed, with structures of a simple nature which can be largely standardised and made to resemble bridge-construction rather than ordinary shipbuilding. They can be built in a short time, the largest vessels occupying about four months in construction. In this way the cost of construction is cheapened, but the rates for labour and materials prevailing in the Lake shipyards are so high relatively to British costs that at present these grain-carriers are said to cost about 40 per cent. more (per ton dead weight carried) than the cost of ordinary "tramp" steamers built in Great Britain. Their holds and hatchways are arranged so as to facilitate the rapid shipment and discharge of cargoes. At their ports of call special mechanical appliances are provided for dealing with cargoes, most of which consist of grain, ore, or coal.

In the design and construction of these cargo-handling appliances the mechanical engineer has displayed great ingenuity, and the results obtained in rate of shipment and discharge of cargoes of grain, ore, and coal are remarkable. Cases are on record where vessels carrying 7000 tons dead weight have been loaded in four hours and discharged in ten hours; more than 5000 tons of ore have been discharged in about four hours. The draught of water of the steamers must be kept within moderate limits and the breadths of the locks are moderate, so that increase in carrying power must be chiefly obtained by increase in length; consequently, as individual cargoes are increased, a greater number of lifting appliances can be brought to bear simultaneously, and the rate of loading or discharge can be maintained or accelerated.

The season of navigation extends over only seven or eight months in the year; consequently, "quick despatch" is essential to success. A large vessel of this class has the following approximate dimensions:—Length, about 600 feet; breadth, 58 to 60 feet; depth, 32 feet; draught of water, 19 to $19\frac{1}{2}$ feet when carrying 10,000 to 11,000 tons of cargo; corresponding displacement, 16,000 tons. The engines of such a ship develop about 2000 horse-power, and drive her at eleven to twelve statute miles per hour in fair weather. The large size and moderate speed result in very economical conditions of working, and the freight rates are exceedingly low. From official returns it appears that for these dead-weight cargoes the freight per ton mile across the Lakes is from 0·04 to 0·05 of a penny per ton mile, the corresponding railway rate being about ten times that amount. The multiplication of this type of vessel on the great Lakes is a proof that it satisfactorily fulfils the conditions of service. Similar vessels would not be well adapted for ocean work, which demands greater structural strength, different proportions, and a more liberal equipment; but shipbuilders generally may benefit from a study of the Lake steamers.

The greater portion of the traffic on the Lakes passes through the "Soo" canals. The voyages are comparatively short, the average length of the trip being about 840 miles. Consequently, individual vessels make several passages during the season when navigation is open, and the total number of passages as well as the total aggregate tonnage of the ships reaches very high figures. In the season of 1907, for example, when the canals were open less than 240 days, 20,440 vessels (counting as a vessel each passage), with an aggregate registered tonnage exceeding 44 million tons, passed through the United States and Canadian canals at the Soo. The aggregate freight tonnage carried exceeded 58 million tons; the weight of coal approached $11\frac{1}{2}$ million tons; the iron ore carried weighed 39,600,000 tons; and the grain transported amounted to 136 million bushels. The conditions of the Suez Canal are, of course, entirely different, as vessels passing through are engaged on long voyages, and individual ships make few passages in the year. On the other hand, Suez Canal traffic proceeds uninterruptedly throughout the year, while the Soo canals are closed during the winter months. Subject to these differences in working conditions, it may be of interest to state that in 1907 4267 vessels of 14,728,000 tons passed through the Suez Canal, and paid transit dues which amounted to 4,460,000*l.*; whereas the passage of the "Soo" canals was free.

The St. Lawrence Ship Channel.

Closely allied with the waterway from Montreal to Lake Superior is the improvement of the channel of the St. Lawrence from Montreal to Quebec and beyond towards the sea. From the Straits of Belleisle to Montreal the distance is 986 miles; from Quebec to Montreal it is 160 miles. Formerly the minimum depth of water between Quebec and Montreal prevented the passage of vessels drawing more than 10 to 12 feet during the greater part of the season of navigation. In 1826 the question of deepening the river channel was raised; in 1844 the work was begun, but was abandoned three years later; in 1851 it was resumed, and has since been continued. In 1869 the minimum depth of the channel at low water was increased to 20 feet, in 1882 it was 25 feet; in 1888 $27\frac{1}{2}$ feet for 108 miles from Montreal to a point within tidal influence. A channel having a minimum width of 450 feet, and 550 to 750 feet wide at the bends, with a minimum depth of 30 feet, was completed in 1906 from Montreal to tide water at Batiscan. Certain work remains to be done between this point and Quebec in order to complete the project adopted in 1889 and amended in 1906, but it is anticipated this will be finished in about four years. Below Quebec the channel is 1000 feet wide. When once dredged it is stated that the channel remains permanent. Accidents in the channel are few. The Superintending Engineer in his Report of July, 1908, indicates the magnitude of the work done by comparisons with the Suez and Panama Canals, the figures standing as follow:—

	Length Miles	Minimum depth Feet	Minimum breadth Feet	Estimated excavation Cubic yards
Suez Canal	100 ...	$29\frac{1}{2}$	100 (bottom)	—
Panama Canal	49 ...	41	200 (min.) 500 (max.)	80,000,000
St. Lawrence Channel.	220[1] ...	30	450 (min.) 1000 (max.)	70,000,000

In 1844 the largest vessels navigating the St. Lawrence to Montreal were of 500 tons; now the *Virginian* and *Victorian* of the Allan Line (12,000 tons), and the *Laurentic* and *Megantic* of the White Star Line (15,000 tons), proceed to that port, and have made the passage from Quebec in less than ten hours. Ordinarily, this passage occupies eleven to twelve hours, the return passage being made in nine to ten hours.

In the execution of these great works a specially designed dredging plant, including several types, has been employed, and works about seven months in the year; and the rock dredging and blasting in the section below Quebec has involved great difficulty. The total amount of rock to be removed amounted to 1,700,000 cubic yards, extending over nearly three miles, and the whole bottom was covered with huge boulders, some of which were 30 to 40 tons in weight. These great masses had to be lifted before blasting and dredging was done. During the fiscal

[1] Length of channel requiring improvement demands dredging and excavation over a length of about 70 miles.

year 1907–8 the expenditure on dredging plant and dredging was nearly 132,000*l.*, and 4,832,000 cubic yards of material were removed. At the close of that year 56 millions of cubic yards out of the estimated total of 70 millions had been dredged; the length completed to 30 feet minimum depth was 59 miles out of 70 miles. These facts indicate the advanced condition of the undertaking and the prospect of its completion at an early date.

In order to secure the safe and continuous navigation of this channel by night as well as by day, under all conditions of weather, during the season when the river is open every precaution and aid which engineering skill and invention can provide has been laid under contribution. A marine signal service with telephonic equipment has been provided; submarine bells have been established for use in foggy weather; a complete system of buoys and lighting has been installed; the channel is periodically examined and swept to ensure that there are no obstructions; the question of prolongation of the season for navigation by the use of ice-breakers is being studied. The harbour of Montreal has been greatly improved in accommodation and equipment, and the aggregate tonnage as well as average size of sea-going vessels using the port have been much increased. In 1898, 868 such vessels aggregating 1,584,000 tons arrived at Montreal; in 1907, 742 vessels aggregating 1,926,000 tons arrived. Of the latter, 522 vessels aggregating 1,525,000 tons were British. At the St. Charles Docks and Wharves, Quebec, in the season of 1907, 235 vessels of 1,009,000 tons were entered inwards, and 67 vessels of 249,000 tons outwards, the first outward steamer leaving on April 7, and the first ocean steamer arriving on April 26. The last arrival from the sea was on December 9, and the ice formed in the tidal basin on December 12.

Still further improvements of the St. Lawrence navigation are now proposed, and the work was commenced in 1907. It is intended to increase the depth of the channel to a minimum of 35 feet from the sea to Montreal, and the Superintending Engineer reported in 1908 that, with certain moderate additions to the dredging and steam plant, this work could be completed in six seasons. The widths and curves of the existing channel will not require any important changes, as they were designed from the first for the largest classes of steamships. When this increased depth has been obtained Montreal as a port will have an approach channel comparing favourably with that of other ports available for Transatlantic traffic. At Southampton the existing depth at low water in the approach channel is about 32 feet, and it is proposed to obtain 34 feet. At Liverpool the minimum depth at low water over the bar and in the approach channel in the Mersey is about 28 feet. The Ambrose Channel leading to New York is to have 40 feet depth at low water when the works are completed. Ample depth of water is of the first importance in the economical working of the largest and swiftest ships, and the Canadian Government has been well advised in deciding to carry out the great scheme above described.

Water-power.

Canada has unrivalled resources in water-power, and its extent and possible utilisation have been made the subject of investigation by engineers for many years past. One of the most important memoirs on the subject was presented to the Royal Society of Canada in his Presidential Address of 1899 by Mr. Keefer, C.M.G. In recent times many other engineers have studied the subject and carried out important works. Exact knowledge of the total power represented by the waterfalls and rapids of the Dominion is not available, nor can any close estimate be made of the power which may be employed hereafter in factories, mills, or industrial processes, because profitable employment obviously depends upon commercial considerations, which must be governed largely by the localities in which water-power may be found, and the cost of works and of transmission of energy to places where it can be utilised. It has been estimated that on the line from Lake Superior through the chain of lakes and rivers leading to Niagara and thence through the St. Lawrence to the sea eleven millions horse-power may be developed.[1] Mr. Langelier has estimated that in the Province of Quebec the water-power aggregates more than eighteen millions horse-power; other provinces all possess large resources of the same kind as yet untouched. The most striking example of the utilisation of water-power is that on the Niagara River, which I had the good fortune to visit in 1904, during my Presidency of the Institution of Civil Engineers; the works on the Canadian side were then in full progress, and at a stage which enabled one to realise completely their great difficulty and immense scale. The three companies the works of which are near the Falls on the Canadian side have provided for a total ultimate development of more than 400,000 horse-power, and a fourth establishment lower down the river, intended chiefly for the use of Hamilton, is to develop 40,000 horse-power. In the construction of the works, in the electric generating plant, the arrangements for transmitting power over long distances, and other features of importance remarkable engineering skill and daring have been displayed. American capital and enterprise have had much to do with these undertakings, as they have with many other important Canadian enterprises; but it may be hoped that British capital will keep its lead and be freely employed in the development and utilisation of all the resources of the Dominion, including that magnificent asset its water-power. The applications of water-power are already very numerous, including, not merely the creation of electrical energy and its use for lighting and power in towns and factories situated at considerable distances from the Falls, but for manufactures and industrial processes carried on near the Falls. Amongst these manufactures, that of aluminium and carbide of calcium may be mentioned, while paper- and pulp-mills and saw-mills constitute important industries. Great advances have been made in the transmission of electrical power over long distances, and very high pressures are being used. Electric traction on railways and tramways also derives its power from the same sources, and is being rapidly developed. In 1901 there were 553 miles of electric railways, and in 1907 815 miles.

[1] The *Times Financial Supplement*, April 2, 1906, contains a valuable article on this subject, from which many of the above figures are taken.

Over-sea Trade and Transport.

It was remarked at the outset that a great truth is embodied in the old toast of "Ships, Colonies, and Commerce," and the efficient and economical transport of passengers, produce, and manufactured goods between the Dominions beyond the Seas and the Mother Country is essential both for the development of Colonial resources and for the continued prosperity of the United Kingdom. The British mercantile marine commands the larger portion of the carrying trade of the world; its earnings constitute a valuable item in the national income; it forms one of the strongest bonds of union between the various parts of the Empire. This general statement may be illustrated by reference to the over-sea trade of Canada and to the shipping engaged therein.

The total value of the Imports and Exports of the Dominion in 1898 was close upon 61 millions sterling; in 1908 it exceeded 130 millions sterling, having more than doubled within ten years. During the year ending March 31, 1908, the vessels which were entered at Canadian ports (*inwards from the sea*) carrying cargoes were classified as follows in the official returns:—

Ships		Tons register	Freight carried: Tons weight	Freight carried: Tons measurement	Crews
British ...	2,603	4,539,256	1,306,822	254,373	165,078
Canadian..	2,803	718,490	202,939	1,449,054	44,594
Foreign ...	2,878	1,758,549	887,154	36,618	86,293
Totals......	8,284	7,016,295	2,396,915	1,740,045	295,965

The corresponding figures for ships entered outwards for sea carrying cargoes were:—

Ships		Tons register	Freight carried: Tons weight	Freight carried: Tons measurement	Crews
British ...	2,533	4,258,960	2,706,334	714,085	136,614
Canadian..	3,557	1,041,053	616,248	291,480	45,658
Foreign ...	4,132	2,211,605	1,454,787	538,499	88,093
Totals......	10,222	7,511,618	4,777,369	1,544,064	270,365

Taking the combined over-sea traffic inwards and outwards, it employed 18,506 ships of 14,528,000 tons, the cargoes of which aggregated 7,174,000 tons dead-weight and 3,284,000 measurement tons, the crews exceeding 576,000 officers and men.

Of the 2603 British ships entered inwards, there came from Great Britain 852 ships of 3,392,000 tons, carrying as cargoes more than 860,000 tons dead-weight and 153,000 tons measurement; while there came from British Colonies 399 ships of nearly 381,000 tons, carrying cargoes of 236,000 tons dead-weight and 44,000 tons measurement. Of the 2533 British ships entered outwards, there proceeded to Great Britain 732 ships of 2,529,000 tons, carrying cargoes of 1,635,000 tons dead-weight and 509,000 tons measurement; while there sailed for British Colonies 648 ships of nearly 400,000 tons, carrying cargoes of 259,000 tons dead-weight and 76,500 tons measurement.

It will be seen, therefore, that the British ships entered inwards carried more than 54 per cent. of the total dead-weight cargoes and 14½ per cent. of the measurement goods, while foreign ships carried about 37 per cent. of the dead-weight and rather more than 2 per cent. of the measurement goods. British ships entered outwards carried more than 56 per cent. of the total dead-weight, and more than 46 per cent. of the measurement; whereas foreign ships carried only about 30 per cent. of the dead-weight, and not quite 35 per cent. of the measurement.

The trade from and to ports in the British Empire amounted to 45 per cent. of the grand total dead-weight freight; and ships carrying the British flag—excluding Canadian vessels—carried about 56 per cent. of the grand total dead-weight, and nearly 30 per cent. of the measurement goods. Including Canadian vessels, the British Empire can claim possession of 67½ per cent. of the total dead-weight trade, and 82½ per cent. of the measurement goods. The average tonnage per ship for the British was about 1700 tons; for the Canadian vessels less than 300 tons; for the foreign ships a little more than 900 tons.

It may be interesting to add a few figures showing the magnitude of the *coasting trade* of the Dominion. In 1908 there arrived and departed 104,527 steamers aggregating nearly 42,857,000 tons, and 50,710 sailing ships aggregating 7,673,000 tons. The sailing ships included nearly 50,200 small schooners, sloops, barges, canal boats, &c., averaging about 150 tons each. The grand totals for the coasting trade were 155,237 ships of 50,530,000 tons, and of these 151,873 ships of 47,356,000 tons were classed as British in the official returns. It will be obvious that great importance must attach to every detail of the business involved in carrying on a shipping trade of the magnitude indicated by the foregoing figures, and still more is this the case in regard to the immensely greater transactions of British shipping considered as a whole. No pains must be spared in promoting economy or improving procedure, and even minute savings on particular items must be secured, since their aggregate effect may be of vast amount.

Since the introduction of iron for the structures of ships and of steam as the propelling power marvellous economies have been effected in the cost of over-sea transport. The chief causes contributing to this result have been (1) improvements in steam machinery, leading to great reductions in coal consumption; (2) considerable enlargement in the dimensions of ships; and (3) the supersession of iron by steel for structures and machinery. It is unnecessary, and would be impossible on this occasion, to deal in any detail with these matters, which have been illustrated repeatedly by many writers, including the speaker. On the other hand, it would be improper to leave altogether without illustration the remarkably low cost of sea transport under existing conditions, since it has great influence on the commerce of the British Empire and of the world.

Rates of freight, of course, vary greatly as the conditions of trade and the stress of competition change. At the present time these conditions remain unfavourable, although it may be hoped that there are signs of improvement, after long and severe depression. It will be preferable, therefore, to give facts for more normal circumstances, such as prevailed five or six years ago. Coal was then carried from the Tyne to London (315 miles) for 3*s.* 3*d.* a ton; to Genoa (2388 miles) for 5*s.* a ton; to Bombay (6358 miles) for 8*s.* 6*d.* a ton, including Suez Canal dues. The corresponding rates of freight were 0·111, 0·025, and 0·016 of a penny per ton-mile.

Grain was brought across the Atlantic for 9*d.* per quarter in large cargo steamers, whereas in former times, when it was carried in small vessels, the charge was 9*s.* 6*d.* Goods were carried 6400 miles eastward *viâ* the Suez Canal in tramp steamers at an inclusive charge of 25*s.* to 30*s.* a ton, the freight rate averaging about 0·05 of a penny per ton-mile. It was estimated at that time that the average railway rate per ton-mile in Great Britain for cost of transport and delivery of goods was about thirty times as great; but the moderate distances travelled, local and national taxation, high terminal charges, and the immense outlay involved in the construction, equipment, and maintenance of railways account for much of the great difference in cost of transport. The ocean furnishes a free highway for the commerce of the world.

Economy of fuel-consumption has played a great part in the reduction of working expenses in steamships. Fifty years ago from 4 to 5 lb. of coal per indicated horse-power represented good practice in marine engineering for screw steamships. At present, with quadruple expansion engines, high-steam pressures, and more efficient reciprocating engines from 1¼ to 1½ lb. is common practice, and better results are claimed in some cases. A cargo steamer of the tramp type, carrying 6500 tons dead-weight, can cover about 265 knots in twenty-four hours in fair weather for a coal consumption of 27 tons per day, representing an expenditure on fuel of 20*l.* to 25*l.* A larger vessel carrying about 12,000 tons dead-weight, driven by engines of similar type, would consume about 45 tons in covering the same distance at the same speed. This increased economy in fuel per ton-mile is the result of an increase in dimensions from 365 feet length, 47 feet breadth, and 24½ feet draught of water to a length of 470 feet, a breadth of 56 feet, and a draught of 27½ feet. The first cost of cargo steamers is small in relation to their carrying capacity and possible earnings, varying, of course, with the current demand for new steamships. In the present depressed condition of shipping, about 5*l.* 10*s.* per ton dead-weight is named as a current rate; in busy times the price may be 40 to 45 per cent. higher; even then it is small in proportion to earning power. Working expenses are kept down also by the use of efficient appliances for rapidly shipping or discharging cargoes, and so shortening the stay of ships in port. As an example a case may be mentioned when a ship of 12,000 tons dead-weight and 800,000 cubic feet measurement capacity had her full cargo discharged at an average rate of 300 tons an hour, a fresh cargo put on board at the rate of 250 tons an hour, and 1600 tons of coal shipped between 7 a.m. on Monday and noon on the following Friday—that is, in 101 hours. In another case a cargo weighing 11,000 tons was discharged in 66 hours. "Quick dispatch" in dealing with cargo is now universally recognised as essential, and it has been asserted that a saving of one day in discharging or loading a tramp steamer when she finds full employment may involve an expense equal to 1 per cent. on her first cost.

The "intermediate" type of steamer—in which large carrying capacity is combined with provision for a considerable number of passengers and moderate speed—is of comparatively recent date, but it has been developed rapidly and is subject to the universal laws to which all classes of shipping conform. Increase of size is adopted in order to favour economy in working and greater earning power, while increase in speed is made in some cases. Vessels like the *Adriatic* or *Baltic* of the White Star Line, the *Carmania* and *Caronia* of the Cunard Line, and the *George Washington* of the Hamburg-American Line illustrate this statement; while its latest and greatest examples are found in the two steamers now building for the White Star Line by Messrs. Harland and Wolff, which are said to be of 45,000 tons, to be intended to steam twenty to twenty-one knots, to provide accommodation for a great number of passengers, and to have large capacity for cargoes. In mail and passenger steamers of the highest speed increase in dimensions is devoted chiefly to provision for more powerful propelling apparatus and for a correspondingly large quantity of fuel, and the cargo-carrying capacity is relatively small; but the law of increase in size and cost is obeyed, and will be followed up to the limit which may be fixed by the vast outlay necessary in order to provide suitable harbours and dock accommodation with an adequate depth of water, or by commercial considerations and the possibility of securing a suitable return on the large capital expenditure. Growth in dimensions of ships will not be determined by the naval architect and marine engineer finding it impossible to go further, for there are even now in view possibilities of further progress if the shipowner so desires. Invention and improvement have not reached their ultimate limits.

The wonderful progress made during the last seventy years is well illustrated by the history of shipping trading between Canada and Great Britain, and it may be of interest to recall a few of the principal facts. For a long period trade and communications were carried on by wood-built sailing ships, many of the finest being Canadian built; but at a very early period Canadians had under consideration the use of steamships. One of the first steamers to cross the Atlantic was the *Royal William* paddle-steamer, built near Quebec in 1831. She was 160 feet long, 44 feet broad, of 363 tons burden, sailed from Quebec on August 5, 1833, and reached Gravesend on September 16, a passage of more than forty days, in the course of which sail-power was largely used. Cabot, in 1497, crossed in the good ship *Matthew*, of 200 tons burden, which was probably from 90 to 100 feet in length; so that three centuries of progress had not made very great changes in size of the ships employed. Wood was still the material of construction, and sails were still used as a motive power, although the steam-engine was installed. In 1839 it was a Canadian, Samuel Cunard, who secured—in association with two British shipowners, Burns and McIver—the contract for a monthly Transatlantic service from Liverpool to Halifax and Boston. The four steamers built were wood-hulled, driven by paddle-wheels, had good sail-power, and were of the following dimensions:—207 feet long, $34\frac{1}{2}$ feet broad, 1150 tons burden, and about eight knots speed. A rapid passage to Boston then occupied about fourteen days.

Another Canadian enterprise, the Allan Line, started about fifty-six years ago. The first steamer built for the company was appropriately named the *Canadian*. At the time of her construction she ranked among the most important mercantile steamers in existence, and was quite up to date. Her dimensions were:—length, 278 feet; breadth, 34 feet; burden, 1873 tons. She had inverted direct-acting engines, driving a screw propeller, and a full sail equipment.

The Transatlantic service to New York, as was natural, rapidly surpassed that to Canadian ports, but the latter has been continuously improved, and its development has been marked by many notable events. For example, the Allan Line was amongst the first to use steel instead of iron for hulls, and in their two largest steamers now on service, dating from 1903, they were the first to adopt steam turbines for ocean-going ships, although their lead of the Cunard Company was not long. The *Virginian* and *Victorian* are 520 feet long, 60 feet broad, of 10,750 tons, and their maximum speed is 18 knots. The Canadian Pacific Railway authorities added shipowning to their great land enterprises at an early period in their career by building for the Pacific service in 1891 three important steamers, each 456 feet long, 51 feet broad, of 5950 tons, and 17 knots speed. These vessels continue on service, and have done splendid work as a link in the "all red" route. Since this step was taken the Canadian Pacific Railway has become possessed of a large fleet of Atlantic steamships, and quite recently has placed on the service from Liverpool to Quebec passenger steamships nearly 550 feet in length, 66 feet in breadth, of 14,200 tons, with a maximum speed of 20 knots.

The latest addition to the Canadian service has been made by the White Star Line in the form of two steamers, the *Laurentic* and *Megantic*, of 15,000 tons, 550 feet long, about 67 feet broad, and 17 knots speed. In the *Laurentic* an interesting experiment has been made—Messrs. Harland and Wolff having introduced a combination of reciprocating engines and a low-pressure turbine. This system was patented as long ago as 1894 by Mr. Charles Parsons, to whom the invention of the modern steam turbine and its application to marine propulsion are due. Mr. Parsons foresaw that while the turbine system would prove superior to reciprocating engines in ships of high speed and with a high rate of revolution, there would be a possibility of getting better results by combining reciprocating engines with low-pressure turbines in ships of comparatively slow speed, where a low rate of revolution for the screw-propellers was necessary to efficient propulsion. His main object, as set forth fifteen years ago, was "to increase the power obtainable by the expansion of the steam beyond the limits possible with reciprocating engines," and subsequent investigations led Mr. Parsons to the conclusion that it would be possible to secure an economy of 15 to 20 per cent. by using the combination system as compared with that obtainable with efficient types of reciprocating engines. Many alternative arrangements have been designed for combining reciprocating engines with low-pressure turbines; that now under trial associates twin-screw reciprocating engines, in which the expansion of the steam is carried down to a pressure of 9 to 10 lb. per square inch when working at maximum power, and then completed to the condenser pressure in a turbine. Triple screws are employed, the central screw—driven by the turbine—running at a higher rate of revolution than the side screws, which are driven by the reciprocating engines. The *Laurentic* has been but a short time on service, and few particulars are available of her performances as compared with those of her sister ship, fitted with reciprocating engines. It has, however, been reported that the results have proved so satisfactory that the combination system will probably be adopted in the two large White Star steamers of 45,000 tons now building at Belfast. This favourable view is fully confirmed by the performances of the *Otaki*, built by Messrs. Denny, of Dumbarton, for the New Zealand Shipping Company, and completed last year. That firm, as is well known, have taken a leading part in the application of the Parsons type of steam turbine to the propulsion of mercantile and passenger steamers, and they possess exceptional experience as well as special facilities for the analysis of the results of trials of steamships, having been the first private firm to establish an experimental tank for testing models of ships and propellers on the model of that designed by Mr. W. Froude and adopted by the Admiralty. Messrs. Denny have generously placed at the disposal of their fellow-shipbuilders the principal results obtained on the official trials and earliest voyages of the *Otaki*, and have compared them with similar results obtained in sister ships fitted with reciprocating engines.[1] The *Otaki* is the first completed ship fitted with the combination system and subjected to trial on service, and as the successful application of that system to cargo steamers and steamers of the intermediate type would result in a considerable economy in the cost of over-sea transport, it may be of interest to give some details of her recorded performance. She is 465 feet long, about 60 feet broad, and of 7420 tons (gross). Her dead-weight capability is about 9900 tons on a draught of 27 feet 6 inches, and the corresponding displacement (total weight) is 16,500 tons. The vessel was designed for a continuous sea-speed of 12 knots when fully laden, and the contract provided for a trial speed of 14 knots with 5000 tons of dead-weight on board. The trials were accordingly made at a displacement of about 11,700 tons. Her installation of boilers is identical with that of her sister ship, the reciprocating-engined twin-screw steamer *Orari*, which is 4 feet 6 inches shorter than the *Otaki*, but generally of the same form. On the measured mile the *Otaki* obtained a speed of 15 knots, while the *Orari* reached 14·6 knots. In order to drive the *Orari* at 15 knots about 12 per cent. more horse-power would have been required, and this is a practical measure of the superiority of the combination system over the reciprocating twin-screw arrangement in the *Orari*. The total water consumption per hour of the *Otaki* at 15 knots was 6 per cent. less than that of the *Orari* at 14·6 knots. If the *Otaki* also ran at 14·6 knots, the water consumption would have been 17 per cent. less than that of the *Orari* at the same speed. On the voyage from Liverpool to New Zealand the *Otaki* averaged about

[1] See a paper by Engineer Commander Wisnom, R.N., in the Proceedings of the Institution of Engineers and Shipbuilders in Scotland for 1909.

11 knots, which would have required on the measured mile only about 40 per cent. of the power developed when running 14·6 knots. With the ship laden more deeply, the average development of power on the voyage was about one-half the maximum developed on the measured mile, and this was disadvantageous to economy in the combination. Even in these unfavourable conditions the *Otaki* realised an economy in coal consumption of 8 per cent. on the voyage from Liverpool to New Zealand and back as compared with her reciprocating-engined sister ship; this represents a saving of about 500 tons of coal. Ordinarily the ship would leave England with sufficient coal on board for the outward passage, so that 250 tons less coal need be carried and a corresponding addition could be made to cargo and freight-earning. Probably as experience is gained the actual economy will prove greater than that realised on the maiden voyage; but even as matters stand there is a substantial gain, and a prospect of the extended application of the steam turbine to vessels of moderate and low speed. In view of results already obtained, the New Zealand Shipping Company have decided to apply the combination system to another vessel just ordered from Messrs. Denny.

In designing turbine machinery for vessels of moderate or low speed there must necessarily be conflicting claims. For maximum efficiency in steam turbines a high rate of revolution is necessary, whereas at moderate or low speeds it is antagonistic to propeller efficiency to run at this high rate of revolution. Engineers are at present much occupied with the study of arrangements by means of which these conflicting claims may be harmonised and greater total efficiency of propulsion obtained. Having regard to the enormous capital invested in cargo steamers of moderate speed, and the importance attaching to their economic working as influencing the cost of over-sea transport, it will be obvious that it is most desirable to find an arrangement in which the high speed of the rotor may be reduced by means of some form of gearing or its equivalent, so as to enable the screw shaft and its propeller to be run at a speed which will secure maximum propeller efficiency. Many proposals have been made, including mechanical gearing and hydraulic or electric apparatus, for transforming the rate of motion. Some of these are actually undergoing experimental trials, and are said to have given very promising results. One of the most important trials is that undertaken by the Parsons Marine Steam Turbine Company, which has purchased a typical tramp steamer, and is carrying out on her a series of trials in order first to ascertain accurately what are the actual conditions of steam and coal consumption with the present reciprocating engines, and then to, ascertain the corresponding facts when those engines have been removed and a steam turbine with its associated gearing has been fitted. It is interesting to note in passing that in the earliest days of screw propulsion with slow-running engines it was found necessary to adoot gearing in order to increase the rate of revolution of the propellers, whereas at present interest is centred in the converse operation. Furthermore, if any system of gearing-down proves successful, it may be anticipated that its application will be extended to swift turbine-driven steamships, since it would enable good propulsive efficiency to be secured in association with rapidly running turbines of smaller size and less weight than have been employed hitherto.

The Marine Steam Turbine.

The rapid development of the marine steam turbine during the last seven years constitutes one of the romances of engineering, and the magnitude of the work done and the revolution initiated by Mr. Charles Parsons will be more justly appreciated hereafter than it can be at present. In some quarters there is a tendency to deal critically with details and to disregard broader views of the situation as it stands to-day. In May, 1909, there were 273 vessels built and under construction in which steam turbines of the Parsons type are employed, the total horse-power being more than three and a half millions. In the Royal Navy every new warship, from the torpedo-boat up to the largest battleships and armoured cruisers, is fitted with turbine engines; and the performances of vessels which have been tested on service have been completely satisfactory, in many instances surpassing all records for powers developed and speeds attained. In the war-fleets of the world this example is being imitated, although in some cases it was at first criticised or condemned. In the mercantile marine as a whole, while the new system has not made equal advance, many notable examples can be found of what can be accomplished by its adoption. It is now admitted that steam turbines enable higher speeds to be attained in vessels of given dimensions; and in steamers built for cross-channel and special services, where high speed is essential and coal consumption relatively unimportant, turbines have already ousted reciprocating engines. For over-sea service and long voyages an impression has existed that the coal consumption of turbine-engined ships would considerably exceed that of ships driven by triple or quadruple expansion reciprocating engines. Critics have dwelt on the reticence in regard to actual rates of coal consumption practised by owners of turbine steamships. Naturally there are other reasons for reticence than those which would arise if the coal consumption were excessive; but pioneers in the use of turbine machinery may reasonably claim the right of non-publication of results of trials in the making of which they have incurred large expenditure and taken considerable risks if they think that silence is beneficial to their business interests. Even if it were true that in the earliest applications of the new system economic results had not been obtained equal to those realised in reciprocating engines which have been gradually improved during half a century, that circumstance should not be regarded as a bar to acceptance of a type of engine that admittedly possesses very great advantages in other ways, but should be regarded as an incentive to improvements that would secure greater economy of coal. The evidence available, however, does not confirm the adverse view, and those familiar with the facts do not admit its truth. One example may be cited as it affects the Canadian service. In June, 1907, it was authoritatively stated that in the Allan liner *Virginian* the reports which had been circulated respecting the excessive coal consumption were unfounded, that the vessel was making passages at speeds of $17\frac{1}{2}$ to $17\frac{3}{4}$ knots, as against the 17 knots estimated, and the rate of coal consumption was really about 1·4 lb. per indicated horse-power which would have been required to attain this speed if the vessel had been fitted with reciprocating engines. This result compares well with the consumption in ordinary passenger steamers running at high speeds in proportion to their dimensions, although in large cargo steamers and vessels of the intermediate type, working under much easier conditions and at very low speeds in proportion to dimensions, lower rates of consumption may be obtained. With these latter vessels the fair comparison is the combination system and not the pure turbine type which is adapted for high speeds.

The crowning triumph of the marine steam turbine up to the present time is to be found in the great Cunard steamships *Lusitania* and *Mauretania*. The passages made this year by the latter ship since she was refitted have been marvellously regular, and the 25 knots average across the Atlantic, which was the maximum contemplated in the agreement between the Government and the Cunard Company, has been continuously exceeded. As one intimately concerned with the design of the *Mauretania*, who has had large experience in ship design, has made a life-long study of the laws of steamship performance, and had the honour of serving on the committee which recommended the employment of turbines in these great ships, the writer ventures to assert that equal results could not possibly have been obtained with reciprocating engines in vessels of the same form and dimensions. Contrary opinions have been expressed, but they have been either based upon incorrect data or have omitted consideration of the fact that in vessels of such great engine-power it was necessary to have time to perfect the organisation of the staff in order to secure uniform conditions of stoking and steam production, and to bring the "human element" into a condition which would ensure the highest degree of efficiency in working the propelling apparatus. This necessity for time and training has been illustrated again and again in the case of new types of Transatlantic steamers, including some which held the record for speed prior to the appearance of the Cunarders. In the *Lusitania* and *Mauretania* the engine-power is fully 60 per cent. greater than that of their swiftest predecessors, yet no similar allowance appears to have been thought necessary by some critics, who assumed that performances on the earlier voyages represented the maximum capabilities of the vessels. Subsequent events have shown this view to be fallacious, and have justified the recommendation of the Turbine Committee and the action of the Cunard directors. Allegations made in regard to excessive coal consumption have also been disproved by experience, and in this respect the anticipations of the committee and of Mr. Parsons have been fully realised.

The marvellous regularity maintained by the *Mauretania* on a long sequence of consecutive Transatlantic passages—made under varying and in many cases very adverse conditions of wind, weather, and sea—illustrates once more, and on an unprecedented scale, the influence which large dimensions have upon the power of maintaining speed at sea. Starting from the eastward passage, beginning on February 3 last, and taking twelve passages (westward and eastward) which followed, the average speed for the thirteen passages, approaching 40,000 sea miles in length, has been $25\frac{1}{2}$ knots; the lowest average speed in the series has been 25·2 knots, the highest average speed 25·88 knots. Many of the winter passages in this series were made in winter weather against strong winds and high seas, which would have considerably reduced the speed of her predecessors, but had small influence on the *Mauretania*. In many instances delays have been caused by fogs.

On seven consecutive passages made since the beginning of last May the average speed of the *Mauretania* in covering about 20,000 sea-miles has been 25·68 knots, the minimum speed for the passage having been 25·62 knots and the maximum 25·88 knots. On her contract trials the *Mauretania* maintained an average speed of 26·04 knots for a distance somewhat exceeding 1200 knots, the steaming time being rather less than forty-eight hours. On the passage when she averaged 25·88 knots, she ran 1215 knots from noon on June 17 to noon on June 19 (about forty-six hours), at an average speed of 26·23 knots, and by noon on June 20 had covered 1817 knots at an average speed of 26·18 knots for sixty-nine hours. The ship has, therefore, surpassed on service her performance on the contract trial.

In view of the foregoing facts and of others of a similar nature, it is reasonable to assume that as experience is enlarged and information is accumulated in regard to forms of propellers likely to prove most efficient in association with quick-running turbines, sensibly improved performances will be obtained. At present, in comparisons made between the efficiency of reciprocating-engined ships and turbine-engined ships, the former have the great advantage attaching to long use and extended experiment; but this is not a permanent advantage, and it may be expected that, good as the position is to which the marine steam turbine has attained in the brief period it has been in practical use, that position will be gradually improved. Whether or not other forms of propelling apparatus in their turn will surpass the steam turbine it would be unwise to predict. Internal-combustion engines are regarded in some quarters as dangerous and probably successful rivals to steam turbines in the near future. Within certain limits of size, internal-combustion engines no doubt answer admirably; but as dimensions and individual power of the engines are increased, the difficulties to be overcome also rapidly increase, and the fact is fully recognised by those having the best knowledge of those types of prime movers. On the whole, therefore, it seems probable that the turbine will not soon be displaced, whatever may happen eventually.

An Imperial Navy.

Three centuries ago a great English seamen and coloniser wrote these words:—

> "Whomsoever commands the sea commands the trade; Whomsoever commands the trade of the world commands the riches of the world, and consequently the world itself."

In these words Sir Walter Raleigh clearly expressed the doctrine of "sea-power," which in recent times has been emphasised by Admiral Mahan of the United States Navy and other writers. Twenty years ago when the movement began which has been followed by an unprecedented series of shipbuilding programmes, great additions to the *personnel* of the Royal Navy and large expenditure on improvements of existing naval bases and the creation of others at important strategical points, the same truth was expressed in a report made by three distinguished Admirals, one of whom, Admiral of the Fleet Sir Frederick Richards, subsequently became First Naval Lord of the Admiralty, and did much to give effect to the policy he had joined in recommending. One passage in this report may be quoted:—"No other nation has any such interest in the maintenance of an undoubted superiority at sea as has England, whose seaboard is her frontier." "England ranks amongst the great Powers of the world by virtue of the naval position she has acquired in the past, and which has never been seriously challenged since the close of the last great war. The defeat of her Navy means to her the loss of India and her Colonies, and of her place amongst the nations."

The "maintenance of an undoubted superiority at sea" in existing circumstances and in face of foreign competition is no easy task, and it is good to know that the Dominions beyond the Seas are ready to take a share of the heavy burden of Empire. In what way effect can best be given to this fundamental idea it is not easy to decide. It is necessarily a matter in which the views of all concerned must be considered, and a policy determined on which shall command hearty support from all portions of the Empire. It may be presumed that the arrangement of such a policy has been the chief object of this year's Defence Conference. The decision which may be reached and the action taken must exercise momentous influence upon the destiny of the Empire. Universal approval has been given to the arrangement for that Conference, and this is a happy augury of its ultimate success in framing a satisfactory scheme for the construction and maintenance of an Imperial Navy. Many valuable suggestions have been made by British and Colonial authorities as to the great lines on which such a scheme should be drawn, but this is not the place to enter upon a discussion of the subject. It may be permitted, however, as a sequence to the preceding remarks on over-sea transport, to remark that the protection of trade routes between the Mother Country and the Dominions beyond the Seas constitutes an essential duty; in the performance of which duty, especially in portions of trade routes adjacent to the Colonies, naval forces maintained by the Colonies may render valuable service. Such a policy in no way infringes the fundamental condition that supremacy at sea ultimately depends upon battle-fleets; while it recognises the fact, which past struggles have demonstrated, that behind and beyond the work of battle-fleets lies the need for adequate protection of commerce and communications. Moreover, it leaves Colonial Governments unfettered in making arrangements for the execution of that portion of the general scheme of defence which they may undertake; and there can be no inconvenience or loss from such independent action provided the scheme of Imperial defence has been considered as a whole, and an understanding reached in regard to the distribution of the work. At present the Mother Country alone possesses experience and means of manufacturing warships and armaments, so that gradual developments, requiring time and experience, will be necessary before the Colonies can become self-supporting in these respects should they desire to do so. On the side of *personnel* and its training also the Royal Navy must be the great school for all parts of the Empire. Finally, the full utilisation of Imperial defensive forces demands the existence of a complete understanding and the pre-arrangement of a common plan of campaign. In order to meet this essential condition there must be an Imperial staff.

The burden of naval defence has hitherto been borne almost entirely by the Mother Country. What the weight has been is hardly realised until the figures for expenditure are examined. As indications of what is involved in creating and maintaining a modern navy of the first class, it may be mentioned that in the ten financial years of the present century (including the current year 1909–10) the total expenditure on the Royal Navy amounts to 328 millions sterling. From 1885 to 1902, during the period the writer occupied the position of Director of Naval Construction and Assistant Controller of the Navy, the total outlay on the 245 ships for the designs of which he was responsible amounted to about 100 millions sterling. The stress of foreign competition and the growth in dimensions and cost of warships is leading to still greater expenditure on the Navy, and it is good to know that Canada, Australia, New Zealand, and South Africa are ready and willing to bear their share of the inevitable burden.

All branches of engineering have been and will be drawn upon freely in the execution of this great task. Mining and metallurgy assist by the production of materials of construction; mechanical and electrical engineers contribute machines and appliances required in shipyards and engine factories, as well as guns, gun-mountings, and mechanical apparatus of all kinds required in modern warships in order to supplement and economise manual power; marine engineers design and construct the propelling apparatus, and constantly endeavour to reduce the proportion of weight and space to power developed; naval architects design and build the ships; constructional engineers are occupied in the provision of docks, harbours, and bases adapted to the requirements of the fleet; and other branches of engineering play important, if less prominent, parts. The progress of invention and discovery is increasing, rapid changes occur unceasingly, the outlay is enormous, the task is never ending, but its performance is essential to the continued well-being of the Empire, and it must and will be performed.

NOTES.

The International Geodetic Association will meet in London on September 21 and following days at the rooms of the Institution of Civil Engineers, Great George Street, Westminster. The permanent commission of the association, consisting of one representative from each contributing country, is constituted as follows:—Belgium, Lieut.-Colonel Gillis; Chile, M. Bertrand; Denmark, Major-General Madsen; France, General Bassot (president); Germany, Prof. Foerster; Great Britain, Sir George Darwin (vice-president); Holland, Prof. H. G. van de Sande Bakhuyzen (perpetual secretary); Hungary, Prof. L. de Bodola von Zagon; Italy, Prof. Celoria; Japan, Dr. Hisashi Terao; Mexico, Sen. Angel Anguiano; Norway, Major-General Per Nissen; Portugal, General the Marquis d'Avila et de Bolama; Russia, General Artomonoff; Spain, Sen. Arrillaga; Sweden, Prof. Rosen; Switzerland, Prof. Gautier; United States, Mr. Tittmann. The Argentine Republic will be represented by Prof. Porro de Somenzi, Roumania by Colonel Rimniceano, India by Colonel Burrard, Egypt by Mr. Keeling, Australia by Mr. G. H. Knibbs. Among the seventy or eighty delegates, other than members of the permanent commission, are Prof. Helmert, chief of the Central Bureau, Potsdam, Prof. Albrecht and Prof. von Seeliger (Germany); Vice-Admiral Ritter v. Kalmar and Major-General von Sterneck (Austria), Lieut-Colonel Bourgeois and M. H. Poincaré (France), Baron Roland Eötvös (Hungary), Prof. Kapteyn (Holland), and Dr. Backlund (Russia). Among the representatives of Great Britain are the Astronomer Royal, Colonel Close, Major Leonard Darwin, Rear-Admiral Field, Sir Archibald Geikie, Sir David Gill, Dr. Glazebrook, Colonel Grant, Major Hills, Captain Lyons, and Colonel Sir William Morris. By command of the King, the delegates are invited to visit Windsor Castle on Saturday, September 25. On Monday, September 27, the meeting will be transferred to Cambridge, where the concluding sessions will be held.

The seventeenth annual exhibition of the Photographic Salon is now open at the Gallery of the Royal Society of Painters in Water Colours, 5A Pall Mall East. As the promoters of this exhibition are interested only in pictorial work, the technician expects to find among the works they have selected for presentation expressions of the most recent ideas as to approved methods, and the finest examples that these methods can furnish. Last year's Photographic Salon included a large number of colour photographs on autochrome plates, but this year there is not a single colour photograph of any kind. This must mean that, in spite of the improvements in the manufacture and in the methods of using plates for colour photography, the results obtained are not generally satisfactory from the artistic point of view. The shortcomings of these plates are well known and appreciated by those who have studied them, but they do offer possibilities of a certain measure of success in the rendering of colour, and we were not prepared for their total exclusion. The one hundred and thirteen pictures hung, selected, presumably, from many hundreds submitted, include examples of many styles and all degrees of merit. They range from a fuzziness that leaves the subject hardly recognisable to the keenest sharpness of definition, from the darkest to the lightest possible, and from those that have large flat patches of an even tint to those that show the most delicate and perfect modelling that can be desired. It is the possibilities of these great varieties of style that are of technical interest. The catalogue is defective in not giving the methods by which the various examples are produced, but we believe that we are correct in saying that the portraits by Mr. E. O. Hoppe are all unsophisticated platinum prints. These, and some of Mr. Frederick H. Evans's exhibits, and the portrait by Mr. Furley Lewis, will be specially instructive to those who print in platinum as showing the rich results obtainable by this method. In addition to the new work, there are nearly thirty examples of photographs by the late David Octavius Hill, made more than sixty years ago. These demonstrate that the vast strides photography has made during the last half-century have tended rather to increase the output and multiply diversity of method than to raise the quality of the work from a pictorial point of view.

By the death of Mr. Thomas Southwell, which took place at his residence in Norwich on September 5, science has lost an amateur naturalist of the very best type, and one who, by the extremely careful and painstaking nature of his work, set an example even to his professional brethren. Moreover, his natural-history studies were not undertaken for the purpose of filling up the time of an idle man, for during the best years of his life Mr. Southwell was in the employ of Gurney's (Barclay's) bank at Norwich, and could study his favourite subject only in the intervals of his professional work. In addition to possessing a great knowledge of the ornithology of his county, Mr. Southwell devoted special attention to whales and whaling, and for a long series of years his annual report in the *Zoologist* on the product of the season's whaling and sealing expedition afforded a mine of valuable information which could be obtained nowhere else. The great value of these reports consists in the fact that the information relating to the British portion of these industries was always at first hand, Mr. Southwell having got in touch with the whaling captains of Peterhead and Dundee. In addition to giving statistics concerning the annual catch of whales and seals, Mr. Southwell studied and collated all the information he could acquire concerning the distribution and migrations of the Greenland right-whale, and was thus enabled to formulate certain important theories on these points. In 1881 he published a small volume on the "Seals and Whales of the British Seas"; and his other writings include the third volume of Stevenson's "Birds of Norfolk," a revised second edition (1890) of Lubbock's "Fauna of Norfolk," Sir Thomas Browne's "Notes and Letters on the Natural History of Norfolk," a "Guide to Norwich Castle Museum," and a paper on the former breeding of the crane in East Anglia. At the time of his death Mr. Southwell was in his seventy-ninth year.

M. SANTOS-DUMONT has accomplished several successful flights with an aëroplane having a supporting surface of only nine square metres. On September 13 he travelled a cross-country distance of about five miles in five minutes upon this machine.

Science announces that the President of the United States has issued a proclamation setting aside the Oregon caves in the Siskiyou National Forest, in the State of Oregon, as a national monument. The area of the reservation is about 480 acres.

THE Paris correspondent of the *Times* announces that the fourth International Aëronautical Congress will be held at Nancy on September 18–23. Major Renard (France) will read a paper on the units of aëronautics and their nomenclature, and will submit a report on the results and lessons of the recent aviation week at Rheims.

MR. F. C. CONSTABLE, Wick Court, near Bristol, sends notes of observations of a remarkable pink glow observed in the direction of the sun between 6.40 p.m. and 6.58 p.m. on September 12. The pink colour seemed to be the same as that observed by him on a steamer journeying from Bombay to Karachi in 1883, a few days after the Krakatoa eruption.

PROF. SILVANUS P. THOMPSON, F.R.S., has consented to become the first president of the Illuminating Engineering Society, and influential support has been received from many distinguished authorities on matters of illumination in this country, on the Continent, and in America. The society will enter upon its opening session in November, and has every reason to hope for a long and prosperous existence. Anyone interested in the objects of the society and desiring to become a member should apply to Mr. L. Gaster, hon. secretary, 32 Victoria Street, London, S.W.

AT the autumn meeting of the Institute of Metals, which will be held at Manchester on October 14 and 15, it is expected that the following papers will be presented:—the constitution and properties of the ternary alloys aluminium-copper-tin, J. H. Andrew and C. A. Edwards; the surface appearance of solders, C. O. Bannister and H. J. Tabor; the technical assay of zinc, H. W. Greenwood; notes on the production of pure spelter, J. S. Glen Primrose; some causes of the corrosion of copper and brass, E. L. Rhead; the elastic breakdown of ductile materials, Prof. C. A. Smith; the copper-zinc alloys—a study of volume changes during solidification, Prof. T. Turner and M. T. Murray.

THE Reale Accademia dei Lincei makes the following announcements:—The royal prize for mathematics is divided equally between Profs. Enriques and Levi-Civita, and that for social and economic sciences is similarly divided between Prof. Rodolfo Benini and Dr. G. Mazzarella. From the Santoro foundation the academy has awarded a prize of 10,000 lire to Prof. Quirino Majorana, for his researches on wireless telephony, which have resulted in communication being established up to distances of 300–400 kilometres or more; in addition, minor awards to Prof. Gabbi, for researches on Malta fever, and Dr. Canovetti, to enable him to continue his experiments on air resistance. From the same benefaction grants have also been made to Profs. Vinassy de Regny and Gortani, for Alpine studies; Prof. Gorini, for investigating diseases of cheese; Prof. Silvestri, noxious insects; Prof. Almagià, study of precipices; the Lombardy commission for seiches on Laghi di Garda and Maggiore; Dr. Abetti, solar physics, in Prof. Hale's observatory. The Carpi prize for experimental physiology is divided between Drs. Baglioni and Lombroso. The late Prof. Sella has bequeathed to the academy a prize of 1000 lire, to be awarded annually to some assistant in an Italian physical laboratory, this being the second gift that the academy has received during the year.

THE seventh annual meeting of the South African Association for the Advancement of Science will be held in Bloemfontein on September 27 to October 2 inclusive, under the presidency of Sir Hamilton Goold-Adams, G.C.M.G. The business of the meeting will be held in three sections as follows:—Section I., astronomy, mathematics, physics, meteorology, geodesy, surveying, engineering, architecture, and geography: president, Prof. W. A. Douglas Rudge, Bloemfontein; Section II., chemistry, bacteriology, geology, botany, mineralogy, zoology, agriculture, forestry, sanitary science: president, Dr. C. F. Juritz, Cape Town; Section III., anthropology, ethnology, education, history, mental science, philology, political economy, sociology, and statistics: president, Mr. Hugh Gunn, Bloemfontein. The second award of the South Africa medal and grant will be made to Dr. Harry Bolus at this meeting. The South African Ornithologists' Union will meet in Bloemfontein at the same time and in the same buildings as the association. A series of lectures, under the auspices of the association, on Darwinism and human life, by Prof. J. Arthur Thomson, is being delivered in South Africa by way of celebrating the Darwin centenary. The honorary general secretaries of the meeting are Dr. J. D. F. Gilchrist, South African College, Cape Town, and Mr. R. T. A. Innes, Government Observatory, Johannesburg.

A LARGE portion of the August number of the *Museums Journal* is taken up by the report of the meeting of the Museums Association held at Maidstone in July. The programme of the meeting included a visit to Ightham to inspect the collection of flint implements brought together by Mr. B. Harrison.

IN the September number of Witherby's *British Birds* Mr. P. H. Barr appears to have disposed effectually of the remarkable idea that the black-headed gull acquires the feature to which it owes its name by means of a mysterious colour-change in the feathers of the head. He has proved that a moult takes place early in the year, usually in February, which embraces, not only the head, but the breast and back, and that at the conclusion of the process, which takes about a week, the black skull-cap is acquired. Occasionally young birds assume the black cap of the breeding plumage while they are still in the immature dress elsewhere.

ACCORDING to Bulletin No. 33 of the Biological Survey of the U.S. Department of Agriculture, which is devoted to the brown rat in the States, serious efforts are being made in North America and Japan to reduce the numbers of this rodent, which is regarded as the worst mammalian pest in the world. So far, however, the campaign has not been crowned with success, the annual destruction of from several hundred thousand to a million head in Japan making no appreciable diminution in its numbers. In the paper before us Mr. D. E. Lantz has given a very full account of the morphology, distribution, migration, and ethology of the rat, with suggestions as to the best means of hunting and trapping, and the elimination of conditions conducive to its rapid increase.

THE Belfast Naturalists' Field Club, the oldest club of the kind in Ireland, has always possessed a strong geological section. An interesting excursion was recently undertaken to the eskers at Dromfane and near Broughshane. The accompanying illustration shows the fine sections that occur in these glacial ridges in co. Antrim. We learn from a report in the *Northern Whig* for August 24 that determinations were made of the source of the material, which proved to be mainly derived from local rocks. The Cainozoic rhyolites of Cloughwater and Ballycloughan were visited later in the day. Rhyolitic lavas are not so limited in the British Isles as the report before us would suggest, since the enormous outpourings in the Snowdon area and in Borrowdale must be borne in mind; but those of Antrim have a thoroughly modern

Gravel Pit, Drumfane, near Ballymena, County Antrim. Photographed by Mr. J. L. S. Jackson.

aspect, and may be compared with types in Hungary or in Mexico. Naturalists in the north of Ireland are fortunate in having established a tradition for good observational work, in which amateurs have played a most important part.

A NICE little question in nomenclature is raised by Dr. Ameghino in a paper published in the *An. Mus. Nat. de Buenos Aires*, vol. xix., pp. 107–209, under the title of "Le *Diprothomo platensis*, un précurseu. de l'homme du Pliocène inférieur de Buénos Aires." It appears that in 1884 the author proposed the generic term Diprothomo for one of the hypothetical ancestors of *Homo sapiens*. Recently Dr. Ameghino obtained from a superficial stratum in Buenos Aires, regarded as of Lower Pliocene age, a calvarium of apparently low type, which in his opinion is generically distinct from Homo. For this supposed new genus he proposes to adopt the name Diprothomo with the new affix platensis. As having no tangible type, "Diprothomo" will probably be regarded as a *nomen nudum*, and if this be so many naturalists will be likely to say that it cannot be employed in a new sense. After restoring the skull to his own satisfaction, Dr. Ameghino concludes that it affords further evidence of his view as to the South American origin of the human race. Additional testimony in favour of this opinion is stated to be afforded by the lower jaw of a child with the angle inflected in marsupial fashion. The extinct South American genus Microbiotherium is regarded as the *fons et origo* of most mammals, and from this sprang Clenialites, the ancestor of the Primates.

THE *West Australian* newspaper of July 7 contains the report of an address, by Dr. J. B. Cleland, read before the West Australian Natural History Society at its annual meeting held at Perth. The subject was the Australian fauna and flora, and especially the effects produced on these by foreign invaders. After alluding to the rabbit-pest, the author stated that the inexcusable introduction of the fox for sporting purposes has led to its rapid multiplication in parts of Victoria, South Australia, &c., and the loss of many sheep. Cats have become wild, and near Perth, for instance, fierce and powerful in build, feeding on the native birds and smaller animals and rabbits where these are present. The Norway rat and the black rat seem not to have extended beyond man's more immediate surroundings. The dominant rat in Perth is the sociable black rat, the larger Norway rat being hitherto obtained only from the neighbourhood of the wharves at Fremantle and Perth. It is otherwise in Sydney, where both are found together in the town. These rats have brought with them several species of fleas, of which some will bite man when their original host is absent (*e.g.* has died). By this means plague, introduced by rats, is communicated to man. The sparrow, the starling, the goldfinch, the blackbird, and the Indian minah have all come to stay. Some of these eat much grain and fruit, while all tend to drive away and usurp the place of the beautiful, interesting, and useful native birds.

DR. E. JANCZEWSKI contributes to the *Bulletin international de l'Académie des Sciences de Cracovie* (No. 6) a short supplement to his monograph on the genus Ribes. In the same part Mr. C. Rouppert presents a revision of the discomycetous fungus Sphærosoma. This genus, of which a new species was discovered by the author, has been variously classed under the Pezizaceæ, Helvellaceæ, and Tuberaceæ. It is here referred to the Helvellaceæ, but is regarded as a connecting link with the other two families.

THE latest issue of the *Kew Bulletin* (No. 7) opens with a review of the known species of Impatiens from the Philippine Islands, communicated by Sir J. D. Hooker, which forms a continuation of the extensive survey of the genus, based on collections from India, China, and the Malayan region. Out of twenty-five species, collected chiefly in the neighbourhood of Luzon, only two agree with previously determined species. The author is of opinion that further exploration will lead to the discovery of many more species. In the same number there is published a decade of Diagnoses Africanæ (No. xxx.), which includes the type of a new liliaceous genus, Neodregea, allied to Dipidax.

IT will add to the general estimation of the common cruciferous plant, the shepherd's purse, when it is realised that the species can be segregated into several elementary species or biotypes. The latest investigation, undertaken by Mr. G. H. Shull at the Station for Experimental Evolution of the Carnegie Institution of Washington, and described in Publication No. 112 of the institution, bears evidence with regard to the existence of at least four biotypes which breed true under ordinary conditions and can readily be crossed; they are distinguished by characteristic lobings of the leaf. The author has also investigated the type known as *Bursa* (*Capsella*) *Heegeri*, which bears round seed capsules; this plant was found in the market-place at Landau, Germany, but has been lost except under cultivation.

BLACK spots varying in size from 1/10-inch to 3/8-inch in diameter are occasionally noticed on chilled beef. Dr. Klein has investigated their nature, and finds them to be caused by the mycelium of a fungus, an oidium, which is quite harmless and does not alter the meat beyond their limits (Report to the Frozen Meat Trade Association).

AN interesting contribution to the September number of *Travel and Exploration* is an account, by a writer calling himself "Pousse Caillou," of the region known as Changchenmo, the home of the Tibetan antelope (*Pantholops hodgsoni*) and the *Ovis ammon*, which lies north-east of Leh, on the Kashmir-Turkestan frontier. Here we find seventy or eighty miles of the most utterly forsaken country which can be imagined. The lower volcanic hills, broken into Gothic pinnacles, are backed by a coal-black precipice, featureless and rigid in outline, while the intervening valleys of pure sand are swept by bitterly cold winds. Game preservation is more rigidly enforced even than in Ladakh, only six licences for shooting being granted annually, and the bag of antelope is limited to six specimens. The writer vividly describes the difficulty of shooting this shy animal, the success of the stalk being often interfered with by the appearance of the kyang, half-wild horse or ass, which roams wild on these plateaux.

THE report of the committee on ancient earthworks and fortified enclosures, prepared for presentation to the Congress of Archæological Societies for the current year, presents no features of startling novelty. Measures for protection of sites have been successful in the cases of Maiden Castle, Dorset; Thetford Castle Meadow and Hill, Norfolk; Stokeleigh Camp, on the Somerset side of the Avon; White Barrow, Wilts; the earthwork at Selsea; the old landmarks of Epping Forest; and Pendina's Camp, Cardiganshire. On the other hand, the committee has to report that in many cases the laying out of golf courses has caused the mutilation of ancient ramparts and ditches. The discovery of a portion of the Roman Wall of London on the site of Christ's Hospital; excavations at Caerwent and Caerleon, Caersws, in Montgomeryshire, and Elslack, near Skipton, in Yorkshire, were the most important operations of the year. The bibliography of current literature on the subject is a useful addition to the report of this committee.

IT very rarely happens that three well-developed typhoons occur within the space of ten days; in the Bulletin of the Manila Weather Bureau for October, 1908, Señor Coronas gives an excellent discussion, with charts, of three such cyclonic storms which reached the central and northern parts of Luzon on October 4, 8, and 13, accompanied by photographs of the destruction caused. They all appear to have originated in the vicinity of the Western Caroline Islands, and to have travelled in a W.N.W. direction; on reaching the archipelago they were considerably modified in shape and extent, and crossed the China Sea in a somewhat more northerly direction. The rates of translation, during which the wind at times reached hurricane force, varied considerably, in one instance attaining the unusual speed of twenty-one miles an hour, but on reaching the China Sea the velocity of translation considerably diminished in all cases. The barometric fall was very rapid, the minimum at one station being 27·99 inches, although it was some fifteen miles from the vortex. Forewarned by valuable observations from Guam (Ladrone Islands) and Yap (Western Caroline Islands), the Manila Observatory was able to give timely notice in each case to its own stations and to foreign services.

SOME interesting results are described and illustrated by Dr. A. S. King in No. 1, vol. xxx., of the *Astrophysical Journal*, where he publishes a paper on the Zeeman effect in the spectrum of titanium. The experiments were carried out at the Mount Wilson Observatory, field strengths of 12,500, 13,800, and 18,400 gausses being employed between the poles of a Du Bois electromagnet; the dispersion used was, generally, such that there were 0·93 Angströms per mm., the spectrograph being the 13 feet vertical Littrow. A table, containing nearly 300 lines, between λ 3904 and λ 6556, gives a summary of the results, and shows that the great majority of titanium lines are resolved into triplets. Notable among the exceptions are the lines at λ 4527·49 and λ 4544·86, each of which is resolved into seven components, and shows a regularity of structure identical in both; the line at λ 4281·53 has eight components. Two sextets and three quintuplets also show a certain regularity in their separations, which is not shown, however, by the lines having four components. Special attention was paid to the forty-four lines given in Lockyer's list of "enhanced" titanium lines, which do not appear to fall in any special class; thirty-five are triple, six are quadruple, one quintuple, and two sextuple. Two plates, which accompany the paper, beautifully illustrate some of the more interesting separations.

ATTENTION is directed by Mr. G. N. Huntly, in a brief paper in the Journal of the Society of Chemical Industry, to a curious case of corrosion occurring in a stand-by boiler at the generating station of the London Electric Supply Corporation. The corrosion had been noticed two years previously, but attempts to check it by the addition of caustic soda to the boiler-water had proved unavailing. The interior of the boiler showed numerous blisters up to 30 mm. in diameter, most of them near the water-level; each blister contained a clear liquid with a black powder in suspension, and a pit was observed to be forming in the centre of each blister. Analysis showed the presence of ferrous sulphate and free sulphuric acid in the liquid contents, although the boiler fluid was alkaline and contained little sulphur. The action was traced to manganese sulphide in the steel, which had become oxidised with formation of sulphuric acid; as the water in the boiler was quiet, the acid remained trapped behind a film of rust, and acid corrosion could thus take place in an alkaline medium, the oxygen required to convert the sulphur into acid penetrating the blister more readily than the alkali of the water. Addition of sodium arsenite to the boiler-water in place of caustic soda completely stopped the trouble, perhaps by eliminating the dissolved oxygen. These experiments confirm the growing impression that the injurious effects of sulphur in steel cannot be wholly removed by the addition of manganese; so far from being harmless, the manganese sulphide appears to be a dangerous constituent, leading to fractures as well as to corrosion.

PROF. O. LEHMANN, of Carlsruhe, who is so well known for his work on liquid crystals, has done a great service to those wishing to repeat any of the beautiful experiments which can be performed with these bodies by giving, in the *Physikalische Zeitschrift* for August 15, detailed descriptions of thirty-two of the most convenient and suitable experiments to perform during a lecture on the subject.

THE *Physical Review* for July contains the second of a series of communications from Mr. G. W. Pierce, of the Jefferson Physical Laboratory of Harvard, on the behaviour of rectifiers of alternating electric currents such as are used as detectors of electric waves. In the present case electrolytic rectifiers have been studied by the aid of the Braun tube oscillograph, and the author finds that the theory of electrolytic polarisation is capable of explaining all the facts observed, if the slight polarisation capacity of the small platinum electrode of the rectifier is taken into account. The detector, when polarised by the superposition of a direct current, is almost perfect, that is, the current it produces is nearly all in one direction. It may therefore be compared with the crystal rectifiers dealt with in the author's first paper. The author proposes to examine the behaviour of vacuum-tube rectifiers before giving definite shape to any theory of crystal rectifiers.

THE *Century Magazine* for September contains two interesting engineering articles. The first of these deals with the great aqueduct now being constructed for bringing water from the Catskill Mountains to the City of New York. This aqueduct will be ninety-two miles long, and, to supply the 500,000,000 gallons required daily, more than 600 square miles of collection area must be utilised and several large reservoirs constructed. The article is well illustrated with photographs, sections, and maps. The second article is a first instalment giving an account of Fulton's invention of the steam-boat. While many engineers in this and other countries experimented towards the end of the eighteenth century, Fulton was the first to secure real success. However, it may comfort some of our British patriots to be reminded that the American vessel was fitted with one of Watt's engines, constructed in Birmingham and shipped to America. The article contains many original documents and drawings, and is of interest as showing that the modern troubles which many inventors have to face in working out their schemes and in overcoming red tape had their counterpart more than a century ago.

THE results of some experiments on solid steel bars under combined stress are given in an article in *Engineering* for August 20. The author, Mr. C. A. Smith, of the East London College, University of London, has already presented useful work in confirmation of Guest's law, and in this series has loaded solid specimens in compression and torsion, and also in tension and torsion. The necessity for doing this will be evident when it is remembered that Lord Kelvin suggested that, as a tension load lowers the torsional yield point, a compression load would raise it. Four different grades of steel were experimented on, of carbon content ranging from 0·09 per cent. to 0·48 per cent. Under combined compression and torsion, the maximum principal stress at yielding varied from 19,800 lb. to 36,500 lb. per square inch, while the maximum shear stress varied from 18,900 lb. to 20,400 lb. per square inch, the average variation from the mean of the latter stress being 2·16 per cent. Another series shows an average variation of the maximum shear stress from the mean of 1·87 per cent. only, this series including tests in tension, compression, torsion, and combined stress. Taking all the results given, the average variation from the mean of the maximum shear stress is about 2 per cent. The importance of these tests will be understood when the difficulties of testing solid specimens under combined stress are remembered, difficulties which seem to have been overcome successfully by use of the author's sphingometer, by means of which the tension and compression measurements are taken in three planes.

REFERRING to the letters published in NATURE of July 22 and 29 in regard to sonorous or musical sands, Prof. J. C. Branner, Stanford University, California, writes to direct attention to articles on this subject by Profs. H. C. Bolton and Alexis A. Julien, published in the Proceedings of the American Association for the Advancement of Science (vol. xxxii., pp. 251–2; vol. xxxiii., pp. 408–13; vol. xxxviii., pp. 137–40). We may remind Prof. Branner that the subject was discussed in NATURE by Prof. Bolton and Mr. Carus-Wilson twenty years ago (vols. xxxix.–xlvi.).

A NEW edition of Mr. P. H. L'Estrange's "Junior Course of Comparative Geography" has been published by Messrs. George Philip and Son, Ltd. Part v. of this book, too, has now been issued separately at the price of 10*d*. In the new edition all the maps of the original work have been reproduced in black and white, the names and symbols required for this course only being retained. The book has been revised throughout, and additional matter added, for example, on local geography.

OUR ASTRONOMICAL COLUMN.

HALLEY'S COMET RE-DISCOVERED.—To Prof. Max Wolf belongs the honour of re-discovering Halley's comet after an absence of more than seventy years. A telegram from the Kiel Centralstelle announces that the comet was discovered at the Königstuhl Observatory on September 11. Its position at 14h. 7·3m. (Königstuhl M.T.) was

R.A. = 6h. 18m. 12s., dec. = +17° 11′,

and its magnitude 16·0.

Mr. Crommelin's ephemeris position for September 11·9 was

R.A. = 6h. 18m. 4s., dec. +17° 16′,

so to the Greenwich calculators, Messrs. Cowell and Crommelin, must be given the credit of having prepared an ephemeris which agrees remarkably well with the observation. At present the comet is approaching the northern limit of Orion from the south-western region of Gemini, forming nearly a straight line with the stars γ Geminorum and 143 OΣ, the three objects being about equally spaced in the order γ—143 OΣ—comet. The following is an extract from Mr. Crommelin's ephemeris:—September 25·7, 6h. 18·5m., +17° 11′; October 9·1, 6h. 14·6m., +17° 8′; October 22·0, 6h. 4·9m., +17° 2′.

OBSERVATIONS OF MARS.—Some interesting observations of changes, during August, in the areas surrounding the southern ice-cap of Mars are reported by MM. Antoniadi, Quénisset, and Jarry-Desloges in the September number of the *Bulletin de la Société astronomique de France* (pp. 385–94). M. Antoniadi, observing at Juvisy on August 12, 14, and 16, found the planetary features so pale as to be almost unrecognisable. On August 15 the Orontes was suspected to be, and the Euphrates was certainly, double, whilst, later, the Amenthes was seen to be broad and diffuse. M. Antoniadi suggests that the pale greyness of the darker regions may be due to the interposition of very light clouds or of a mist in the Martian atmosphere. Both MM. Quénisset and Jarry-Desloges also direct attention to the unusual paleness of the dark regions of the planet during the past few weeks, and each account is illustrated by reproductions from the original drawings showing various aspects of the planet.

A LARGE GROUP OF SUN-SPOTS.—Despite the fact that we are now drawing near to a sun-spot minimum, the solar disc has, during the past fortnight, exhibited an extensive group of spots. An observation on August 28 showed a bright patch of faculæ some distance south of the equator on the eastern limb, and on the following day a small spot was observed near the limb to the north of this. Observations on September 6 showed that there was a group of small spots in about the latitude of the previously observed faculæ, and this developed until, on September 11, it was a diamond-shaped group, of medium-sized spots, of which the longest diagonal was about one-sixth the length of the sun's diameter; each of the four main spots was surrounded by a number of smaller nuclei.

THE TRANSVAAL OBSERVATORY.—From a note in the *Observatory* (No. 413, p. 369) we learn that the Transvaal Government, on behalf of the Government observatory, has accepted the gift of a photographic astronomical telescope from Mr. Franklin Adams. The triple-objective is of 10 inches aperture, and made by Messrs. Cooke and Sons. Two guiding telescopes, each of 6 inches diameter, accompany the main instrument. The telescope is erected, and is to be employed mainly in assisting Prof. Kapteyn, in his studies of the construction of the sidereal universe, by securing photographs of the southern heavens.

ARTIFICIAL IMITATION OF LUNAR LANDSCAPE.—By cooling the slag from an iron-ore, smelted in a furnace and run off at a temperature of about 1100° C., Mr. Paul Fuchs succeeded in obtaining a surface structure which appears to be a very good imitation, in miniature, of a typical lunar landscape. The cooling was done with water applied in various ways, and produced craters, mountains, and plains according to the conditions of the slag and of the cooling. Photographs of the results are reproduced on a plate accompanying No. 4348 of the *Astronomische Nachrichten*, wherein Mr. Fuchs describes his experiments.

TEMPERATURE AND PRESSURE CONDITIONS IN THE SOLAR ATMOSPHERE.—Two interesting letters dealing with the conditions obtaining in the solar atmospheres appear in No. 413 of the *Observatory* (September, pp. 359–63).

In the first, Mr. Buss returns to the question of the radial motions in sun-spots exhibited by Mr. Evershed's spectrograms, and shows how they may be interpreted to indicate that the visible umbral area of a spot is caused by the efflux of material from within rather than the influx of cooler matter from above. The facts that spots often endure for months, and that Mr. Evershed finds that the radial motions are confined to the "reversing layer," *i.e.* to the lower levels of the sun's general atmosphere, are quoted as supporting this view; the vortices are effects of the outrush. This idea of the spots being produced by effluence leads to the sequel that the vapours of the actual spot must be at a higher temperature, whereas the observations of Sir Norman Lockyer and others show the reverse. To overcome this difficulty Mr. Buss suggests that the spectrum observed is that of the vapours high above the visual umbral level, and that, could we but observe the unveiled spectrum of the umbra itself, we would find it to be a bright-line spectrum.

In the second letter Mr. Evershed continues the discussion with Prof. Whittaker regarding pressure in the "reversing layer." After quoting experimental evidence to show that pressure-shifts are apparently independent of the manner in which luminosity is produced, Mr. Evershed points to the fact that the spectrum of the "reversing layer" consists of bright lines, as demonstrating that there is no enormous pressure on the emitting vapours; otherwise one would expect a more continuous spectrum. Finally, he states that measures of spot spectra, made at Kodaikánal, do exhibit small, differential pressure-shifts; the most affected lines are slightly displaced, relatively, towards the violet, thus indicating a pressure in the umbræ of about one-third of an atmosphere less than in the surrounding regions. Further details of these results are to be published shortly.

PARALLAX OF THE DOUBLE STAR Σ 2398.—In No. 4348 of the *Astronomische Nachrichten* (p. 63), Dr. Karl Bohlin announces that the reduction of photographic observations, made at the Stockholm Observatory during 1907–8, shows that the parallax of the double star Σ 2398 is 0·484″. This star thus becomes the nearest known neighbour, in the northern sky, to the solar system, its distance being 426,000 astronomical units, or 6·7 light-years. A previous observation by Lamp, at Kiel in 1883–7, gave the parallax as 0·353″.

OUR FOOD FROM THE WATERS.[1]

AT the last meeting of the British Association in Canada (Toronto, 1897) I was able to lay before Section D a preliminary account of the results of running sea-water through four silk tow-nets of different degrees of fineness continuously day and night during the voyage from Liverpool to Quebec. During the eight days' traverse of the North Atlantic, the nets were emptied and the contents examined morning and evening, so that each such gathering was approximately a twelve-hours' catch, and each day and each night of the voyage was represented by four gatherings. This method of collecting samples of the surface fauna of the sea in any required quantity per day or hour from an ocean liner going at full speed was suggested to me by Sir John Murray of the *Challenger* Expedition, and was first practised, I believe, by Murray himself in crossing the Atlantic. I have since been able to make similar traverses of several of the great oceans, in addition to the North Atlantic, namely, twice across the equator and through the South Atlantic, between England and South Africa, and four times through the Mediterranean, the Red Sea, and the Indian Ocean to Ceylon; and no doubt other naturalists have done much the same. The method is simple, effective, and inexpensive; and the gatherings, if taken continuously, give a series of samples amounting to a section through the surface layer of the sea, a certain volume of water being pumped in continuously through the bottom of the ship, and strained through the fine silk nets, the mesh of which may be one two-hundredth of an inch across, before passing out into the sea again. In examining with a microscope such a series of gatherings across an ocean, two facts are brought prominently before the mind: (1) the constant presence of a certain amount of minute living things; (2) the very great variation in the quantity and in the nature of these organisms.

Such gatherings taken continuously from an ocean liner give, however, information only in regard to the surface fauna and flora of the sea, including many organisms of fundamental importance to man as the immediate or the ultimate food of fishes and whales and other useful animals.

It was therefore a great advance in planktology when Prof. Victor Hensen (1887) introduced his vertical, quantitative nets, which could be lowered down and drawn up through any required zones of the water. The highly original ideas and the ingenious methods of Hensen and his colleagues of the Kiel School of Planktology—whether all the conclusions which have been drawn from their results be accepted or not—have at the least inaugurated a new epoch in such oceanographic work, and have inspired a large number of disciples, critics, and workers in most civilised countries, with the result that the distribution of minute organisms in the oceans and the fresh waters of the globe is now much more fully known than was the case twenty, or even ten, years ago. But perhaps the dominant feeling on the part of those engaged in this work is that, notwithstanding all this activity in research and the mass of published literature which it has given rise to, much still remains to be done, and that the planktologist is still face to face with some of the most important unsolved problems of biology.

It is only possible in an address such as this to select a few points for demonstration and for criticism—the latter not with any intention of disparaging the stimulating work that has been done, but rather with the view of emphasising the difficulties, of deprecating premature conclusions, and of advocating more minute and more constant observations.

The fundamental ideas of Hensen were that the plankton, or assemblage of more or less minute drifting

[1] Evening discourse delivered before the British Association at Winnipeg on August 31 by Prof. W. A. Herdman, F.R.S.

organisms (both animals and plants) in the sea, is uniformly distributed over an area where the physical conditions are approximately the same, and that by taking a comparatively small number of samples it would be possible to calculate the quantity of plankton contained at the time of observation in a given sea area, and to trace the changes of this plankton both in space and time. This was a sufficiently grand conception, and it has been of great service to science by stimulating many workers to further research. In order to obtain answers to the problems before him, Hensen devised nets of the finest silk of about 6000 meshes in the square centimetre, to be hauled up from the bottom to the surface, and having their constants determined so that it is known what volume of water passes through the net under certain conditions, and yields a certain quantity of plankton.

Now if this constancy of distribution postulated by Hensen could be relied upon over considerable areas of the sea, far-reaching conclusions, having important bearings upon fisheries questions, might be arrived at; and such have, in fact, been put forward by the Kiel planktologists and their followers—such as the calculation by Hensen and Apstein that the North Sea in the spring of 1895 contained at least 157 billions of the eggs and larvæ of certain edible fish; and from this figure and the average numbers of eggs produced by the fish, their further computation of the total number of the mature fish population which produced the eggs—a grand conclusion, but one based upon only 158 samples, taken in the proportion of one square metre sampled for each 3,465,968 square metres of sea. Or, again, Hensen's estimation, from 120 samples, of the number of certain kinds of fish eggs in a part of the West Baltic, from which, by comparing with the number[1] of such eggs that would normally be produced by the fish captured in that area, he arrived at the conclusion that the fisherman catches about one-fourth of the total fish population—possibly a correct approximation, though differing considerably from estimates that have been made for the North Sea.

Such generalisations are most attractive, and if it can be established that they are based upon sufficiently trustworthy data, their practical utility to man in connection with sea-fishery legislation may be very great. But the comparatively small number of the samples, and the observed irregularity in the distribution of the plankton (containing, for example, the fish eggs) over wide areas, such as the North Sea, leave the impression that further observations are required before such conclusions can be accepted as established.

Of the criticisms that have appeared in Germany, in the United States and elsewhere, the two most fundamental are:—(1) that the samples are inadequate; and (2) that there is no such constancy and regularity in distribution as Hensen and some others have supposed. It has been shown by Kofoid, by Lohmann, and by others that there are imperfections in the methods which were not at first realised, and that in some circumstances anything from 50 to 98 per cent. of the more minute organisms of the plankton may escape capture by the finest silk quantitative nets. The mesh of the silk is 1/200th inch across, but many of the organisms are only 1/3000th inch in diameter, and so can readily escape.

Other methods have been devised to supplement the Hensen nets, such as the filtering of water pumped up through hose-pipes let down to known depths, and also the microscopic examination in the laboratory of the centrifuged contents of comparatively small samples of water obtained by means of closing water-bottles from various zones in the ocean. But even if deficiencies in the nets be thus made good by supplementary methods, and be allowed for in the calculations, there still remains the second and more fundamental source of error, namely, unequal distribution of the organisms in the water; and in regard to this a large amount of evidence has now been accumulated, since the time when Darwin, during the voyage of the *Beagle* on March 18, 1832, noticed off the coast of South America vast tracts of water discoloured by the minute floating alga *Trichodesmium erythraeum*, which is said to have given its name to the Red Sea, and which Captain Cook's sailors in the previous century called "sea-sawdust." Many other naturalists since have seen the same phenomenon, caused both by this and by other organisms. It must be of common occurrence, and is widespread in the oceans, and it will be admitted that a quantitative net hauled vertically through such a trichodesmium bank would give entirely different results from a haul taken, it might be, only a mile or two away, in water under, so far as can be determined, the same physical conditions, but free from Trichodesmium.

[1] It is probable that too high a figure was taken for this.

Nine nations bordering the north-west seas of Europe, some seven or eight years ago, engaged in a joint scheme of biological and hydrographical investigation, mainly in the North Sea, with the declared object of throwing light upon fundamental facts bearing on the economic problems of the fisheries. One important part of their programme was to test the quantity, distribution, and variation of the plankton by means of periodic observations undertaken four times in the year (February, May, August, and November) at certain fixed points in the sea. Many biologists considered that these periods were too few and the chosen stations too far apart to give trustworthy results. It is possible that even the original promoters of the scheme would now share that view, and the opinion has recently been published by the American planktologist, C. A. Kofoid—than whom no one is better entitled, from his own detailed and exact work, to express an authoritative verdict—that certain recent observations "can but reveal the futility of the plankton programme of the International Commission for the investigation of the sea. The quarterly examinations of this programme will, doubtless, yield some facts of value, but they are truly inadequate to give any trustworthy view of the amount and course of plankton production in the sea."[1] That is the latest pronouncement on the subject, made by a neighbour of yours to the south, who has probably devoted more time and care to detailed plankton studies than anyone else on this continent.

It is evident that before we can base far-reaching generalisations upon our plankton samples, a minute study of the distribution of life in both marine and fresh waters at very frequent intervals throughout the year should be undertaken. Kofoid has made such a minute study of the lakes and streams of Illinois, and similar intensive work is now being carried out at several localities in Europe.

Too little attention has been paid in the past to the distribution of many animals *in swarms*, some parts of the sea being crowded and neighbouring parts being destitute of such forms, and this not merely round coasts and in the narrow seas, but also in the open ocean. For example, some species of Copepoda and other small crustacea occur notably in dense crowds, and are not universally distributed. This is true also of some of the diatoms, and also of larger organisms. Many naturalists have remarked upon the banks of Trichodesmium, of Medusæ and Siphonophora, of Salpæ, of Pteropods, of Peridinians, and of other common constituents of the plankton. Cleve's classification into Tricho-Plankton (Arctic), Styli-Plankton (temperate), and Desmo-Plankton (tropical) depends upon the existence of such vast swarms of particular organisms in masses of water coming into the North Atlantic from different sources.

It is possible that in some parts of the ocean, far from land, the plankton may be distributed with the uniformity supposed by Hensen. It is important to recognise that at least three classes of locality exist in the sea in relation to distribution of plankton:—

(1) There are estuaries and coastal waters where there are usually strong tidal and other local currents, with rapid changes of conditions, and where the plankton is largely influenced by its proximity to land.

(2) There are considerable sea areas, such as the centre of the North Sea and the centre of the Irish Sea, where the plankton is removed from coastal conditions, but is influenced by various factors which cause great irregularity in its distribution. These are the localities[2] of the greatest economic importance to man, and to which attention should especially be directed.

(3) There are large oceanic areas in which there may

[1] "Internationale Revue der Hydrobiologie und Hydrographie," vol. i. p. 846, December, 1908.

[2] See Dakin, Trans. Biol. Soc. Liverpool, xxii., p. 514.

be uniformity of conditions, but it ought to be recognised that such regions are not those in which the plankton is of most importance to men. The great fisheries of the world, such as those of the North Sea, the cod fishery in Norway, and those on the Newfoundland Banks, are not in mid-ocean, but are in areas round the continents, where the plankton is irregular in its distribution.

As an example of a locality of the second type, showing seasonal, horizontal, and vertical differences in the distribution of the plankton, we may take the centre of the Irish Sea, off the south end of the Isle of Man. Here, as in other localities which have been investigated, the Phyto-Plankton is found to increase greatly about the time of the vernal equinox, so as to cause a maximum, largely composed of Diatoms, at a period ranging from the end of March to some time in May—this year to May 28, in the Irish Sea. Towards the end of this period the eggs of most of the edible fishes are hatching as larvæ.

This Diatom maximum is followed by an increase in the Copepoda (minute crustacea), which lasts for a considerable time during the early summer, and as the fish larvæ and the Copepoda increase there is a rapid falling off in Diatoms. Less marked maxima of both Diatoms and Copepoda may occur again about the time of the autumnal equinox. These two groups—the Diatoms and the Copepoda—are the most important economic constituents in the plankton. A few examples showing their importance to man may be given:—Man eats the oyster and the American clam, and these shell-fish feed upon Diatoms. Man feeds upon the cod, which in its turn may feed on the whiting, and that on the sprat, and the sprat on Copepoda, while the Copepoda feed upon Peridinians and Diatoms; or the cod may feed upon crabs, which in turn eat "worms," and these feed upon smaller forms which are nourished by the Diatoms. Or, again, man eats the mackerel, which may feed upon young herring, and these upon Copepoda, and the Copepoda again upon Diatoms. All such chains of food matters from the sea seem to bring one through the Copepoda to the Diatoms, which may be regarded as the ultimate "producers" of food in the ocean. Thus our living food from the waters of the globe may be said to be the Diatoms and other microscopic organisms as much as the fishes.

Two years ago, at the Leicester meeting of the British Association, I showed that if an intensive study of a small area be made, hauls being taken, not once a quarter or once a month, but at the rate of ten or twelve a day, abundant evidence will be obtained as to (1) variations in the distribution of the organisms, and (2) irregularities in the action of the nets. Great care is necessary in order to ensure that hauls intended for comparison are really comparable. Two years' additional work since in the same locality, off the south end of the Isle of Man, has only confirmed these results, viz. that the plankton is liable to be very unequally distributed over the depths, the localities, and the dates. One net may encounter a swarm of organisms which a neighbouring net escapes, and a sample taken on one day may be very different in quantity from a sample taken under the same conditions next day. If an observer were to take quarterly, or even monthly, samples of the plankton, he might obtain very different results according to the date of his visit. For example, on three successive weeks about the end of September he might find evidence for as many different far-reaching views as to the composition of the plankton in that part of the Irish Sea. Consequently, hauls taken many miles apart and repeated only at intervals of months can scarcely give any sure foundation for calculations as to the population of wide sea areas. It seems, from our present knowledge, that uniform hydrographic conditions do not determine a uniform distribution of plankton.

These conclusions need not lead us to be discouraged as to the ultimate success of scientific methods in solving world-wide plankton and fisheries problems, but they suggest that it might be wise to secure by detailed local work a firm foundation upon which to build, and to ascertain more accurately the representative value of our samples before we base conclusions upon them.

I do not doubt that in limited, circumscribed areas of water, in the case of organisms that reproduce with great rapidity, the plankton becomes more uniformly distributed, and a comparatively small number of samples may then be fairly representative of the whole. That is probably more or less the case with fresh-water lakes, and I have noticed it in Port Erin Bay in the case of Diatoms. In spring, and again in autumn, when suitable weather occurs, as it did two years ago at the end of September, the Diatoms may increase enormously, and in such circumstances they seem to be very evenly spread over all parts and to pervade the water to some depth; but that is emphatically *not* the case with the Copepoda and other constituents of the plankton, and it was not the case even with the Diatoms during the succeeding year.

I have published elsewhere an observation that showed very definite limitation of a large swarm of crab Zoëas, so that none were present in one net while in another adjacent haul they multiplied several times the bulk of the catch and introduced a new animal in enormous numbers. Had two expeditions taken samples that evening at what might well be considered as the same station, but a few hundred yards apart, they might have arrived at very different conclusions as to the constitution of the plankton in that part of the ocean.

It is possible to obtain a great deal of interesting information in regard to the "hylokinesis" of the sea without attempting a numerical accuracy which is not yet attainable. The details of measurement of catches and of computations of organisms become useless, and the exact figures are non-significant, if the hauls from which they are derived are not really comparable with one another and the samples obtained are not adequately representative of nature. If the stations are so far apart and the dates are so distant that the samples represent little more than themselves, if the observations are liable to be affected by any incidental factor which does not apply to the entire area, then the results may be so erroneous as to be useless, or worse than useless, since they may lead to deceptive conclusions. It is obvious that we must make an intensive study of small areas before we draw conclusions in regard to relatively large regions, such as the North Sea or the Atlantic Ocean. Our plankton methods are not yet accurate enough to permit of conclusions being drawn as to the number of any species in the sea.

The factors causing the seasonal and other variations in the plankton already pointed out may be grouped under three heads, as follows:—

(1) The sequence of the stages in the normal life-history of the different organisms.

(2) Irregularities introduced by the interactions of the different organisms.

(3) More or less periodic abnormalities in either time or abundance caused by the physical changes in the sea, which may be grouped together as "weather."

These are all obvious factors in the problem, and the constitution of the plankton from time to time throughout the year must be due to their interaction. The difficulty is to disengage them from one another, so as to determine the action of each separately.

Amongst the physical conditions coming under the third heading, the temperature of the sea is usually given a very prominent place. There is only time to allude here to one aspect of this matter.

It is often said that tropical and sub-tropical seas are relatively poor in plankton, while the colder Polar regions are rich. In fishing plankton continuously across the Atlantic it is easy from the collections alone to tell when the ship passes from the warmer Gulf Stream area into the colder Labrador current. This is the reverse of what we find on land, where luxuriant vegetation and abundance of animal life are characteristic of the tropics in contrast to the bare and comparatively lifeless condition of the Arctic regions. Brandt has made the ingenious suggestion that the explanation of this phenomenon is that the higher temperature in tropical seas favours the action of denitrifying bacteria, which therefore flourish to such an extent in tropical waters as seriously to diminish the supply of nitrogen food and so limit the production of plankton. Loeb,[1] on the other hand, has recently revived the view of Murray, that the low temperature in Arctic waters so

[1] "Darwin and Modern Science" (Cambridge, 1909), p. 247.

reduces the rate of all metabolic processes, and increases the length of life, that we have in the more abundant plankton of the colder waters several generations living on side by side, whereas in the tropics with more rapid metabolism they would have died and disappeared. The temperature of the sea-water, however, appears to have little or no effect in determining the great vernal maximum of Phyto-Plankton.

Considering the facts of photosynthesis, there is much to be said in favour of the view that the development, and possibly also the larger movements of the plankton, are influenced by the amount of sunlight, quite apart from any temperature effect.

Bullen[1] showed the correlation in 1903–7 between the mackerel catches in May and the amount of Copepod plankton in the same sea. The food of these Copepoda has been shown by Dakin to be largely Phyto-Plankton, and Allen has lately[2] correlated the average mackerel catch per boat in May with the hours of sunshine in the previous quarter of the year, thus establishing the following connection between the food of man and the weather:—Mackerel—Copepoda—Diatoms—Sunshine. One more example of the influence of light may be given. Kofoid has shown that the plankton of the Illinois River has certain twenty-nine-day pulses, which are apparently related to the lunar phases, the plankton maxima lagging about six days behind the times of full moon. The light from the sun is said to be 618,000 times as bright as that from the full moon; but the amount of solar energy derived from the moon is sufficient, we are told, appreciably to affect photosynthesis in the Phyto-Plankton. The effectiveness of the moon in this photosynthesis to that of the sun is said to be as two to nine, and if that is so Kofoid is probably justified in his contention that at the time of full moon the additional light available has a marked effect upon the development of the Phyto-Plankton.

As on land, so in the sea, all animals ultimately depend upon plants for their food. The plants are the producers and the animals the consumers in nature, and the pastures of the sea, as Sir John Murray pointed out long ago, are no less real and no less necessary than those of the land. Most of the fish which man uses as food spawn in the sea at such a time that the young fry are hatched when the spring Diatoms abound, and the Phyto-Plankton is followed in summer by the Zoo-Plankton (such as Copepoda), upon which the rather larger but still immature food fishes subsist. Consequently, the cause of the great vernal maximum of Diatoms is one of the most practical of world problems, and many investigators have dealt with it in recent years. Murray first suggested that the meadows of the sea, like the meadows of the land, start to grow in spring simply as a result of the longer days and the notable increase in sunlight. Brandt has put forward the view that the quantity of Phyto-Plankton in a given layer of surface water is in direct relation to the quantity of nutritive matters dissolved in that layer. Thus the actual quantity present of the substance—carbon, nitrogen, silica, or whatever it may be—that is first used up determines the quantity of the Phyto-Plankton. Nathansohn in a recent paper[3] contends that what Brandt supposes never really happens; that the Phyto-Plankton never exhausts any food constituent, and that it develops just such a rate of reproduction as will compensate for the destruction to which it is subjected. This destruction he holds is due to two causes: currents carrying the Diatoms to unfavourable zones or localities, and the animals of the plankton which feed on them. The quantity of Phyto-Plankton present in a sea will then depend upon the balancing of the two antagonistic processes—the reproduction of the Diatoms and their destruction. We still require to know their rate of reproduction and the amount of the destruction. It has been calculated that one of these minute forms, less than the head of a pin, dividing into two at its normal rate of five times in the day, would at the end of a month form a mass of living matter a million times as big as the sun. The destruction that keeps such a rate of reproduction in check must be equally astonishing. It is claimed that the *Valdivia* results, and observations made since, show that the most abundant plankton is where the surface water is mixed with deeper layers by rising currents. Nathansohn, while finding that the hour of the day has no effect on his results, considers that the development of the Phyto-Plankton corresponds closely with evidence of vertical circulation. Like some other workers, he emphasises the necessity of continuous intensive work in one locality: such work might well be carried on both at some point on your great lakes and also on your Atlantic coast. The *Challenger* and other great exploring expeditions forty years ago opened up problems of oceanography, but such work from vessels passing rapidly from place to place could not solve our present problems—the future lies with the naturalists at biological stations working continuously in the same locality the year round.

The problems are most complex, and may vary in different localities—for example, there seem to be two kinds of Diatom maxima found by Nathansohn in the Mediterranean, one of Chætoceros due to the afflux of water from the coast, and one of *Rhizosolenia calcaravis*, due to a vertical circulation bringing up deeper layers of water. As a local example of the importance of the Diatoms in the plankton to man, let me remind you that they form the main food of your very estimable American clam. The figures I now show, and some of the examples I am taking, are from the excellent work done on your own coasts in connection with fisheries and plankton by Prof. Edward Prince and Prof. Ramsay Wright and their fellow-workers at the Canadian biological station, on your eastern seaboard.

The same principles and series of facts could be illustrated from the inland waters. Your great lakes periodically show plankton maxima, which must be of vast importance in nourishing animals and eventually the fishes used by man. Your geologists have shown that Manitoba was in post-Glacial times occupied by the vast lake Agassiz, with an estimated area of 110,000 square miles; and while the sediments of the extinct lake form your celebrated wheat fields, supplying food to the nations, the shrunken remains of the water still yield, it is said, the greatest fresh-water fisheries in the world. See to it that nothing is done to reduce further this valuable source of food! Quoting from your neighbours to the south, we find that the Illinois fisheries yield at the rate of a pound a day throughout the year of cheap and desirable food to about 80,000 people—equivalent to one meal of fish a day for a quarter of a million people.

Your excellent "whitefish" alone has yielded, I see, in recent years more than 5,000,000 lb. in a year; and all scientific men who have considered fishery questions will note with approval that all your fishing operations are now carried on under regulations of the Dominion Government, and that fish hatcheries have been established on several of your great lakes, which will, along with the necessary restrictions, form, it may be hoped, an effective safeguard against depletion. Much still remains to be done, however, in the way of detailed investigation and scientific exploitation. The German institutes for pond-culture show what can be done by scientific methods to increase the supply of food-fishes from fresh waters. It has been shown in European seas that the mass of living food matters produced from the uncultivated water may equal that yielded by cultivated land. When aquiculture is as scientific as agriculture, your regulated and cultivated waters, both inland and marine, may prove to be more productive even than the great wheat lands of Manitoba.

Inland waters may be put to many uses: sometimes they are utilised as sewage outlets for great cities, sometimes they are converted into commercial highways, or they may become restricted because of the reclamation of fertile bottom lands. All these may be good and necessary developments, or any one of them may be obviously best in the circumstances; but, in promoting any such schemes, due regard should always be paid to the importance and promise of natural waters as a perpetual source of cheap and healthful food for the people of the country.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A NUMBER of resolutions concerned with education were adopted last week at the Trade Union Congress held at Ipswich. Some called for the State maintenance of school children, for scientific physical education, and the development of the medical department of the Board of Education. Others demanded that secondary and technical education be an integral part of every child's education, and be secured by such a reform and extension of the scholarship system as would place a maintenance scholarship within the reach of every child, and thus make it possible for all children to be full-time day pupils up to the age of sixteen; and that the best intellectual and technical training be provided for the teachers of the children, that each educational district be required to train the number of pupil teachers demanded by local needs and to establish training colleges, preferably in connection with universities or university colleges. The interest in education thus manifested by the leaders of our working men may be regarded as a gratifying sign of the times. All who desire the welfare of the nation would welcome any real improvement in our system of educating suitably the men upon whom the success of our industries largely depends; but many competent persons will doubt the wisdom of the great extension of our scholarship system demanded by the Trade Union Congress. In any system of awarding scholarships every care must be taken to ensure that each scholarship holder has shown by his previous record that he is mentally qualified to benefit by the secondary and technical education which the scholarship makes possible, and will complete the course at the school. It is important to educate every person to the full extent of his capabilities, but it is folly to imagine that every boy or girl who is made to attend a technical school must of necessity be able to benefit from such attendance.

THE technical colleges throughout the country are now issuing their programmes of work for the coming session. We have received the educational announcements of the Northampton Polytechnic Institute, Clerkenwell, the syllabus of classes at the Sir John Cass Technical Institute, Aldgate, London, and the prospectus of the East Ham Technical College evening classes. The educational aim of the Northampton Institute is to provide classes in technological and trade subjects, attention being first paid to the immediate requirements of Clerkenwell, the district of London in which the institute stands. The day courses are for students willing to give the whole of their time for one, two, or more years to a systematic training in technology. Day courses are provided in mechanical engineering, electrical engineering, watch-making, and horological engineering. In horology, a very large amount of time is given to workshop practice. There are also day courses in technical optics, electrochemistry, and other subjects. Evening classes are held in a very great variety of subjects. At the Aldgate institution graded courses of study extending over several years are provided in the various departments, and also special lectures, with accompanying laboratory practice, are given to meet the needs of persons holding responsible positions in the manufacturing establishments in the neighbourhood who desire to keep in touch with modern developments in applied science. Among the announcements of such special work may be mentioned the course on liquid, gaseous, and solid fuel arranged for the benefit of workers in chemical and engineering establishments and others concerned with the use of fuel as a motive power; that on the fermentation industries, with particular attention to microbiology; and that concerned with metallurgical problems. The evening classes at East Ham are under the general supervision of a responsible principal, and it is consequently possible for a student to obtain advice in the direction of securing a properly coordinated course of study continuing from year to year. The numerous classes are adapted particularly to meet the requirements of young men and women engaged in the manual and other industrial trades of the locality.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 6.—M. Bouchard in the chair.—The theoretical tides of the geoïd, on the hypothesis of an absolute rigidity of the earth: Ch. **Lallemand.** Defining the geoïd as the surface of mean level confining a volume equal to that of the globe, the mean tides at the equator are worked out for both the solar and lunar waves.—The Brownian movement and molecular constants: Jean **Perrin** and M. **Dabrowski.** Experiments have been made on two emulsions of different substances containing minute particles in suspension. The results are applied to determine the constant N of Avogadro in Einstein's formula, and also in a formula based on the distribution of the particles under the action of gravity. The former leads to a value of 70×10^{22}, and the latter to 70.5×10^{22}. The close accord of these results is a striking confirmation of the kinetic theory on which the formulæ are based. The most probable value of the charge of the electron e from these values is 4.1×10^{-10}.—Calorimetric and cryoscopic constants of mercuric bromide: M. **Guinchant.** The measured latent heat of fusion gives a cryoscopic constant according to van 't Hoff's formula of 403; actual cryoscopic determinations in various solvents furnished a constant of 283 to 407, the average value being 340.—The life of fungi in fatty media: A. **Roussy.** For various moulds it was found that fatty substances were capable of replacing carbohydrates in culture media. The concentrations of fat most favourable for growth of the moulds were determined.—Some wild yams of Madagascar: Henri **Jumelle** and H. THURSDAY, SEPTEMBER 23, 1909.

PHILOSOPHY AND HISTORY OF SCIENCE.

(1) *Das Prinzip der Erhaltung der Energie.* By Dr. Max Planck. Zweite Auflage. Pp. xvi+278. (Leipzig: B. G. Teubner, 1908.) Price 6 marks.

(2) *Vererbung, Gedächtnis und Transzendentale Erinnerungen vom Standpunkte des Physikers.* By Dr. Gustav Eichhorn. Pp. x+116. (Stuttgart: Julius Hoffmann, 1909.) Price 2.50 marks.

(3) *De la Méthode dans les Sciences.* By Profs. H. Bouasse, &c. Pp. 412. (Paris: Félix Alcan, 1909.)

(4) *Materialistische Epoche und monistische Bewegung.* By Paul Volkmann. Pp. 30. (Leipzig: B. G. Teubner, 1909.) Price 1 mark.

(5) *Das Theorem des Pythagoras.* By Dr. H. A. Naber. Pp. xii+240. (Haarlem: P. Visser, 1908.) Price 7s.

(6) *Essai sur la notion de Théorie physique de Platon à Galilée.* By Pierre Duhem. Pp. 144. (Paris: A. Hermann and Son, 1908.) Price 5 francs.

(7) *Il passato ed il presente delle principali Teorie geometriche.* Terza editione. By Prof. Gino Loria. Pp. xxiv+476. (Torino: Carlo Clausen, Hans Rinck Succ, 1907.)

(1) IN 1887 the Göttingen Faculty of Philosophy offered a prize for the best essay, historical and critical, on the physical concept of energy, and the principle of conservation of energy. The prize was awarded to Dr. Max Planck, and his essay now, in its second edition, finds a fitting place in the series which the Teubner Press are issuing bearing the title of the first volume by Poincaré, "Science and Hypothesis."

The volume is divided into three sections. The first is historical; the second deals with statements and proofs of the principle; while the third discusses the various forms of energy and their symbolic representations.

"The Principle of Conservation of Energy" is a somewhat elastic title for a thesis. Had Prof. Planck included every application of the principle or every investigation in which the principle plays an important part, his work would have swelled out into a treatise containing pretty well the whole of physics and a large part of chemistry. The author has been wise in restricting his inquiries to a narrow field. He excludes all reference to the less easily understood second law or principle of degradation of energy. That principle is far more difficult to understand than the first law, and it is doubtful whether at the time of writing the essay Prof. Planck could have been in a position to give a satisfying account of it. It teaches us that a community of molecules tends towards a state of socialism in which wealth in the form of energy is evenly distributed among the molecules, but that as the change takes place, this energy becomes less and less available for useful purposes, until the system comes to a deadlock, when all progress and activity ceases, and no further work is done by the system. The first law, which tells us that wealth in the form of energy cannot be created or destroyed, so that one molecule cannot grow richer without making another poorer, is much easier of comprehension, and gave Prof. Planck abundant material for discussion.

While the treatment can scarcely be described as exhaustive, this impression may be to a large extent attributed to the changes which have taken place in our knowledge of physical phenomena since the thesis was written. It would have been next to impossible for the author to have brought the book up to date by the inclusion of this later work; and, after all, what has happened in the interval? Have we not, as a general rule, taken the principle of conservation of energy for granted, and merely investigated fresh applications of it? Even in connection with the phenomena of radio-activity, no one has cast any very serious doubts on the validity of the principle. For critical writings on the subject, we must go back to the time of Clausius, Mayer, Joule, and the earlier works of Helmholtz and Lord Kelvin; and these are discussed in the first section. An attempt to draw in recent applications might have confused the issue rather than otherwise.

(2) While many attempts have been made to formulate a physical basis for the phenomena of life—for example, by Loeb in Germany and Dr. F. J. Allen in this country—considerable difficulty is experienced in explaining thought, memory, and the hereditary transmission of characters, none of which concepts appears easily reconcilable with the ordinary properties of matter, at any rate in its inert state. Dr. Gustav Eichhorn would now maintain that electric theories of matter open up new possibilities. For the discovery of electrons, the theory that matter is a complicated aggregate of electrons, and the existence of mutual relations between matter and æther, are fully consistent with the view that the phenomena of thought and heredity are caused by particular states of the æther associated with the molecules of the material organism. Part of the book, dealing with hallucinations and "transcendental memories," was written ten years ago. The author does not profess to give an exhaustive or complete study of the problems with which the book deals, and in view of the fact that the electron theory is comparatively recent, his claims to have treated the subject from a new standpoint are not without foundation; but isn't all this the old notion of spiritualism and "animal magnetism" merely served up under a different name? If not, the resemblance is very striking, and the difference not very obvious.

(3) The collection of articles edited by Dr. Thomas under the designation of "Method in the Sciences" owes its publication to the growing importance attached to philosophy of science, and in particular to methodology in French educational curricula following Auguste Comte. It is pointed out that both textbooks and original articles leave a gap in such literature of the subject as is available for students, and this gap it has been the object of the present volume to assist in filling. In reviewing this book, one is tempted to enlarge on the fact that an educational system which tries to mould all teachers or students according to a common pattern can never be efficient. No better preventive against this deadly uniformity can be suggested than the publication of a book representing the combined experience of all sorts and con-

O

ditions of men each a specialist in his own particular department of science; and if it is found that doctors disagree on points of detail, it is claimed that an examination of their views will have the beneficial effect of making the student think for himself instead of merely taking what is written for granted. The mere learning machine, who is frequently devoid of powers of clear exposition, probably exists in every country, but he is not the kind of man to be encouraged. This volume consists of articles on science, by Émile Picard; pure mathematics, by Jules Tannéry; mechanics, by P. Painlevé; general physics, by H. Bouasse; chemistry, by A. Job; morphology, by A. Giard; physiology, by F. Le Dantec; medical sciences, by Pierre Delbet; psychology, by Th. Ribot; sociology and social science, by E. Durkheim; morale, by L. Lévy Bruhl; and history, by G. Monod, all under the editorship of Dr. P. F. Thomas.

(4) Prof. Volkmann's pamphlet is an address delivered at the graduation ceremony of the Albertus University on January 18. It deals with the materialistic philosophy of the nineteenth century, with phenomenology and monism, and with the idealism of Kant, whose connection with the university in question is too well known to require mention.

(5) Dr. Naber deals in a pleasant and chatty way with many points in the history of Greek and Egyptian geometry. The discussion is in no way confined to the proposition now more generally known as "One Forty-Seven," which forms the title of the book, but we have sections dealing with "Pi" and its supposed value $\sqrt{10}$, with spirals and limaçons and their applications to angle-trisection and cube-duplication, with the history of the "Golden" or median section, and finally with the "pentalpha," or pentagonal star, and the dodecahedron. "Spirals in nature and in art" receive considerable attention, and are illustrated by numerous figures. It would be impossible to dwell at length on the historic side of the book. If it has one fault, that fault is a certain diffuseness and lack of definiteness. By this we mean that in some places it is not very certain what conclusions the author is seeking to prove. But possibly that is because the author is endeavouring to give a general idea of what mathematical thought was like in the Pythagorean times, and to do this he reasons largely from conjecture where historic evidence is wanting. He cannot certainly be accused of being long-winded, his sections being very short and concise, and his language terse.

(6) "To save appearances" (σωζειν τα φαινομενα or to account for observed facts was the object of Greek philosophy, which forms the motto of Prof. Duhem's book. Not less is it the object of the modern physicist. In tracing the development of physics from the time of Plato to that of Galileo a good many points may be observed which have left their traces on modern physical theory. We notice, in Prof. Duhem's words, that where we now speak of physics, the Greek and Mussulman philosophers and the men of science of the Middle Age spoke of astronomy; that the laws of motion of celestial bodies were studied ages before anyone thought of applying similar methods to terrestrial (or "sublunary") bodies; that the first discussions of the phenomena of the material world were metaphysical, and that optics and statics were the earliest subjects to form the basis of mathematical theories. We observe with interest the division of physics into two branches, one dealing with celestial and the other with sublunary bodies, of which the first was regarded as infinitely more perfect than the second, and was for this reason wrongly supposed to be only accessible to divine intelligence, while the latter or terrestrial physics was supposed to be summed up in the work of Aristotle. And we reflect that even nowadays the once supposed easier task of "saving the phenomena" of sublunary matter is the one which physicists as a rule shirk. It is true that electricity and not astronomy is the subject now usually under investigation, but in either case the philosopher turns his thoughts to the ether as the seat of the phenomena under investigation, and finds that the hypotheses necessary to "save" these phenomena are greatly simplified owing to the omission of irreversible effects. It is not claimed by Prof. Duhem that his is the first attempt at a history of physics as distinct from mathematics, but as a general account of the subject in a moderate compass it would be difficult to write a better book.

(7) Prof. Gino Loria's book needs little comment. Its merits can be summed up in a few words. It is a book with which no geometer can afford to dispense. It is a bibliography of geometry classified under such headings as "Geometry up to 1850," "Algebraic Curves," "Differential Geometry," "Non-Euclidian Geometry," "Geometry of Multi-dimensional Space." Every page is filled with references, and the number of papers and memoirs which have been consulted in the preparation of the book must be counted by thousands; indeed, if we mistake not, the mere names of authors contained in the index number well into the four figures. The second edition appeared in 1896, and in this third edition the author has added an appendix of about 120 pages dealing with the progress of geometry during the last ten years. In the epilogue, the author compares geometry to a fertile region the vegetation of which still offers numerous prizes in the form of flowers and fruits to the explorer and cultivator. If this analogy be pursued a little further, the need had arisen for a flora of the new territory, and no better botanist could be found for the purpose than Prof. Gino Loria.

THE FLUIDS OF THE BODY IN HEALTH AND DISEASE.

(1) *The Mercers' Company Lectures on the Fluids of the Body.* By Prof. Ernest H. Starling, F.R.S. Pp. viii+186. (London: Archibald Constable and Co., Ltd., 1909.) Price 6s. net.

(2) *Studies on Immunisation and their Application to the Diagnosis and Treatment of Bacterial Infections.* By Sir A. E. Wright, F.R.S. Pp. xv+490. (London: Archibald Constable and Co., Ltd., 1909.) Price 16s. net.

ALL important as the cells and cellular tissues of the body are, the fluids of the body may claim an equal importance, both in physiological or normal and in pathological or abnormal processes. In fact the one is a supplement to the other, and probably neither is able to exert its full activity without the simultaneous cooperation of the other.

(1) The first book under review comprises courses of lectures delivered by Prof. Starling at University College under the auspices of the Mercers' Company, at the Bellevue Hospital, New York, under the foundation of Dr. Herter, and at the Royal College of Surgeons. It is written in a simple and attractive style, and gives an admirable description of such subjects as the physical properties of protoplasm, the osmotic relationships of cells, the intake, exchange, absorption, and output of fluids in the body, and the production of lymph (the fluid which bathes the tissues), and the relationship of these normal processes to disease processes, such as dropsy. Many important physical and chemical conceptions, such as osmotic pressure, adsorption, the nature of colloids, surface tension, and the like, are here brought together and explained, and their relation to vital processes is examined. In the discussions of the connection between normal and pathological processes many suggestions of value to the medical practitioner are made. Thus the regeneration of the constituents of the blood after bleeding is considered to be due to the stimulus of lack of oxygen, and the value of occasional blood-letting is compared to that of a sojourn at high altitudes, the beneficial and recuperative effects of which are well recognised, and it is suggested that the practice of *occasional* blood-letting may be restored to the position of honour it once held in medical practice.

(2) The second book includes numerous papers contributed by Sir Almroth Wright, his co-workers, and friends to various journals and societies, and deals more or less directly with the problems of immunisation against disease-producing micro-organisms. The first part of the book deals primarily with the protective elements of the blood, agglutinins, bactericidins, and opsonins; in the second part the problem of fighting bacterial infections by those defensive agencies which the organism itself employs when it contends with microbic invasions, is discussed. The formation of a book by a collection of separate papers, collated together though they be to some extent by numerous foot-notes, necessarily leads to a certain amount of repetition, and to a somewhat irritating use of cross-references. Nevertheless, all workers in this field of research cannot but be grateful to Sir Almroth Wright for thus bringing together and rendering accessible a number of scattered papers.

Opsonins and vaccine therapy necessarily occupy a prominent place. Opsonins are substances present in the blood which act upon invading microbes, and render these susceptible to phagocytosis, that is, to ingestion by certain amœboid, wandering, and other cells, which brings about their destruction. By the injection of a certain quantum of a killed bacterial culture the production of opsonins specific for the particular organism injected tends to be increased; phagocytosis of the organism in question therefore is also rendered more active, and if an infection with the organism exists, it tends to be got rid of. The use of bacterial vaccines has been successful or useful in many infections; this is vaccine therapy. The present-day employment of vaccine therapy must in the main be ascribed to the work of Sir Almroth Wright, his co-workers and pupils, and to them all honour is due. At the same time we cannot help thinking that to some extent a balanced perspective is wanting in some of the statements. Thus the condemnations of the antiseptic system, and of the value of surgical extirpation of infective foci, are too wide and sweeping (pp. 280 and 318). The same criticism applies to the remarks on serum therapy (pp. 300 and 321).

Whatever be the failures of serum therapy, we cannot help thinking that neutralisation of the existing "poison" *at the moment* is a goal to be aimed at, however much we strive to reinforce the defensive powers of the body and render it later able to take care of itself. In very acute infections, such as some forms of septicæmia, which may prove fatal in twenty-four to forty-eight hours, or in cholera, in which the patient may be dead in a few hours after the commencement of the attack, the direct neutralisation of the "poison" would seem to be the only treatment that affords hope of success. The comparative failure of serum therapy should therefore be a stimulus to the elaboration of new methods of preparation of therapeutic serums rather than an argument for considering serum therapy futile.

TEXT-BOOKS OF PHYSICS.

(1) *Heat and other Forces.* By Colonel W. F. Badgley. Part i.: "Heat"; part ii.: "Physical Forces." Pp. 221+vi. (London: King, Sell and Olding, Ltd., 1907.) Price 5s. net.

(2) *An Elementary Course in Practical Science.* By C. Foxcraft and T. Samuel. Part i. Pp. 48. Part ii. Pp. 58. (London: G. Philip and Son, Ltd., n.d.) Price 6d. net each.

(3) *Horbare, Sichtbare, Elektrische und Rontgen-Strahlen.* By Dr. Friedrich Neesen. Pp. 132. (Leipzig: Quelle and Meyer, 1909.) Price 1.25 marks.

(4) *An Elementary Text-book of Physics.* By Dr. R. W. Stewart. Part ii.: "Sound," pp. iii+141. Part iii.: "Light," pp. vii+219. (London: C. Griffin and Co., Ltd., 1909.) Price, part ii., 2s. 6d. net; part iii., 3s. 6d. net.

(1) COLONEL BADGLEY'S book is an extraordinary production. The contents might be guessed from the title, which implies that heat is a force. The author has evidently read a great deal of current scientific work, to which he frequently refers, but has not the exact knowledge necessary for writing on the subject. Indeed, he suggests that the differences between work, energy, power, force, and motion are only mythical, and that the terms are really interchangeable. Typical, also, is the statement that "the heat given off by the spontaneous decomposition of radium is, perhaps, about a degree and a half centigrade." The preface is very cynical. It is questioned whether men of science believe in one

another's discoveries, and hinted that few of the latter are worthy of acceptance. The main object of the book is said to be to try to prove that "heat is not a vibration of material, not even of aether," but we search in vain for a clear alternative definition. It is a difficult book to follow because of the entire lack of order. The whole is an intricate mixture of simple experimental facts, quotations from books on many subjects, some of which are very remotely connected with heat, and a large amount of astounding new theory. Most of the ordinary phenomena in heat are dealt with, and a chapter in defence of the British systems of measurement is included. We can neither recommend the book to beginners—for it would confuse them—nor to those conversant with the subject—for it would waste their time.

(2) The two little books on practical science are for use in elementary schools, and the authors claim that the scheme has already been thoroughly tested with success. Part i. consists of a series of exercises in measurements of length, area, volume, weight, and density. Part ii. contains rather more advanced exercises on the same subjects, together with some on atmospheric pressure and heat, and a suggested course of woodwork. The exercises do not consist of detailed instructions of what to do and expect, but require some initiative on the part of the student. This is, indeed, the intention of the authors, who hold the view that the pupil should discover facts for himself. Thus, some of the exercises simply consist of a series of questions to be answered by making experiments. The books, although cheap, are clearly printed, and will probably be found to serve their purpose.

(3) Dr. Neesen has undertaken a difficult task in dealing with such a large subject in so small a volume. Nevertheless, most of the phenomena proper to the various subjects are referred to, although briefly. With a few exceptions, the book is non-mathematical, and deals rather with the experimental side. The reader, therefore, has no need of an advanced knowledge of physics, and it is doubtless advantageous for such to study the different kinds of wave motion together. Besides the subjects mentioned in the title, there are several paragraphs on radioactivity, in which the properties of the α, β, and γ rays are dealt with. Many of the diagrams are poorly drawn and printed. This is particularly unfortunate in a book dealing with wave motion and geometrical optics.

(4) Quite otherwise in this respect are the two text-books of physics by Dr. Stewart. That on sound especially should supply the much-felt need of an elementary treatment of that subject. Exception may be taken to the definition of simple harmonic motion as the projection on a diameter of the uniform circular motion of a point, because it leads students to believe in the existence of such a point in all cases of simple harmonic motion. It is rather surprising, also, to find Doppler's principle and the production of beats not referred to, especially as the latter is so commonly used as a method of estimating frequencies. Omissions are the chief fault in these volumes, and they are even more frequent in the part on light. There is no treatment of microscopes and telescopes, nor the methods of measuring the velocity of light. These are surely not out of place even in an elementary text-book. In reading this part alone it is noticeable that the undulatory theory is not sufficiently insisted upon, but this is compensated for by the fact that the laws of refraction and reflection are proved according to this theory in the volume on sound. On the whole, however, the books are distinctly good, and the large number of experiments suggested will no doubt serve to demonstrate the principles involved.

VOLUMETRIC CHEMICAL ANALYSIS.

A Manual of Volumetric Analysis. For the Use of Pharmacists, Sanitary and Food Chemists, as well as for Students in these Branches. By Dr. H. W. Schimpf. Fifth edition, revised and enlarged. Pp. xx+725 (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 21*s.* net.

THE plan of this work is as follows:—First, the general principles of volumetric chemical analysis are explained and illustrated. Next, the knowledge thus gained is applied to practice-work upon the commoner inorganic elements and their chief compounds, and upon certain organic acids. Finally, two branches of specialised work are taken up—namely, the analysis of various food-stuffs and pharmaceutical products—and the book concludes with a few examples of gasometric analysis applied to articles met with in pharmacy and medicine.

The treatment is generally fairly exhaustive, and the descriptions lucid. Often, indeed, the author gives almost a superabundance of detail in explaining the principles of the methods used. For example, he supplies not only the equations involved, but frequently the arithmetic as well. In the early part of the book he appears to have in mind the very elementary student, and is at some pains to explain such matters as the law of definite proportions. This seems hardly necessary in a book of this character. Knowledge of the elementary principles on the part of the student might well be taken for granted. In fact, the author is scarcely consistent; a page or two later on we find ourselves talking of univalent and divalent compounds, monobasic and dibasic acids, without previous explanation of the terms. A reader who knows what they mean would not be likely to want an exposition of the law of definite proportions.

A very useful description of the properties of indicators is contained in the fourth chapter. The reactions involved are dealt with mainly as ionisation phenomena, but a brief explanation is given of the chromophoric theory also.

The special feature of the volume, however, is the amount of attention devoted to the assaying of pharmaceutical preparations, particularly alkaloidal drugs. No fewer than a hundred and fourteen pages are taken up with these, and the sections appear to have been brought well abreast of modern practice. One division treats of the general volumetric estimation of alkaloids, explaining the principles, and describing some of the newer methods, as well as those which are older and better known. Afterwards comes a chapter dealing with the extraction of alkaloids from the various crude drugs—seeds, leaves, roots—in which they occur, and the determination of the proportion present. This is followed by sections which treat of the individual drugs and the galenical preparations containing them. The alkaloids of gelsemium, hyoscyamus, stramonium, coca, colchicum, conium, hydrastis, ipecacuanha, physostigma, pilocarpus, tobacco, strophanthus, and veratrum are included, as well as the commoner alkaloids, and this part of the work should be a boon to chemists or students interested in the examination of these products.

The space allotted to the analysis of water and food-stuffs does not allow of the articles being discussed at any length. Milk, butter, oils and fats, starch, and sugar are dealt with, and the outlines of principles and processes given are trustworthy as far as they go.

For the sake of the numerous references which the author supplies, one can readily forgive him his occasional lapses into slipshod English. The book contains a wealth of information, and considered as a whole is an excellent production. C. S.

OUR BOOK SHELF.

Geologischer Führer durch Dalmatien. By Dr. R. Schubert. Pp. xxiv+176. (Berlin: Borntraeger, 1909.) Price 5.60 marks.

THERE are few portions of the map of Europe more attractive to the eye of the geographer and the geologist than the coast of the northern Adriatic. On the one hand we have the coast of deposition, starting from the Apennine foothills north of Pesaro, and more and more emphasised in the swampy flats of Ravenna and Venice, until we reach the jungle-like woods of Monfalcone. Beyond this we come against steeply descending limestone hills, with a "karst" character already manifest. The blue water at Trieste speaks of the coast of subsidence that stretches to the south-east, with chains of islands parallel with the tectonic features of the land.

Dr. Schubert sums up the geological features of Dalmatia in a work intended for the instructed traveller. Cretaceous limestones play a large part in the country, but are concealed over much of the north by fresh-water and marine Eocene strata. The marine limestones of Middle Eocene age are here overlapped by the brackish-water marls and fluviatile conglomerates of the Promina series, which were laid down in Upper Eocene, and possibly finally in Oligocene, times, after a general uplift of the area (p. xvii). The Eocene sea itself had represented a return to marine conditions after a terrestrial and lagoon stage which closed the local Cretaceous system. The folding from north-east to south-west, which has determined the salient features of modern Dalmatia, took place in Oligocene times (p. 173).

While the corresponding depression of the Adriatic may have begun, through the production of faults, soon after the Oligocene period, the sea did not invade the northern part of its present basin until what we may call human times. The Po and its tributaries, dependent on the growth of the Alpine chain, carried detritus across this area, and the sinking that has separated the alluvial Italian region from the rocky shore of Istria began in the Glacial and continued into the Roman epoch. The chains of islands off the Dalmatian coast have thus a very modern origin.

Dr. Schubert guides the traveller on a series of excursions, with useful notes as to the accommodation on the way. He wisely points out that a knowledge of either Italian or Croatian, preferably the latter, is essential for those who go beyond the tourist routes. The price of his compact volume, with its numerous references to other literature, will not seem high, when one considers how long it will be before any large number of visitors will venture far from the comfortable steamers on the coast. The desire for luxury during travel fortunately leaves many European districts, like Dalmatia, free for those who prefer to study and observe at their own leisure.

Entwickelung und Untergang des Kopernikanischen Weltsystems bei den Alten. By O. T. Schulz. Pp. 143. (Stuttgart, Verlag: Neue Weltanschauung, 1909.)

THIS essay is the first of a series entitled "Weltanschauungs-Fragen." It deals with the ideas of the Greeks about the construction of the world, but, notwithstanding the title, the standpoint of the author is that of an historian of geography, and not that of an historian of astronomy. He is evidently quite at home when sketching the gradual rise of geographical knowledge and illustrating it by maps. But when he comes to the astronomical part of his subject he has apparently only Zeller's "Philosophie der Griechen" and Schiaparelli's memoir on the precursors of Copernicus to build on, while Schiaparelli's later paper on the very subject indicated by the title of the present essay, as well as the writings of Tannery, Hultsch, and others, are unknown to him.

The author makes no attempt to point out how Aristarchus may have been led to the idea of the earth's motion round the sun, and tells the reader nothing about the systems of movable excentrics or epicycles. He states that Aristarchus at first believed in the motion of the sun round the earth, and that he says so in his little book on the distances of the sun and moon. But there is not a word in this book as to whether the sun or the earth is in motion. As regards the failure of the heliocentric idea to secure acceptance, the only reason given by the author is that Hipparchus considered it not to be based on sufficiently lengthy observations. We cannot imagine where the author got this piece of information from, as there is no allusion to the system of Aristarchus in the preserved writings of Hipparchus and Ptolemy. What Hipparchus did say was that he did not himself possess sufficient observations to work out the theory of the orbital inequalities of the five planets. But these have nothing to do with the motion of the earth. The author adds that there is no original research in the Almagest!

When dealing with the views of Plato, the author repeats the statements current sixty years ago about Plato's doctrine respecting the rotation of the earth and about his change of opinion in his old age as to which body was in the centre of the world. One cannot help wondering whether it really is of any use to try to kill historical errors. They seem to be immortal. At least, popular writers on the history of science are generally not aware that they are dead and buried long ago. J. L. E. D.

Excursionsbuch zum Studium der Vogelstimmen. By Prof. Voigt. Pp. 326. (Leipzig: Quelle und Meyer, n.d.) Price 3 marks.

THIS is the fifth edition of an excellent manual of the songs and other notes of birds, suitable for carrying in the pocket during walks and excursions. As a matter of fact, it is better for the learner to find out for himself what bird it is to the voice of which he is listening, for in the process, even if it be a long one, he will learn a good deal about the bird and its habits. But some learners are less gifted than others with a capacity for listening carefully, and have little or no musical ear, and a book like this may be of good service to these. Dr. Voigt's method is a very sensible one; he makes no great use of musical notation, but has invented a notation of his own which is likely to be much more useful to the ordinary observer. By a series of dots and dashes, inclining or curving up or down if necessary, he contrives to give a very fair idea of the character of the notes he wishes to represent, and also of their tendency to rise and fall. In some cases, *e.g.* in that of the swallow, he does not make use of either kind of notation, simply because neither would be any real help. His descriptions of the songs seem remarkably accurate. We have tested them in the case of many of the small warblers, which are among the most difficult to describe, and have invariably found them excellent, and the tendency of particular individuals of a species to vary the utterance is also duly noted. Thus of the marsh warbler (*Acrocephalus palustris*), Dr. Voigt says that it has troubled him more in the way of variation than any other species. In writing of this species he seems to have omitted the peculiar alarm-note uttered when an intruder is near the nest, but as a rule something is said of alarm- and call-notes. On the whole, we consider this book the most useful practical manual we have met.

W. W. F.

The Force of the Wind. By Prof. Herbert Chatley. Pp. viii+83; illustrated. (London: C. Griffin and Co., Ltd., 1909.) Price 3*s.* net.

PROF. CHATLEY has evidently devoted himself to a study of hydrodynamics and of its literature. He has attempted to boil down into an inordinately small compass, so as to be useful to engineers, an exposition of one of the most difficult and elusive subjects with which either the engineer or the mathematician has to deal. Explanation of principles which might be useful to a novice is replaced by a multiplicity of formulæ, which are flung at the reader with but little regard to dimensions or units. Numerical examples which, even in the case of clear exposition, always assist the student who wishes to apply a formula to any case in which he is interested are entirely absent.

Much information is collected, and numerous authorities are cited, but the result can hardly be considered satisfactory.

LETTERS TO THE EDITOR.

Stability of Aëroplanes.

I HAVE recently been occupied with a comparative study of the theories of stability of aëroplanes deduced by Prof. Bryan, Captain Ferber, and Mr. F. W. Lanchester, and have just noticed a parallelism between the formulæ of Ferber and Lanchester which is strongly corroborative of the practical application of both.

In Ferber's "Les Progrès de l'Aviation par le vol Plane" (*Revue d'Artillérie*, November, 1905) he deduces from an extension of Prof. Bryan's analysis a formula for the conditions of longitudinal stability

$$\frac{P^2 b}{2Bg^2 kS} > 0{\cdot}8,$$

where P is the total mass of the machine, B is the moment of inertia about a transverse axis through the *cg*, S is the area of the supporting surfaces, *b* is the distance of the centre of pressure from the centre of area of the supporting surfaces, and K is an aërodynamic constant (0·7) kilometre-second system.

Lanchester's equation for longitudinal stability is

$$\Phi = \frac{4lH_n^2 \tan\gamma}{I\left(\frac{1}{K} + \frac{1}{\iota C\rho a\beta}\right)} > 1,$$

where l is the distance from the centre of pressure on a tail plane to the Cg, H_n is the kinetic head of the machine corresponding to its normal velocity, γ is the normal gliding angle, I is the moment of inertia about a transverse axis through the Cg, $K = \frac{\text{weight}}{(\text{normal velocity})^2}$, and the denominator of the second term in the expression within brackets is the lift on the tail plane (ft.-lbs.-sec.-units) divided by the square of the velocity.

Now the mass varies as the lifting force, which again varies as the square of the velocity, so that $P^2 \propto H_n^2$.

The torque which restores the machine to equilibrium depends in the case of a machine without a tail plane on b, and with a tail plane on l, so that if Lanchester's form is to refer to a machine without a tail plane b must be substituted for l.

B and I are identical in kind.

K varies as the lift ÷ square of the normal velocity, and since the lift varies as the product of the area and the square of the velocity, $K \propto S$.

The term relating to the tail plane is peculiar to that type studied by Lanchester, so that it can be omitted from our comparison.

Tan γ is a constant for any one type of surface.

Hence it will be seen that the two formulæ are exactly of the same form, and it only remains exactly to determine the appropriate constants to discover if the two expressions can be made identical.

As has been pointed out by Prof. Bryan, everything (except for a machine with a tail) depends on b, and unless $db/d\alpha$, where α is the angle of attack, is negative, the torque will not produce equilibrium. The Government's committee is, I believe, giving this attention.

I would further point out that the variations in velocity leading to Lanchester's "phugoid oscillations," and the oscillations due to the variation of b with α, will serve to explain the two types of oscillation, respectively of long and short periods, observed by Prof. Bryan and Mr. W. E. Williams, and shown by the former to be deducible from the equations of motion.

HERBERT CHATLEY.

Imperial Railways of North China, Engineering and Mining College, August 24.

IT is dangerous to draw conclusions from half-finished investigations, and anything I may now say must be subject to confirmation or modification when I have completely disposed of the mathematical theory of stability, both longitudinal and lateral, as I hope to do in a very few months unless any further pressure of professorial duties necessitates again hanging the matter up indefinitely. But results which I have recently obtained seem rather to corroborate instead of contradicting Lanchester's equation as holding good, subject to suitable assumptions and for the types of machine to which such a formula is applicable. I may state that I have already obtained expressions for the conditions that the quick or slow small motions may be subsident or oscillatory, and for their coefficients of subsidence in the first case and their periods and moduli of decay in the second. This applies to longitudinal stability, and a similar investigation is in progress regarding lateral stability.

It will, I believe, be easy to explain also *why* Lanchester's method, which to a mathematician certainly appears wanting in rigour, may lead to a correct result. But the matter will, I hope, be cleared up very shortly.

In the meanwhile, Prof. Chatley's comparative studies appear to indicate that we are within measurable distance of obtaining consistent results from widely differing methods.

G. H. BRYAN.

Chinese Names of Colours.

The correspondence on the above subject, started by Mr. A. H. Crook in Nature of January 11, 1906 (p. 246), was lately recalled to me when I heard, for the first time, the phrase "hsüeh ch'ing" (Cantonese sut$_0$ ts'eng)—snow-blue—used in conversation. It was used in this case in naming the colour of a flower, and struck me as particularly appropriate; the colour might well be described as one of those termed "ch'ing" diluted to a pale shade with white snow.

It hardly seems likely that any natural colour of snow itself should be the origin of the phrase, or how would one account for "shui hung"—water-red? The latter means pink, or, as one might say, a watery and "washed-out" red. Natural water of a pink colour is scarcely common.

Independently of the foregoing, though perhaps bearing on it, I should like to point out how the origin of some Chinese phrases may well have been obscured; this is by the substitution of one character for another nearly like it in sound, but not in sense. This may be illustrated by a case in which the change appears to be now taking place.

"Wang^4 pa^1"—forget eight—is a term denoting a person of infamous occupation, and also a kind of tortoise. This looks already sufficiently obscure, but is fully accounted for to the satisfaction of dictionary-makers and their kind.

It happens, however, that illiterate persons frequently wish to write this name. In many cases they may not know the character for "forget," but they well know that for "king" (wang^2), and the slight difference in sound is easily overlooked. The practice is being copied among the more literate, and it seems likely that in the end "wang^2 pa^1"—king eight—will entirely supplant the original (and now less common) form, and when this process is complete a sensible derivation will be impossible without reference to an older literature.

The process is almost parallel to some changes of spelling in English, but results in more complete obscurity.

Pei Yang Mint, Tientsin.

Percentages in School Marks.

Mr. Cunningham's inquiry (August 5) is aimed, apparently, at obtaining a kind of *index mark* for each candidate in an examination containing several papers. In getting a boy's percentage mark in any one paper there is no trouble; but the question is, By what law are percentages in different papers to be combined in order to get an index mark? Percentages may be combined in an infinite number of ways; which is the way Mr. Cunningham desires?

Consider three papers:—(1) looking at all the questions in the three papers as a whole, if marks have been assigned to each question with due relativity to all the other questions, (2) if the boys have each been properly prepared for all these questions, and (3) if fair time has been allowed for each of the papers, then each boy's index mark is clearly his total marks gained in the three papers divided by the total maximum marks of the three papers. The whole matter may be expressed more easily thus:—Let a boy gain marks x, y, z in three papers the maximum marks of which are a, b, c; his index mark may be expressed by $px+qy+rz$, and will depend on the constants p, q, r. For example, if $p=1/a$, $q=1/b$, $r=1/c$, the index mark is $x/a+y/b+z/c$ (or this divided by 3, the mean of the averages). Again, let $p=l/(la+mb+nc)$, $q=$&c., $r=$&c., then the index mark will be $(lx+my+nz)/(la+mb+nc)$, which reduces to the first example when $l=m=n$. In this case we have still the ratios $l:m:n$ in our power. For example, suppose papers set in Latin, French, and Greek, and take Mr. Cunningham's numbers for them respectively, namely, 37 out of 50, 50 out of 50, 71 out of 100, and suppose, on comparing the papers, that Latin is reckoned half as hard again as French, and Greek a quarter harder than Latin, then their difficulties would be Latin, French, Greek as 12 : 8 : 15, and it would seem fair to take these values for $l:m:n$. Thus the index mark for this boy would be $(12.37+8.50+15.71)/(12.50+8.50+15.100)$, or 1909/2500, or 0·7636 (per cent. 76·36). If, however, each one of the questions has had marks assigned to it relatively fair when compared with the marks of all the other questions of the three papers, and if the time allowed for each paper is proportionate to the work required by an average boy to answer the paper, then would $l=m=n=1$, and the index mark would be 158/200 (or per cent. 79·00). Thus, Mr. Cunningham must settle for himself, *in accordance with the circumstances of each case*, the values of the ratios $l:m:n$. The above includes the cases of Mr. Whalley and Mr. Abegg, and, I believe, will cover Mr. Pickering's case too, but I have tried unsuccessfully to understand his numerical table.

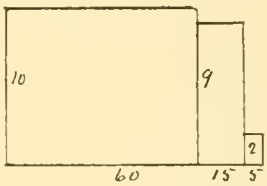
A kindred question is sometimes asked, What is the master-average of a set of averages? For example, thirty schools send in candidates for a paper; each school gets its own average of the marks gained by its pupils in the paper (this is the mark of value for the school); but the examining body wants some information as to how the paper has been done in general, for the sake of comparison with similar papers in other years, hence a master-average, or some equivalent, has to be determined. Assuming all the candidates from the whole thirty schools to be equally prepared for the paper, obviously the examining body will obtain its desired result by dividing the total sum of all gained marks by 100 N, if N be the total number of candidates and 100 be the maximum marks of the paper. This amounts to putting

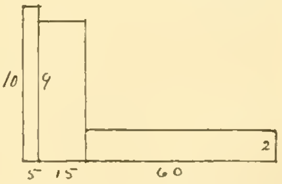
$$l=m=n= \ldots =1;$$

but if it be known that very bad work has come from a certain school, and if in fairness its marks should be valued at (say) one-third of the general run of the schools, then in this case we should put

$$l=m= \ldots =3$$

for twenty-nine of the schools, and $n=1$ for the school in question. To add the thirty averages and take one-thirtieth of the result is of no value at all. This is easily seen from the adjacent diagrams; in the first, sixty boys have an average of 10 marks, fifteen an average of 9, and five an average of 2; the mean of the averages is $(10+9+2)/3$, or 7; in the second case, five boys have an average of 10 marks, fifteen of 9 marks, and sixty of 2 marks; the mean of the averages is still only 7. Hence the same mean of averages is derived from two obviously different and even independent cases. Is it not fairer, in the absence of any other information, to take





$$(600+135+10)/80=9{\cdot}31 \quad\text{and}\quad (50+135+120)/80=3{\cdot}81$$

as the means of the averages, or rather as the representative index marks of the two groups of candidates? In other words, is not one group about two and a half times better than the other? Hence, for a single paper in a number of schools, the apparently easiest plan is to treat all candidates as equally well prepared, and to take the index mark required by the examining body as equal to the total marks gained by all the candidates in the thirty schools divided by 100 N as before; and this seems also fair. This index mark may be got as the quotient $(fu+gv+hw+\ldots)/100(f+g+h\ldots)$, where u, $v \ldots$ are school averages, and f, g, $h \ldots$ are the numbers at each school, so that $f+g+h+\ldots=$N. The same problem is presented to the headmaster of a school who wants to get an index mark either of a form, or of the work of a master, or of the whole school, for comparison from year to year.

Peterhouse, Cambridge.

EXPLORATIONS IN CENTRAL ASIA.

THE detailed results of Dr. Stein's latest achievement in the world of scientific exploration are awaited with the deepest interest by all who concern themselves with the problems of Asiatic research, and it seems probable that we may sit expectant for many months yet before the extraordinary mass of information contained in his collections can be reduced to concrete form. Meanwhile, the Royal Geographical Society has published the text of the lecture (considerably amplified) which he delivered before it last March, and has issued a neat little map which is in itself a most necessary illustration to the story of his adventures.

FIG. 1.—Hall of Ancient Dwelling (Third Century A.D.) after Excavation, Niya Site.

The particular field of exploration which Dr. Stein has made his own is the Tarim basin of Chinese Turkestan. It was here at the very beginning of the century that he unearthed the first relics of an ancient civilisation, which, under the joint influence of India and China, had flourished in the oases of the Takla Makan desert and surrounded the shores of that elusive lake, Lop-nor, some fifteen or twenty centuries ago. It has been usual to think and to write of these buried Buddhist cities of the past as if the gradual encroachment of a great sand-sea, sweeping in huge progressive waves from the westward, had in the course of ages irresistibly engulfed them, and driven forth their ancient population to seek for more profitable fields elsewhere. To a certain extent this is true, but the movement of the sand-drifts was frequently the result rather than the cause of the desertion of these ancient sites. It was the failure of the water supply, the universal process of desiccation which now almost ranks as a geological feature recognisable throughout the world, that permitted the sand-waves. Yet there are points in Dr. Stein's systematic investigation of cause and effect which might lead us to believe in a return swing of the climatic pendulum; another beat in the "pulse of Asia" of which Mr. Huntington writes so convincingly. Here and there were found a people pushing gradually outward from the narrow ring of cultivation which borders the desert back again towards the old-world sites, although, in Dr. Stein's opinion, the sources of water supply once dried up will never again reopen.

However that may be, the important part of Dr. Stein's work in the field was the collection of those archæological relics of the past, including miscellaneous records (some of which are far older than any which have as yet come to light in Central Asia or China), bearing inscriptions in Indian Kharosthi and Brahmi, and specimens of early Buddhist art in moulding and in painting, the classification and interpretation of which will certainly prove to be the work of several years. Undoubtedly Dr. Stein has added a new chapter to Indian history, a chapter which deals with the period of Indo-Chinese religious affinity, when Buddhism, still rooted in the land of its birth, had spread outwards to the older civilisations of Central Asia and a never-resting tide of pilgrims passed to and fro, seeking inspiration at every wayside fount of knowledge that marked the weary road from the Chinese frontier through Khotan to Kashmir, or, striking farther west, refreshed the devotee in Badakshan and Kabul.

FIG. 2.—Southern Series of Cave Temples at the "Halls of the Thousand Buddhas."

The bourne of pilgrimage was ever the same. It was northern India and the cradle of Buddha on the borders of Nepal that was the end of all endeavour; and the marvel of our present knowledge (derived chiefly from the results of Dr. Stein's researches) is that the way was made so plain and the facilities for travel were so great in the early centuries of our era. We read of regular posts and connected lines of open route which must have been furrowed by the feet of thousands where never a soul passes in these later days.

With new history we have also to welcome a broad expanse of new geography. Dr. Stein's methods are nothing if not thorough. We have no uncertainty as to whereabouts he found this or that most ancient site; and when he records his remarkable discovery of a long extension of the time-worn wall of China he is able to define, not only its exact position, but its geographical significance as a defensive work with regard to surrounding topography. He does ample justice to the ability of his geographical assistant, Rai Sahib Ram Singh, but Ram Singh would never have effected such results without Dr. Stein's effective guidance and active help. One hundred and thirty sheets of the standard degree size, on the scale of four miles to the inch (which is what has been secured for the records of the Indian Survey), is a solid addition to our geographical knowledge which ranks well even with his vast store of accumulated archæological lore. Perhaps the most noteworthy discovery made by Dr. Stein during his investigations was the extension of the Turkestan basin eastwards to a point some seven degrees farther east than had been previously recorded. From the Chinese frontier town of Suchau a clearly defined line of drainage follows a course parallel to the extension of the Great Wall towards the central depression at Lop-nor; nor can there be much doubt that in the early days of Buddhist settlements in this region this now partially desiccated line of drainage marked the main trade-route from China to Turkestan. That route now hugs the foothills of the Altyn Tagh to the south between Anshi and Lop-nor, but it is a desolate and forsaken route, untrodden by the trader and unsanctified by the pilgrim.

FIG. 3.—Frescoed Wall in Cave Temple at "The Ten-thousand Buddhas."

It may be long yet ere we are able to appreciate as they deserve the discoveries and collections of Dr. Stein in relation to their bearing on the history of India; for the mass of raw material which has yet to be classified is so great as to have proved almost an embarrassment to its owner. In the meantime the short and instructive booklet on the subject now issued by the Geographical Society is well worth careful study.

THE SIXTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

MEDICINE is so self-centred, and its practice is conducted so largely in private, that an international congress, where men meet on a level, rub shoulders, and part again once in three or four years, is an excellent corrective. It serves the same function in the profession as is answered by a public school for the only son of wealthy parents. It is not so much what is taught as what is seen and heard. The knowledge which is obtained by conversing with men brought up in different schools of thought, under various forms of civilisation, and often with wholly divergent ideals, is in itself remarkable, and is sufficient to start new trains of thought in many lines of research. In a great gathering like the International Congress of Medicine, where five or six thousand medical men are gathered together at fixed intervals, old friendships are cemented, new ones are formed, and whilst the scientific reputation of some falls to the ground, others are exalted. The quack is taken at his true value, for his work is judged by those who know the truth, whilst the humble and earnest worker in the difficult paths of research goes home strengthened by the encouragement which he has received from fellow toilers.

The sixteenth International Congress of Medicine was held at Budapest during the first week of September. The seventeenth congress will be held in 1913 at some town in Great Britain. Budapest lends itself especially to a large gathering of foreigners. It is a splendid city, magnificently placed on the Danube, easy of access both to the northern and eastern races of Europe. The inhabitants are active, intensely patriotic, eager to show the progress that has been made, and to prove that the youngest civilised State in Europe has not much to learn, and is in some respects already ahead of the older civilisations the best points of which it has endeavoured to copy. It is, indeed, very difficult to realise that Budapest was a Turkish possession little more than two hundred years ago, though the vigilant observer will notice the very faintest trace of orientalism as he walks amongst the people and through the smaller streets of the town. For a medical congress, Budapest is ideal, because it is full of springs and baths which would in themselves have brought it fame, the Hunyadi and Apenta springs being known throughout the world.

The congress was excellently organised, and the greatest credit is due to the president, Prof. Kálmán Müller, and the general secretary, Prof. Emil de Grósz, for the manner in which they brought things to a successful issue. His Royal and Imperial Highness the Archduke Joseph, acting on behalf of the King of Hungary, was indefatigable in the cause of the congress, for he not only attended the inaugural meeting in the municipal buildings, where 5000 persons were gathered together on one of the hottest days in the year, and remained throughout the whole sitting of three hours, but later in the week he welcomed the members to the palace and spoke personally to a very large number of the more important official delegates. He was ably assisted throughout by Count Albert Apponyi, the Hungarian Minister of Education, who made several important and statesmanlike speeches showing that he was in touch and in full sympathy with the work of the medical profession throughout the world.

The work of the congress was divided into official, sectional, and general. The official work was of unusual importance. It was decided that in future a meeting should be held once in four years instead of once in three years, as has been the case hitherto; that a permanent committee should be formed, with a president, a paid secretary, and a fixed office. Dr. F. W. Pavy, F.R.S., the president of the National Committee for Great Britain and Ireland, was nominated president, and it was determined that the office of the paid secretary should be at The Hague. By these means it is hoped that there will be a continuity of policy in the affairs of the congress which has hitherto been impossible, because there has been no permanent board to which difficulties and questions of policy could be referred.

The work of the sections did not prove of much interest, although many members attended and the papers were exceptionally numerous. The subjects chosen for discussion, like appendicitis, malignant disease of the larynx, the tuberculin treatment of tuberculosis, and uterine myomata, did not lend themselves to the expression of very novel views, and if the speakers who took part in them were not very inspiring, they were not belligerent, and the congress was spared the painful scenes which have occasionally turned the arena into a veritable battlefield.

Puerperal infection was selected appropriately as a subject of discussion. It was a tardy tribute to the memory of Semmelweis, the pioneer of modern obstetric prophylaxis, who died broken-hearted in the town where he had spent the best years of his life in declaiming against the fearful mortality of childhood and showing some of the means by which it might be avoided. He remained a voice crying in the wilderness until the end, but the statue erected by international effort, and placed in the gardens of the Ergebet-teren, was visited by every member of the congress, and was duly decorated with tributes from every nation.

The general addresses were excellent, and drew very large audiences, who listened most attentively. Prof. Holländer showed by means of lantern-slides some of the diseases and mutilations depicted in the records of the Incas and Huacos. Dr. Bashford, director of the Imperial Cancer Research in London, explained by similar means the present state of the cancer question, whilst Prof. Loeb, of Berkeley, made a remarkable communication upon artificial parthenogenesis.

The net outcome of the congress was the hold which the doctrine of immunity has gained upon the whole of the scientific side of the medical profession. Evidence of its importance was forthcoming from every side. There was a general discussion upon the subject. Dr. Bashford laid much stress upon it in his general address, and it formed an important factor in the work done by Prof. Loeb. It is evident that a great future lies before those who are working at the subject. At the present time there is much confusion and overlapping, a jargon of confusing terms masks the principles, but it is clear that before long the whole theory will be simplified and a most important agent will be added to the practice of medicine.

THE INTERNATIONAL SEISMOLOGICAL ASSOCIATION.

THE third meeting of the permanent committee of the International Association of Seismology was held at Zermatt on Monday, August 30, and the three succeeding days. Out of twenty-two States which now belong to the association, seventeen were represented. In his presidential address, Prof. Schuster directed attention to the importance of determining the movement of the soil in a seismic disturbance, and laid stress on the conditions which seismographs must satisfy, in order that the components of the displacements should be capable of being deduced from the records obtained.

A number of committees, which had been appointed at the previous meeting, now presented their reports. Perhaps the most important of these referred to the microseismic oscillations, which have lately attracted attention in many places. Two kinds of oscillations are to be distinguished, one having a period varying between four and nine seconds, and the other a period of about half a minute. The short-period microseism is often observed simultaneously over large portions of the earth's surface; its most interesting feature, which was independently discovered by Prince Galitzin in Pulkowa, by Hecker in Potsdam, and by Omori in Japan, is that there is a direct relationship between the amplitude of the oscillation and the period, the larger amplitude corresponding to the longer period. Dr. Klotz, the representative of Canada, has also investigated the subject, and found that whenever a centre of low barometric pressure, after traversing the continent, reaches the ocean, these microseismic waves of short period appear. Though we cannot at present give a quite satisfactory explanation of these waves, Prof. Wiechert's suggestion that they are caused by the impact of ocean waves on land areas deserves further investigation. For this purpose the committee intends to set up, probably on the west coast of Ireland, an instrument capable of registering the number and height of the waves. The microseismic disturbances, which have a period of about half a minute, have been found to depend on the intensity of local winds. They seem due to a wave-motion set up on land in a similar manner to that in which waves are set going on the ocean.

Probably the most important communication made to the meeting was that in which Prince Galatzin showed that it is possible to determine the azimuth of the seat of an earthquake by combining the indications of two seismographs, set up so as to give displacements in two directions at right angles to each other. The coincidence of the azimuth determined in this way for a number of earthquakes with that known independently was quite remarkable, the difference in many cases being less than a degree. As the distance of the earthquake can be determined from the interval elapsing between the arrivals of the forerunners and surface waves, Prof. Galitzin's investigations show that it is possible to fix the locality of an earthquake by observations at one distant station only; but such a result could only have been achieved by means of a perfection of instrumental appliances consequent on a complete mastery of the problems involved. Mr. H. F. Reid, of Baltimore, unable, unfortunately, to be present himself, sent a communication, in which he summarised his experiences gained by a study of the San Francisco earthquake. After directing attention to various instrumental matters, notably the absence of damping in many of the American instruments, which rendered the investigation difficult, he suggests the theory of a slow secular displacement as a preliminary condition leading to a seismic catastrophe, and shows how, if this theory be true, a certain class of earthquakes might be predicted.

Prof. Omori communicated a report on the Messina earthquake, in addition to his report on microseismic waves.

Communications were also made, among others, by Prof. Palazzo, of Rome; M. Angot, of Paris; M. Rosenthal, of Tiflis; M. Choffat, of Lisbon; while Prof. Hecker, of Potsdam, gave an account of his more recent results of tidal displacements in the earth. The meeting concluded with a lecture by Prof. Heim, in which an historical summary of the subject was given from the geologist's point of view.

At previous meetings the desire had been expressed that a complete bibliography of the subject should be published annually; a committee was appointed which reported in favour of coming to an arrangement with the International Catalogue of the Royal Society, all papers on seismology in that catalogue to be joined together in one volume, instead of, or perhaps in addition to, their being classified, as at present, partly under geology, partly under physics, and partly under applied mathematics. There is good ground for believing that such an arrangement could be made, and the meeting adopted the committee's report.

A report on the arrangements for an annual catalogue of earthquakes was presented by Prof. Forel, of Morges. The method to be adopted in such a catalogue, in order to make it most generally useful, gave rise to a good deal of difference of opinion; but after discussion in committee a compromise between different views was effected. Prof. Forel having completed his tenure of office as vice-president, M. Hipites, of Bucarest, was elected to be his successor.

The Federal Council of the Swiss Republic had entrusted the arrangements for the meeting to the Schweizerische Naturforschende Gesellschaft, and, with the assistance of Mr. Seiler, the delegates and their families were cared for in a most excellent manner. At the conclusion of the meeting satisfaction was expressed both at the success of the scientific results, and at the hospitable reception accorded to the members present.

BRONZE-AGE INTERMENTS IN SWITZERLAND.

UNDER the title of "Le Cimetière du Boiron de Morges," M. F. A. Forel has issued a report on some remarkable prehistoric interments in Switzerland, and though it occasionally lacks the lucidity of arrangement and grace of style which characterise French work of this kind, it will still be found full of interest.

These interments are attributed to the Bronze age, or, as the author terms it, "le bel-âge du bronze des Palafitteurs." The graves are flat, without mounds or stone pedestals, the latter, he thinks, having been probably replaced by wooden posts which have now decayed. They lie in no definite order or in lines one behind another; nor is there any rule of orientation in the graves themselves. It is remarkable that earth burial and cremation are found side by side; in fact, the two methods of disposal of the dead seem to be contemporary, if the evidence of identity in the style of vases and bronzes deposited with the corpse be accepted as conclusive. It may be noted that M. Forel treats as cases of inhumation those in which the teeth are found intact; those of incineration when the roots of the teeth alone survive. There is nothing in the shape of a regular cist, only a slab laid in a horizontal position over the head and upper part of the body. The slab graves of this class contained funeral plates and dishes, or piles of urns and bowls, three or four in number, laid one above another. Only one tomb which held a cremated corpse contained a cinerary urn; in the others the bones lay in the mass of charcoal and other remains of the cremation. In such interments only a single corpse was discovered; hence it is supposed that the custom of sacrificing slaves or animals in the belief that their spirits would accompany the dead to the other world did not prevail. There are occasional remains of some kind of coffin; and in the cremation graves the jars probably contained offerings of food to the dead, meat in some cases forming part of such deposits. It is thus obvious that the people who used this cemetery believed in the survival of the spirit after death. M. Forel seems to imagine that this custom of providing food for the dead implies the existence of a sacerdotal class; but this is not confirmed by the analogy of the customs of modern savages, among whom the head of the household or some tribal elder performs the death rites.

The paper is accompanied by photographs of the graves and their contents, and is, on the whole, a useful contribution to our knowledge of the Bronze Age on the continent of Europe.

NOTES.

WE learn from the *Pioneer Mail* that the Government of India has issued a resolution concerning malaria in India. The Governor-General has had under consideration a proposal of the sanitary commissioner that a permanent organisation should be formed to inquire systematically into the problems connected with malaria. The number of deaths ascribed to fever throughout India approximates to four and a half millions, representing a mean death-rate of nearly twenty per thousand, and though this total is greatly in excess of the actual figure, owing to the practice of ascribing to "fever" deaths which are in reality due to other causes, yet it has been estimated that the actual death-rate from malarial fever is about five per thousand. The Governor-General has decided to convene a conference to examine the whole question, and to draw up a plan of campaign for the consideration of the Government of India and of the local governments. The conference will assemble at Simla on October 11, and it is expected that it will last about a week. The following is a rough outline of the subjects to be discussed:—(1) the distribution of malaria in India as a whole and in various provinces, with special reference to the sickness and mortality to which it gives rise; (2) the measures of prevention which have been adopted in the different provinces—drainage, mosquito destruction, the distribution of quinine—and the measure of success which has attended each; (3) the improvement of schemes of prevention, including the question of the most suitable form of quinine and the agency by which it can most effectively be distributed.

THE International Aëronautical Congress at Nancy opened on Saturday last, and will conclude to-day. The programme included papers on dirigible airships, on light motors for airships and aëroplanes, on the history of aëroplanes, on cartography, on photographic topography from balloons, on the properties and uses of hydrogen, and on the theory and practice of aërodynamics.

AT the Brescia aviation meeting a record in altitude flight was made on Monday last by M. Rougier, who ascended to a height of 198·50 metres (645 feet), as compared with the previous records made by Mr. Orville Wright in Berlin, 172 metres, and M. Latham at Rheims, 155 metres.

THE following is a list of the awards made in connection with the Brescia aviation meeting:—grand prize of Brescia (international) for a speed test over 50 kilometres: 1st, Mr. Curtiss, 2nd, Lieut. Calderara, 3rd, M. Rougier; Modigliani prize (international) for height: 1st, M. Rougier, 2nd, Mr. Curtiss; prize for carrying passenger (international): Lieut. Calderara; prize for starting in shortest time: 1st, Mr. Curtiss, 2nd, M. Leblanc; world's record for height: M. Rougier; Oldofredi prize (national) for 1 kilometre: Lieut. Calderara; prize given by the Corriere della Sera (national) for 20-kilometre flight: Lieut. Calderara; King's cup: Lieut. Calderara. The gold medal given by the King has been awarded to Buzio and Restilli, the engineers who constructed the Rebus engine of Lieut. Calderara's machine.

AVIATION meetings, according to the *Times*, are to take place at Johannisthal, Berlin, from September 26 to October 3, and at Issy-les-Moulineaux, near Paris, from October 30 to November 1.

ACCORDING to a New York correspondent of the *Times* great damage to property and some loss of life has been caused in the neighbourhood of the Mexican Gulf by a hurricane. On September 21 the waters of the Gulf and of the Mississippi were reported to be still rising, and trains were water-bound in many places.

THE thirteenth annual fungus foray of the British Mycological Society will be held at Baslow, Derbyshire, from Monday next until the following Saturday. In the evening of Wednesday the president of the society—Prof. M. C. Potter—will deliver an address on bacteria in their relation to plant pathology, and on Thursday Prof. R. H. Biffen will read a paper on the Laboulbeniaceæ, and Mr. A. D. Cotton will present some notes on new or critical British Clavariæ.

THE Allahabad *Pioneer Mail* announces that an agricultural association is in course of formation in Poona which has as its object the development of agriculture in the Deccan. The programme of work laid down by the promoters is a large one. It embraces an annual show in one of the Deccan districts, the publication of up-to-date agricultural information, chiefly, if not entirely, in the vernacular, the encouragement of better cattle breeding, the pressing of the importance of agricultural education, especially in the vernacular schools, and many other departments.

IN connection with the Hudson-Fulton celebration (September 25 to October 9), a list has been issued by the committee of the celebration commission of the museums, institutions, and societies which have prepared free exhibitions relating to Henry Hudson, Robert Fulton, and the history of steam navigation; paintings, objects of art, archæological specimens, and other things relating to the three centuries of New York's history; the discovery of the Hudson River and the introduction of steam navigation; plants, fish, and animals indigenous to the Hudson River valley.

AN expedition, consisting of members of the Utah Archæological Society, is reported to have made important discoveries along the Colorado River, in northern Arizona and southern Utah. The most important is a natural bridge, which spans 274 feet and is more than 300 feet high. On the top of it several fossils of remarkable size were found embedded.

ACCORDING to *Science*, the palæontological expedition of the University of Chicago to the Permian of northern Texas has returned from a successful trip. Numerous skulls and skeletons of small reptiles and amphibians were secured, giving to the University of Chicago, with its previous collections from that formation, an excellent representation of Permian vertebrates.

MR. HENRY ADAMS has been elected president of the Association of Engineers-in-Charge, in succession to Mr. James Swinburne, F.R.S.

LIEUT. SHACKLETON has been invited to deliver a lecture on October 9 before the Danish Royal Geographical Society.

DR. E. A. WILSON, who served under Captain R. F. Scott in that explorer's former Antarctic expedition, has accepted the post of medical officer for the projected expedition of Captain Scott to the South Pole.

QUESTIONED as to the truth or otherwise of the statement that he was to lead an expedition to the Antarctic regions, Commander Peary has replied:—"My work in the field of either the Arctic or the Antarctic is at an end, although my services will always be available if desired in promoting organisation or other work in those regions."

THE death of Mr. Bryan Cookson has robbed astronomy of one who, during but a short life, had already achieved much, and who gave promise of still further advancing our knowledge of that science. Mr. Bryan Cookson was a son of the late Mr. N. C. Cookson, of Wylam-on-Tyne. He was educated at Harrow, and at Magdalen College, Oxford. After some time spent in travelling he took up his residence at Cambridge, where he designed a new form of floating photographic zenith-telescope for the purpose of making original investigations on change of latitude and the constant of aberration. Later he worked for two years at Cape Town under Sir David Gill, His Majesty's astronomer at the Royal Observatory, Cape of Good Hope, and some of his results were published in a paper on the determination of the mass of Jupiter and the elements of the orbits of the satellites of that planet. On his return to Cambridge he erected his zenith-telescope, with which he continued his observations, many of which still await publication. About a year ago Mr. Cookson was appointed assistant at the Cambridge Observatory. He was a man of the highest character and of singular charm of manner, and his death, at the comparatively early age of thirty-six, is keenly felt amongst a large circle of acquaintances.

THE death is announced of Mr. T. Currie Gregory, a civil and mining engineer who was concerned in the building of the Great Western Railway of Canada, now merged in the Grand Trunk line.

THE death is announced, at the age of seventy-four, of Mr. Peter Barr, well known as a horticulturist, to whom in 1897 the Victoria medal of honour was awarded by the Royal Horticultural Society.

AN exceptionally cool September is being experienced this year, and the entire absence of really warm days is very unusual. At Greenwich during the first twenty-two days of the month the thermometer has only once exceeded 70°, the absolutely highest reading being 71°. The mean of all the maximum day temperatures is 64°, which is 5° below the average, and the mean of the minimum night temperatures is 48°, which is 2° below the average, the mean result for the first three weeks being 3.5° below the average. During the corresponding period last year there were six days with the shade temperature above 70° at Greenwich, and in 1907 there were nine such warm days, whilst in 1906 there were as many as eleven days with the thermometer above 70°, and on each of the first three days the shade temperature exceeded 90°. The rainfall for September is so far generally somewhat below the average, and the duration of bright sunshine is about normal. During the greater part of the period the United Kingdom has been under the influence of a region of high barometer readings, and this has warded off very greatly the inroad of cyclonic disturbances from the Atlantic.

WE have received from the editor (Dr. Ziegeler, Spandau Jagowstrasse 4) a copy of the *Wochenschrift für Aquarien- und Terrarien-kunde*, containing several articles of interest. The chief of these refers to the successful importation into Germany from Mexico of that rare Cyprinodont fish Xiphophorus, so called on account of the pointed process borne on the caudal fin of the male. A good description is given of the habits and appearance of both sexes. Notes on the common viper, on the reproduction of the frogs and toads of Germany, and sketches of fishing and of hunting make up an attractive number. In a covering letter the editor points out that his *Wochenschrift* is international in scope, and he invites those who are interested in the cult of the aquarium to assist him in realising this object by contributing to its pages. The subject is not merely one for amateur fanciers, but is capable of forwarding research in genetics.

THE second number of vol. ii. of "Memoirs of the Indian Museum" is devoted to the first portion of an account of the Indian Cirripedia Pedunculata, by Dr. N. Annandale, the stalked barnacles of the family Lepadidæ, in its modern restricted sense, forming the subject of this section. The collection of Indian cirripedes of this group in Calcutta is unusually rich both in the matter of species and individuals, and since it has been supplemented by specimens from various European museums Dr. Annandale has had before him a wealth of material which ought to render his monograph well-nigh complete. In the author's opinion, the primitive cirripede was provided with a large number of calcareous plates or valves, and from this ancestral type evolution has taken place along several lines, both as regards the structure of the internal parts and the various appendages, and as regards the valves. In each division occur partially parasitic types in which the valves have undergone more or less complete degeneration.

To the September number of the *Popular Science Monthly* Dr. H. S. Colton contributes a specially interesting article on Peale's Philadelphia Museum. Charles Willson Peale, who was born in 1741, was at first a portrait-painter, but about the year 1785 set about the formation of a natural-history museum, which was, indeed, opened in Philadelphia, with the addition of grounds where a certain number of live animals were kept. In the exhibition-cases Peale attempted, with the aid of artistically painted backgrounds, to show his zoological specimens amid their natural surroundings, a practice which, after long disuse, has of late years come into favour in museums on both sides of the Atlantic. Peale's greatest achievement was the recovery and reconstruction of the first skeleton—or rather two skeletons—of the American mastodon. In the spring of 1801 Peale was informed that the bones of a mastodon had been discovered in a marl-pit near Newburg, in New York State, and he proceeded to the spot and purchased from the owner for 300 dollars the bones already disinterred, and the right to drain and excavate the morass for the purpose of endeavouring to recover the remainder of the skeleton. With the aid of pumps and other machinery lent by Government, the recovery of the missing bones was successfully carried out, and the skeleton, lacking the lower jaw and part of the crown of the skull, was eventually mounted, with additions in wood of the missing parts, from a second skeleton obtained in the neighbourhood and likewise mounted. These skeletons are noticed by Cuvier in his memoir on the great mastodon. At the sale of the Peale Museum in 1850 the second skeleton was probably bought by P. T. Barnum, and, if so, may have been burnt in the destruction of his museum by fire in 1851. The first skeleton, after having been taken by Peale and his brother to London in 1803, where it was exhibited before the Royal Society, eventually found a home in the American Museum of Natural History at New York, where it is known, from having been in the museum of the latter city, as the Baltimore mastodon.

IN the *Journal of Morphology* for July (vol. xx., No. 2) Mr. O. P. Dellinger makes an interesting contribution to the discussion on the physical structure of protoplasm. There is still, in spite of the elaborate researches of Bütschli and others, much difference of opinion on this question. The present author makes the cilium the starting point of his investigations, and brings forward evidence to show that all contractile protoplasm has a fibrillar structure. He demonstrates, in an apparently satisfactory manner, that the cilia of Stylonychia are composed of spirally coiled fibrils, and that the flagella of Euglena, Chilomonas, and Spirillum consist each of four spiral filaments, which will account for the complexity of their movements. He finds that by using those methods and reagents by which cilia are best preserved it is possible to demonstrate the existence of a finely meshed reticulum in Amœba, and maintains that such a reticulum of contractile fibres would explain all the facts of amœboid movement. Osmic acid appears to be the most satisfactory reagent for fixing the contractile structures investigated.

AN investigation of the epiphytic mycorrhiza that invests the roots of *Monotropa Hypopitys* forms the subject of a paper contributed by Dr. J. Peklo to the *Bulletin International*, Prague (1908). He points out that there is a marked difference between the amount of mycorrhiza investing Monotropa roots in clay or humic soils, and that specimens in clay soils may be entirely free from the fungal covering. As is generally known, the fungus penetrates only into the epidermal cells, and for this reason is termed epiphytic. The plant secretes tannin products in these cells, which serve, in the author's opinion, to prevent the fungus from penetrating further within the root.

THE first of an announced series of pamphlets providing information on special Indian timbers deals with the timber yielded by *Diospyros Kurzii*, and known as Andaman marble or zebra wood. As the name implies, the wood is streaked in bands ranging from black to a brownish or pinkish grey, and it has been described as one of the handsomest timbers in the world. The pamphlet, compiled by Mr. R. S. Troup and published by the Government of India as Forest Pamphlet No. 7, supplies details regarding the qualities, available size, and amount of timber; it also contains an actual specimen of the wood.

ARISING out of an inquiry addressed to the director of Kew Gardens, Dr. O. Stapf supplies in the *Kew Bulletin* (No. 7) an article on the identification and properties of the wood known as "lignum nephriticum," which was regarded some three centuries ago as a valuable remedy for disorders of the bladder and kidneys; it was also known that an infusion of the wood was fluorescent. This property, together with a reference to the Mexican vernacular name "coatl," provided the clue to its identification as the product of the leguminous tree *Eysenhardtia amorphoides*. A chemical examination to ascertain the principles which give the wood its physical and possible therapeutical qualities is postponed until more material is available. Another determination by the same authority refers to the fodder grass which is making a reputation in Australia and Natal as *Phalaris commutata*, but which should be known as *Phalaris bulbosa*.

WE have received a copy of "The Problem of Practical Eugenics," a lecture delivered by Prof. Karl Pearson at the Galton Laboratory for National Eugenics. Prof. Pearson directs attention to the falling birth-rate, particularly in a manufacturing city like Bradford, and the conclusion is arrived at that this is due mainly to factory legislation, which has destroyed the economic value of the child. A Bradford doctor assured him that in the days before the Factory Acts more care was taken of the children on this account. Prof. Pearson says "the mistake of most legislation is that it is carried by appeal to the sentiment and feelings of relatively small classes—the cultured and highly sensitive upper and middle classes. The biological and economic bases of life are disregarded, and the result is only manifest twenty or thirty years later. The whole trend of legislation and social action has been to disregard parentage and to emphasise environment." Various suggestions are offered to remedy this effect while still maintaining factory legislation. The lecture is one which should be carefully studied by the educated public and our legislators who have the well-being of the race at heart.

AN important report, by Prof. W. J. Simpson, on the general state of sanitation and of public health in the West African colonies, has been issued by the Colonial Office. Prof. Simpson was sent to the Gold Coast with special reference to an outbreak of plague which occurred in Accra and the surrounding district in January, 1908. The outbreak lasted for six months; there were 344 cases with 300 deaths. Preventive inoculation was resorted to with conspicuous success, and was performed on 35,000 persons without a single accident or ill-effect. The general insanitary conditions existing in the colony are described by Prof. Simpson as being fraught with danger to the community. No real, effectual, and steady campaign against malarial fever in West Africa has yet been begun. There are no mosquito brigades maintained throughout the year, and it is no one's special duty to look after and to be responsible for the public health. No real progress is possible except by the formation of an organised health department completely distinct from the existing medical service of the colonies, and charged with the duty of advising the Government concerning improvements, and of seeing that they are effectively carried out. Owing to the absence of such a department towns are suffered to grow up from villages without any forethought, the result being often an insanitary condition that nothing but costly demolition will remedy. The report sketches an outline of the organisation and composition of the proposed sanitary service, and discusses its relations with the existing West African medical staff and with the Government.

THE Bulletin of the Sleeping Sickness Bureau (No. 9) contains *résumés* of a number of papers on trypanosomes and sleeping sickness. Dr. Moffat reports on a sleeping-sickness-like disease in Bechuanaland. He concludes that the disease closely resembles sleeping sickness, but if it is this disease it is probably imported, and not indigenous.

THE craniometrical evidence from India, which is at present scanty and in various respects unsatisfactory, has been usefully supplemented by the publication of the measurements of a series of skulls deposited in the Indian Museum, Calcutta, which have been carried out by Mr. B. A. Gupte under the supervision of Dr. Annandale. The collection contains 614 specimens, but many are broken and others do not indicate the caste or tribe of the subjects. Besides this, practically all come from the lowest strata of the population, from jails and hospitals, the more respectable members of the community being invariably cremated. The record is also vitiated by the impossibility of segregating the skulls of emigrants from other parts of India who happened to die in eastern India. These records, therefore, afford no safe basis for generalisation, but they may be useful to supplement measurements of the living subject, which are necessarily less trustworthy than those of skulls, because it is easier to arrange the position of the latter, and because the soft tissues of the head and face exhibit much individual variation and capacity for contraction and expansion. Mr. Gupte has good reason for appealing to persons throughout India who are in a position to collect skulls, the *provenance* and records of which can be accurately determined, to supplement the present collection, which is of little value for the classification of the multitudinous races and castes to be found within the Indian Empire.

THE first annual report (1908) of the Liverpool Committee for Excavation and Research in Wales and the Marches, which has its headquarters in the Liverpool University Institute of Archæology, and is closely associated there with the School of Celtic Studies, contains valuable preliminary surface surveys and detailed reports of tentative excavations at the Roman camps of Chester and Caerleon. The discovery of a Palæolithic implement at the former site is of special interest. A list of the relative number of coins found at Caerleon indicates an occupation of the camp in, or soon after, the principate of Vespasian. Mr. Evelyn-White adduces literary evidence pointing to occupation under Claudius. Two excellent plans of the camp have, apparently, a true north bearing, though the fact is not stated, for the orientation indicated is about 51° N.W.-S.E., which on paper is near enough to the theoretical azimuth for the district of sunrise at the winter solstice. In the preliminary surveys of cromlechs there is not a single reference to their orientation, and the subject has yet to be formally recognised by a committee which, as the list shows, represents all the archæological societies of Wales and the Marches.

DR. GEORG VON SMOLENSKI, of Cracow, contributes to *Petermann's Mitteilungen* (v., p. 101) an interesting study of the causes of the asymmetrical form of the north-and-south river valleys in Galicia, which are characteristically steeper on the eastern side than on the western. A careful examination of the different theories which have been proposed from time to time leads Dr. von Smolenski to conclude that no single hypothesis can account for all the observed facts, and he divides the valleys into two groups, those in which the asymmetrical form is being developed and extended at the present time, and those in which it remains as the result of a former condition no longer in existence. In the first group the asymmetry is due to the normal action of "Hilber's law," the base-level of each tributary of the master stream (the Dniester) being lower than that of the tributary next it to the westward. The second group is found to be due to the action of wind, and must have been formed at a time when the prevailing winds of the region were east and north-east. It appears independently that the formation did actually take place in late Pleistocene times.

The report of the Meteorological Committee for the year ended March 31 presents several points of especial interest. The various publications containing statistical results have been grouped together under the title "British Meteorological Year-book"; it appears strictly up to date, which will be a great advantage with regard to the supply of information to inquirers, the number of whom have much increased in recent years. Several publications on interesting subjects are in course of preparation. The 7h. a.m. international service of telegraphic weather reports, which was brought into operation on July 1, 1908, has been found to work satisfactorily, and since the commencement of the present year the reports by radio-telegraphy hitherto received from H.M. ships have been supplemented by wireless telegrams from Atlantic liners. The observations and accuracy of transmission have been satisfactory, but only a small number of the messages were received in time for current use, and much remains to be done before they can be utilised in a day map of the ocean. The weather forecasts issued in the morning newspapers and those issued during the harvest season (June–September) have been very successful, the percentage of accuracy (complete and partial) amounting to 92 and 96 respectively. The committee contemplates making some important modifications in the practice of the office as regards marine observations. Instead of devoting attention almost exclusively to the compilation of average results, it is proposed to compare the current with the mean values. Monthly outline charts in suitable form, with the mean values of various elements, are being prepared as the ground-work for plotting the observations recorded on voyages. By this means it is hoped eventually to trace the meteorological relationships of changes in different parts of the world.

The *Physikalische Zeitschrift* for September 1 contains a long illustrated article by Dr. Max Iklé on old and new little-known auxiliary apparatus for use in physical and chemical laboratories. The pieces of apparatus mentioned are taken from the catalogues of nineteen German firms of instrument makers, and are well worthy of the attention of instrument makers in general. Of special interest are the funnel holder of bent wire, the small instrument stand of adjustable height, the metal lens holder of the Schuster and Lees type, the Bunsen burner with the gas inlet at the side so as not to be stopped up by fused salts falling down the tube, the "emaille" insulated connecting wire for electrical work, and, finally, the list of monographs dealing with cements for physical and chemical work.

The well-known paradox of twisting a strip of paper and joining its ends in such a way as to form a surface with only one face and only one edge gives rise to the cubic surface known as Möbius's surface. This is, in fact, a surface generated by a straight line which revolves about a point in its plane through an angle of 180°, while the plane revolves about a straight line in itself through 360°. A discussion of the properties of this surface, by Prof. C. E. Cullis, forms one of the papers in the first number of the new Bulletin of the Calcutta Mathematical Society.

The Calcutta Mathematical Society has commenced the issue of a Bulletin which promises to be an important addition to our mathematical periodicals. In addition to original papers it contains a "summary of principal mathematical journals," with abstracts of many papers; a section headed "Societies and Academies," with full list of titles of papers read; "Reviews"; "Notes and News"; a bibliography of "New Publications," together with proceedings of the society itself, and lists of members and of books in the society's library. While the new bulletin thus assumes the cosmopolitan character of its American contemporary, several of the features which characterise it are distinctly new. The journal should fill a want which is felt no less by English than by Indian mathematicians. We had almost forgotten to mention another commendable feature—there are no "problems and solutions."

A paper on the liquefaction of clay by alkalis and the use of fluid clay casting in the ceramic industry, by Dr. E. Weber, which formed the subject of an interesting demonstration at the International Congress of Applied Chemistry, appears in full in German and in English in the eighth volume of the Transactions of the English Ceramic Society, before which society the paper had previously been read. The author shows that by the addition of a suitable quantity of alkali a stiff clay, containing not more than a normal quantity (15 to 20 per cent.) of water, can be made quite fluid; on pouring into plaster moulds the water and alkali are drawn out, and the clay quickly sets. The addition of the alkali does not affect the properties of the finished material, provided that it is only used in moderation, and the use of plaster moulds tends still further to neutralise its effects. In addition to the saving of labour-charges, it is claimed for the casting process that, by completely disintegrating the clay, it gives a very dense and uniform product free from all defects, and that when porous materials are admixed with the clay these become thoroughly impregnated, giving an absolutely dense, homogeneous, and strong mass. The method is in use on a considerable scale for the manufacture of glass furnaces, muffles for zinc distillation, gas retorts, and sanitary goods, as well as smaller articles. The same volume contains a description of a new casting machine, by J. G. Roberts, which is claimed to work with less manual labour than those previously in use, and to have an output of forty-five dozen articles per hour. The society is to be congratulated on the initiation of a series of abstracts from pottery journals, of which a first instalment, covering forty pages, and dealing with twenty journals, is now published.

The Parseval airship has recently passed the stipulated tests, and has been accepted by the Prussian War Office. The conditions laid down were capability of remaining at a height of about 5000 feet for more than ten hours, of landing at any specified place, and, in addition, capability of being quickly taken to pieces, transported by rail or by two-horse vehicles, fixed up, filled again, and started from any place. At the trials the airship actually kept afloat for $11\frac{1}{2}$ hours. We learn from a description in *Engineering* for September 10 that the ship has a cigar-shaped body about 190 feet long, and has a maximum diameter of about 31 feet. The balloon is charged with hydrogen, and has sufficient rigidity imparted to it by a slight excess of gas pressure—0·8 inch of water. To produce and maintain this gas pressure two *ballonets* or air-sacks have been provided within the balloon; these are charged with compressed air at a pressure of about $1\frac{1}{4}$ inch of water, and this supply is controlled by means of a system of valves. The motor develops from 100 horse-power to 120 horse-power, and the petrol tank contains nearly 100 gallons.

FEW present-day engineers are aware that Watt produced a steam tilt hammer some years before Nasmyth designed the type of hammer that bears his name. The works at Soho held at one time a great reputation for coppersmith work, and this class of work was done with a Watt tilt hammer, which continued to be in use until quite recently. A photograph of the hammer, together with many others showing machines used by Boulton and Watt, appears in an article in the *Engineer* for September 10. In examining the illustration of one of the Soho boring machines, we are reminded of Watt's early troubles in boring his cylinders—on one occasion we find him rejoicing over a finished cylinder which was nowhere more than ⅜-inch from true circularity. We agree with our contemporary that it is greatly to be deplored that the history of machine tools has not been preserved. The ingenuity which has produced the development of machine tools has contributed in no small degree to the rise and progress of mechanical engineering.

A CONSIDERABLE extension of our knowledge of the electrical strength of air has been made by Mr. E. A. Watson, of the University of Liverpool, who has measured the potential difference necessary to cause a spark to pass between two small metal spheres at various distances apart in air at pressures between one and fifteen atmospheres. His paper, and the discussion which arose on it, will be found in the August number of the Journal of the Institution of Electrical Engineers. From it we gather that air compressed to fifteen atmospheres will stand an electrical stress of 40,000 volts per millimetre, and it is to be hoped that this fact will soon find its application in apparatus in which high insulation is required.

Erratum.—In NATURE of September 16, p. 339, second column, line twenty-two from bottom, the word satisfactory should be unsatisfactory. The sentence should read:—"With a sextant and artificial horizon, a low altitude, such as 10° or 11° or below, is very unsatisfactory."

OUR ASTRONOMICAL COLUMN.

HALLEY'S COMET.—From a Central News telegram published in Monday's *Daily Telegraph*, we learn that Prof. Burnham has obtained two photographs of Halley's comet, with instruments at Yerkes Observatory.

OBSERVATIONS OF PERRINE'S COMET, 1909*b*.—A further observation of Perrine's comet, made by Dr. Max Wolf on September 5, is recorded in No. 4355 of the *Astronomische Nachrichten* (p. 179, September 12). With the reflector, and a power of 140, the comet appeared as a round, nebulous mass, of about 10′ diameter, increasing in intensity towards the centre. The brightness of the whole comet is about equal to the fourteenth magnitude, while the nucleus is about equal to a star of that magnitude.

Dr. Ebell gives an ephemeris for this comet in the same journal showing that it should become about 1·5 magnitudes brighter than it is at present by October 17. The observation of September 5 shows that this ephemeris then required corrections of −1m. 39s. and −23′.

OBSERVATIONS OF MARS.—In No. 4354 of the *Astronomische Nachrichten* (p. 159) M. Jonckheere gives a drawing illustrating his observation of August 11–12. The peculiar interest of the observation was the aspect of the Novissima Thyle, which, although still covered with ice, was detached from the polar cap. This feature of the Martian landscape appeared oval, with its broad extremity in long. 330° and its narrow end in long. 310°, its apparent length being 1·42″.

Measures of the polar cap show that its apparent diameter decreased from 4·33″ on July 16 to 3·00″ on August 21.

Further changes are recorded by M. Jarry Desloges in No. 4355 of the same journal. Observations made with a 37-cm. refractor on the Revard plateau on September 3 showed that the white polar spot was divided completely by a crevasse and a greyish region in long. 80°. The region of the Lacus Solis and d'Auroræ Sinus, so pale during the previous rotations, showed considerable changes, the details now appearing very different in form, colouring, and position to what they did in 1907. Juventæ Fons is dark and easily visible, and the canal Coprates appears to have changed its position since 1907. Nectar is dark and broad, and Araxes is double and very complicated in its structure. Lacus Phœnicis is blackish and is doubled, the southern portion being the smaller. Lacus Tithonius has very indefinite edges, and two dark spots are seen within its area. The Solis Lacus presents a number of detailed features, and is much elongated in the direction east-west. A number of canals, single and double, were observed, and all the regions observed presented such a complicated structure that it was found impossible to make complete drawings.

WATER VAPOUR IN THE MARTIAN ATMOSPHERE.—According to a despatch published in the *Times* of September 17, spectrograms of Mars and the moon, secured by a party of Lick observers on the summit of Mount Whitney, indicate that there is no appreciable quantity of water vapour in the Martian atmosphere. Prof. Campbell suggests that the positive results obtained by Prof. Lowell and other observers may be attributable to water vapour in the earth's atmosphere, but further details should be awaited ere the recent negative results are accepted as final. The photographs are stated to have been taken when Mars and the moon were at the same altitude, and under similar conditions of the earth's atmosphere, yet the vapour bands in the Martian are no stronger than in the lunar spectra; hence it follows that, at the time the spectra were obtained, the quantity of water vapour on Mars was apparently no greater than that on the moon.

THE MAXIMUM OF MIRA IN OCTOBER, 1908.—Dr. Nijland's observations of the magnitude of Mira, made at the Utrecht Observatory during the period July, 1908, to February, 1909, showed that the maximum (mag. = 3·5) occurred on October 6, 1908 (J.D. 2418221), five days before the time given by Guthnick's ephemeris (*Astronomische Nachrichten*, No. 4355, p. 165).

THE SPECTROHELIOGRAPH OF THE CATANIA OBSERVATORY.—In an extract from vol. xvii. of the *Rendiconti della R. Accademia dei Lincei*, Prof. Riccò describes the spectroheliograph now in use at the Catania Observatory, the first to be erected in Italy.

The instrument is made to attach to a telescope, and may be used with a prismatic, or a grating, dispersion. The regulation of the transit of the primary slit across the solar image is effected by a clepsydra containing water with 20 per cent. of glycerine added. The diameter of the solar image operated upon is 52 mm., but the primary slit is but 37 mm. long, therefore the whole disc takes two exposures. Some of the results obtained at Catania, in 1908, are reproduced with the paper, which is also printed in No. 8, vol. xxxviii., of the *Memorie della Società degli Spettroscopisti Italiani*.

Hα IMAGES ON SPECTROHELIOGRAMS.—In concluding a letter to the *Observatory*, M. Deslandres states that, on spectroheliograms taken in Hα light at Meudon, he has, this year, noted numerous instances where the spectroregister of velocities has revealed some very large radial displacements, similar to those observed by Young in 1872 and Hale in 1892. These were thought to be exceptional phenomena, but Mr. Buss, who calls them "horns," claims that he has seen them with relative frequency. The Meudon observations now confirm Mr. Buss's ocular observations.

DOUBLE-STAR MEASURES.—In Nos. 4353–4 of the *Astronomische Nachrichten*, Prof. Burnham continues the record of the observations of double stars made since the publication of his General Catalogue. The majority of measures refer to doubles otherwise neglected, and comparatively few of the Σ or $O\Sigma$ are considered to require present attention. About 150 systems are included in the list of measures now published.

COPENHAGEN CONGRESS ON THE TESTING OF MATERIALS OF CONSTRUCTION.

THE fifth Congress of the International Association for the testing of engineering materials met at Copenhagen on September 7–11. The attendance at this congress was very much larger than that at the previous meeting, which took place at Brussels three years ago. There was a particularly marked increase in the British representation, which had risen from about fifteen at Brussels to more than forty at Copenhagen. Among the British representatives were Mr. G. C. Lloyd, British member of council of the International Association, Mr. J. E. Stead, F.R.S., and Messrs. B. Blount, F. W. Harbord, L. Robertson, E. O. Sachs, F. Tomlinson, W. Rosenhain, and A. G. Roberts. Among the Continental members, Profs. Martens and Heyn (Berlin), H. Le Chatelier and L. Guillet (Paris), Messrs. Webster, Moldenke, Hatt, and Windsor-Richards (U.S.A.), were some of the best known. The membership of the congress thus very fully represented both engineering science and practice.

The formal opening of the congress took place in the presence of the King of Denmark in the large hall of the University of Copenhagen. The opening ceremony was performed in a few graceful words by the Crown Prince of Denmark. In his presidential address the president, Mr. Foss, explained the general aims of the association, and pointed out the fact that the present year was the twenty-fifth anniversary of the first inception of the association. He referred specially to the increased interest displayed in the present congress by British engineers, and said he hoped that this might lead to the establishment of a better mutual understanding between the Continental and the English-speaking engineers. An address by Mr. P. Larsen on the development of the Danish cement industry completed the proceedings, which were, however, considerably enlivened by the spirited rendering of a typically Scandinavian cantata by a choir of students.

The actual business of the congress, which occupied the mornings of September 8, 9, and 10, was divided into three sections, the meetings of which took place simultaneously in various rooms set apart for the purpose in the splendid Town Hall of Copenhagen, where every possible provision for the comfort and convenience of members had been thoughtfully made. Section A, being devoted to subjects connected with metals, was the largest as regards attendance, although Section B, devoted to cement and reinforced concrete, also attracted many members and much attention. Section C, devoted to miscellaneous materials, proved less important.

The papers and reports submitted to the three sections occupy the closely printed pages of several voluminous pamphlets, and these, as well as the discussions upon them, can only be indicated here in the briefest outline.

Section A devoted its first sitting to the subject of metallography, an official report of the progress of that science being presented by Prof. Heyn, of Berlin. The extent of this report, in which a considerable number of British papers are referred to in abstract, is striking evidence of the great strides which this new science has made—the period covered by this report marking an epoch through the loss of Dr. Sorby, the actual founder of the science. Although the report of Prof. Heyn referred to a large number of papers, some of considerable importance which have appeared in England and America were, no doubt inadvertently, omitted; in the discussion, therefore, it was suggested by Dr. Rosenhain that it would be desirable in the preparation of future progress reports of this kind to obtain the collaboration of competent members from each country with the view of compiling a complete triennial bibliography. Out of the subject-matter of this report a discussion arose as to the nature of the constituents of steel, in which Benedicks, Le Chatelier, and Heyn took part. A further and very satisfactory outcome of this discussion, followed by a private conference of some of the delegates, was the formulation of a set of international definitions referring to the nomenclature of the constituents of iron and steel; this set of definitions was placed before the congress under the unanimous recommendation of Messrs. Le Chatelier, Guillet, and Charpy (France), Heyn (Germany), Benedicks (Sweden), and Stead and Rosenhain (England). The new term "meteral," suggested by Howe and Sauveur (U.S.A.), was accepted with the significance in the case of the constituent of a metal which attaches to the term "mineral" in the case of the constituents of a rock, complexes of two or more meterals to be known as "aggregates"; these terms having the great advantage of being of international applicability, and also fairly obvious in meaning, have met with general approval. The terms "martensite," "osmondite," "austenite," and "pearlite," as well as the already universal terms "ferrite" and "cementite," have received clear definitions; thus the new term "osmondite" is to denote that constituent which is present in partly hardened or tempered steels which no longer consist of either austenite or martensite, but contain an intermediate constituent which arises in the passage of martensite into pearlite; this constituent, which some authors have hitherto called "troostite," is now to be known as "osmondite," and it is hoped that the full definition adopted by the congress will free the term "osmondite" from the haze of controversy which has hitherto obscured the term "troostite." The two terms "troostite" and "sorbite" have been left entirely out of these international definitions in the hope that their use will either be entirely dropped or, at all events, accompanied in each case by a special definition.

The adoption of these definitions constitutes one of the few quite definite results attained by the congress; in most other matters the discussions either produced no definite conclusion or the questions under consideration were referred to international committees to be subsequently appointed by the council. Thus the question of slag-enclosures in steel, raised by a paper by Rosenhain, led to a discussion in which the general trend of opinion was strongly in the direction of attaching greater importance to these enclosures than has hitherto been done. Guillet proposed that in order to keep this matter before the congress a committee be appointed to consider the subject and to carry out investigations as to the nature of these slag-enclosures and their effect on the mechanical properties of steel, and this proposal was adopted.

The questions of hardness tests on the one hand and of impact tests on the other each occupied almost an entire day's session of Section A. In regard to hardness tests, the Brinell ball test found many ardent supporters, but, on the other hand, Dr. Ludwik, of Vienna, presented a paper emphasising the advantages of cone-indentation tests, and a cone-hardness testing machine of Swedish manufacture was shown which appeared to be a serious rival to the Brinell machine of Martens-Heyn, which is regarded as the standard machine in Germany. The British delegates directed attention to the "hardness" testing machines in which the rebound of a hardened falling weight is observed, as these appeared to be unknown on the Continent.

The importance of impact tests was recognised by all who took part in the lengthy discussion on this subject, but the importance of standardising what was still a purely empirical test was also insisted upon. After some opposition from the German section, the congress finally adopted a set of standard test-bars for notched bar single-blow impact tests, but although the Charpy impact tester appears to be widely recognised as a satisfactory machine, it was decided not to adopt definitely any one apparatus.

Perhaps the most difficult question with which the congress had to deal was that of the standardisation of specifications as between different countries; the acceptance of an international specification by the congress being a matter which would seriously affect the industrial interests of the countries concerned, much difficulty and some little friction inevitably arose. It was quite evident from the outset that the final adoption of any universal specification was not yet possible at the present congress, and in nearly every case the questions of unified specifications were referred back to their respective committees. Perhaps the largest amount of progress was reported by M. Guillet as chairman of the committee on specifications for copper; at a meeting of this committee, which took place just before the congress at Copenhagen, the members present were able to agree on most points of an international specification. Unfortunately, the attendance at this meeting was not very large, but it is hoped that when the conclusions arrived at by this committee are circulated to all the members a universal agreement as to a specification very much on the lines of the British standard specification will be reached. In regard to iron and steel, the difficulties are much greater, but it is hoped that a nearer approach to agreement may be reached in time for the next congress; meanwhile, the only definite result in this direction is a carefully worded resolution indicating that the congress recommends the sale of pig-iron on a basis of chemical analysis alone, the old method of grading by fracture being discarded as too indefinite.

In Section B the papers dealing with reinforced concrete were first discussed, but the discussion was of a very general nature, the desire being widely expressed that methods of testing and experimenting should first of all be systematised and standardised. One of the subjects which received most attention was that of the action of sea-water on cement, the report by Poulsen describing the elaborate series of tests carried out on various points of the coast of Scandinavia from Esbjerg, in the south-west, to Vardö, at the extreme north of Norway, being very favourably received. Ultimately the section passed a resolution, combining one proposed by Mr. Sachs and another proposed by a French representative, setting up a committee to bring the whole question up to date for the next congress by preparing a summary of the papers already before the association, and also to carry out further experiments with specially prepared cements exposed to sea-water to test the influence of various percentages of sulphates.

In connection with cement-testing there was a good deal of heated discussion, principally as to the definition of a "standard sand," while Mr. Blount and his committee had to contend with some strong opposition in carrying their proposals in regard to volume-constancy tests.

A general business meeting of the congress took place on the concluding day (Saturday, September 11). After the formal business had been disposed of, Mr. J. E. Stead, F.R.S., was asked to deliver his lecture on the practical application of the microscopic examination of metals at the present time. So little time remained, however, that Mr. Stead could only give a very brief summary of his subject-matter, the lantern-slides being, however, shown in the afternoon by special request. While the report of Heyn on the progress of metallography had summarised the work of laboratories and investigators, Mr. Stead dealt with the use of the microscope in works practice, and was able to give an account of the manner in which microscopic methods were employed by a large number of firms both in England and in America. Examples of successful application of microscopic methods in the case of cast-iron, steel, copper, brass, and many other metals were given, the names of the firms in question being stated, including all those best known in their respective industries. The use of the microscope in the investigation of failures and breakages was finally described.

In addition to the actual business of the congress, the programme arranged by the reception committee included a large number of interesting visits and excursions; these included the new railway repair workshops, the works of Messrs. Burmeister and Wain, where shipbuilding is carried on, the Royal Danish Porcelain Works, and a number of municipal institutions, such as the electric power station, the refuse destructor, &c., as well as the newly organised State testing laboratories, the great breweries of Carlsberg and the fine museums endowed from their profits. The evenings of the congress week were occupied by a series of brilliant functions, including a reception by the Danish Society of Engineers, another by the Municipality of Copenhagen, a special performance at the Royal Opera House, and, finally, excursions to Sgodsborg and to Elsinore on the Oresund; the former, carried out by means of a steamer, which first took the party around the harbour of Copenhagen, was especially enjoyable, and it was followed by an informal dinner of huge dimensions (more than 900 sat down) at the beautifully situated Sgodsborg Hotel. Our Danish hosts were most warmly hospitable, and everything was done to make the impressions of Copenhagen as pleasant as possible—even the weather was favourable, so that the 500 visiting engineers saw Copenhagen at its very best. Although it may perhaps be said that no very striking decisions have been reached at this congress, it has undoubtedly served a very valuable purpose in bringing together a large number of scientific and technical workers who had hitherto known one another by correspondence only. Linguistic difficulties were, of course, of frequent occurrence, but willing interpreters were generally at hand; the discussions of the congress were, as a rule, translated into the three official languages—a difficult task, in which one or two of the British delegates displayed considerable activity. In fact, it was a widely expressed feeling—not a little gratifying to the British representatives—that at this congress there was much evidence of the fact that a great revival in matters of applied science had taken place in England since the last meeting of the congress. It is to be hoped that when the congress meets next—in America in 1912—still further evidence of this revival will make itself felt. Adequate British representation at these congresses is of great importance, not only in securing the due consideration of British interests, but also in securing due respect for British achievements and British capacity—respect which will help to promote the cause of universal peace.

GERMAN BOTANICAL CONGRESS.

A FEW years ago the three German societies specially interested in one or other branch of botany agreed to meet in the same district and at the same time each year, and the arrangement has proved so advantageous that it has become permanent. This year the societies met at Geisenheim, on the Rhine, in the Rheingau. The Botanical Institute at Geisenheim, where the meetings were held, is liberally supported by the Prussian Government, and in most respects seems ideal. Both staff and students are well housed on the spacious premises, and the courses are arranged to suit many different types of students. Owing, however, to the continuity of courses throughout the year, there is no regular vacation for the staff, the members of which must in time, one would think, lose somewhat in vigour and freshness of teaching. The institute exists for the promotion of the interests, scientific and practical, of the vineyard, and its wine, and of the fruit and vegetable industries.

There are separate buildings for chemistry, plant physiology, pathology, and fermentation, each fully equipped and under its own chief. The connection between science and practice is very intimate, and research is encouraged. From the fermentation station pure yeast cultures are sent all over the world. The whole institute is under the able administration of Prof. Wortmann, to whom the success of this year's meeting is largely due.

Naturally, several papers on the vine and on wine, too specialised for general notice, were contributed by experts. Attention was directed to the fungus *Rhacodium cellare*, which lives on cork, and causes the deterioration of wine in store. Sound sterilised corks, replaced unconditionally each year, are a necessary precaution against the damage wrought by this trouble.

Much of the time of the economic botanists was occupied by papers on the potato and its diseases. Particular attention was directed to the disease called "leaf-roll," not to be confused with "leaf-curl." Alarmist reports of the extent of the disease and of the injury it was inflicting appeared in the German Press last year. Though these reports have been shown to be exaggerated, the disease is clearly doing much harm. It is, as the writer noticed, widely spread in many parts of Ireland, but not yet recorded for Great Britain, or for France (judging from a conversation recently with M. Maublanc at the Pathological Institute in Paris). There are several features of striking interest in connection with leaf-roll. It is generally recognisable by the more or less dwarfed, stunted haulms, and the inrolled, often more or less coloured, leaflets. In leaf-curl the surface of the leaflets is crumpled. In the first year of attack the tubers may appear sound and of normal weight. The disease is, however, in them, as shown by the next year's diminished, diseased crop. Appel's view, that Fusarium is generally present in the vessels of the stem, is not supported by others. One hypothesis is that the disease is due to degeneration of the particular variety attacked, another that manure and soil may have a disturbing influence on the metabolism and ferments of the plant. No one has yet succeeded in infecting healthy stock with leaf-roll. It is readily transmitted by tubers, and, Count Arnim thinks, possibly by seeds also. In spite of all the attention devoted to the investigation of this disease, its cause is still a mystery, and until this is solved it is impossible to suggest general preventive measures. On no account should the tubers from a leaf-roll plant be used as seed.

During the meeting Wittmack summarised his views on the tuber-bearing species of Solanum. He holds that all European potatoes come from one true species, *Solanum tuberosum*, that *S. Maglia* is also a true, closely allied species, and that both differ from *S. Commersonii*. He praised highly the drawings, made for Sutton and Sons, of the Solanums by Worthington Smith. Wittmack was sent by the German Government to inspect the plots of *S. Commersonii violet*, believed by Labergerie and Heckel to be a valuable disease-resisting variety, and, they think, derived from *S. Commersonii* by mutation. It appears, however, to be identical with Paulsen's Blue Giant, a variety of *S. tuberosum*, and, like all other varieties, liable to leaf-blight and other potato diseases.

Lindner directed attention to the difficulties of identification of fermentation organisms. He proposed the creation in Berlin of a central station where photomicrographs of such organisms from all parts of the world could be stored, named when necessary, and registered for consultation. He illustrated his views by three volumes of such photographs, and in the course of the meeting used them to name a soil organism exhibited by H. Fischer. Hosseus described the rice industry in Siam, and urged the claims of rice on the Germans as a cheap and nutritious food. Ewert described the over-wintering of the conidia of Fusicladium, the cause of apple and of pear spot. The systematists devoted one day to the reading of papers by Drude, Gilg, Diels, Ross, &c. Schwendener was elected honorary president of the Deutsche Botanische Gesellschaft, before which, at a morning sitting, two important papers were read, one by Senn on the movements of chromatophores, including a beautiful illustration of diatom cell-division, and another by Kniep on assimilation activity under different rays of light.

A special feature of this year's meeting, which ought not to go unrecorded, was the testing in different localities of the wine of the district. On the last day at Geisenheim the three bodies sat in common for three hours to test no fewer than thirty-five different kinds of wine, provided by the Rheingau Wine Society.

Some forty members subsequently spent several days in botanical excursions in the valleys of the Nahe and Mosel. At Bertrich fine specimens of *Buxus sempervirens* and *Acer monspessulanum* were to be seen growing in plenty on the rocky slopes. On the shores of the crater-lake (Pulvermaar) at Gillenfeld, *Pilularia globulifera* formed a regular sward.

It was agreed to meet next year at Münster in time to allow members to attend the International Botanical Congress, and also the Seed-testing Conference at Brussels at Whitsuntide. T. J.

THE BRITISH ASSOCIATION AT WINNIPEG

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS (ABRIDGED) BY PROF. JOHN L. MYRES, M.A., F.S.A., PRESIDENT OF THE SECTION.

The Influence of Anthropology on the Course of Political Science.

ANTHROPOLOGY is the Science of Man. Its full task is nothing less than this, to observe and record, to classify and interpret, all the activities of all the varieties of this species of living being. In the general scheme of knowledge, therefore, anthropology holds a double place, according to our own point of view. From one standpoint it falls into the position of a department of zoology, or geography; of zoology, since man, considered as a natural species, forms only one small part of the animal population of this planet; of geography, because his reason, considered simply as one of the forces which change the face of nature, has, as we shall see directly, a range which is almost world-wide. From another point of view anthropology itself, in the strictest sense of the word, is seen to embrace and include whole sciences such as psychology, sociology, and the rational study of art and literature; since each of these vast departments of knowledge is concerned solely with a single group of the manifold activities of man. In practice, however, a pardonable pride, no less than the weighty fact that man, alone among the animals, truly possesses reason, has kept the study of man a little aloof from the rest of zoology. Dogmatic scruples have intervened to prevent man from ever ranking merely as one of the "forces of nature," and have set a hard problem of delimitation between historians and geographers. And the pardonable modesty of a very young science—for modern anthropology is barely as old as chemistry—has restrained it from insisting on encyclopædic claims in face of reverend institutions like the sciences of the mind, of statecraft, and of taste.

Yet when I say that anthropology is a young science I mean no more than this, that in the unfolding of that full bloom of rational culture, which sprang from the seeds of the Renaissance, and of which we are the heirs and trustees, anthropology found its place in the sunlight later than most; and almost alone among the sciences can reckon any of its founders among the living. This was of course partly an accident of birth and circumstance; for in the House of Wisdom there are many mansions; a Virchow, a Bastian, or a Tylor might easily have strayed through the gate of knowledge into other fields of work, just as Locke and Montesquieu only narrowly missed the trail into anthropology.

But this late adolescence was also mainly the result of causes which we can now see clearly. Man is, most nearly of all living species, the "ubiquitous animal." Anthropology, like meteorology, and like geography itself, gathers its data from all longitudes, and almost all latitudes, on this earth. It was necessary therefore that the study of man should lag behind the rest of the sciences, so long as any large masses of mankind remained withdrawn from its view; and we have only to remember that Australia and Africa were not even crossed at all—much less explored—by white men, until within living memory, to realise what this limitation means. In addition to this, modern Western civilisation, when it did at last come into contact with aboriginal peoples in new continents, too often came, like the religion which it professed, bringing "not peace but a sword." The customs and institutions of alien people have been viewed too often, even by reasonable and good men, simply as "ye beastlie devices of ye heathen," and the pioneers of our culture, perversely mindful only of the narrower creed, that "he that is not with us is against us," have set out to civilise savages by wrecking the civilisation which they had.

Before an audience of anthropologists, I need not labour the point that it is precisely these two causes, ignorance of many remoter peoples, and reckless destruction or disfigurement of some that are near at hand, which are still the two great obstacles to the progress of our science. But it is no use crying over spilt milk, and I turn rather to the positive and cheering thought that the progress of anthropology has been rapid and sure, in close proportion to the spread of European intercourse with the natives of distant lands, and that its further advance is essentially linked with similar enterprises.

Anthropology and Politics in Ancient Greece.

Philosophy, as we all know, begins in wonder; it is the surest way to jostle people out of an intellectual groove into new lines of thought, if they can be confronted personally and directly with some object of that numerous class which seems uncouth only because it is unfamiliar. The sudden expansion of the geographical horizon of the early Greeks, in the seventh and sixth centuries B.C., brought these earliest and keenest of anthropologists face to face with peoples who lived for example in a rainless country, or in trees, or who ate monkeys, or grandfathers, or called themselves by their mothers' names, or did other disconcerting things; and this set them thinking, and comparing, and collecting more and more data, from trader and traveller, for an answer to perennial problems, alike of their anthropology and of ours. Can climate alter character or change physique, and if so, how? Does the mode of life or the diet of a people affect that people's real self, or its value for us? Is the father, as the Greeks believed, or the mother who bore them, the natural owner and guardian of children? Is the Heracles whom they worship in Thasos the same god as he whose temple is in Tyre? Because the Colchians wear linen, and practise circumcision, are they to be regarded as colonists of the Egyptians? or can similar customs spring up independently on the Nile and on the Phasis? Here, in fact, are all the great problems of modern anthropology, flung out for good and all, as soon as ever human reflective reason found itself face to face with the facts of other human societies, even within so limited a region as the old Mediterranean world.

And I would have you note that these old Greek problems, like all the supreme problems of science old and new, were not theoretical problems merely. Each of them stood in direct relation to life. To take only cases such as I quoted just now from the Father of History—is there, for example, among all the various regions and aspects of the world, any real earthly paradise, any delectable country, where without let or hindrance the good man may lead the good life? Is there an ideal diet, an ideal social structure, or in general, an ideal way of life for men; or are all the good things of this world wholly relative to the persons, the places, and the seasons where they occur? I do not mean that the ancient Greeks ever found out any of these things, for all their searching; or even that all ancient seekers after marvels and travellers' tales were engaged consciously in anthropological research at all. I mean only this: that the experiences, and the problems, and the practical *end* of it all, were as certainly present to the minds of men like Herodotus and Hippocrates, as they have been in all great scientific work that the world had seen.

In the same way it has for some while been clear to me that neither Plato nor Aristotle, the great outstanding figures of fourth-century Greece, was constructing theories of human nature entirely in the air. Their conceptions both of the ideal state of society, and of the elements which were fundamental and essential in actual societies as they knew them, were determined to a very large extent by their observation of real men in Sparta, Persia, or Scythia. But it is also clear that much that had been familiar to the historians of the fifth century, and particularly to Herodotus, had fallen out of vogue with the philosophers of the fourth. Systematic clearness had been attained only by the sacrifice of historic accuracy. Thucydides, in fact, standing right in the parting of the ways between history and rhetoric, might fairly have extended his warnings to a dissociation of history from political philosophy, which was just as imminent.

Anthropology and the Renaissance.

At the Revival of Learning it was the same as in the great days of Greece. New vistas of the world were being opened up by the voyagers; new types of men, of modes of life, of societies and states, were discovered and described; new comparisons were forced upon men by new knowledge crowding thick into their minds; and new questions, which were nevertheless old as the hills, made eddies and rapids in the swift current of thought, and cried out for an answer. Take the central political problems, for example: What constitutes the right to govern, and what is the origin of law? In mediæval Europe this was simple enough. The duke, or the king, or the bishop governed by authority of the emperor, or the pope; and pope and emperor ruled (like Edward VII.) "by the Grace of God." Yet here, in Guinea, in Monomotapa, in Cathay, and in Peru, were great absolute monarchies which knew nothing of the pope or the emperor, and were mighty hazy about God. Yet their subjects obeyed them, and gave good reasons for their obedience, and chiefest of their reasons (as in all times and places) was this: "We should be much worse off if we didn't."

Unsocial Man and the Pre-Social State.

It would take me very far afield if I were to try to show how this universal answer came to change its ground from politics to anthropology, so that to the question—how men knew that they would be much worse off if they didn't—the answer came, that "once upon a time they *had been* much worse off, *because* they didn't." For my present purpose it is enough to note that, in all ages, philosophers who set out to define the *nature* of the State, have become involved in speculations about its *origin*; that historians in their researches into its origin have been forced into conclusions as to its nature; and that in both cases every belief about the Nature of the State has been found to involve a belief about a State of Nature; an answer of some kind, that is, to the question whether man was originally and naturally a social animal, or whether at some early period of his history he became social and domestic. In the latter event, how was domestication effected, and what sort of thing was undomesticated man? In the ancient world, after long controversy, Aristotle's definition of man as the "social animal" had carried the day, and ruled that question out of court. But at the Revival of Learning, the unnatural behaviour of certain actual societies towards their individual members had revived irresistibly the whole question whether society was part of the natural order at all, and not a "device of the heathen," a mistake or a *pis aller*; and whether, if society was not thus "natural," men would not really be better off if they returned to their natural, pre-social, *unsocial* state, and began again at the beginning, to work out their own salvation. This belief in a pre-social state played a large part in the political philosophy of the seventeenth and eighteenth centuries; and conversely it was the very fact that the pre-social state as a philosophical conception fell out of vogue at the beginning of the nineteenth, which has distinguished modern political philosophy so markedly from its predecessors.

The Patriarchal Theory.

All theories of a Social Contract as the starting-point of human societies presupposed that mankind had actually passed through a Pre-Social State; and the proof which had been offered of this supposition, though partly theoretical and *a priori*, had partly also been inductive and based on experience. Further, the experience of "primitive Man" which was actually open to the philosophers of the seventeenth and early eighteenth centuries had been, in fact, such as to force the conclusion not merely that a Pre-Social State had once existed, but that some barbarous peoples had not yet emerged from it. It was a sad error of observation, as we now know, which led to that conclusion; but given the travellers' tales, in the form in which we can read them in the "Cosmographies" and "Voyages" of the time, I do not see how that conclusion could have been avoided without culpable neglect of such evidence as there was. If blame is to be assigned in this phase of inquiry at all, it is to be assigned to the travellers and traders, for making such poor use of their eyes and ears. All, however, that I am concerned to establish at present is this, that one of the most important and far-reaching speculations of modern political philosophy, the speculation as to a Pre-Social Condition of Mankind, and a Social Contract which ended it and brought in Society and the State, arose directly and inevitably from the new information as to what primitive man *was* and *did*, when he was studied in the seventeenth century at Tombutum, or Saldanha Bay, or the "backwoods of America," or the "bank of the Orinoco river."

But the Social Contract Theory has long since passed out of vogue. Its political consequences are with us to-day, like the political consequences of the belief in the Divine Right of Kings; but the theories themselves are dead, and likely to remain so. Plato and Aristotle, with their belief in Man as a Naturally Social Animal, have come by their own again, for most of us, if not for all; and the search for an ideal State, which shall realise and fulfil Man's social instincts, is again in full cry.

What part, if any, has the direct study of barbarous people played at this fresh turn of the wheel? Let us look once again at the state of geographical knowledge, and more particularly, as before, at the regions in which by transitory chance of circumstances, there was most to be learned at the moment. First, the British occupation of India was the occasion, on the one hand, of the discovery of Sanskrit, the creation of this science of comparative philology, and the demonstration of a new link of cultural affinity over the whole realm of Aryan speech. The same political event led no less directly to the discovery of the patriarchal structure of Hindoo society, and so through the comparative study of Indian, Roman, and ancient Celtic and Teutonic law to an inductive verification of Aristotle's doctrine of the "naturalness" of patriarchal society. This doctrine dominated political science for nearly fifty years. "The effect of the evidence derived from comparative jurisprudence," Sir Henry Maine could write in 1861,[1] "is to establish that view of the primæval conditions of the human race which is known as the Patriarchal Theory. There is no doubt, of course, that this theory was originally based on the Scriptural theory of the Hebrew patriarchs in Lower Asia. . . . It is to be noted, however, that the legal evidence comes nearly exclusively from the institutions of societies belonging to the Indo-European stock, the Romans, Hindoos, and Sclavonians supplying the greater part of it; and indeed the difficulty, at the present stage of the inquiry, is to know where to stop: to say of what races of men it is *not* allowable to lay down that the society in which they are united was originally organised on the patriarchal model." And he refers explicitly to the former controversy between Filmer and Locke, to point out how the tables had now been turned upon the latter.

Thus in the half-century which intervenes between Herder and Maine, the political philosophy of Europe seemed to have turned almost wholly from exploration to introspection; from the Pacific to early Rome and the German forests; and from the study of survivals in the modern practice of savages, to that of primæval custom betrayed by the speech and customs of the civilised world. It was Aristotle over again, with his appeal to custom, ancestral belief, and canonical literature, following hard upon the heels of the visionary revolutionary Plato. Maine's own words, indeed, about Rousseau[2] would be applicable almost without change to the course of Greek thought in the fourth century B.C. "We have never seen in our own generation," he says, "indeed the world has not seen more than once or twice in all the course of history, a literature which has exercised such prodigious influence over the minds of men, over every cast and shade of intellect, as that which emanated from Rousseau between 1749 and 1762. It was the first attempt to re-erect the edifice of human belief after the purely iconoclastic efforts commenced by Bayle, and in part by our own Locke, and consummated by Voltaire; and besides the superiority which every constructive effort will always enjoy over one that is merely destructive, it possessed the immense advantage of appearing amid an all but universal scepticism as to the soundness of all foregone knowledge in matters speculative. . . . The great difference between the views is that one bitterly and broadly condemns the present for its unlikeness to the ideal past, while the other, assuming the present to be as necessary as the past, does not affect to disregard or censure it."

I have devoted some space to these first steps of Linguistic Palæontology and Comparative Jurisprudence because the method of inquiry which they announced promised at first sight to make good a very serious defect in the instruments of anthropological research. Human history, outside of Europe and of one or two great oriental States like China, hardly went back beyond living memory; even Mexico had no chronicles beyond the first few hundred years, and the records of old-world States like China, which at first sight offered something, turned out on examination to have least to give. They had lived long, it is true, but their lives had been "childlike and bland," devoid of change, and almost empty of experience. Consequently there was no proof that the "wild men" of the world's margins and byways were really primitive at all. The Churches held them children of wrath, degenerate offspring of Cain; the learned fell back upon pre-Adamite fictions, to palliate, rather than to explain their invincible ignorance of Europe and its ways.

[1] Maine, "Ancient Law," pp. 122-3.

[2] *Ibid.*, pp. 86-9.

Here, however, in the new light thrown by the history of speech, there seemed to be a prospect of deep insight into the history of human societies. Disillusionment came in due course, when doctors disagreed; but illusion need never have taken the form it did, had either the philologists or the philosophers realised that all the really valuable work was being done within the limits of a single highly special group of tongues; that the very circumstance that this group of tongues had spread so widely, pointed to some strong impulse driving the men who spoke them into far-reaching migrations; that one of the few points upon which linguistic palæontologists were really unanimous was that both the Indo-European and the Semitic peoples, in their primitive condition, were purely pastoral; and that this pastoral habit was itself an almost coercive cause for their uniformly patriarchal organisation. The last point, however, belongs so completely to another phase of our story that it is almost an anachronism to introduce it here. It serves however to indicate, once again, if that be necessary, how completely the philosopher, and even the man of science, is at the mercy of events in the ordering of his search after knowledge. It is, indeed, almost true to say that if the primitive Aryan had not had the good fortune not merely to live on a grass-land, but also to find domesticable quadrupeds there, there could no more have been a science of comparative philology in modern Europe than there could be among the natives of your own Great Plains or of the Pacific Coast: for in no other event would there have been any such "family of languages" to compare.

In the absence of warning thoughts like these, however, the comparative philology and the comparative law of the patriarchal peoples of the North-West Quadrant and of India went gaily on. What Maine had done for India, Maine himself, with Solm and von Maurer, in Germany; Le Play, de Laveleye, and d'Arbois de Joubainville in France; W. F. Skene in far-off Scotland; Whitley Stokes and others in Ireland; Rhys in Wales; and Mackenzie Wallace and Kovalevsky in Russia, had done for the early institutions of their respective countries: all emphasising alike the wide prevalence of the same common type of social structure, based upon the same central institution, the Patriarchal Family, with the *Patria Potestas* of its eldest male member as its overpowering bond of union: and Maine's own words do not the least exaggerate the beliefs and expectations which were evoked by this new aspect of the Study of Man.

The Matriarchate in Southern India, Africa, and North America.

The Patriarchal Theory lasted barely fifty years. It had owed its revival, as we have seen, to two fresh branches of research, comparative jurisprudence and comparative philology, both stimulated directly by the results of European administration in Northern India. It owed its decline to the results of similar inquiries in other parts of the world, stimulated no less directly by other phases of the great colonising movement, which marks, above all other things, the century from 1760 to 1860. Here again a small number of examples stand out as the crucial instances. British administration in India had, of course, been extended over the non-Aryan south, as well as over the north; and in Travancore, and other parts of the Madras Presidency, British commissioners found themselves confronted with types of society which showed the profoundest disregard of the Patriarchal Theory. Like the Lycians of Herodotus, these perverse people "called themselves after their mothers' names": they honoured their mother and neglected their father, in society, and government, as well as in their homes; their administration, their law, and their whole mode of life rested on the assumption that it was the women, not the men, in whom reposed the continuity of the family and the authority to govern the State. Here was a *parecbasis*, a "perverted type" of society, worthy of Aristotle himself. It is a type which, as a matter of fact, is widely distributed in Southern and South-eastern Asia, and had been repeatedly described by travellers from the days of Tavernier (in Borneo) and Laval (in the Maldive Islands), if not earlier still. It existed also in the New World, and Lafitau had already compared the Iroquois with the ancient Lycians. But it was Buchanan's account of the Nairs of the Malabar

Coast, published in 1807, which came at the "psychological moment," and first attracted serious attention. At the other extremity of India, also, analogous customs were being recorded, about the same time, by Samuel Turner in Tibet, which might have given pause at the outset to the speculators who hoped to base general conclusions on anything so special and peculiar as the customs of Aryan India.

Similar evidence came pouring in during the generation which followed; partly, it is true, as the result of systematic search among older travellers, but mainly through the intense exploitation of large parts of the world by European traders and colonists. Conspicuous instances are the Negro societies of Western and Equatorial Africa, first popularised by the re-publication of William Bosman's "Guinea" (1700), in Pinkerton's "General Collection of Voyages and Travels" (London, 1808, &c.), and by Proyart's "Histoire de Loango" (1776), which also reached the English public in the same invaluable collection. But it was from the south that the new African material came most copiously, in proportion as the activity of explorers, missionaries, and colonists was greater. Thunberg's account of the Bechuanas[1] takes the lead here; but for English thought the principal authorities are, of course, John Mackenzie[2] and David Livingstone.[3]

It was not to be expected that America, which had made such remarkable contributions to the study of Man in the seventeenth and eighteenth centuries, should fall behind in the nineteenth, when its vast resources of mankind, as of Nature's gifts, were being realised at last. From Hunter,[4] Gallatin,[5] and Schoolcraft,[6] in the 'twenties, to Lewis Morgan[7] in 1865, there was hardly a traveller "out West" who did not bring back some fresh example of society destructive of the Patriarchal Theory.

As often happens in such cases, more than one survey of the evidence was in progress simultaneously. Bachofen was the first to publish,[8] and it is curious that his great book on "Mother-right" appeared in the very same year as Maine's "Ancient Law." Lubbock's "Prehistoric Times," in the next year, represents the same movement of thought in England in a popular shape, but almost independently. In America, Lewis Morgan, whom I have noted already as an able interpreter of Iroquois custom, followed up his detailed studies of Redskin law by a Smithsonian monograph in 1871 on "Systems of Consanguinity and Affinity of the Human Family," and, in 1877, by his book on "Ancient Society." Meanwhile Post had published his great work on the "Evolution of Marriage"[9] in 1875, and J. F. McLennan his first "Studies in Ancient History" in 1876. It was the generation of Darwin and of the great philologists, as we have seen, and "survivals" were in the air: Dargan[10] pointed out traces of the Matriarchate in the law and custom of Germany, and Wilken[11] in those of early Arabia. The period of exploration, if I may so term it, closed on this aspect of the subject with Westermarck's "History of Human Marriage," which was published in London in 1891.

Australian Evidence: Totemism and Classificatory Kinship.

I have now mentioned India, South Africa, and North America, three principal fields of English-speaking enterprise during the nineteenth century, and have indicated the contribution of each to modern anthropology in its bearing on political science. Only Australia remains; and, though Australia's task has been shared more particularly with North America, I shall be doing no injustice to Lewis Morgan or to McLennan if I couple with their names those of Fison and Howitt,[1] as the discoverers of classical instances of societies which observe neither paternal nor maternal obligations of kinship as we understand them, but have adopted those purely artificial systems of relationships which in moments of elation we explain as "Totemic," or, in despair, describe as "classificatory."

Hermann Post: Comparative Jurisprudence.

Our retrospect, therefore, of the last fifty years shows clearly once again how intimately European colonisation and anthropological discoveries have gone hand in hand: first to establish a "Matriarchal Theory" of society as a rival of the Patriarchal; and then to confront both views alike with the practices and with the theories of "Totemism."

From the point of view of political science, all this mass of inquiries finds applications already in more departments than one; though it is probably still too early to appraise its influence adequately. The new Montesquieu has not yet arisen to interpret to us the "Spirit of the Laws." Most directly, perhaps, we can trace such influence in the "Comparative Jurisprudence" of Hermann Post, whose first work on the "Evolution of Marriage" appeared, as we have seen, in 1875. Post's general attitude is best seen in his "Introduction to the Study of Ethnological Jurisprudence," which was published in 1886, and in his "African Jurisprudence" of 1887.[2] As the result of a survey of social organisations, considered as machinery in motion, Post points out very justly that it is useless to attempt to explain social phenomena on the basis of the psychological activities of individuals, as is too commonly assumed, because all individuals whose conduct we can possibly observe have themselves been educated in some society or other, and presume in all their social acts the assumptions on which that society itself proceeds. "I take the legal customs of all peoples of the earth," so he wrote in 1884,[3] "the residual outcome of the living legal consciousness of humanity, for the starting-point of my inquiry into the science of law; and then, on this basis, I propound the question, What is law? If by this road I arrive eventually at an abstract conception of law, or at an idea of law, then the whole fabric so created consists, from base to summit, of flesh and blood." It is the same method, of course, which had already yielded such remarkable results to Montesquieu, and even to Locke. The point of view is no longer that of a Maine or a McLennan, students of patriarchal or of matriarchal institutions by themselves. It is that of a spectator of human society as a whole; and such a point of view only became possible at all when it was already certain that no great section of humanity remained altogether unexplored, however fragmentary our knowledge might still be, of much that we ought to have recorded. And its immediate outcome has been to throw into the strongest possible relief the dependence of the form and still more of the actual content of all human societies on something which is not in the human mind at all, but is the infinite variety of that external Nature which Society exists to fend off from Man, and also to let Man dominate if he can.

This was, of course, already the standpoint of Comte, with his emphasis on the *monde ambiant*. But Comte, the citizen of a State which except in Canada had failed to colonise, and therefore had little direct contact with non-European types of society, confined himself far too exclusively to European data. His strength is precisely where the science of France was so magnificently strong in his day, in the domain of pure physics; it is his analogies between politics and physics which are so illuminating in his work, as in that of his English compeer, Herbert Spencer;[4] and it is the weakness of both in the direction

of anthropology which mainly accounts for the shortness of their respective vogues.

Friedrich Ratzel: Anthropo-geography.

At the point which we have now reached in this rapid survey of our science, it was obviously to Geography—the systematic study of those external forces of Nature as an ordered whole—that Anthropology stretched out its hands; and it did not ask in vain. But while English geography had remained exploratory, descriptive, and (like English geology) *historical* in its outlook, the new German science of *Erdkunde*—"earth-knowledge" in the widest sense of the word—had already come into being on the basis of the labours of Ritter and the two Humboldts, and under the guidance of such men as Wagner, Richthofen, and Bastian; the last named also an anthropologist of the first rank. It was, thus, to a distinguished pupil of Wagner, Friedrich Ratzel, that anthropology owed, more than to any other man, the next forward step on these lines. In Ratzel's mind, History and Geography went hand in hand as the precursors of a scientific Anthropology.[1] History to define *when*, and in what order, Man makes his conquests over Nature; Geography to show *where*, and within what limits, Nature presents a conquerable field for Man. Much of this, of course, was already implicit in the teaching of Adolf Bastian, whose monumental volumes on "Man in History" had appeared at Leipzig as early as 1860; his "Contributions to Comparative Psychology" in 1868; and his "Legal Relations among the Different Peoples of the Earth" in 1872[2]—three years before Post's first essay. But Bastian, inaccessible for years together in Tibet or Polynesia, was rather an inspiration to a few intimate colleagues than a great propagandist; and besides, it was not until the appearance of his "Doctrine of the Geographical Provinces" in 1886[3] that he touched on this precise ground, and by that time Ratzel's "History of Man" had already been out for a year.[4]

Epilogue.

These examples, I think, are sufficient to show how intimately the growth of political philosophy has interlocked at every stage with that of anthropological science. Each fresh start on the never-ending quest of *Man as he ought to be* has been the response of theory to fresh facts about *Man as he is*. And, meanwhile, the dreams and speculations of one thinker after another—even dreams and speculations which have moved nations and precipitated revolutions—have ceased to command men's reason when they ceased to accord with their knowledge.

And we have seen more than this. We have seen the very questions which philosophers have asked, the very questions which perplexed them, no less than the solutions which they proposed, melt away and vanish, *as problems*, when the perspective of anthropology shifted and the standpoint of observation advanced. This is no new experience; nor is it peculiar either to anthropology among the natural sciences, or to political science among the aspects of the Study of Man. It is the common law of the mind's growth, which all science manifests, and all philosophy.

And now I would make one more attempt to put on parallel lines the course of political thinking. It is not so very long ago that a great British administrator, returning from one of the gravest trials of statesmanship which our generation has seen, to meet old colleagues and classmates at a college festival, gave it to us as the need he had most felt, in the pauses of his administration, that there did not exist at present any adequate formulation of the great outstanding features of our knowledge (as distinct from our creeds) about human societies and their mode of growth, and he commended it to the new generation of scholarship, as its highest and most necessary task, to face once more the question: What are the forces, so far as we can know them now, which, as Aristotle would have put it, "maintain or destroy States"?

But if a young student of political science were to set himself to this life work, where could he turn for his facts? What proportion of the knowable things about the human societies with which travellers' tales and the atlases acquaint him could he possibly bring into his survey, without a lifetime of personal research in every quarter of our planet?

I have in mind one such student setting out this coming session to investigate, on the lines of modern anthropology, the nature of *Authority* and the circumstances of its rise among primitive men; and the difficulty at the outset is precisely as I have described. In the case of the "black fellows" of Australia such a student depends upon the works of some four or five men, representing (at a favourable estimate) one-twentieth even of the known tribes of the accessible parts of that continent. For British South Africa he would be hardly better served; for British North America, outside the ground covered in British Columbia by Boas and Hill-Tout, he would have almost the field to himself; and the prospect would seem to him the drearier and the more hopeless when he compared it with things on the other side of the forty-ninth parallel.

Now, our neighbours south of that line have the reputation of being practical men; in other departments of knowledge they are believed to know well "what pays." And I am forced to believe that it is because they know that it *pays*, to know all that can still be known about the forms of human society which are protected and supervised from Washington, that they have gone so far as they have towards rescuing that knowledge from extinction while still there is time. The Bureau of Ethnology of the United States of America is the most systematic, the most copious, and, I think, taking it all in all, the most scientific of the public agencies for the study of any group of men, *as men*. The only other which can be compared with it is the ethnographical section of the last census of India, and that was an effort to meet, against time, an emergency long predicted, but only suddenly foreseen by the men who were responsible for giving the order. Thus, humanly speaking, it is now not improbable that in one great newly settled area of the world every tribe of natives, which now continues to inhabit it, may at least be explored, and in some cases really surveyed, before it has time to disappear. But observe, this only applies to the tribes which now continue to exist; and what a miserable fraction they are of what has already perished irrevocably! It is no use crying over spilt milk, as I said to begin with; the only sane course is to be doubly careful of whatever remains in the jug.

An Ethnological Survey for Canada.

And now I conclude with a piece of recent history, which will point its own moral. When the British Association met first outside the British Isles, it celebrated its meeting at Montreal by instituting, for the first time, a section for Anthropology; and it placed in the chair of that section one of the principal founders of modern scientific anthropology, Dr. Edward Burnett Tylor, then recently installed at Oxford, and still the revered Professor of our science there. Through his influence mainly, but with the active goodwill of the leading names in other sciences in Canada, a research committee was formed to investigate the north-west tribes of the Dominion; and for eleven consecutive years expeditions wholly or partly maintained by this Association were sent to several districts of British Columbia. These expeditions cost the Association about 1200*l*. in all. I am glad to think that the chief representative of this Committee's work, Dr. Franz Boas, has long since realised, in his great contributions to knowledge, the high hopes which his early reports inspired.

When the Association met the second time on Canadian soil, at Toronto, the occasion seemed opportune for a fresh step. Dr. Boas had already undertaken work on a larger scale and under other auspices. But it was thought likely that if a fresh Committee of the Association were appointed, with wider terms of reference and further grants, it would be possible to select and to train a small staff of Canadian observers, and by their means to produce such a series of preliminary reports on typical problems of Canadian anthropology as would satisfy the Dominion Government that the need for a thorough systematic survey was a real one, and that such a survey would be practicable with the means and the men which

Canada itself could supply. Among the leading members of this Ethnographic Survey Committee I need only mention three—the late Dr. George Dawson, Mr. David Boyle, and Mr. Benjamin Sulte, each eminent already in his own line of study, and all convinced of the great scientific value of what was proposed. The first year's enterprise opened well: workers were found in several districts of Canada; the Association sent out scientific instruments, and formed in London a strong consultative committee to keep the Canadian field-workers in touch with European students of the subject. But the premature death of George Dawson in 1901 broke the mainspring of the machine; the field-workers fell out of touch with one another and with the subject; the instruments were scattered, and in 1904 the Ethnographic Survey Committee was not recommended for renewal.

I need not say how great a disappointment this failure has been to those of us who believe that in this department of knowledge Canada has great contributions to make, and who know—as this meeting too knows perfectly well—that if this contribution to knowledge is not made within the next ten years, it can never be made at all. I am not speaking merely of the urgency of exact study of the Indian peoples. This indeed is obvious and urgent enough; and the magnificent results of organised effort in the United States are there to show how much you too can still rescue, if you will. But at the moment I appeal rather for the systematic study of your own European immigrants, that stream of almost all known varieties of white men with which you are drenching yearly fresh regions of the earth's surface, which if they have had experience of human settlements at all, have known man only as a predatory migratory animal, more restless than the bison, more feckless and destructive than the wolf. Of your immigrants' dealings with wild nature, you are indeed keeping rough undesigned record in the documents of your Land Surveys, and in the statistics of the spread of agriculture over what once was forest or prairie; and in time to come, *something*—though not, I fear, much—will exist to show what good (and as likely as not, also, what irremediable harm) this age of colonisation has done to the region as a whole. But what you do not keep record of is Nature's dealings with your immigrants; you do not *know*—and so long as you omit to *observe*, you are condemned not to know—the answer to the simple all-important question, *What kinds of men do best in Canada? What kind of men is Canada making out of the raw material which Europe is feeding into God's Mills on this side?*

Over in England, we are only too well aware how poor a lead we have given you. We, too, for a century now, have been feeding into other great winnowing chambers the raw crop of our villagers. We have created (to change the metaphor), in our vast towns, great vats of fermenting humanity, under conditions of life which at the best are unprecedented, and at their worst almost unimaginable. That is *our* great experiment in modern English anthropology—*What happens to Englishmen in City slums?* and we shall hear, before this meeting ends, something of the methods by which we are attempting now to watch and record the outcome of that experiment in the making of the English of to-morrow. We are beginning to know, in the first place, what types of human animal can tolerate and survive the stern conditions of modern urban life. We are learning, still more slowly, what modes of life, what modified structure of the family, of the daily round, of society at large, can offer the adjustment to new needs of life, which human nature demands under this new, almost unbearable strain. We are seeing, more clear in the mass, even if hopelessly involved in detail, the same process of selection going on in the mental furniture of the individuals themselves; new views of life, new beliefs, new motives and modes of action; new, if only in the sense that they presuppose the destruction of the old.

That is our problem in human society at home. And yours, though it has a brighter side, is in its essentials the same. Geographers can tell you something already of the physical "control" which is the setting to all possible societies on Canadian soil. Scientific study of the vanishing remnants of the Redskin tribes may show you a little of the effects of this control, long continued, upon nations whom old Heylin held to be "doubtless the offspring of the Tartars." Sympathetic observation and friendly intercourse may still fill some blanks in our knowledge of their social state; how hunting or fishing—or, in rare cases, agriculture—forms and reforms men's manners and their institutions when it is the dominant interest in their lives. But what climate and economic habit have done in the past with the Redskins, the same climate and other economic habits are as surely doing with ourselves. In the struggle with Nature, as in the struggle with other men, it is the weakest who go to the wall; it is the fittest who survive. And it is our business to *know*, and to record for those who come after us, what manner of men we were when we came; whence we were drawn, and how we are distributed in this new land. An Imperial Bureau of Ethnology, which shall take for its study all citizens of our State, as such, is a dream which has filled great minds in the past and may some day find realisation. A Canadian Bureau is at the same time a nearer object, and a scheme of more practicable size. In the course of this meeting, information and proposals for such a Bureau of Ethnology are to be laid before this section by more competent authorities than I. My task has only been to show, in a preliminary way, what our science has done in the past, to stimulate political philosophy, and to determine its course and the order of its discoveries.

"Some men are borne," said Edward Grimstone just three centuries ago, "so farre in love with themselves, as they esteeme nothing else, and think that whatsoever fortune hath set without the compasse of their power and government should also be banished from their knowledge. Some others, a little more carefull; who finding themselves engaged by their birth, or abroad, to some one place, strive to understand how matters pass there, and remaine so tied to the consideration of their owne Commonweale, as they affect nothing else, carrying themselves as parties of that imperfect bodie, whereas in their curiositie they should behave themselves as members of this world." It is as "members of this world," I hope, that we meet together to-day.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY PROF. E. H. STARLING, M.D., F.R.S., PRESIDENT OF THE SECTION.

The Physiological Basis of Success.

DURING past years it has been customary for the Presidents of Sections in their addresses either to give a summary of recent investigations, in order to show the position and outlook of the branch of science appertaining to the Section, or to utilise the opportunity for a connected account of researches in which they themselves have been engaged, and can therefore speak with the authority of personal experience as well as with that imparted by the presidential Chair. The growing wealth of publications with the special function of giving summaries and surveys of the different branches of science, drawn up by men ranking as authorities in the subject of which they treat, renders such an interpretation of the presidential duties increasingly unnecessary, and the various journals which are open to every investigator make it difficult for me to give in an address anything which has not already seen the light in other forms. The Association itself, however, has undergone a corresponding modification. Founded as a medium of communication between workers in different parts of the country, it has gradually acquired the not less important significance of a tribunal from which men of science, leaving for a time their laboratories, can speak to an audience of intelligent laymen, including under this term all those who are engaged in the work of the world other than the advancement of science. These men would fain know the lessons that science has to teach in the living of the common life. By standing for a moment on the little pinnacle erected by the physicist, the chemist or the botanist, they can, or should be able to, gain new hints as to the conduct of the affairs of themselves, their town or their State. The enormous advance in the comfort and prosperity of our race during the last century has been due to the application of science, and this meeting of the Association may be regarded as an annual mission in which an attempt is made to bring the latest results of scientific investigation into the daily routine of the life of the community.

We physiologists, as men who are laying the foundation on which medical knowledge must be built, have as our special preoccupation the study of man. Although every animal, and indeed every plant, comes within the sphere of our investigations, our main object is to obtain from such comparative study facts and principles which will enable us to elucidate the mechanism of man. In this task we view man, not as the psychologist or the historian does, by projecting into our object of study our own feelings and emotions, but by regarding him as a machine played upon by environmental events and reacting thereto in a way determined by its chemical and physical structure.

Can we not learn something of value in our common life by adopting this objective point of view and regarding man as the latest result of a continuous process of evolution which, begun in far-off ages, has formed, proved and rejected myriads of types before man himself appeared on the surface of the globe?

Adaptation.

In his study of living beings, the physiologist has one guiding principle which plays but little part in the sciences of the chemist and physicist, namely, the principle of adaptation. Adaptation or purposiveness is the leading characteristic of every one of the functions to which we devote in our text-books the chapters dealing with assimilation, respiration, movement, growth, reproduction, and even death itself. Spencer has defined life as "the continuous adjustment of internal relations to external relations." Every phase of activity in a living being is a sequence of some antecedent change in its environment, and is so adapted to this change as to tend to its neutralisation and so to the survival of the organism. This is what is meant by adaptation. It will be seen that not only does it involve the teleological conception that every normal activity must be for the good of the organism, but also that it must apply to *all* the relations of living beings. It must therefore be the guiding principle, not only in physiology, with its special preoccupation with the internal relations of the *parts* of the organism, but also in the other branches of biology, which treat of the relations of the living animal to its environment and of the factors which determine its survival in the struggle for existence. Adaptation therefore must be the deciding factor in the origin of species and in the succession of the different forms of life upon this earth.

Origin of Life.

A living organism may be regarded as a highly unstable chemical system which tends to increase itself continuously under the average conditions to which it is subject, but undergoes disintegration as a result of any variation from this average. The essential condition for the survival of the organism is that any such disintegration shall result in so modifying the relation of the system to the environment that it is once more restored to the average in which assimilation can be resumed.

We may imagine that the first step in the evolution of life was taken when, during the chaotic chemical interchanges which accompanied the cooling down of the molten surface of the earth, some compound was formed, probably with absorption of heat, endowed with the property of polymerisation and of growth at the expense of surrounding material. Such a substance could continue to grow only at the expense of energy derived from the surrounding medium, and would undergo destruction with any stormy change in its environment. Out of the many such compounds which might have come into being, only such would survive in which the process of exothermic disintegration tended towards a condition of greater stability, so that the process might come to an end spontaneously and the organism or compound be enabled to await the more favourable conditions necessary for the continuance of its growth. With the continued cooling of the earth, the new production of endothermic compounds would probably become rarer and rarer. The beginning of life, as we know it, was possibly the formation of some complex, analogous to the present chlorophyll corpuscles, with the power of absorbing the newly penetrating sun's rays and of utilising these rays for the endothermic formation of further unstable compounds. Once given an unstable system such as we have imagined, with two phases, viz. (1) a condition of assimilation or growth by the endothermic formation of new material; (2) a condition of "exhaustion," in which the exothermic destructive changes excited by unfavourable external conditions came to an end spontaneously—the great principle of natural selection or survival of the fittest would suffice to account for the evolution of the ever-increasing complexity of living beings which has occurred in the later history of this globe. The adaptations, *i.e.* the reactions of the primitive organism to changes in its environment, must become continually more complex, for only by means of increasing variety of reaction can the stability of the system be secured within greater and greater range of external conditions. The difference between higher and lower forms is therefore merely one of complexity of reaction.

The naked protoplasm of the plasmodium of Myxomycetes, if placed upon a piece of wet blotting-paper, will crawl towards an infusion of dead leaves, or away from a solution of quinine. It is the same process of adaptation, the deciding factor in the struggle for existence, which impels the greatest thinkers of our times to spend long years of toil in the invention of the means for the offence and defence of their community or for the protection of mankind against disease and death. The same law which determines the downward growth of the root in plants is responsible for the existence to-day of all the sciences of which mankind is proud.

The difference between higher and lower forms is thus not so much qualitative as quantitative. In every case, whatever part of the living world we take as an example, we find the same apparent perfection of adaptation. Whereas, however, in the lower forms the adaptation is within strictly defined limits, with rise in type the range of adaptation steadily increases. Especially is this marked if we take those groups which stand, so to speak, at the head of their class. It is therefore important to try and find out by a study of various forms the physiological mechanism or mechanisms which determine the increased range of adaptation. By thus studying the physiological factors, which may have made for success in the struggle for dominance among the various representatives of the living world, we may obtain an insight into the factors which will make for success in the further evolution that our race is destined to undergo.

It is possible that, even at this time, objections may be raised to the application to man of conclusions derived from a study of animals lower in the scale. It has indeed been urged, on various grounds, that man is to be regarded as exempt from the natural laws which apply to all other living beings. When we inquire into the grounds for assuming this anomic, this outlawed condition of man, we generally meet with the argument that man creates his own environment and cannot therefore be considered to be in any way a product of it. This modification or creation of environment is, however, but one of the means of adaptation employed by man in common with the whole living kingdom. From the first appearance of life on the globe we find that one of the methods adopted by organisms for their self-preservation is the production of some artificial surroundings which protect them from the buffeting of environmental change. What is the mucilaginous envelope produced by micro-organisms in presence of an irritant, or the cuticle or shell secreted by the outermost cells of an animal, but the creation of such an environment? All unicellular organisms, as well as the units composing the lowest metazoa, are exposed to and have to resist every change in concentration and composition of the surrounding water. When, however, a body cavity or *coelom*, filled probably at first with sea-water, made its appearance, all the inner cells of the organism were withdrawn from the distributing influence of variations in the surrounding medium. The cœlomic fluid is renewed and maintained uniform in composition by the action of the organism itself, so that we may speak of it as an environment created by the organism. The formation of a body cavity filled with salt solution at once increased the range of adaptation of the animals endowed therewith. Thus it enabled them to leave the sea, because they carried with them the watery environment which was essential for the normal activity of their constituent cell units. The assumption of a terrestrial existence on most parts of the earth's surface involved, however, the exposure to greater ranges of temperature than was the case in the sea, and indicated the necessity for still further increase in the range of adaptation. Every vital process has its optimum temperature at which it is carried out rapidly and effectively. At or a little above freezing point the chemical processes concerned in life are suspended, so that over a wide range of the animal kingdom there must be an almost complete suspension of vital processes during the winter months, and at all times of the year a great dependence of the activity of these processes on the surrounding temperature. It is evident that a great advantage in the struggle for existence was gained by the first animals which succeeded in securing thermal as well as chemical constancy of environment for their cells, thus rendering them independent of changes in the external medium. It is interesting to note that the maintenance of the temperature of warm-blooded animals at a constant height is a function of the higher parts of the central nervous system. An animal with spinal cord alone reacts to changes of external temperature exactly like a cold-blooded animal, the activity of its chemical changes rising and falling with the temperature. In the intact mammal, by accurately balancing heat loss from the surface against heat production in the muscles, the central nervous system ensures that the body fluid which is supplied to all the active cells has a temperature which is independent of that of the surrounding medium. These are fundamental examples of adaptation effected by creation of an environment peculiar to the animal. Numberless others could be cited which differ only in degree from the activity of man himself. In some parts of this country, for instance, the activity of the beaver in creating an artificial environment has until lately been more marked than that of man himself. We are not justified, then, in regarding mankind as immune to the operation of natural forces which have determined the sequence of life on the surface of the globe. The same laws which have determined his evolution and his present position as the dominant type on the earth's surface will determine also his future destiny.

We are not, however, dealing with or interested in simple survival. Lower forms of life are probably as abundant on the surface of the globe as they were at any time in its history. Survival, as Darwin pointed out, is a question of differentiation. When in savage warfare a whole tribe is taken captive by the victorious enemy, the leaders and fighting men will be destroyed, while the slaves will continue to exist as the property of the victors. Survival, then, may be determined either by rise or by degradation of type. Success involves the idea of dominance, which can be secured only by that type which is the better endowed with the mechanisms of adaptation required in the struggle against other organisms.

Among the many forms of living matter which may have come into being in the earlier stages of the history of the earth, one form apparently became predominant and must be regarded as the ancestor of all forms of life, whether animal or vegetable, viz., the nucleated cell. The almost complete identity of the phenomena involved in cell division throughout the living kingdom indicates that all unicellular organisms and all organisms composed of cells have descended from a common ancestor, and that the mode of its reproduction has been impressed upon all its descendants throughout the millions of years which have elapsed since the type was first evolved. The universal distribution of living cells renders it practically impossible for us to test the possibility of a spontaneous abiogenesis or new formation of living from non-living matter at the present time. We cannot imagine that all the various phenomena which we associate with life were attributes of the primitive life stuff. Even if we had such stuff at our disposal, it would be difficult to decide whether we should ascribe the possession of life to it, and there is no doubt that any such half-way material would, directly it was formed, be utilised as pabulum by the higher types of organism already abounding on the surface of the globe.

Integration and Differentiation.

An important step in the evolution of higher forms was taken when, by the aggregation of unicellular organisms, the lowest metazoon was formed. In its most primitive forms the metazoon consists simply of a cell colony, but one in which all individuals are not of equal significance. Those to the outer side of the mass, being exposed to different environmental advantages from those within, must even during the lifetime of the individual have acquired different characteristics. Moreover, the sole aim of such aggregation being to admit of cooperation by differentiation of function between the various cell units, the latter become modified according to their position, some cells becoming chiefly alimentary, others motor, and others reproductive. Cooperation and differentiation are, however, of no use without coordination. Each part of the organism must be in a position to be affected by changes going on in distant parts, otherwise cooperation could not be effected. This cooperation in the lowest metazoon seems to be carried out by utilisation of the sensibility to chemical stimuli already possessed by the unicellular organism. We have thus coordination by means of chemical substances ("hormones") produced in certain cells and carried thence by the tissue fluids to other cells of the body, a mechanism of communication which we find even in the highest animals, including man himself. To such chemical stimuli we may probably ascribe the accumulation of wandering mesoderm cells—*i.e.* phagocytes—in an organism such as a sponge, around a seat of injury or any foreign substance that has been introduced. By this mechanism it is possible for distant parts of the body to react to stimulation of any one part of the surface. Communication by this means is, however, slow, and may be compared to the state of affairs in civilised countries before the invention of the telegraph, when messengers had to ride to different parts of the kingdom in order to arouse the whole nation for defence or attack.

Foresight and Control.

Increased speed of reaction and therefore increased powers in the struggle for existence were obtained when a nervous system was formed, by a modification of the cells forming the outer surface of the organism. By the growth of long processes from these cells a conducting network was provided, running through all parts of the body and affording a channel for the rapid propagation of excitation from the surface to the deeper parts, as well as from one part of the surface to another. From this same layer were produced the cells which, as muscle fibres, would act as the motive mechanism of the organism. Thus, from the beginning, the chief means of attack or escape were laid down in close connection with the surface from which the stimuli were received. A further step in the evolution of the nervous system consisted in the withdrawal of certain of the sensory or receptor cells from the surface, so that a specially irritable organ, the central nervous system, was evolved, which could serve as a distributing centre for the messages or calls to action initiated by changes occurring at the surface of the body. At its first appearance this central nervous system would hardly deserve the epithet of "central," since it formed a layer lying some distance below the surface, and extending over a considerable area; though we find that very soon there is an aggregation of the special cells to form ganglia, each of which might be regarded as presiding over the reactions of that part of the animal in which it is situated. Thus in the segmental worm-like animals a pair of ganglia is present in each body segment, and the chain of ganglia are united by longitudinal strands of nerve fibres to form the ganglionated cord, or central nervous system.

Such a diffused nervous system, in which all ganglia were of equal value, could, however, only act for the common weal of the whole body when a reaction initiated by stimulation at one part was not counteracted by an opposing reaction excited from another part of the surface. For survival it is necessary that in the presence of danger, *i.e.* an environment threatening the life of the individual or race, the whole activities of the organism should be concentrated on the one common purpose, whether of escape or defence. This could be effected only by making one part of the central nervous system predominant over all other parts, and the part which was chosen for this predominance was the part situated in the neighbourhood of the mouth. This, in animals which move about, is the part which always precedes the rest of the body, and therefore the part which first experiences the sense impressions, favourable or dangerous, arising from the environment. It is this end that has to appreciate the presence or approach of food material, as well as the nature of the medium into which the animal is being driven by the movements of its body. Thus a predominance of the front end of the nervous system was determined by the special development at this end of those sense organs or sensory cells which are *projicient*—*i.e.* are stimulated by changes in the environment proceeding from disturbances at a distance from the animal. The sensory organs of vision and the organs which correspond to our olfactory sense organs and are aroused by minute changes in chemical composition of the surrounding medium, are always found especially at the front or mouth end of the organism. The chances of an animal in the struggle for existence are determined by the degree to which the responses of the animal to the *immediate* environment are held in check in consequence of stimuli arising from *approaching* events. The animal, without power to see or smell or hear its enemy, will receive no impulse to fly until it is already within its enemy's jaws. It must therefore be an advantage to any animal that the whole of its nervous system should be subservient to those ganglia or central collections of nerve cells which are in direct connection with the projicient sense organs in the head. This subservience is secured by endowing the head centre with a power, firstly, of controlling and abolishing the activities (*i.e.* all those aroused by external stimuli) of all other parts of the central nervous system, and, secondly, of arousing these parts to a reaction immediately determined by the impression received from the projicient sense organs of the head and originated by some change in the surroundings of the animal which has not yet affected the actual surface of its body.

Education by Experience.

The factors which so far determine success in the struggle for predominance are, in the first place, foresight and power to react to coming events, and, in the second place, control of the whole activities of the organism by that part of the central nervous system which presides over the reaction. The animal therefore profits most which can subordinate the impulses of the present to the exigencies of the future.

An organism thus endowed is still, however, in the range of its reactions, a long way behind the type which has attained dominance to-day. The machinery we have described, when present in its simplest form, suffices for the carrying out of reactions or adaptations which are determined immediately by sense impressions, advantage being given to those reactions which are initiated by afferent stimuli affecting the projicient sense organs at the head end of the animal. With the formation of the vertebrate type, and probably even before, a new faculty makes its appearance. Up to this point the reactions of an animal have been what is termed "fatal," not in the sense of bringing death to the animal, but as inexorably fixed by the structure of the nervous system inherited by the animal from its precursors. Thus it is of advantage to a moth that it should be attracted by, and fly towards light objects—*e.g.* white flowers—and such a reactivity is a function of the structure of its nervous system. When the light object happens to be a candle flame the same response takes place. The first time that the moth flies into and through the candle flame, it may only be scorched. It does not, however, learn wisdom, but the reaction is repeated so long as the moth can receive the light stimuli, so that the response, which in the average of cases is for the good of the race, destroys the individual under an environment which is different from that under which it was evolved. There is in this case no possibility of educating the individual. The race has to be educated to new conditions by the ruthless destruction of millions of individuals, until only those survive and impress their stamp on future generations whose machinery, by the accumulation and selection of minute variations, has undergone sufficient modification to determine their automatic and "fatal" avoidance of the harmful stimulus.

The next great step in the evolution of our race was the modification of the nervous system which should render possible the education of the individual. The mechanism for this educatability was supplied by the addition, to the controlling sensory ganglia of the head, of a mass of nervous matter which could act, so to speak, as an accessory circuit to the various reflex paths already existing in the original collection of nerve ganglia. This accessory circuit, or upper brain, comes to act as an organ of memory. Without it a child might, like the moth, be attracted by a candle flame and approach it with its hand. The injury ensuing on contact with the flame would inhibit the first movement and cause a drawing back of the hand. In the simple reflex mechanism there is no reason why the same series of events should not be repeated indefinitely, as in the case of the moth. The central nervous system, however, is so constituted that every passage of an impulse along any given channel makes it easier for subsequent impulses to follow the same path. In the new nerve centre, which presents a derived circuit for all impulses traversing the lower centres, the response to the attractive impulse of the flame is succeeded immediately by the strong inhibitory impulses set up by the pain of the burn. Painful impressions are always predominant. Since they are harmful, the continued existence of the animal depends on the reaction caused by such impressions taking the precedence of and inhibiting all others. The effect therefore of such a painful experience on the new upper brain must far outweigh that of the previous impulse of attraction. The next time that a similar attractive impression is experienced the derived impulse traversing the upper brain arouses, not the previous primary reaction, but the secondary one, viz. that determined by the painful impressions attending contact with the flame. As a result, the whole of the lower tracts, along which the primary reaction would have travelled, are blocked, and the reaction—now an educated one—consists in withdrawal from or avoidance of the formerly attractive object. The burnt child has learnt to dread the fire.

The upper brain represents a nerve mechanism without distinct paths, or rather with numberless paths presenting at first equal resistance in the various directions. As a result of experience, definite tracts are laid down in this system, so that the individual has the advantage not only of his lower reflex machinery for reaction, but also of a machinery which with advance in life is adapted more and more to the environment in which he happens to be. This educable part of the nervous system—*i.e.* the one in which the direction of impulses depends on past experience and on habit—is represented in vertebrates by the cerebral hemispheres. From their first appearance they increase steadily in size as we ascend the animal scale, until in man they exceed by many times in bulk the whole of the rest of the nervous system.

We have thus, laid down automatically, increased power of foresight, founded on the Law of Uniformity. The candle flame injures the skin once when the finger is brought in contact with it. We assume that the same result will follow each time that this operation is repeated. This uniformity is also assumed in the growth of the central nervous system and furnishes the basis on which the nerve paths in the brain are laid down. The one act of injury which has followed the first trial of contact suffices in most cases to inhibit and to prevent any subsequent repetition of the act.

The Faculty of Speech.

If we consider for a moment the vastness and complexity of the stream of impressions which must be constantly pouring into the central nervous system from all the sense organs of the body, and the fact that, at any rate in the growing animal, every one of these impulses is, so to speak, stored in the upper brain, and affects the whole future behaviour of the animal, even the millions of nerve cells and fibres which are to be found in the human nervous system would seem to be insufficient to carry out the task thrown upon them. Further development of the adaptive powers of the animal would probably have been rendered impossible by the very exigencies of space and nutrition, had it not been for the development of the power of speech. A word is a fairly simple motor act and produces a correspondingly simple sensory impression. Every word, however, is a shorthand expression of a vast sum of experience, and by using words as counters it becomes possible to increase enormously the power of the nervous system to deal with its own experience. Education now involves the learning of these counters and of their significance in sense experience; and the reactions of the highest animal, man, are for the most part carried out in response to words and are governed by past education of the experience-content involved in each word.

The power of speech was probably developed in the first place as a means of communication among primitive man living in groups or societies; as a means, that is to say, of procuring cooperation of different individuals in a task in which the survival of the whole race was involved. But it has attained still further significance. Without speech the individual can profit by his own experience and to a certain limited extent by the control exercised by the older and more experienced members of his tribe. As soon as experience can be symbolised in words, it can be dissociated from the individual and becomes a part of the common heritage of the race, so that the whole past experience of the race can be utilised in the education—*i.e.* the laying down of nerve tracts—in the individual himself. On the other hand, the community receives the advantage of the foresight possessed by any individual who happens to be endowed with a central nervous system which transcends that of his fellows in its powers of dealing with sense impressions or other symbols. The foresight thus acquired by the whole community must be of advantage to it and serve for its preservation. It is therefore natural that in the processes of development and division of labour, which occur among the members of a community just as among the cell units composing an animal, a class of individuals should have been developed, who are separated from the ordinary avocations, and are, or should be, maintained by the community, in order that they may apply their whole energies to the study of sequences of sense impressions. These are set into words which, as summary statements of sequence, are known to us as the Laws of Nature. These natural laws become the property of the whole community, become embodied by education into the nervous system of its individuals, and serve therefore as the experience which will determine the future behaviour of its constituent units. This study of the sequence of phenomena is the office of Science. Through Science the whole race thus becomes endowed with a foresight which may extend far beyond contemporary events and may include in its horizon not only the individual life, but that of the race itself as of races to come.

Social Conduct.

I have spoken as if every act of the animal were determined by the complex interaction of nervous processes the paths of which through the higher parts of the brain had been laid down by previous experience, whether of phenomena or of words as symbolical of phenomena. The average conduct, however, of the individual, determined at first in this way, became by repetition automatic—*i.e.* the nerve paths are so facilitated by frequent use that a given impulse can take only the direction which is set by custom. The general adoption of the same line of conduct by all the individuals of a community in face of a given condition of the environment gave in most cases an advantage to those individuals who were endowed with a nervous system of such a character that the path could be laid down quickly and with very little repetition. Thus we get a tendency, partly by selection, largely by education, to the establishment of reactions which, like the instincts of animals, are almost automatic in character. As MacDougall has pointed out, the representations in consciousness of automatic tendencies are the emotions. Moral conduct, being that behaviour which is adapted to the individual's position in his community, is largely determined by these paths of automatic action, and the moral individual is he whose automatic actions and consequent emotions are most in accord with the welfare of his community, or at any rate with what has been accepted as the rule of conduct for the community.

Rise in Type dependent on Brain.

Thus, in the evolution of the higher from the lower type, the physiological mechanisms, which have proved the decisive factors, can be summed up under the headings of integration, foresight and control. In the process of integration we have not only a combination of units previously discrete, but also differentiation of structure and function among the units. They have lost, to a large extent, their previous independence of action and, indeed, power of independent action, the whole of their energies being now applied to fulfilling their part in the common work of the organism. At first bound together by but slight ties and capable in many cases of separating to form new cell colonies, they have finally arrived at a condition in which each one is absolutely dependent for its existence on its connection with the rest of the organism and is also essential to the well-being of every other part of the organism.

This solidarity, this subjection of all selfish activity to a common end, namely, preservation of the organism, could only be effected by a gradual increase in the control of all parts by one master tissue of the body, the actions of which were determined by impulses arriving from sense organs which themselves were set into activity by coming events. We thus have with the rise in type a gradually rising scale in powers of foresight, in control by the central nervous system, and in the solidarity of the units of which the organism is composed.

In the struggle for existence the rise in type has depended therefore on the central nervous system and its servants. Rise in type implies increased range of adaptation, and we have seen that this increased range, from the very beginning of a nervous system, was bound up with the powers of this system. Whatever opinion we may finally arrive at with regard to the types of animals which we may claim as our ancestors on the line of descent, there can be no doubt that Gaskell is right in the fundamental idea which has guided his investigations into the origin of vertebrates. As he says, "the law for the whole animal kingdom is the same as for the individual. Success in this world depends upon brains." The work by this observer which has lately appeared sets forth in greater detail than I have been able to give you to-day the grounds on which this assertion is based, and furnishes one of the most noteworthy contributions to the principles of evolution which have been published during recent years.

We must not, however, give too restrictive or common a meaning to the expression "brains" used by Gaskell in the dictum quoted above. By this word we imply the whole reactive system of the animal. In the case of man, as of some other animals, his behaviour depends not merely on his intellectual qualities or powers, to which the term "brain" is often in popular language confined, but on his position as a member of a group or society. His automatic activities in response to his ordinary environment, all those social acts which we ascribe in ourselves to our emotions or conscience, are determined by the existence of tracts in the higher parts of his brain, access to which has been opened by the ruthless method of natural selection and which have been deepened and broadened under the influence of the pleasurable and painful impressions which are included in the process of educatinn. All the higher development of man is bound up with his existence as a member of a community, and in trying to find out the factors which will determine the survival of any type of man, we must give our attention, not to the man, but to the tribe or community of which he is a member, and must try to find out what kind of behaviour of the tribe will lead to its predominance in the struggle for existence.

Political Evolution.

The comparison of the body politic with the human body is as old as political economy itself, and there is indeed no reason for assuming that the principles which determine the success of the animals formed by the aggregation of unicellular organisms should not apply to the greater aggregations or communities of the multicellular organisms themselves. It must be remembered, however, that the principles to which I have directed your attention are not those that determine survival, but those which determine rise of type, what I have called success. Evolution may be regressive as well as progressive. Degeneration, as Lankester has shown, may play as great a part as evolution of higher forms in determining survival. The world still contains myriads of unicellular organisms as well as animals and plants of all degrees and complexity and of rank in the scale of life. All these forms are subordinate to man, and when in contact with him are made to serve his purposes. In the same way all mankind will not rise in type. Many races will die out, especially those who just fall short of the highest type, while others by degradation or differentiation may continue to exist as parasites or servants of the higher type.

Mere association into a community is not sufficient to ensure success; there must also be differentiation of function among the parts, and an entire subordination of the activity of each part to the welfare of the whole. It is this lesson which we English-speaking races have at the present time most need to learn. In the behaviour of man almost every act is represented in consciousness as some emotion, experience or desire. The state of subordination of the activities of all units to the common weal of the community has its counterpart in consciousness as the "spirit of service." The enormous value of such a condition of solidarity among the individuals constituting a nation, inspired, as we should say, by this spirit of service, has been shown to us lately by Japan. In our own case the subordination of individual to State interests, such as is necessary for the aggregation of smaller primitive into larger and more complex communities, has always presented considerable difficulty and been accomplished only after severe struggle. Thus the work begun by Alexander Hamilton and Washington, the creation of the United States, is still, even after the unifying process of a civil war, incomplete and marred by contending State and individual interests. The same sort of difficulties are being experienced in the integration of the units, nominally under British control, into one great nation, in which all parts shall work for the good of the whole and for mutual protection in the struggle for survival.

The Lesson of Evolution.

Just as pain is the great educator of the individual and is responsible for the laying down of the nervous paths, which will determine his whole future conduct and the control of his lower by his higher centres, so hardship has acted as the integrator of nations. It is possible that some such factor with its attendant risks of extermination may still be necessary before we attain the unification of the British Empire, which would seem to be a necessary condition for its future success. But if only our countrymen can read the lesson of evolution and are endowed with sufficient foresight, there is no reason why they should not, by associating themselves into a great community, avoid the lesson of the rod. Such a community, if imbued by a spirit of service and guided by exact knowledge, might be successful above all others. In this community not only must there be subordination of individual to communal interests, but the behaviour of the community as a whole must be determined by anticipation of events—*i.e.* by the systematised knowledge which we call Science. The universities of a nation must be like the eyes of an animal, and the messages that these universities have to deliver must serve for the guidance and direction of the whole community.

This does not imply that the scientific men, who compose the universities and are the sense organs of the community, should be also the rulers. The reactions of a man or of a higher mammal are not determined immediately by impulses coming from his eyes or ears, but are guided by these in association with, and after they have been weighed against, a rich web of past experience, the organ of which is the higher brain. It is this organ which, as the statesman of the cell community, exercises absolute control. And it is well that those who predicate an absolute equality or identity among all the units of a community should remember that, although all parts of the body are active and have their part to play in the common work, there is a hierarchy in the tissues—different grades in their value and in their conditions. Thus every nutritional mechanism of the body is subordinate to the needs of the guiding cells of the brain. If an animal be starved, its tissues waste: first its fat goes, then its muscles, then its skeletal structures, finally even the heart. The brain is supplied with oxygen and nourishment up to the last. When this, too, fails, the animal dies. The leading cells have first call on the resources of the body. Their needs, however, are soon satisfied, and the actual amount of food or oxygen used by them is insignificant as compared with the greedy demands of a working muscle or gland cell. In like manner every community, if it is to succeed, must be governed, and all its resources controlled by men with foreseeing power and rich experience—*i.e.* with the wisdom that will enable them to profit by the teachings of science, so that every part of the organism may be put into such a condition as to do its optimum of work for the community as a whole.

At the present time it seems to me that, although it is the fashion to acquiesce in evolution because it is accepted by biologists, we do not sufficiently realise the importance of this principle in our daily life, or its value as a guide to conduct and policy. It is probable that this doctrine had more influence on the behaviour of thinking men in the period of storm and controversy which followed its promulgation fifty years ago, than it has at the present day of lukewarm emotions and second-hand opinions. Yet, according to their agreement with biological laws, the political theories of to-day must stand or fall. It is true that in most of them the doctrine of evolution is invoked as supporting one or other of their chief tenets. The socialist has grasped the all-importance of the spirit of service, of the subordination of the individual to the community. The aristocrat, in theory at any rate, would emphasise the necessity of placing the ruling power in the hands of the individuals most highly endowed with intelligence and with experience in the affairs of nations. He also appreciates the necessity of complete control of all parts by the central government, though in many cases the sense organs which he uses for guidance are the traditions of past experience rather than the science of to-day. The liberal or individualist asserts the necessity of giving to each individual equal opportunities, so that there may be a free fight between all individuals in which only the most highly gifted will survive. It might be possible for another Darwin to give us a politic which would combine what is true in each of these rival theories, and would be in strict accord with our knowledge of the history of the race and of mankind. As a matter of fact the affairs of our States are not determined according to any of these theories, but by politicians, whose measures for the conduct of the community depend in the last resort on the suffrages of their electors—*i.e.* on the favour of the people as a whole. It has been rightly said that every nation has the government which it deserves. Hence it is all-important that the people themselves should realise the meaning of the message which Darwin delivered fifty years ago. On the choice of the people, not of its politicians, on its power to foresee and to realise the laws which determine success in the struggle for existence, depends the future of our race. It is the people that must elect men as rulers in virtue of their wisdom rather than of their promises. It is the people that must insist on the provision of the organs of foresight, the workshops of exact knowledge. It is the individual who must be prepared to give up his own freedom and ease for the welfare of the community.

Whether our type is the one that will give birth to the super-man it is impossible to foresee. There are, however, two alternatives before us. As incoherent units we may acquiesce in an existence subordinate to or parasitic on any type which may happen to achieve success, or as members of a great organised community we may make a bid for determining the future of the world and for securing the dominance of our race, our thoughts and ideals.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ST. ANDREWS.—At a meeting of the University Court held on Saturday last, Dr. Arnold Hartley Gibson, senior demonstrator and assistant lecturer in engineering and lecturer on hydraulics at Manchester University, was appointed to the chair of engineering at University College, Dundee, in the room of Prof. Fidler, resigned.

Mrs. Edwin Neave was appointed lady warden of University Hall, St. Andrews, in the room of Miss Melville, who was recently appointed to Queen Margaret's College, Glasgow.

Mr. F. M. Milne was appointed lecturer in clinical pathology, and Mr. Charles Kerr clinical medical tutor.

The eighty-seventh session of Birkbeck College will be begun on Monday next, when an address will be delivered by Principal H. A. Miers, F.R.S.

Harvard University has received the sum of 3000*l.* from Mrs. J. A. Rumrill in memory of her late husband. It will be used to establish three scholarships.

Mr. T. Mather, F.R.S., has been appointed professor of electrical engineering at the City and Guilds Central Technical College in succession to the late Prof. Ayrton, F.R.S.

The new buildings of the Nicol Russell Engineering School and the Fisher Library (in connection with the University of Sydney, New South Wales) were opened by Lord Chelmsford on September 20.

The inaugural address of the session 1909–10 of the University of Bristol will be delivered on Thursday evening, September 30, by the Vice-Chancellor of the University, Sir Isambard Owen, who will take as his subject "The Significance of a University."

The Tulane University of Louisiana has during the past year come into possession of the following amounts:—400,160*l.* from the Newcomb estate, which sum will go to the Newcomb College—the women's department of the University—founded by Mrs. J. L. Newcomb as a memorial to her daughter; 10,000*l.* from Mrs. I. A. Richardson towards the establishment of a chair of botany; and 1000*l.* from the late Miss L. Miles for the purchase of books for the library.

The Home Secretary has signified to the council of the Royal College of Surgeons his decision to approve the by-laws regarding the admission of women to the examinations for the diplomas of the college. He has further expressed his willingness to sign the formal document which is to be submitted after the next meeting of the council of the college on October 14. It is understood, however, that meanwhile it will be possible to complete the necessary formalities in time for women to enter for the examinations of the Royal College to be held in January next.

Mr. W. Buchanan has been appointed lecturer on electrotechnics and the design of electrical machinery to Faraday House, London. Mr. Buchanan had a distinguished college career, first at the Royal College of Science, London, and subsequently at Glasgow University, where he was "Thomson experimental scholar" in Lord Kelvin's laboratory. He has been for fifteen years with the Electric Construction Company, Wolverhampton, first as designer of alternating current machines and subsequently as chief engineer.

The calendar of the Merchant Venturers' Technical College, Bristol, is now available. It will be remembered that in connection with the inauguration of the University of Bristol it was arranged that this college should provide the faculty of engineering in the University. A preliminary prospectus has been issued of the lectures and courses of practical work in the laboratories and workshops, designed, amongst other things, to prepare students for the various degrees in engineering to be conferred by the University. In addition to this university work the college is to continue to provide the continuous and complete preparation for an industrial career which it has hitherto done. Day and evening classes in a great variety of technological subjects have been arranged for the coming winter. It is satisfactory to find from the calendar that earnest efforts are being made by the governors and principal of the college to secure the active cooperation of enployers in their endeavours to provide suitable technical education for the men and women engaged in the industries of Bristol and neighbourhood.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 13.—M. Bouchard in the chair.—H. Deslandres communicated a telegram from P. **Lowell**, stating that the presence of free oxygen has been proved in the atmosphere of Mars. The oxygen band B is clearly stronger in the Mars spectrum than in that of the moon.—The movements of the upper solar atmosphere above and round the faculæ. The cellular vortices of the sun: H. **Deslandres.** Details of the work done with the new spectrograph at the Observatory of Meudon. A diagram is given showing the radial movements of the upper K_3 layer of the solar atmosphere above and round a facula.—The study of sea temperatures: A. Bouquet **de la Grye.** A knowledge of the temperatures of the sea over a wide area is an important factor in weather forecasts.—The trypanolytic power of the blood of some cold-blooded vertebrates with respect to *Trypanosoma evansi*: A. **Laveran** and A. **Pettit.** The blood of some of the cold-blooded vertebrates contains active trypanolytic substances, and there seems to be a relation between the presence of these substances and the toxicity of the serum. Closely related vertebrates showed differences in the trypanolytic power, the case of *Rana esculenta* and *R. temporaria* being especially remarkable in this respect.—The problem of Sophus Lie: N. **Saltykow.**—Practical formulæ for the calculation of aërial helices: M. **Drzewiecki.**—The magnetic *rôle* of oxygen in organic compounds: P. **Pascal.** The constants given in this paper enable the value for the magnetic susceptibility of an organic compound containing oxygen to be used as a guide to its structure.—The estimation of phosphorus in combustible substances by the calorimetric bomb: P. **Lemoult.** If certain precautions are taken, details of which are given, the determination of phosphorus in organic compounds by combustion in the calorimetric bomb possesses advantages over the methods in general use both in rapidity and accuracy.—The law of the fading of mnemonic traces as a function of the time in *Limnaea stagnalis*: Henri **Piéron.**—The natural means of defence of certain cold-blooded vertebrates against the trypanosome of surra, *Trypanosoma evansi*: A. **Massaglia.** Phagocytosis appears to play no part in the destruction of the trypanosomes.

THURSDAY, SEPTEMBER 30, 1909.

APPRECIATIONS OF CARL VON LINNÉ.

Carl von Linné's Bedeutung als Naturforscher und Arzt. Schilderungen herausgegeben von der Königl. Schwedischen Akademie der Wissenschaften anlässlich der 200-jährigen Wiederkehr des Geburtstages Linné's. Pp. iv+168; 48; 43; 188; 86, 2 pl.; 42. (Jena: G. Fischer, 1909.) Price 20 marks.

THIS volume is a German version of that issued in May, 1907, by the Royal Swedish Academy of Science, and consists of six appreciations of the great Swedish naturalist.

The first of these, by Emeritus Prof. Otto E. A. Hjelt, was written at the request of the Academy, and is a revised edition of a former work prepared for the celebration of the quatercentenary of Upsala University in 1877, embodying various improvements through recent investigation into Linnean matters, due to the devotion of the late Dr. E. Ährling and Prof. T. M. Fries. In common with the other essays, this is separately paged, and may be procured apart from its accompanying discourses.

Linné's remarkable services to botany and zoology have thrown somewhat into the shade his acquirements as a practising physician and professor of medicine. This essay will do much to draw attention to this side of Linné's activities. It must not be forgotten that he was rescued from a suggested apprenticeship to a tailor or shoemaker, by the sagacity of his early teacher, Rothman, who assured Nils Linnæus that his son showed great aptitude for medicine. It was for this that Linné entered the University of Lund, and afterwards migrated to Upsala for further improvement; he took his degree of M.D., to earn a livelihood, and he practised in Stockholm after his return to Sweden. His first chair at Upsala was of medicine, and though soon afterwards he exchanged it for that of botany, he continued to keep in touch with it during his career, and left manuscripts showing his unabated interest, in spite of his exertions in other directions. A list of his medical writings at the end of this essay contains eighty-six titles.

This is followed by "Carl von Linné und die Lehre von der Wirbelthieren," of Prof. Einar Lönnberg, in which a *résumé* is given of Linné's predecessors in zoology, from Conrad Gesner, Rondelet, Aldrovandi, and others, to Ray and Willoughby, and contrasting the order brought in by methodical arrangement under Classes, Orders, and Genera.

The third essay, "Carl von Linné als Entomolog," is by Dr. Chr. Aurivillius, and is here separately given; in the original Swedish edition, Linné was considered as a zoologist, in a joint memoir with the previous author, but in this issue the part of each writer is set out separately. Following the same line of thought as in the foregoing essay, Dr. Aurivillius points out that the collections formerly belonging to Queen Lovisa Ulrika at Drottinngholm and of King Adolf Fredrik at Ulriksdal, which had been arranged and catalogued by Linné, have been in the keeping of the University of Upsala since 1803.

Dr. C. A. M. Lindman is responsible for the next memoir, "C. v. L. als botanischer Forscher und Schriftsteller," and is the longest of the series. Beginning with Linné's early training and first catalogues of local plants, it deals with that wonderful series of books which were printed in Amsterdam, the "Systema Naturæ," "Genera plantarum," "Flora lapponica," "Hortus Cliffortianus," &c., especially drawing attention to such parts of Linné's botanical teaching which are apt to be overlooked, such as his attempts at a natural system, and observations in morphology and physiology of plants; of these, many are to be found in his dissertations and travels, rarely looked at now. Indeed, Linné's books are chiefly referred to at the present day from the systematic point of view. The fact that his busy mind had occupied itself on problems which even now are unsolved is lost sight of, because his observations must be sought for in their original Latin or Swedish dress. The latter portion especially of Dr. Lindman's work should be carefully read, and will heighten our wonder at the enormous amount of work accomplished by the occupant of the Chair of Botany at Upsala.

Linné regarded as a geologist forms the next part of this volume, and is due to Prof. Nathorst; it is illustrated with two plates, and ten figures in the text. Both as petrologist and palæontologist the merits of Linné are set out, and his keen insight into geological causes are dwelt upon. Linné had but little opportunity as a field geologist; his travels were practically bounded by his official journeys to Gotland, Westgotland, and Skåne, and yet his observations merit careful reading in the light of modern science.

A similar appreciation is given by Prof. Sjögren in the last section, "Carl von Linné als Mineralog." The Linnean collection of minerals was sold by Dr. J. E. Smith in 1796, when about to remove from Chelsea to Norwich, and its present condition and place are unknown. But it is enough to gather from the various statements in the writings of Linné to put before us the views of the great naturalist in honour of whom these essays were composed.

The chief difference noticed between the original and the present edition is the omission of the reprint of Linné's "Clavis medicinæ," which formed an appendix of ninety pages to Prof. Hjelt's memoir.

B. D. J.

INDIA-RUBBER MANUFACTURE.

The Manufacture of Rubber Goods. A Practical Handbook for the Use of Manufacturers, Chemists, and Others. By Adolf Heil and Dr. W. Esch. English Edition by E. W. Lewis. Pp. viii+236. (London: C. Griffin and Co., Ltd., 1909.) Price 10*s*. 6*d*. net.

IT is now several years since the late Dr. Weber's treatise upon "The Chemistry of India Rubber" was published. The book was reviewed in these columns at the time, and has become a standard work upon the scientific principles involved in the production of rubber. A companion volume upon the practical manufacture of rubber articles was con-

P

templated by the author, but his decease prevented its production; and the present work is to be regarded as a substitute. It is a translation of Heil and Esch's "Handbuch der Gummiwarenfabrikation," adapted for English usage in respect of the machinery generally employed in this country.

Non-technical readers may be reminded that crude rubber as imported contains a number of impurities—water, woody tissue, sand, and other mineral matter. Moreover, it is unvulcanised, and to fit it for diverse uses various "filling" substances must be incorporated with it. The process of manufacture consists, therefore, in the purification of the raw material; the mixing of this with ingredients which will impart the required colour, durability, or other special property to the article; the fashioning of this plastic mixture into tyre, tube, or whatever finished article is desired; and lastly, the vulcanisation of the object with sulphur, or chloride of sulphur, whereby the rubber becomes non-adhesive, harder, and more durable.

The authors give the plan and arrangement of a factory for the carrying out of these operations in what they consider to be the most advantageous manner. They direct special attention to the necessity for excluding dust in the making-up of rubber goods, since leaky seams are liable to develop in goods if particles of dust are allowed to settle on the edges of the article during the joining process. Another point to which they direct attention is the necessity, after the rubber has been washed free from admixed impurities, of drying it in a rational way. Far too little regard is had to this important detail. The large surface-area exposed favours atmospheric oxidation of the moist, warm rubber, and the time of exposure should therefore be as short as practicable. On the other hand, if the material is imperfectly dried, goods made from it are liable to rapid deterioration. To dry it thoroughly, quickly, and safely is the desideratum; and the authors describe modern drying-rooms and centrifugal plant adapted to this purpose. While not recommending any one method as the best in all circumstances, they discuss the general principles involved, and plead for an intelligent application of them.

The necessity for avoiding undue "working" or kneading of the dried rubber is also insisted upon. Not only does it increase the expense, but the quality suffers deterioration thereby. True, "rubber substance" is regarded as a mixture of polymerised hydrocarbons, and too much kneading results in a presumed depolymerisation of a portion of the material, with consequent injury to the texture.

A number of examples are given illustrating the composition of "mixings" for making different kinds of rubber articles; and the machinery for working and calendering the mixtures is described at some length.

As regards vulcanisation, it is a remarkable fact that the processes still used are carried out essentially in the same way as when first introduced, some seventy years ago, by Goodyear, Hancock, and Parkes. The details, of course, differ with the different factories; and the empirical methods evolved are guarded as trade secrets. In fact, so perfectly has long experience developed the rule-of-thumb indications that the authors think scientific investigation can hardly result in any noteworthy revolution in the methods of manufacture. It may be so; but this is not quite the spirit in which progress is made. A few years ago indigo-planters would have said much the same thing.

Many illustrations accompany the text, which is generally lucid, though occasionally with a leaning to Teutonic stolidity. Except in this respect, the translator has eliminated any lingual indication of the origin of the book, which can be recommended as a very practical and useful work. C. S.

VECTOR ANALYSIS.

Vector Analysis: an Introduction to Vector-methods and their Various Applications to Physics and Mathematics. By Dr. J. G. Coffin. Pp. xix+248. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 10*s*. 6*d*. net.

THIS "Introduction to Vector-methods and their Various Applications to Physics and Mathematics" is an exposition of the late Willard Gibbs' vector analysis. The author in his preface warns us that "no attempt at mathematical rigor is made"—which perhaps explains the opening sentence of chapter i.: "A vector is any quantity having direction as well as magnitude." What of finite rotations? Are they not to be considered quantities having direction and magnitude? In an appendix the author compares notations, not always quite accurately. He believes Willard Gibbs' notation to be the simplest and most symmetrical of any of the existing kinds. Burali-Forti and Marcolongo, who believe they have devised the perfect notation, object to Willard Gibbs's "dot" in the scalar product, using a "cross" instead. As regards the question of symmetry, the truth is that the vector product is not symmetrical, for in Gibbs's notation $\mathbf{a}\times\mathbf{b}=-\mathbf{b}\times\mathbf{a}$. As a matter of fact each vector analyst can always find sufficiently self-pleasing arguments in favour of his pet notation.

Notation apart, the book is well put together, and lays stress on many important applications in dynamics, elasticity, hydrodynamics, electricity, and magnetism. The differential operator ∇, in its Gibbsian phase, is developed in considerable detail. But will non-Hamiltonian vector analysts never realise how much they lose by working with what is not, after all, the real Hamiltonian operator? By discarding the associative law in vector products they lose the flexibility of the real ∇. Pages of definitions would be saved by a simple return to Hamilton and Tait; and not only so, but the mind of the student would be freed from the task of committing to memory the laws of the equivalent operators as used by Gibbs, Heaviside, Gans, Jahnke, Bücherer, Föppl, Burali-Forti and Marcolongo, &c. In the exercises at the end of chapter v. we notice two mistakes. In exercise (4) we are told that $\nabla.(\mathrm{a}\times\mathrm{r})=2a$, where a is the length of the vector $\mathbf{a}$. In quaternions this is $S\nabla Va\rho$. But $\nabla Va\rho=2a$, a *vector*, which can have no scalar part. Again, in Exercise (13) we have by definition

$$\epsilon^{\mathbf{a}} = 1 + \mathbf{a} + \frac{\mathbf{a}^2}{1.2} + \frac{\mathbf{a}^3}{1.2.3} + \ldots,$$

where

$$\mathbf{a}^2 = \mathbf{a}.\mathbf{a},\ \mathbf{a}^3 = \mathbf{aa}.\mathbf{a},\ \mathbf{a}^4 = \mathbf{a}.\mathbf{aa}\ \mathbf{a},$$

and we are to prove that

$$\epsilon^{\mathbf{a}} = \cos a + \mathbf{a}_1 \sin a,$$

where a is the length of $\mathbf{a}$, and $\mathbf{a}_1$ is the unit vector along $\mathbf{a}$. Now according to Gibbs $\mathbf{a}.\mathbf{a} = +a^2$, so that all the terms of the assumed expansion must be positive. How then can they give the *sine* and *cosine*? The statements are true *only* if we use the Hamiltonian vector whose square is *minus* the square of its length. The linear vector function is introduced for the discussion of the kinetics of a rigid body. This is purely Hamiltonian, and is very good so far as it goes. The investigation, however, seems to lack here and there the strength and spontaneity of Tait's classical discussion.

RETAINING WALLS AND ROAD BRIDGES.

(1) *Graphical Determination of Earth Slopes, Retaining Walls, and Dams.* By Prof. C. Prelini. Pp. ix+129. (London: A. Constable and Co., Ltd., 1908.) Price 8s. net.

(2) *The Design of Highway Bridges, and the Calculation of Stresses in Bridge Trusses.* By Prof. M. S. Ketchum. Pp. xxi+544. (New York: The Engineering News Publishing Co.; London: A. Constable and Co., Ltd., 1908.) Price 16s. net.

(1) THIS book brings together for the use of the engineering student in a handy form for reference the various graphical methods due to Culmann, Rebhann, and others, for solving problems connected with earth pressures.

The first chapter treats of the stability of earth slopes; the cohesive force in a bank of earth is determined by graphical methods, and hence is deduced the most probable plane of sliding; by means of the parabola of cohesion the various slopes of equilibrium for various heights of bank are determined, and its application to practice is then discussed; the considerable economy in excavating deep trenches with slopes correctly designed is proved by worked out examples.

In the second chapter the design of retaining walls is taken up; the author points out that all the various theories which have been employed can be divided into two groups, (*a*) those depending on the theory of the sliding prism, (*b*) those depending on analytical theory. A graphical solution, due to Rebhann, of the sliding prism type is then given; this method is then applied to a series of practical cases, both for retaining walls when surcharged, and when free of surcharge. The variation of pressure with height of wall, and position of the centre of pressure are dealt with, and also the effect of cohesion on the pressure against retaining walls, and the pressure of passive resistance of the earth in the case of abutments which are pushed outwards by arches.

In the next chapter there is an analytical demonstration of Rebhann's theory, and brief statements of the formulæ of Rankine and Weyrauch. In a series of three tables the author gives the values of the earth pressure against walls of different heights as deduced by these three formulæ, and the results agree so well that it is evident that any one of the three methods is equally trustworthy from the practical point of view.

The results obtained in the preceding chapters are applied in chapter iv. to the design of various types of retaining walls; and the important problem of the determination of the necessary thickness at the base of a retaining wall in order that it may be stable under earth pressure is fully discussed for each type of wall.

The last chapter of the book is devoted to masonry dams, which, as the author points out, are simply a particular case of retaining wall, with the material sustained practically frictionless; it is shown that the most economical profile, theoretically, is a triangular one, but in practice this is an impossible section. The modification needed in order that the dam may have a certain thickness at the top is then discussed, and the pentagonal profile deduced. It is shown that this theoretical profile is the basal form of all modern high dams. The book should prove especially useful to civil engineering students during their final college year.

(2) While many text-books have been devoted to the design of railway bridges, but little attention has been hitherto given to the equally important question of the design of road bridges, and, although the work of calculating the stresses in the different members is the same for both types, there are, owing to the very different requirements to be met, radical differences in the design of the two classes of bridge. This book, therefore, meets a distinct want, and it will be especially useful to the young designer, in view of the fact that the author has given special attention to the problem of the design of the substructure, which is usually quite neglected in books on bridge design. An entire chapter has been devoted to the design of floor beams, floors, shoes, and pedestals, and other similar details, and it is in regard to such matters that the young engineer most commonly finds the need of help and guidance.

The ninth chapter will prove of considerable use, not only to the student, but also to the teacher; as the author points out, in order to obtain a thorough knowledge of the calculation of stresses in bridge trusses, it is essential that the student should work through numerous problems—altogether twenty-four problems are worked out in detail in this section of the book, and a second similar one has been added to each of the twenty-four problems as a further exercise for the student to solve with the help afforded by the worked-out example; some of the solutions are obtained graphically, others by algebraic methods. Another valuable section is that devoted to influence diagrams, or influence lines, which are required in studying the variation of the effect of a moving load or system of loads, on a truss.

Special attention has been given to the design of high truss steel bridges, and to plate girder bridges, and this section of the book is well illustrated with reproductions of working drawings, which, in spite of the necessary small scale, are perfectly clear and distinct in all the essential details. The stresses in, and the design of, solid masonry arches and culverts form the subject of two chapters, and, though there is nothing specially novel in the treatment adopted, these sections of the book will be welcome to the draughtsman who is engaged in this branch of bridge design, especially as the author has given some useful notes on the theory of reinforced concrete.

In part iii. of the book there is a full critical investigation of an existing structure—the weights, costs, and efficiencies of the members of a Pratt highway bridge of 160 feet span are fully worked out, and the errors in design pointed out, and the modifications which would improve the design are suggested. There is no doubt that such an investigation is bound to make students familiar with bridge details, and we would commend this method to the notice of engineering teachers.

OUR BOOK SHELF.

Die Strahlen der positiven Elektrizität. By Prof. E. Gehrcke. Pp. xi+124. (Leipzig: S. Hirzel, 1909.) Price 4.50 marks.

At a moment when scientific thought is being concentrated on the consideration of the nature of positive electricity, we can only welcome the appearance of a book which aims at bringing together, in the short compass of a hundred pages, all the principal facts bearing on the subject. This Prof. Gehrcke has done, and he has done it well, for, with the exception of a few slight omissions, he has put before his reader all that is essential with regard to positive rays. But we could wish that more than this had been done, for it is a little disappointing to find the results of experiments given, often with little, if anything, to indicate the theoretical deductions which can be drawn from them. Indeed, not infrequently the opinions of different investigators as to the interpretation of the results of experiments are recorded without any comment as to the relative merits of rival theories. No doubt it was the intention of the author to keep the work within definite limits, but it seems that much has been sacrificed merely for the sake of brevity. In no part of the book is this more apparent than in the portion devoted to radio-activity and the nature of the α rays. Here descriptions are often so short that it is questionable whether anyone not already fully acquainted with the subject will be able to follow the reasoning.

In the part dealing with radio-activity there are a few inaccuracies which call for comment. On p. 90 the author states that it is usually supposed that one α particle is given off from each atom during any radio-active process involving the emission of such particles. In view of the work of Bronson, who showed, for example, that an atom of thorium emanation, in breaking up, gives off four times as many α particles as an atom of thorium B or C, this is clearly not the case. Again, the table on p. 89 contains some mistakes. The volatilisation point of radium A, given as 1000° C., is too high, and that of radium C, as 1100° C., is too low. The volatilisation point of radium B is given as 20° C., instead of 600° C. That radium B can escape, at ordinary temperatures, from a surface coated with active deposit is correct, but the phenomenon is not due to any true volatility of the substance at ordinary temperatures, and has been explained on quite different lines.

Das Seelenleben der Tiere. By Dr. P. Ohm. Pp. 117. (Stuttgart: Neue Weltanschauung, 1909.)

This little book is the fourth of a series called "Weltanschauungs-Fragen," and apparently intended to include contributions to the monistic philosophy of Haeckel. Consequently, Dr. Ohm brings forward the two principal theories of animal intelligence—one that it is totally different in kind from human, and the other that it is the product of evolution, and differs only in degree, but is essentially of the same nature. After a brief historical introduction to the subject, and noticing the opinions held by various authors from Plato to Wasmann, Darwin, and Harold Höfding, Dr. Ohm speaks of the dawning intelligence indicated in Protista, sponges, Medusæ, Hydra, molluscs, &c., and then inserts a chapter on instinct to controvert the view advocated by Wasmann that it is a perfect and divine inspiration, quite different from reason. Here he deals especially with the manifestations and imperfections of the intelligence of insects, especially ants and bees.

Another chapter is devoted to the "Seelenleben" ("soul-life," or, more correctly, intelligence) of insects and spiders, with special reference to their eyes, antennæ, sense of direction, &c., and a figure is given of the Indian tree-ant (*Œcophylla smaragdina*) using one of its own larvæ to spin threads. An illustration is also given of the large garden diadem spider and its web. Another chapter follows, on the senses, habits, and intelligence of vertebrate animals, and the book concludes with a comparison between human and animal intelligence; and the author regards the faculty of speech as the essential difference between them. A short bibliography is appended.

Dr. Ohm has written a thoughtful little book, and has dealt with a difficult subject fairly and moderately. His work will be read with interest by students interested in the important questions with which it deals; but everyone is so much influenced by preconceived ideas, on one side or another, that it is almost impossible to form an unbiassed opinion about them.

W. F. K.

Comment Former un Esprit. By Dr. Toulouse. Deuxième Édition. Pp. x+260. (Paris: Librairie Hachette et Cie., 1908.)

This book is the reply to a request for ten lessons to professional teachers and parents which should embody what Dr. Toulouse's experience as a psychologist and a medical man has taught him to think essential to "the cultivation of an intelligence." He starts from a position with which critics of educational institutions on this side of the Channel have made us familiar; "we teach everything in school to-day except how to think and how to act." His remedy is also familiar—education should aim at teaching us not so much to know as how to apply knowledge to the regulation of the important affairs of life. To achieve this end it must train us, in accordance with sound principles of "method" (in the Cartesian sense), to observe, to judge, to feel, to act. The author's discussion of these methodical principles is broad-minded and suggestive, but it is too brief and schematic to be of much direct service to the teacher in the class-room or the parent in the home. His recommendations have much more value when they either express the practical wisdom of a man who has managed his life successfully or deal with specific topics on which his experience as a medical psychologist gives him authority. Under the latter heading attention may be directed to a vigorous argument for the frank instruction of boys and girls in "the phenomena of life."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Visibility of Halley's Comet.

THE discovery of Halley's comet at a time so far preceding the date of perihelion passage adds another proof of the great capacity of the photographic method. The interesting point to many observers is as to when the comet will become visible to them as a telescopic object. This must, of course, depend in a large measure upon the diameter of their glasses and on their powers of vision. After the present moon has left the sky, say during the second week in October, the comet ought to have increased in light sufficiently for it to be observed in a 12-inch telescope. The calculated magnitude of the comet will be $14\frac{1}{2}$ on October 15, and its distance from the earth about 230 millions of miles. Its apparent position will then be five degrees west of γ Geminorum, and near 72 Orionis. On October 16 the comet will be just two degrees south of 71 Orionis (mag. 5·5), and ought to be visible as a very faint nebulosity, especially if the night is good. The transparency of the air has an important influence on the perception and aspect of faint comets and nebulæ, for a really suitable sky will enable objects to be glimpsed which are utterly invisible on bad nights when there is diffused light, thin cloud, mist, or fog prevalent. The comet will be visible in an excellent position nearly all night during most of the winter, but will continue small and faint until it blazes out next April. W. F. DENNING.

The Presence of Hæmoglobin in Invertebrate Blood.

MAY I make use of your columns to correct a statement in my article on Crustacea in vol. iv. of the "Cambridge Natural History," which I am afraid may seriously mislead the reader? Referring to the alleged presence of hæmoglobin in the blood of Branchipus and Daphnia, I have stated in a footnote on p. 30 that the fact that the red blood of Lernanthropus has been proved not to contain hæmoglobin throws doubt on the reality of its presence in the other two animals. At the time of writing I was not aware that the authority on which the presence of hæmoglobin in Branchipus and Daphnia rested, and I was inclined to impugn, was Sir Ray Lankester, who, in the late 'sixties and early 'seventies, published a series of researches which laid the foundation of a comparative knowledge of the distribution of hæmoglobin and similar respiratory pigments in the animal kingdom (see especially Proc. Roy. Soc., vol. xxi., December, 1872, p. 70). After reading these articles it is clear to me that Sir Ray Lankester's statement as to the presence of hæmoglobin in the blood of Branchipus and Daphnia, resting as it does on careful microspectroscopic examination, is quite unaffected by what may or may not be the case in Lernanthropus, so that I can only withdraw my footnote with many apologies to him and to readers of the "Cambridge Natural History." With regard to Lernanthropus and its allies, small crustacea parasitic on fish and mussels, which possess a closed vascular system containing a red fluid, there is still some doubt. Van Beneden, who discovered Lernanthropus in 1880, states (*Zoologischer Anzeiger*, Bd. iii., p. 35) that he examined the blood spectroscopically, and found the oxyhæmoglobin lines.

More recently Dr. Steuer (*Arbeiten Zool. Inst. Wien*, vol. xv., p. 14, 1903) sent numerous specimens of an allied form, Mytilicola, to Prof. R. von Zeynek in Vienna, who came to the conclusion that the blood did not contain hæmoglobin, since (1) with glacial acetic acid and sodium chloride no hæmin crystals were obtained; (2) after reduction with potassium cyanide and ammonium sulphide, the characteristic reduced hæmoglobin lines were not formed; (3) there was no hæmochromogen reaction.

Curiously enough, we are not told whether the simple examination of the blood gives the oxyhæmoglobin lines, as Van Beneden stated, or not, so that we are left in doubt whether Van Beneden was altogether in error or the red substance in the blood of Lernanthropus possesses one of the properties of hæmoglobin but not the others. The matter being in this unsatisfactory state, it is very desirable that someone, to whom the opportunity is offered, should re-investigate the blood of Lernanthropus.

New College, Oxford. GEOFFREY SMITH.

MAGNETIC STORM OF SEPTEMBER 25.

DR. CHREE, F.R.S., has sent us the following communication on the above:—

The magnetic storm of September 25 exhibited the rapid oscillatory movements that are usually associated with the appearance of aurora. As recorded at Kew, the storm commenced suddenly at about 11.43 a.m. During the next nine hours there was an almost uninterrupted succession of large oscillatory movements in the magnetic curves, especially those of declination and horizontal force. The storm was of comparatively short duration, no movements of any great size being recorded after 8.30 p.m. on September 25, and by 1 a.m. on September 26 little trace of disturbance was left. When the storm was at its height the oscillatory movements were so rapid that the record left on the photographic paper was frequently too faint to show minute details, and the limits of registration were at times exceeded.

At the commencement there would appear to have been an exceedingly rapid oscillatory movement of the declination needle, after which the needle moved to the east continuously for about 15 minutes. After the first 12 minutes, during which a movement of 72′ was recorded, the trace got off the sheet, so that the full extent of the easterly drift is not shown. After a few minutes' absence the trace reappeared, but, after some oscillatory movements of the needle, the trace got off the sheet again on the same side as before at about 12.12 p.m., and remained off on this occasion for nearly 40 minutes. During the whole of this time the needle pointed at least 70′—at times, probably, a good deal more—to the east of its normal position. After coming on the sheet about 12.52, the trace exhibited some minor oscillations superposed on a rapid drift across the sheet. The entire width, representing 2° 7′, was crossed in less than half an hour, and the trace at about 1.20 p.m. got off the sheet on the opposite side. The needle then pointed about 1° to the west of its normal position. Between 1.20 p.m. and 8.30 p.m. there were a number of large oscillations, movements of 40′, 60′, or more, now east, now west, taking place in the course of a few minutes. The largest of the rapid oscillations clearly shown took place between about 8.7 and 8.22 p.m., a westerly movement of 98′ being followed by an easterly movement of 84′. The disturbance shown by the horizontal-force curve was no less remarkable. The commencing movement at 11.43 a.m. went beyond the lower limit of registration, a fall of 430 γ taking place in about 10 minutes. At this time the trace was off the sheet for only about 5 minutes. After reappearing it showed large oscillations. By 12.53 p.m. it had crossed the sheet to the other side, the change of force during one period of 13 minutes being no less than 625 γ. The trace was off the sheet continuously from 3.55 to 5.10 p.m., the horizontal force during the whole of this time exceeding its normal value by more than 300 γ. Except when off the sheet, the trace showed continuous large oscillatory movements during the whole afternoon. The largest clearly shown was partly synchronous with the large declination oscillation near 8 p.m. already described; it consisted of a rise of 520 γ and fall of 710 γ, all in the course of 17 minutes.

The declination range, 2° 7′, and the horizontal-force range, 740 γ, actually recorded, represent merely the full width of the photographic paper. How much these ranges were exceeded it is impossible to say, but, judging by the look of the curves, the excess was probably considerable. The vertical-force trace got off the sheet only on one side, and this element would appear to have been less disturbed than the other two. Still, as the trace was off the sheet continuously for nearly an hour after 3.35 p.m., the chances are that the true range exceeded somewhat largely the range 530 γ actually recorded. The duration of the storm was comparatively short, but whilst it lasted it exhibited an energy which has been very seldom rivalled at Kew. The oscillatory movements were quite as rapid as those of October 31, 1903, and the range of the elements has probably not been exceeded during the last twenty years, not even during the great storm of February 13, 1892.

Magnetic storms such as the present inevitably create an interest in the explanations that have been advanced to account for the phenomenon. The theories of Arrhenius and of Nordmann, the theories and researches of Birkeland, and the deductions made by Maunder from the Greenwich disturbances all point to the sun as the ultimate source, and to some form of discharge—ions, electrons, or such like carriers of electricity—as the immediate vehicle. The electrical nature of aurora is difficult to dispute, and the fact that storms like the present appear to be invariably associated with aurora visible far outside the polar regions unquestionably supports in some ways theories such as those of Birkeland or Arrhenius.

When we come, however, to details, difficulties present themselves. If magnetic storms are directly due to the electrical currents which render the upper atmosphere luminous, how comes it to pass that the visual phenomena of aurora are so constantly changing, whilst even in the most conspicuously variable of magnetic storms the larger movements of the magnets take usually 5, 10, or 20 minutes to accomplish, the force appearing to alter at a nearly uniform rate for minutes on end? The relatively gradual nature of the magnetic change is a true phenomenon—as clearly indicated by the short-period magnets of the Eschenhagen pattern, as in the larger Kew magnets with periods of 10 seconds or more. There is, again, the very remarkable fact that when we go to high latitudes, where aurora and magnetic disturbance are both almost daily occurrences, the association of the two phenomena becomes much more difficult, if not impossible, to recognise. The absence of visible aurora during active magnetic disturbances may be reasonably accounted for during the Arctic summer, when the sun is above the horizon, but it is a different matter when we find the magnets rather quieter than usual during the occurrence of a bright aurora. Unless we are to assume a fundamental difference of type between auroras presenting the same spectroscopic lines, or a variety of sources for different magnetic storms, there is a difficulty which is not easily surmounted. The only explanation that has occurred to me is the possibility that the visual phenomena may represent merely intense local concentration of electrical current, and that the main portion of the discharge frequently makes no appeal to the eye, and is of a much more steady and persistent character. Another difficulty in regarding the phenomena of magnetic storms as entirely and directly due to the action of electrical currents associated with aurora is that it is a frequent occurrence—as on the present occasion—for the horizontal force to be considerably depressed below the normal value when the storm has apparently ceased and for some considerable time thereafter. It is possible, of course, that the external currents have partly demagnetised the earth, or at least modified its distribution of magnetism, and that there are recuperative tendencies tending to cause reversion to what is for the time being a more stable distribution; but if this be the true explanation, the demagnetising action and the recuperative tendencies are presumably in action during the course of the storm, and profoundly modify the magnetic phenomena. To many minds subscription to some theory may be a necessity for intellectual comfort, but in the case of magnetic storms reservation of judgment appears at present the more scientific attitude.

In addition to the foregoing we have received the following communication from Prof. A. Fowler, of the Imperial College of Science and Technology, South Kensington:—The possible occurrence of a magnetic storm and auroral display on September 24 or 25 was suggested by observations of the large spot which was then on the sun's disc. On September 24 the spot was a little west of the central meridian—which appears to be the most favourable position in relation to magnetic disturbances—and spectroscopic observations showed that it was of the same disturbed type as the spot associated with the great magnetic storm of October 31, 1903 (NATURE, vol. lxix., p. 6).

On Friday evening (September 24) the sky was overcast, and it did not then occur to me to test the possible presence of aurora by the spectroscope. On Saturday evening, however, although the sky was at first completely clouded over, the spectroscope gave unmistakable evidence that an auroral display was in progress. From 6.40 to about 7.30 (the sun set at 5.52), the whole sky was filled with a feeble light, with brighter patches here and there, and the characteristic green line of the auroral spectrum was seen in every direction. The greatest intensity was at first near the zenith, but the line was easily visible over the entire sky, and was even seen in the light reflected by a pocket handkerchief. This condition continued with diminished brightness until near 8 p.m. Between 8 and 9 o'clock the display was very feeble, but shortly after 9 the auroral line was again fairly distinct in a faintly luminous belt about 10° above the northern horizon. After 9.30 no evidence of aurora was obtained, although the sky was then partially clear.

The general distribution of the green line over the heavens in clearer skies has been occasionally noted by Ångström and others, but I have not yet found any previous record of such a wide diffusion of the auroral light when the sky was completely clouded. If wholly above the clouds, the aurora must have been of extraordinary brightness in order to produce this effect.

Besides the green line, there were three fainter nebulous lines or bands in the green and blue, which have been frequently mentioned by previous observers. A careful search was made for the red line which appears in "crimson" auroræ, but its presence was not even suspected.

As to the sun-spot, there was a brilliant reversal of the C line of hydrogen over one of the umbræ when I observed it at 12.20 p.m. on September 24, and on opening the slit it was clear that this appearance was produced by a very bright overlying prominence. Reversals of the chromospheric lines b_3 and 1474 K were also suspected, but the observations were stopped by clouds. According to Tacchini and Lockyer, it is the prominence, rather than the spot, which should be considered as related to the magnetic disturbance.

AVIATION.

THE successful aviation week recently concluded at Rheims should do much to popularise aviation, if that subject is not sufficiently popular already. The large number of newspapers and periodicals devoted to aërial navigation is, however, sufficient evidence of the amount of public interest which centres round the new form of locomotion. At a railway bookstall at Tarbes, in the Pyrenees, a few weeks back, the present writer saw no fewer than five different papers devoted to flying machines. Possibly the number of such journals is equal to, even greater than, or at any rate comparable with, the number of successful flights that have been performed; it certainly appears as if the frequency with which a new journal comes out is not small in proportion to the frequency of aëronautical successes. Indeed, at the present rate, the assigning of new titles to these journals will soon take the form of a problem in permutations and combinations.

When it is attempted to draw scientific conclusions from these successful flights there is not, after all, so very much to be said. The difference between a machine that will fly one mile and a machine that will fly a hundred miles is mainly that the latter must be able to carry a heavier load in the form of petrol or other fuel than the former. In the case of high flights the same remarks apply, though the construction of a machine which is capable of ascending or safely descending at a considerable angle to the horizon presents many points of scientific interest which, no doubt, will receive the attention they deserve sooner or later, unbeknown to the average newspaper reader. In saying that when aviation takes the form of record-breaking it ceases to be a science and becomes a sport, we are, of course, not taking into account all the work of an experimental character in the construction and perfection of motors, propellers, and aëroplanes which has to be gone through behind the scenes before the sport can be indulged in. We have, however, failed to find that any very definite and striking new result has been proved by the recent triumphs.

It would seem, in fact, as if writers on the subject were directing their attention to the early history of aërial navigation to make up for the fact that there is very little to write about in a mere statement of records. Under the title of *Ila*, a weekly journal is appearing in connection with the International Aëronautical Exhibition at Frankfurt, of which the historical section is an important feature. It is interesting to revive acquaintance with the early, and in many cases fantastic, devices of Barthélemy Lourenço de Gusman, Besnier, Jacob Degen, Blanchard, the *Minerva* of Robertson, with its suspended ship and cabins, and an old cartoon of an omnibus and horses hanging from a balloon. As for Lourenço, a special number (Illustrierte Aëronautische Mitteilungen xiii, 17, *Ila* iii.) contains references to his exploits in view of August 8 of this year being the 200th anniversary of his supposed flight. The article by Mr. B. Wilhelm is prefaced by a short editorial note by Capt. H. W. L. Moedebeck, and seems to support the view that Lourenço actually went so far as to make a small model of a fire-balloon rise in the air in presence of the King of Portugal. Of pictures of Lourenço's grotesque and fantastic design we have two in the number in question, but in No. 10 of *Ila* it is pointed out that if Gusman really did fly, his ship must certainly have looked quite different.

Another article dealing with the general history of aërial navigation, both past and present, forms the subject of a special number of *La Nature*, issued on August 21 in connection with the Rheims meeting of the following week. A useful feature is the series of illustrations, each showing in one figure a collection of the principal types of airships and aëroplanes, in much the same way that the early history of the subject is summarised in the interesting old "Tableau d'Aviation" of fame. Of these we reproduce the two illustrations of the most recent aëroplanes. The article concludes with a calendar of "the great dates of aviation," which is here given, with addition of the Rheims records:—

Date	Aeronaut	Place	Distance and Duration
Oct 14, 1897	Ader	Satory ...	Flight of 300 metres.
Sept. & Oct. 1905	Wright Bros.	Kitty Hawk	Flights of 17 to 38 km.
Nov. 12, 1906	Santos Dumont ...	Bagatelle ...	220 m. in a straight line.
Jan. 13, 1908	H. Farman	Issy	Kilometre in closed circuit.
July 6, 1908	H. Farman	Issy	Prize for ¼ hour.
Sept. 9, 1908	O Wright...	Fort Meyer.	63·975 km. in 1h. 3m. 15s.
Oct. 10, 1908	W. Wright	Mans	1h. 9m. 45s., two persons.
Oct. 30, 1908	H. Farman	Bouy to Rheims ...	First actual journey, 27 km.
Oct. 31, 1908	Blériot ...	Toury to Artenay & back ...	First circular trip.
Dec. 31, 1908	W. Wright	Pau	123 km. in 2h. 18m. 33·6s.
June 5, 1909	Latham ...	Camp de Châlons ...	1h. 7m. 35s. on monoplane.
July 18, 1909	Paulhan ...	Douai... ...	150 metres altitude on biplane.
July 25, 1909	Blériot ...	Sangatte to Dover ...	Channel flight, 37 m.
Aug. 4, 1909	R. Sommer	C. de Châlons	2h. 10m. on biplane.
Aug. 7, 1909	R. Sommer	,, ,,	2h. 27m., time record
Aug. 23, 1909	Curtiss ...	,, ,,	10 km. in 8m. 37·6s. (speed).
Aug. 24, 1909	Blériot ...	,, ,,	10 km. in 8m. 4·4s. ,,
Aug. 25, 1909	Paulhan ...	,, ,,	131 km. in 2h. 43m. 24·8s.
Aug. 26, 1909	Latham ...	,, ,,	154·5 km. in 2h. 13m. 9·6s.
Aug. 27, 1909	Farman ...	,, ,,	180 km. in 3h. 4m. 56·4s.
Aug. 28, 1909	Latham and Farman	,, ,,	Altitude 120–130 m.

When the newspapers state that one portion of the course has come to be called "the valley of death," from the numerous wrecks that every day strew its fields, and when we refer to the accidents to Paulhan, Fournier, Blériot, and still later to the death of Lefèbvre and the accidents to Lieut. Calderara, to Bossi, and to Le Blanc, it will be seen that aëroplane triumphs are being bought at the expense of many thousands of pounds spent in rebuilding completely smashed-up machines, not to mention the risk to life and limb.

Of course, a considerable proportion of these accidents are undoubtedly accidents in the true sense of the word, but when we read, as we have done over and over again, that machines have suddenly stopped dead from no explicable cause, and then suddenly plunged to the ground, the idea of longitudinal instability at once suggests itself, and the obvious remedy is that aviators should wait until this subject has at least been thrashed out mathematically, or should devote a fraction of the sum they spend on repairs of broken parts to furnishing the assistance which would enable the theoretical investigations to be pushed forward without delay instead of being hung up for months at a time owing to pressure of other work.

Such a course would have been by far the shortest, cheapest, and best way of disposing of one of the important difficulties connected with aviation. But what chance of success would a mathematician have if he made an appeal of this kind? The world is full of people who have made, or imagine they have made, epoch-making discoveries, and who only require funds for their development. Their effusions find their way into every journal that does not adopt the most strict censorship over the scientific value of its contributions. The time has passed when any value can be attached to projects for aërial navigation which are not supported by either theory or experiment, yet such projects still succeed in appearing in print, and naturally ninety-nine people out of every hundred mistake the chaff for the grain. In the Journal of the Franklin Institute for July, for instance, Mr. Russell Thayer propounds the idea that all you have to do is to attach a gyroscope to a dirigible balloon and provide it with a sail in order to make it abandon its path of least resistance, drifting with the wind, and plough through the air in a different direction. Even the heading of the paper contains the sentence "The lever in space without a fulcrum on the earth!"

We leave readers of NATURE to form their own opinions of this recent contribution to a journal professing to be "devoted to science and the mechanic arts." But if Mr. Russell Thayer will turn to *Ila*, No. 10, p. 174, he will see that his idea of an airship supported by balloons and driven by sails was anticipated in the year 1670 by the Jesuit priest Francesco Lana, of Brescia, whose design possesses the additional merit of dispensing with the gyroscope!

Returning to the serious side of the problem, it suggested of enabling an aviator to observe the resistance, and consequently to ascertain the relative velocity of his machine. Captain Renard concludes his "conferences" on aviation in the *Bulletin de la Société d'Encouragement* for June. From Mr. Octave Chanute we have received by a recent mail papers on "The Evolution of the Two-surface Machine," and "Soaring Flight" (American *Aëronautics*, September and October, 1908, April, 1909), which remind us of the useful pioneer work in which Mr. Chanute was engaged, particularly before the Wright brothers took the subject so much in hand. In the *Revue scientifique* for August 14, Capt. Paul Renard writes on "The Antoinette Aëroplane and High Flights." Prof. Houssay, as a zoologist, writes, in the *Revue générale des Sciences*, xx., 14, on the stabilisation of fishes by fins and other appendages, and points out a certain analogy with the stabilisation of dirigibles. Photography by carrier pigeons is discussed in *Ila* for July 10, which also contains illustrations, which should interest philatelists, of letters sent by balloon post during the siege of Paris in 1870, and now exhibited at Frankfurt.

In view of the immense amount of popular enthusiasm aroused by aëroplanes, long before they have reached the stage at which they are likely to be used as a common means of transport, it is somewhat interesting to think that an invention has appeared almost unnoticed which is accessible to everyone, and is capable of affording quite as much genuine enjoyment to those who use it as the aëroplane, at a fraction of the cost. The piano-player was heralded by no flourish of trumpets, it received no attention in the Press, save in the makers' advertisements, and there is no journal devoted to its interests. Yet from a scientific point of view it possesses many remarkable—almost marvellous—properties, which afford abundant material for research. But if such researches were undertaken, no one would publish or read them. All the fashion is for aëroplanes.

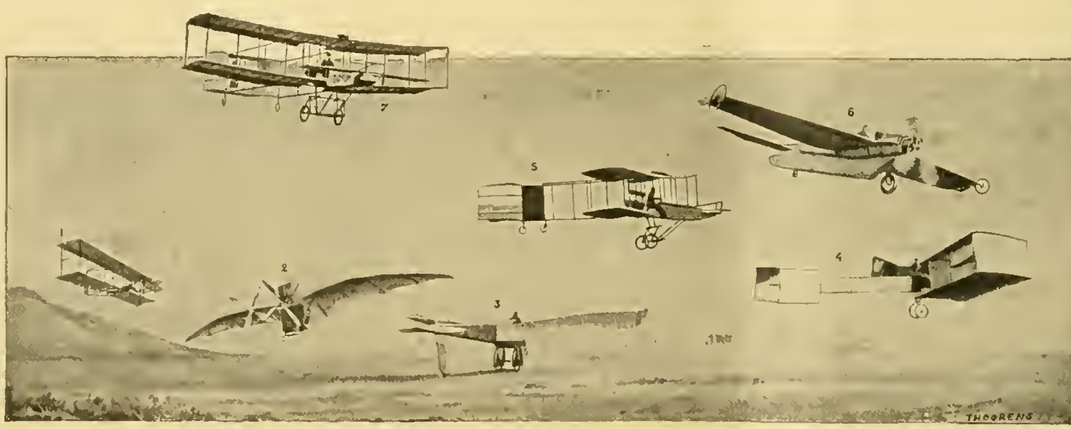

FIG. 1.—1. Wright glider (1900–3). 2. Ader (1890–7). 3. First Blériot monoplane (1906). 4. Santos Dumont's machine which made the first officially recorded flight (1906). 5. Farman's biplane which made the first circuit of a kilometre (January 13, 1908). 6. Robert Esnault Pelterie monoplane (1907–8). 7. Delagrange biplane (1908).

is impossible to glance at the two illustrations accompanying this article without forming the general impression that in many of the types figured the longitudinal stability is defective and the lateral stability *nil*, or worse than *nil*. It is merely the danger of making statements which are unsupported by the most circumstantial evidence that prevents us from expressing a very strong and emphatic view regarding pretty well every machine in the collection. The one fact which appears definitely established is that aëroplanes which are unstable, both longitudinally and laterally, can perform flights of indefinite length in the hands of skilled aviators, and this result will receive its full and proper explanation in the prospective mathematical theory. Indeed, for those who can appreciate them, mathematical researches on stability are much more fascinating than flights on aëroplanes.

A few further papers are deserving of mention. In the number of *La Nature* referred to, an apparatus called "wrightmeter" is suggested, invented by M. Dalloz for the stated purpose of determining the coefficient of resistance of air. As this resistance is measured on a *sphere*, this does not go very far in determining the resistances commonly occurring in aërodynamics, the more useful application being that

G. H. BRYAN.

Since the above article was in proof, the science of aviation has sustained a sad loss by the death of Captain Ferber. Although Captain Ferber's name has not come prominently before the public as a record-breaker, this perhaps is in some measure due to the scientific spirit in which he studied aviation. Captain Ferber commanded the Alpine Battery at Nice from 1900 to 1904, and during that time became interested in aviation. His first models, like the old-fashioned quadrilateral boy's kite, had aëroplanes of considerable longitudinal dimensions, but on becoming acquainted with the gliding experiments of Chanute, Herring, and the Wright Brothers, he was not long in adopting the two-surfaced rectangular type. Captain Ferber materially developed our theories of longitudinal stability, and he also gave a mathematical investigation, probably the first, of lateral stability. In view of the last statement, and the fact that Ferber's machines were furnished with special triangular sails in order to render them laterally stable, it seems somewhat rash to suggest that his fatal accident was due to the precautions being inadequate; yet it is just possible we may find that such was the case; if so, it is remarkable that Ferber should fail when others who have taken less adequate precautions have succeeded. Before his death Captain Ferber attributed the accident to flying too low, so that the machine struck the ground when it heeled over. Captain Ferber was the author of a number of papers and articles dealing with aviation, and also a keen balloonist.

G. H. B.

THE ROYAL OBSERVATORY AND ELECTRIC TRAMWAYS.

FROM statements recently appearing in the public Press, many people have been led to regard the Astronomer Royal as an uncompromising opponent of tramway electrification; but as it is perfectly well known that Greenwich is very well supplied with electric trams, it must be quite evident that this impression cannot be correct.

It is specifically alleged that:—

(1) The extension of the overhead trolley system from the Arsenal gates to the Woolwich Free Ferry is blocked by the refusal of official sanction.

(2) The same official sanction is withheld from all schemes for the authorised electric tramway from Woolwich to Eltham.

The facts we have been able to ascertain are as follows, premising that the Admiralty, and not the Astronomer Royal, is officially responsible for safeguarding the efficiency of the observatory records, and that the Board of Trade has to provide for adequate protection of the observatory for the magnetic portion of the work.

FIG. 2.—8. Blériot monoplane after accident. 9. Luyties American helicopter. 10. Bonnet Labranche biplane. 11. Vuia helicopter. 12. Goupy triplane. 13. Curtiss's American biplane. 14. Zeus aëroplane. 15. Ferber biplane. 16. Santos Dumont's Demoiselle. 17. Gastambide Mangin biplane. 18. Farman's biplane which travelled from Bouy to Rheims (October 30, 1908). 19. Wright's machine which made the record flight with two passengers (1h. 9m. 45s.). 20. The Antoinette V., which made the record for monoplanes (1h. 7m. 35s.) and attempted to cross the Channel. 21. The Blériot XI., which crossed the Channel on July 25, 1909.

(1) The proposal appears to have been brought up suddenly, without previous warning, towards the latter part of August, at a time when, as is well known, many Government officials are expected to be away on leave, and, consequently, delay is almost certain. It appears also that as soon as the question was gone into by those concerned, it was decided to consent to the proposal on the strict understanding that any further step in the conversion of the existing horse-tramway between East Greenwich and Woolwich should be by extension of the conduit system eastwards, and not of the trolley system westwards. It is, of course, impossible to say how long it will be before this decision can have any practical effect, but it is certain that no further delay can be attributed to the observatory.

(2) As regards the authorised tramway from Woolwich to Eltham, we find that many Eltham residents are strongly opposed to the overhead system, while the official position is not one of hostility to the overhead system *per se*, but of insisting on insulated returns, any system which ensures this for the protection of Greenwich magnetic records being free from this official objection. As a case in point, the G.B. surface-contact system was proposed by the County Council several years ago and sanctioned officially, but was then dropped after some inconclusive experiments. Recently a new surface-contact system, the S.P. system, was made the subject of an article in *Engineering*, May 28, and claims to avoid the risk of danger alleged against the G.B. system. It has been tried and favourably reported on, but has not apparently been suggested for the Woolwich and Eltham tramway.

The official attitude thus seems perfectly consistent and reasonable, and not unsympathetic. The suggestion of overhead wires without insulated returns within a radius of three miles from the observatory ought once for all to be dropped. If the County Council objects to the expense of the conduit system and to the inconvenience of equipping the overhead system with insulated returns, it is for them to find a satisfactory alternative. Unless the protective clauses insisted on by the Government are to become a dead letter, it is futile to try to blame the observatory for delay or obstruction, and it is in the last degree unlikely that the Admiralty will be persuaded to stultify its own action and contention by allowing these clauses to be overridden.

PETER BARR.

THE name of this eminent horticulturist, whose death we announced last week, will ever be associated with the development of narcissi. Born in 1826, in the former village of Govan, which has long since been absorbed in the city of Glasgow, he was the son of a mill-owner who found recreation from weaving in the cultivation of tulips and other florists' flowers. The son appears to have inherited a strong love for floriculture, for he soon tired of the looms, and obtained employment in various seed businesses, until in 1861 he commenced business, with a partner, on the site of the present premises of Messrs. Barr and Sons, King Street, Covent Garden, under the title of Barr and Sugden. Barr then directed his attention to practical floriculture, experimenting with hellebores (Christmas roses), tulips, lilies, and pæonies. For these purposes he found it necessary to take up a piece of ground at Tooting, where he conducted trials which interested the leading florists of the day. He next scoured the country over for narcissi, meeting with considerable success in his quest. Two amateurs had already formed wonderful collections of these flowers which, unknown to the general public, they had cultivated for nearly a quarter of a century. These were Mr. W. Backhouse, of Darlington, and Mr. Edward Leeds, of Manchester. Barr made up his mind that if he could only obtain possession of these collections he would have all the best of existing daffodils in his own possession. By dint of perseverance and enterprise he succeeded in this, and the collections were removed to Tooting, where for years afterwards new seedling varieties flowered every year. Every variety worth cultivating was named and its name registered, for he recognised that no commercial success would follow unless the public could be assured that every plant catalogued was accurately and intelligently named. But the varieties continued to multiply so greatly that he found it necessary to elaborate a classification, grouping the sorts into sections according to the length of the trumpet or perianth tube and other characteristics. Mainly owing to Barr's representations, the Royal Horticultural Society promoted a Daffodil Conference in 1884, and his system of classification was then, in the main, adopted. Not long after this the attention of market growers was directed to these bulbs, and in the Scilly Isles, in Cornwall, in Lincolnshire, and other places acres of land were planted for the purpose of supplying the markets with cut blooms, with the result we see to-day in the millions of flowers that are offered everywhere for sale.

Peter Barr retired from business in 1896, after botanising in various places in Europe for the purpose of collecting rare daffodils in their native habitats. In 1808 he began a tour round the world, which lasted seven years. He visited America, Canada, Japan, China, Australia, New Zealand, and, on his way home, spent twenty-one months in South Africa. During this world tour he lectured on daffodils, and was interviewed and acclaimed almost everywhere as the "Daffodil King," a title which had been given him in this country by his fellow-floriculturists.

One of the finest white trumpet daffodils ever raised was distributed a few years ago by his firm, and it was named after Peter Barr.

NOTES.

WE learn from the *Times*, with deep regret, of the death, on Sunday last, of Prof. Anton Dohrn, the founder and director of the Zoological Station at Naples.

SIR THOMAS ELLIOTT, Secretary to the Board of Agriculture and Fisheries, has been nominated by the French Government to be a Companion of the Order "du Mérite Agricole."

IN view of the retirement, to which reference has been made in these columns already, of Prof. J. Cleland, F.R.S., from the chair of anatomy, and of Prof. Jack from the chair of mathematics, at the end of the present month, there has been set on foot, on the initiative of the business committee of the general council of the University of Glasgow, a movement for making appropriate recognition of their long and distinguished services. Circulars have been issued to the whole body of university graduates and to members of other learned bodies with which Profs. Cleland and Jack have been connected. In the circulars it is stated that the form of recognition will, to a large extent, depend on the amounts subscribed, but it is thought that it might fitly include the provision of some fund for the advancement of anatomical and anthropological science in the case of Prof. Cleland, and of mathematical science in the case of Prof. Jack, and the presentation to the University of portraits or busts by an eminent artist. Representative committees have been formed to administer each fund, and the preliminary lists of subscriptions show that the movement has already met with a hearty response. Men of science and others desiring to take part in the recognition and to contribute to either fund are invited to communicate with the honorary secretary and treasurer, Mr. Archibald Craig, clerk of the University general council, 149 West George Street, Glasgow.

The Antarctic vessel *Nimrod*, now moored in the Thames off the Temple Pier, was opened yesterday for the inspection of the public by the Lord Mayor of London.

Shocks of earthquake on the morning of September 22 are reported from the Bouches-du-Rhône, Rognes, Reggio di Calabria, Messina, and Athens, but in no case does much damage appear to have been done.

It is stated by the British Antarctic Expedition, 1910, that arrangements have been made for the purchase of the *Terra Nova* for the projected expedition of next year. The vessel, which is a whaler, was built in 1884. In 1903 she was purchased by the Admiralty as relief ship for the *Discovery* expedition. The year 1905 saw her in the service of the North Polar expedition, on a visit to Franz Josef Land. The size and strength of the ship make her a fitting receptacle for the extensive equipment which it is necessary she should carry for the full success of the plans of the expedition. After being duly inspected on behalf of the expedition in Newfoundland she will sail for England and, it is hoped, reach the Thames about the end of October or early in November. The officers and crew for the expedition have now been selected.

The presidential address of Mr. W. Noble Twelvetrees will be delivered to the Civil and Mechanical Engineers' Society at Caxton Hall, Westminster, on Thursday, October 7.

According to a *Times* correspondent a group of French, German, and Belgian patrons of aviation are offering a prize of 10,000*l.* to be awarded to the aviator who rises, with a fixed point as centre, to a height of 250 metres, flies a thousand metres from this altitude in a horizontal direction, and finally, returning, soars for a quarter of an hour at a height of 20 metres over the point of departure. An alternative feat is to make a flight from Brussels to Paris or from Brussels to Cologne, without a stop, at a speed of 60 kilometres an hour.

It is stated in *Tropical Life* that an International Cotton and Fibre Exhibition will be held in London in 1912, and that in conjunction with it there will be an important conference for the purpose of considering the cotton and fibre questions in their various aspects. A section of the exhibition will be devoted to other fibres, animal, vegetable, and mineral.

According to a Reuter message from Rome, the Juba, in Benadir, has formed a new mouth. Some months ago a violent typhoon broke through the spit of land separating the sea from that part of the river which runs parallel with the coast, and the action of the sea and the current combined have since made a new mouth 450 yards in breadth and formed a long lagoon which, with little expense, can be converted into a serviceable harbour. The same message states that the Italian Resident, Captain Ferrari, has found that the Webbi Shebeli does not, as was supposed, lose itself in marshes in the Ballis country, but is an affluent of the Juba, into which it runs some 120 miles from the latter's mouths.

The *Electrician* states that a gift has been made to the American Institute of Electrical Engineers by the Western Electric Company of a valuable collection of patent specifications. The specifications range from May 30, 1871, to December, 1908, and number approximately 100,000.

Among the popular lectures shortly to be delivered at the Royal Victoria Hall, Waterloo Bridge Road, are the following:—on October 5, "Marconi's Transatlantic Wireless Telegraphy," by Prof. W. Lynd; on October 19, "The Great Earthquake in Jamaica," by Dr. Vaughan Cornish; on October 26, "New Guinea," by Mr. J. E. Liddiard.

The annual exhibition of the Royal Photographic Society, at the New Gallery, Regent Street, will remain open until the end of October. It is divided into four principal sections—pictorial, scientific and technical, professional work, and trade exhibits of apparatus and materials. The scientific student will find matters of interest in every section, including even the pictorial, for, as the society has reverted to its old custom of stating the method of production, the pictorial photographs may be looked upon, if so desired, as specimens of the various processes. The section specially devoted to scientific and technical subjects is this year of a wider interest than usual. The greater number of exhibits represent the character and habits of various living creatures, from the largest to the smallest, and in this department is included special collections of work by the Zoological Photographic Club and by a number of German naturalists, the latter having been collected by R. Voightländer, of Leipzig. The astronomical photographs include recent plates from Greenwich, Stonyhurst College, and the Heidelberg Observatory. Among those who show spectrum photographs we notice the names of Prof. Zeeman, Prof. H. Kayser, A. Fowler, and C. H. Fabry and H. Buisson. Dr. C. L. Leonard contributes Röntgen-ray photographs that show peristaltic waves in the stomach and intestines. Experiments on the resolving power and other properties of photographic plates are shown by C. E. K. Mees and E. K. Hunter. Photomicrography, telephotography, and balloon photography are well represented, and there are a few interesting exhibits that refer to the methods of process work. Of colour photography, although there are many specimens, the only progress indicated is in the direction of the perfecting of the newer plates, more particularly the Thames plate. The regular disposition of the three colours in this plate renders it specially adaptable to reproduction by different methods. We would point out that many photographs of great interest are mounted as lantern-slides, and that these are shown on a stand by themselves, away from the general collection of scientific and technical exhibits.

Rainy, cool, and unsettled weather has prevailed throughout September, and although the rainfall in the aggregate has not generally been excessive, there have been few days without rain, except during the third week of the month. The total measurement of rain is in excess of the average in London by about 0·3 inch, and rain fell on nineteen days. The day temperatures have continued remarkably low for the time of year, and at the London reporting station of the Meteorological Office, in St. James's Park, the sheltered thermometer has not once touched 70°. At Greenwich there was only one day with 70° or above, the highest reading being 71°, on September 6. There has not been so cold a September since 1897, and as recently as 1907 there were fifteen days during the month with a temperature of 70° or above. Our weather over the British Islands has been chiefly under the influence of cyclonic disturbances, which have arrived with considerable frequency from off the Atlantic.

In the September number of the *American Naturalist* Dr. R. F. Scharff reviews the evidence in favour of an early Tertiary land-connection between North and South America. He believes in the existence during early Tertiary times of a strip of land connecting western North America with Chile, when Central America and northern South America were submerged. Such a connection, it is urged, is supported by many lines of evidence, and would serve to explain the occurrence of Eocene armadillos in North America and the affinity between the Canadian porcupine (Erethizon) and the Santa Crucian Stiromys.

In addition to their great abundance, the star-fishes of Alaska and British Columbia are remarkable, according to a paper by Prof. A. E. Verrill in the September issue of the *American Naturalist*, for the redundancy in the number of their rays, this being specially noticeable in the family Asteriidæ, the members of which, despite many exceptions, are generally five-rayed in other parts of the world. "Besides the species that normally have an increased number of rays, or vary indefinitely, there are others which have, more or less rarely, a smaller or larger number as monstrosities. . . . Various other monstrous variations occur somewhat frequently, such as forked rays, supernumerary rays arising from the dorsal surface, &c."

The second part of the first volume of the Records of the Canterbury Museum (New Zealand) contains an account of the scientific results of a trawling expedition undertaken by the New Zealand Government in 1907. The expedition seems to have been organised entirely from the commercial point of view, and the facilities afforded for scientific investigation were by no means so great as they might have been. It is therefore not surprising that the scientific results are somewhat meagre. This is the more unfortunate, as we still know comparatively little about the marine biology of the waters around the New Zealand coast. The investigations, chiefly of local naturalists, have made us very fully acquainted with the terrestrial fauna of the Dominion, and much has been done in the way of shore-collecting; but systematic marine biological research is, as a rule, beyond the reach of private individuals, and it is here that an enlightened Government might be fairly expected to take an opportunity for encouraging the advancement of science.

Protozoology is very much in evidence in vol. liii., part iv., of the *Quarterly Journal of Microscopical Science*, which contains no fewer than five papers on this subject. Miss Muriel Robertson describes the life-cycle of a new trypanosome from Ceylon, of which the principal host is the soft tortoise, *Emyda vittata*, and the intermediate host a leech of the genus Glossiphonia. Mr. C. Clifford Dobell describes the processes of physiological degeneration and death in *Entamoeba ranarum*. Dr. McCarrison places on record his observations on the Amœba in the intestines of persons suffering from goitre in Gilgit; Dr. Row describes the development of the parasite of oriental sore in cultures; and Prof. Minchin discusses the structure of *Trypanosoma lewisi* in relation to microscopical technique. Several of these papers are remarkable for the beauty of the coloured plates which accompany them, and the same is true of a short paper by Messrs. Muir and Kershaw describing, under the name *Peripatus ceramensis*, a new species of Peripatus from Ceram, the first to be recorded from the Moluccas. In the same number Mr. Joseph Mangan describes the entry of zooxanthellæ into the ovum of Millepora, and gives some particulars concerning the medusæ.

The report on forest administration in Southern Nigeria for 1907 contains an account of a tour through the west provinces, described by Mr. H. N. Thompson, the conservator of forests. Two fine forest tracts were explored at Ijaye and Ilesha, both of which are situated in the dry-zone vegetation. The first-named is called after an ancient town which was destroyed about sixty years ago, and since that time part of the forest has grown up. Here there were found to be mahogany trees with a girth measurement exceeding 10 feet, which implies a much more rapid rate of growth than is betokened by ring counts. The same conclusion is derived from the dimensions of trees planted in the botanical gardens, wherefore Mr. Thompson advances the opinion that probably the mahogany trees show three or four well-marked zones of growth each year, corresponding to the four definite seasons.

The reasons for deterioration that follow upon self-fertilisation or inbreeding of the maize plant have been investigated by Dr. G. H. Shull, who puts forward in the publication of the American Breeders' Association (vols. iv. and v.) certain conclusions based on the results of experimental cultivation. Plants selected according to the number of rows of grain in the ear were allowed to self-fertilise, when two strains became evident. For reasons which are given, it is considered that the individuals in a maize field are generally very complex hybrids, and that these strains are elementary species or biotypes, so that, according to the author's premises, self-fertilisation tends to isolate elementary forms, producing a homozygous condition, *i.e.* pure forms. Crosses between the two strains led to a distinct increase in the yield, whence the following method of propagation is suggested. Pure races of maize are to be obtained by self-fertilisation, and the crosses made between these pure races provide seed corn for the field crop.

Botanical teachers making use of lantern-slides may be glad to know of a new series of slides produced by Messrs. F. E. Becker and Co., Hatton Wall, London, from original photomicrographic negatives prepared by Mr. C. W. Greaves. A first series of fifty slides is announced, of which several relate to sections of anomalous dicotyledonous stems, others to the anatomy of stem, leaf, and root of angiosperms and the pine; a few represent cryptogamic and fossil sections. The phanerogamic specimens examined are clear and well defined, being taken from good microscopic sections, and the section of a Fucus conceptacle is excellent in general contour and detail.

An abstract of the report of the director of the Bombay Bacteriological Laboratory for 1908 appears in the *British Medical Journal*, from which we learn that the issue of anti-plague vaccine was little short of that of the preceding year, when the disease was severely and widely prevalent, the number of doses dispatched being 533,315 against 620,923. Experiments were carried out regarding the efficiency of rat and rat-flea destroyers, but they were not satisfactory or conclusive. The general bacteriological work was of a varied description. Special inquiry was made regarding an outbreak of malaria in the fort and dock area of Bombay; the investigation is still in progress. An outbreak of relapsing fever in the Kolaka district was also made the subject of special study. The laboratory rendered assistance and advice regarding questions relating to plague and other infective diseases, and courses of instruction were arranged for hospital assistants and others with reference to plague inoculation and bacteriological work.

Mr. C. Carus-Wilson has printed a paper, read by him before the Geological Society of London, on the pitting of flint surfaces. He directs attention to the frequently polygonal and rudely hexagonal character of the outer ends of the pits found on flints in a certain stage of decomposition, and to the considerable amount of water that may be absorbed by the external layers of such flints. But he shows much uncertainty of view as to the mode of origin of the pits; the suggestion made in the text that their polygonal outlines are connected with the crystalline form of the absorbed water as it froze seems, to say the least, fantastic. In a footnote, however, the author compares these outlines with the shrinkage-cracks of such rocks as basalt, and regards the ice merely as the agent that split off the lost portions of the flint. Would it not be simpler to regard the rudely polygonal outlines as resulting from the intersection of successively formed and adjacent cup-like surfaces of fracture?

We have received the report of the chief inspector of mines in Mysore for the year 1907–8, which opens with the statement that there was a large diminution in the number of applications for mining licenses as compared with the previous year; the statistics of licenses granted show, on the other hand, an increase from 101 in 1906 to 242 in 1907. The gold production showed a decrease of 5·84 per cent. as against a decrease of 8·67 per cent. in 1906, the comparison in each case being with the previous year; it amounted to a value of 2,041,129*l*. in 1907, and the total value of bullion produced from the commencement of mining operations in 1882 to the end of June, 1908, was 28,598,155*l*. Air blasts seem still to be frequent, but there was a decrease in the number of accidents. Statistics are given of the production of manganese and chrome, 82,835 tons and 11,197 tons respectively, but as regards other minerals it is reported that the statistics have been handed over to the curator of the Geological Museum for report as to whether it is possible to extract any useful information from them.

The Proceedings of the Royal Society of Edinburgh (vol. xxix., p. 602) contains a paper, by Mr. E. M. Wedderburn, on the deep-water oscillations recently described by Prof. Pettersson (Nature, August 12, p. 197). Working on a suggestion made by Sir John Murray, Mr. Wedderburn adduces evidence to show that the oscillations observed in the Skagerak are analogous to those which have been observed by the Scottish Lake Survey, and that they really show the presence, not of a long-period tide, but of a temperature seiche, having its node at the mouth of the Skagerak and its loop at the point of observation.

A preliminary summary report on coast changes in east Yorkshire, by Mr. T. Sheppard, of The Museum, Hull, forms a contribution to the investigation of the larger question of changes on the east-coast region of England during the historical period, undertaken by the research department of the Royal Geographical Society. Mr. Sheppard, after pointing out that the coast line between Bridlington and Spurn Point is of special interest because, while on the one hand enormous tracts of land have disappeared within historic times, on the other large areas have been formed, embanked, and cultivated, divides his district into five sections, the Holderness coast from Bridlington to Kilnsea, Spurn Point, the North Humber shore, the South Humber shore, and the Humber itself. Each district is treated from the point of view of geological evidence, historical evidence, and actual measurement. The general results indicate a wastage of the thirty miles of cliff between Bridlington and Spurn at a rate of about 7 feet per annum, and a growth on the Spurn during recent years of 17 feet per annum southward, with a net increase of 9 feet per annum in the width of the point. To the west of the Humber are large areas of land, now partly cultivated and productive, which were formerly watery wastes.

An important paper on evaporation in Egypt and the Sudan, by Mr. B. F. E. Keeling, is published by the Survey Department of Egypt. The author first deals with the results of comparisons of various types of evaporimeters used in Egypt at different times. Those now in use are mostly of the Piche and Wild patterns, exposed in double-louvred screens; their readings are apparently comparable in different climates, if similarly exposed, where the mean wind velocities are not widely different. A table is given showing the mean daily evaporation at stations in the Nile Valley; in Egypt and the North Sudan it is greater in the summer, while in the rainy areas it is at a maximum in the dry winter season, as is to be expected. One section of the report deals with the evaporation from open expanses of water. In the neighbourhood of Cairo the mean amount was 4·2 mm. per day (winter 3 mm., summer 5·3 mm.); on Lake Victoria it is estimated at 3 mm. per day. In the last section some remarks are made on the relation of evaporation to other meteorological factors; the mean daily curve of evaporation at Helwan closely follows the curve of saturation deficit.

In the September issue of *Man* Prof. Flinders Petrie describes a find of string nets of the seventeenth Egyptian dynasty which are practically unique. They were found associated with an untouched burial near Thebes. This is, perhaps, the most varied and rich collection of funeral remains which has ever been brought from Egypt. It will be preserved as an entire group in the Royal Scottish Museum, Edinburgh. The corpse was enclosed in a single coffin painted with wings in blue and gold. On the neck was a splendid golden collar; on each arm a gold armlet; round the waist an electrum girdle, copied from a Nubian pattern, made of seeds and leather. The whole collection of jewellery weighs half a pound avoirdupois—the largest group of gold-work which has ever left Egypt. The string nets associated with these remains, of which Prof. Petrie gives photographs, illustrate the remarkable skill in string-working attained by the Egyptians of that era. He also announces the discovery, at Memphis, of the great palace of King Apries (about 580 B.C.). Scale armour, bronzes, a remarkable silver plaque with a gold figure of Hathor, and a great carved portal, now in ruins, are part of the discoveries at this site.

In the September issue of *Man* Dr. C. G. Seligmann describes what is known as the Bandar cult among the Kandyan Sinhalese. It is a form of ancestor worship, Bandar being the title applied to the canonised spirits of eminent persons to whom, soon after their death, offerings are presented in order to induce them to protect the worshipper from evil and to grant him good fortune. One of the most important of these spirits is Kosgama Bandar, who takes his name from the village in which he lived in the eighteenth century or earlier. He seems to have rebelled against the King of Kandy, by whom he was captured and executed. He and similar spirits exercise authority under the control of Skanda, one of the four guardian deities of Ceylon. Dr. Seligmann prints, with a translation, a curious invocation addressed to this spirit.

FASCICULES 1 and 2 of the *Bulletin des Séances de la Société français de Physique* for 1909 contain thirteen memoirs, several of which have already been noticed in these columns. Amongst those not previously dealt with may be mentioned that by M. G. Delvalez, on the Hall effect in liquids. According to the electronic theory of conduction of electricity, this effect should be extremely small, while experiment appeared to show that it was a million times greater than the theoretical value. M. Delvalez has succeeded in showing that these observed effects were due to the convection currents in the liquid, set up because it is a mobile conductor carrying current through a magnetic field. The motion generates an electromotive force, which has been measured as the Hall effect. By using an alternating electromotive force to produce his main current, and arranging to balance the Hall electromotive force against the fall of potential down an induction free resistance traversed by the main current, he has shown that the effect is very small, certainly less than one three-thousandth of the value previously observed.

THE use of platinum felt, as suggested by Monroe in 1888, in place of asbestos as a filtering medium is recommended by Mr. W. O. Snelling in a paper in the Journal of the American Chemical Society (vol. xxxi., pp. 456–461). In addition to its insolubility in almost all the ordinary chemical agents, it has the advantage of extraordinary porosity, combined with the power of retaining completely and easily such finely divided precipitates as barium sulphate and calcium oxalate; a series of tests showed that the filtration was six times more rapid than with an asbestos filter containing one-third the quantity of asbestos. The precipitate can be dissolved off, and the felt used again and again; moreover, a damaged filter can readily be patched by the adding of chloroplatinic acid and igniting. The use of the "Monroe crucible" for atomic-weight determinations is especially advocated. Another issue of the same journal contains a paper by Mr. J. T. Stoddard on rapid electro-analysis with stationary electrodes (*ibid.*, pp. 385–390), in which it is claimed that by using a kathode of gauze or of mercury, a stationary anode, and a heavy current, complete decomposition of the metal can be effected as rapidly as with a rotating electrode; under these conditions the liberation of gas, and the convection currents consequent on the heating of the liquid, appear to provide sufficiently for the agitation of the fluid without recourse to mechanical methods.

THE *Philippine Journal of Science* for March contains a third paper by Raymond F. Bacon on the Philippine terpenes and essential oils, and a paper by Mr. H. D. Gibbs on the oxidation of phenol. The latter author has taken advantage of the tropical sunshine to study the red coloration which is developed by phenol when exposed to air and light, and has carried out the investigation with remarkable care and thoroughness. He shows that the phenol becomes coloured in presence of oxygen, but not of hydrogen, nitrogen, and carbon dioxide. The action is caused by oxidation, quinol, quinone, catechol, and carbon dioxide being produced; the principal coloured compounds are probably quinone condensation products, the red colour being attributed to phenoquinone. The oxidation is not appreciable in the dark at room-temperatures, but becomes measurable at 100°, and fairly rapid at the boiling point of phenol. In sunlight the rate of coloration is rapid, and increases with the temperature; it is affected by the ultraviolet absorption of the glass, by atmospheric conditions, and by the altitude of the sun. Ozone is very reactive; it gives the same products as oxygen, and in addition glyoxylic acid has been detected. Anisol, the methyl ether of phenol, gives no coloration either by the action of ozone or of oxygen and sunlight.

MESSRS. E. B. ATKINSON AND CO., of Hull, forward us an improved pattern of Soxhlet's apparatus for the extraction of oils and fats. The new form is fitted with a glass stop-cock on the syphon tube. By regulating the overflow, the thimble can be kept full of the solvent during the extraction, instead of being alternately filled and emptied. Also, by closing the stop-cock at the end of an operation, the solvent can be retained in the upper part of the apparatus; this allows the flask containing the extracted fat to be almost freed from the solvent, so that it can be placed straightway in the drying-oven. A bulb on the upper part of the side-tube facilitates the passage of the vaporised solvent if liquid should collect there. The new pattern thus appears to have distinct advantages over the older form.

THE use of the Walschaerts valve gear on American locomotives has been greatly extended since its introduction into the States a few years ago. The advantages of this gear render it very suitable for the large engines employed in America, and its success has led to experiments with others of a similar type. Several railways are now trying the Pilliod motion, a gear made by the Pilliod Company of Chicago, and described in the *Engineer* for September 3. In this gear, as in the Walschaerts, the motion is derived partly from a return crank on the main crank-pin and partly from the crosshead. The moving parts are the same for any class of engine, and weigh about 1000 lb. There is no load on the reversing lever, which can be unlatched and moved in any condition with the regulator either open or closed. The motion is expected to effect a considerable saving in fuel and in maintenance and repairs. The release is late; thus with cut-off at 25 per cent. the release is at 85 per cent.; the Walschaerts gear, with a similar cut-off, releases at about 65 per cent. of the stroke. Special adaptability for high speeds is claimed.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN OCTOBER:—

Oct. 6. 11h. 59m. to 12h. 34m. Moon occults κ Geminorum (mag. 3·7).
8. 10h. 37m. Minimum of Algol (β Persei).
11. 7h. 26m. ,, ,,
12. 23h. Venus in conjunction with δ Scorpii (star 0° 7′ S.).
13. 6h. Saturn in opposition to the Sun.
17. 17h. Venus in conjunction with the Moon (Venus 2° 17′ S.).
18–24. Epoch of October meteoric shower (Orionids, Radiant 92° + 15°).
20. Saturn. Major axis of outer ring = 46″·15, Minor axis = 9″·21.
27. 8h. Saturn in conjunction with the Moon (Saturn 1° 17′ N.).
,, 19h. Mercury at greatest elongation west.
31. 9h. 8m. Minimum of Algol (β Persei).

OBSERVATIONS OF HALLEY'S COMET, 1909*c*.—Photographs showing Halley's comet were obtained at the Greenwich Observatory, with the 30-inch reflector, on September 9, two days before it was discovered by Prof. Wolf. Owing to the proximity of the moon the two exposures were limited to thirty minutes and twenty-five minutes respectively, and the very faint cometary images were not identified until after the receipt of the telegram announcing the discovery at Heidelberg. The positions determined gave corrections of +24s. and −4′ to the ephemeris published in No. 4330 of the *Astronomische Nachrichten*.

In a supplement to No. 4356 of the *Astronomische Nachrichten*, where the above observations are recorded, Prof. Wolf states that the comet is already a fairly bright object, of about the sixteenth magnitude, appearing as a nebulous mass of 8″–10″ diameter having a central condensation.

Photographs were also secured by Mr. Knox Shaw at the Helwan Observatory on September 13 and 15, and by Dr. H. D. Curtis, with the Crossley reflector at the Lick Observatory, on September 12, 13, and 14.

ANOTHER LARGE SUN-SPOT.—During last week another large sun-spot was to be seen on the solar disc. It was first observed, at South Kensington, on September 18 near to the limb and a few degrees south of the sun's equator. Developments took place until on Saturday last, when just past the central meridian, it consisted of one large nucleus and several smaller ones, and was visible to the naked eye. It is perhaps worthy of note that a magnetic storm, of sufficient magnitude to interfere seriously with the transmission of telegrams, took place on Saturday.

OBSERVATIONS OF MARS.—In a telegram to the Kiel Centralstelle (Circular No. 112), Prof. Lowell announces that the Martian antarctic canals are disappearing, and that the general pallor of the various features continues. He also states that the Solis Lacus is double.

Regarding the naked-eye appearance of the planet, Mr. J. H. Elgie recently directed attention to the apparent nearness of Mars as compared with the neighbouring stars of Pegasus. He suggests that this sense of nearness might be due to the propinquity of a wooded ridge over which the planet was rising, the Pegasus stars being well above the ridge, and therefore beyond this influence. At the same time, the brilliant irradiation of the planet seems quite sufficient to account for a phenomenon which must appeal to anyone seeing the planet on a clear evening.

OBSERVATIONS OF SATURN.—A telegram from Prof. Lowell to the Kiel Centralstelle, published in Circular No. 113, announces that a dark medial streak has been observed on Saturn's equator, and that there is an appearance of lacings similar to those seen on Jupiter. Further, an intense white spot, in saturnian latitude 50° S., was detected by Mr. Slipher and transitted at 14h. 5m. (Washington time) on September 23.

THE FUTURE OF ASTRONOMY.—In an address delivered at the Case School of Applied Science, Cleveland (U.S.A.), in May, Prof. E. C. Pickering took as his subject the future development of astronomy, paying special attention to the methods whereby the limited financial resources and *personnel* may be used with the greatest advantage to the science. After a review of the several past epochs of astronomy, and some rather amusing remarks as to how monetary gifts are made and used at present, he outlined the general scheme, to which he has previously referred on various occasions, and the principle of which underlies the splendid organisation of resources built up at the Harvard College Observatory. The central feature of the scheme is one large, and perforce international, observatory employing, say, 200 or 300 assistants, and maintaining three stations. Of the latter, one would be in latitude about 30° N., and another the same distance south; western America is suggested as a suitable *locale* for the former, South Africa for the latter, and each would be selected wholly for its climatic conditions, which premises fairly great altitudes and desert regions. Each observing station would have instruments of the largest size, such as the 7-foot reflector previously suggested for South Africa, and would do practically no reductions or measuring. These would be carried out at the third station, situated where living and labour are cheap, where the photographs, &c., would be stored. Such an organisation would exist for the benefit of all serious astronomers; anyone wishing to engage on any piece of work would simply requisition the raw material, *e.g.* sets of special photographs, from the central bureau. If not in stock, the required photographs would be secured at the earliest convenient opportunity. By thus centralising and organising astronomical resources, Prof. Pickering claims that the science would benefit immensely, because the waste at present resulting from overlapping, or from being forced to use inadequate raw material, would thereby be eliminated (*Popular Science Monthly*, vol. lxxv., No. 2).

THE INSTITUTE OF METALS.

THE publication of the first volume of the Journal of the Institute of Metals marks the completion of a full year's work. The institute has been formed to advance and disseminate knowledge in connection with the manufacture and properties of the non-ferrous metals and alloys. The members are fortunate in having for first president Sir Wm. White, who delivered an excellent address, in the course of which he dealt in a very able manner as well with the delicate subject of "trade secrets" as with the important one of the relationships between manufacturers and users of metals, although his oft-reiterated special pleading for the National Physical Laboratory during the meetings must have been rather wearying to the other important workers represented.

The paper by Mr. J. T. Milton, chief engineer of Lloyd's, on some points of interest concerning copper and copper alloys, is mainly about troubles experienced by users, and is valuable for members of all types; but the statement on p. 68 that the temperature of pouring the white metal into bearings is left to the ordinary workman is not the case in at least one of the great Sheffield-Clyde firms, as for many years this has been done with the aid of a suitable pyrometer, and probably is so still. The paper drew a very long and good discussion, in which Prof. Gowland's remarks that ancient bronzes were very impure, so that their hardness could not be due to exceptional purity, and that by careful hammering modern bronzes can be made as hard as ancient, were of interest to those who are often being met by the statement that the method of hardening bronze tools is a lost art.

The mechanism of annealing in the case of certain copper alloys, by Messrs. G. D. Bengough and O. F. Hudson, is of a very theoretical nature as a whole, but gives several practical hints on the treatment of brass. Mr. J. T. W. Echevarri's paper, on aluminium and some of its uses, is most interesting, although his reasons for its efficacy in preventing blow-holes in steel (p. 130)—that it combines with the gases and produces an innocuous slag—would hardly be accepted. In the discussion the president remarked that not only had aluminium proved unsatisfactory for shipbuilding because of serious corrosion (p. 156), but that, though suitable aluminium alloys might yet be obtained, they had to be discovered. Notes on phosphor-bronze, by Mr. A. Philip, is thoroughly practical, and contains several tables of tests with corresponding analyses, with a full discussion as to the most suitable compositions and tests for different purposes.

In metallographic investigations of alloys Mr. W. Rosenhain gives a good critical summary of methods, but, unfortunately, attempts to bolster up the discredited differential method of taking cooling curves. On p. 213 he recommends that "the slowest possible rate of cooling should be adopted in cooling-curve experiments"; but long experience teaches that the rate of cooling must be chosen according to the nature of the alloy and the objects of the investigation. In Dr. Desch's paper, on inter-metallic compounds, surely the complicated "broken solidus curve MBNPQRESTUG" for an institute of metals might have been better chosen from a real example than an imaginary one, so that such members as waded through it all would have a reward of facts as well as principles. Dr. Shepherd in the discussion endeavoured to explain to the members what the present writer has tried to impress on several investigators, namely, that though a pyrometer be capable of great accuracy, it does not follow that the phenomena are observed to the same degree of accuracy, and also that though the phase rule is a guide, it must be remembered that it was deduced for ideal conditions, and takes no account of the time factor or of the rate of diffusion or viscosity. Dr. Shepherd favours the use of heating curves, but his remark that "in the case of transformations in the solid phase he had found no satisfactory results with cooling curves" must sound strange to investigators on steel—the pioneers in this type of work—the well-known Ar_1, Ar_2, Ar_3 being all points on cooling curves. For demonstration purposes cooling curves are generally taken because more convenient, but for a complete investigation both heating and cooling curves must be studied. Had this not been done, the important effect on suitable hardening temperatures for steel of the difference between Ar1 and Ac1 would still be left not fully explained. The remarkable irreversibility in certain nickel-iron alloys of the A2 point, the only one reversible in ordinary mild steel, demands the consideration of both curves.

Mr. W. H. A. Robertson's paper, on plant used in the manufacture of tubes, is of a practical and descriptive nature.

The last paper of all, the relation between science and practice and its bearing on the utility of the Institute of Metals, by Sir Gerard A. Muntz, Bart., treats of a subject probably the most important of the series for a first volume. It is a short paper written by invitation of the president, but it gives formal expression to a general feeling, much in evidence in personal conversation with all grades of workers connected with the metal trades, that information is needed in a form not too academic, expressed in language that the intelligent who are not mere theoretical specialists can understand. When the practical man, who must produce results, compares the air of omniscience assumed by some purely theoretical metallurgists with the smallness of the help they seem able to give him in his work, he is apt to be discouraged and to have thoughts about metallurgical science that he ought not to be led to think. The science underlying metallurgy is not yet sufficiently understood to do entirely without the extremely useful empirical conclusions of intelligent practical men, and hence elaborate generalisations, often on inadequate bases (the "raw science" of Mr. Rosenhain), can generally only be suggestive of methods of attack on matters of difficulty in works, and one must take all available help from practice to command success. Long personal experience in connection with delightful and somewhat successful investigations of this nature, made in conjunction with those actually engaged in works, serves only continually to strengthen this view. The Institute of Metals, to be worthy of its name, must welcome any paper on purely scientific original work connected with non-ferrous metals if convinced that the results are trustworthy, however remote their practical utility may seem; but it must also consider the immediate needs of the great majority of its members by encouraging papers of a practical scientific nature, expressed in language that may be understood by the most intelligent members who are actually engaged in works practice.

A. McWILLIAM.

THE BRITISH ASSOCIATION AT WINNIPEG.

SECTION K.

BOTANY.

OPENING ADDRESS BY LIEUT.-COLONEL DAVID PRAIN, C.I.E., LL.D., F.R.S., PRESIDENT OF THE SECTION.

Sutor ne supra crepidam judicaret, probably an old saying when Pliny wrote, is still a safe guide. The limitations of life and of knowledge are different, and human effort is thereby so conditioned that progress depends on specialisation in study. Specialisation lessens the temptation to forget this caution; but the force of the proverb is not weakened. It also conveys a behest, and compliance with this behest helps to counteract the narrowed outlook which specialisation sometimes encourages.

Those whose studies are confined to some limited field often welcome a sketch of the aims and methods of work with which they are not familiar. Such a sketch may be held to have served its purpose if the subject discussed, and its relationship to cognate studies, be rendered intelligible.

No apology, therefore, is made for the subject now taken up, even if it be sometimes hinted that this subject —Systematic Botany—is inimical to originality, the antithesis of scientific, and outside the limits of botany proper. These views depend on half-truths and arbitrary connotations. They do not affect the fact that the primary purpose of systematic study is to advance natural knowledge. The systematic worker, in furthering this object, does not halt to consider whether his work be applied rather than original, technical rather than scientific.

As a matter of history, the scope of systematic study practically coincides with what botany once implied; as a matter of fact, it corresponds to what zoology implies now. The accident that man, on his physical side, is like the beasts that perish has led to the recognition of animal physiology and anatomy as independent sciences. Owing to the absence of any such fortuitous circumstance vegetable anatomy and physiology remain under the ancestral roof. These off-shoots of botany are as vigorous as their zoological counterparts. They may be entitled to think that systematic methods are old-fashioned, and it may be desirable that they should set up separate establishments or form alliances with the corresponding off-shoots of zoology. But nothing in all this justifies the eviction of systematic botany from the family home.

The statement that systematic methods are old-fashioned may be accepted without conceding that these methods are out of date. Systematic work, while sharing in the general advance in knowledge, has been able, amid far-reaching changes, to maintain continuity of method in the pursuit of its double purpose. This has been a benefit to botany as a whole when crucial discoveries or illuminating theories have, in other fields, led to a re-orientation of view requiring the use of fresh tablets for the record of new results.

Disintegration and re-adjustment due to altered outlook are familiar processes. Histology, parting company with organography to serve physiology, is now an independent study, one of the branches of which occasionally declines to accept any doctrine unconfirmed by cytological methods. The study of problems relating to nutrition and reproduction has been considered the especial task of physiology. Now, the chemist at times claims the problems of nutrition as part of his field, and we look for advances in our knowledge of reproductive problems to the cytologist and the student of genetics. These instances are adduced from without because relative exemption from distintegration is a distinctive feature of systematic study. The two-sided task of the systematist is to provide a census of the known forms of plant life and to explain the relationships of these forms to each other. The work on one side is mainly descriptive, on the other mainly taxonomic, but the two are so interdependent, and their operations so intimately blended, that it is difficult to treat them apart. Re-orientation in botanical study has led to seismic disturbances in the taxonomic field, but the materials supplied by descriptive work have remained unaffected, and therefore have been ready for use in the repair or reconstruction of shattered "systems."

The exemption from radical change in method, which marks systematic work, is due to those characteristics that expose it to the charges of discouraging originality and of calling only for technical skill. It also largely explains why systematic study, especially on the descriptive side, is not attractive to minds disposed towards experimental inquiry. The labour involved is as exacting, accurate record and balanced judgment are as necessary, in descriptive as in experimental research. "A skill that is not to be acquired by random study at spare moments" is as essential in descriptive as in other work, while the relief that variation in method affords is precluded. Increased experience, here as elsewhere, leads to more satisfactory results, but without, in this case, mitigating the toil of securing them. The testing of theories, often an inspiring task in experimental research, in the descriptive field retards progress. But if in descriptive work imagination and the spirit of adventure are undesirable, these qualities are not inhibited by systematic study as a whole. Imagination is legitimate and useful in the taxonomic field, and in another line of activity—the acquisition of the material on which descriptive work is based—the spirit of adventure is essential to success.

The untravelled descriptive worker is not without consolations. His work is as necessary to botany as that of the cartographer to geography, or the grammarian to literature. His results are means to the ends that others have in view. If these results often appeal to coming rather than to contemporary workers, the descriptive writer is at least largely spared the doubtful benefit of immediate appreciation. He can pursue his studies unaffected by any considerations save those of adding to the sum of human knowledge and of bringing a necessary task appreciably nearer completion. In descriptive study it is the work rather than the personality of the worker that tells. Yet the work is not without human interest, because systematic writings rarely fail to reflect the character of the writers. The intimate knowledge of descriptive treatises, which floristic or monographic study entails, usually leads to mental estimates of the actual authors. The evidence on which these estimates depend is unwittingly given and unconsciously appreciated. But its value is not thereby diminished, and estimates so formed may prove useful checks on contemporary judgments.

The descriptive worker as a rule makes his work "the primary business of his life, which he studies and practises as if nothing else in the world mattered." But he does not hold aloof from those engaged in other lines of botanical activity. His evidence is mainly obtained from organography and organogeny; but, just because his results are for the use of others, the descriptive botanist has to keep abreast of all that is done in every branch of his science. New weapons are constantly being forged, and not in morphological workshops only; with these and their uses the descriptive worker must be familiar, for the need to employ them may arise at any moment. If he does not always abandon old friends for new, this is not because the systematist is unaware of their existence, or unprepared to apply new methods. The descriptive worker employs his tools as a craftsman; like other craftsmen, he finds that tools do not always fulfil the hopes of their designers. In descriptive work, too, as elsewhere, a steam hammer is not required to break every nut; the staff and sling may be arms as effective as those of the hoplite. There are occasions when the descriptive writer does appear to hold aloof by declining to accept proffered evidence. But his motive is not arrogant; it is only altruistic. If he is to avoid the risk of causing those who depend on his results to reason in a circle, the descriptive writer must obtain these results, if not without extraneous aid, at least without help from those for whose immediate use they are provided.

Taxonomic study is pursued in an environment which differs from that surrounding descriptive work. The descriptive student can hardly see the wood for its trees. The taxonomic student works in more open country, and can look on the wood as a whole. He has, too, the benefit of companionship. The palæobotanist meets him, with all the lore of mine and quarry, as one ready to exchange counsel; other workers attend to give or gather information.

The community of interest which unites the systematic worker, chiefly concerned with existing plant-types, and the palæobotanist, primarily interested in types now extinct, is strengthened by the bond which identity of purpose supplies. But the two are differently circumstanced; the systematic worker is ordinarily better acquainted with the characters than with the relationships of his types; the palæobotanist usually knows more of the relationships of his types than he does, or ever may do, of their characters. The material of the palæobotanist rarely lets him rely on ordinary descriptive methods in defining his plants; he has to depend largely on anatomical evidence, which supplements and confirms, but hardly replaces, the data of organography. On the taxonomic side the palæobotanist is restricted to phylogenetic methods; here again he is handicapped, though less than on the descriptive side, by the fragmentary character of his specimens. The palæobotanist hardly does more than the phylogenist, hardly as much as the anatomist, towards advancing the object all have in common.

The same community of interest unites in their labours the organographic systematist and the morphologist whose interests are phylogenetic. Here, however, though the task of the two be complementary, the mode of attack is so different as almost to mask their identity of purpose. The comparative morphologist studies the planes of cleavage indicated by salient differences in structure and development. The system he evolves is composed of the entities, sometimes more or less subjective, that combinations of characters suggest. The method in intention, and largely in effect, passes from the general to the more particular, though the process is tempered by the fact that the characters used are derived from such types as exhibit them. The organographic systematist, after summing up the characters which mark individual types, aggregates these according to their kinds. Having estimated the features that characterise individual kinds, he aggregates these according to their families. Families are thereafter aggregated in higher groups, and these groups are subjected to further aggregation. The system thus evolved is composed of those entities, always in theory objective, that successive aggregations indicate, and the process is one of constantly widening generalisation.

The comparative morphologist, though glad when his results can be practically applied, follows truth for its own sake. His work is thus on a higher plane than that of the organographic systematist, whose aggregations are primarily utilitarian. But the work of the latter is not less valuable because its scientific character is incidental. Were our knowledge of plant-types exhaustive, a generally accepted artificial arrangement of these would be as useful to the applied botanist as a professedly natural one. But our knowledge is incomplete, and the accession and intercalation of new types renders any artificial, and most attempts at a natural, system sooner or later unworkable. The more closely an arrangement approximates to the natural system, the less can the intercalation of new forms affect its stability. The more stable a system is, the more easily will its details be remembered and the more useful will it prove in practical reference work. Here, therefore, for once, self-interest and love of truth go hand in hand.

Since the organographic systematist learns their characters from his groups, while the comparative morphologist defines groups by the characters he selects, their results, were knowledge complete, should be identical, and this identity should prove their accuracy. But knowledge is finite, and these results are not always uniform. The want of uniformity is, however, often exaggerated because the reasons are not always appreciated.

One cause is the difference in personal equation, which affects alike the worker who deals with things and him who considers attributes. It would be contrary to expectation were every phylogenist to assign the same value to each character, or every systematist to apply the same limitation to each type or group of types. The divergence of view on the part of two observers may show a small initial angle; it may nevertheless lead them to positions far apart. But while divergence of view is the most obvious explanation of the want of uniformity apparent in systematic results, it is the least effective cause. This inherent tendency to differ manifests itself in contrary directions; in the long run individual variations are apt to cancel each other.

The nature of the work counts for more than the predisposition of the worker. The aggregations on organographic lines, which were the main guides to the composition of the higher groups until phylogenetic study was seriously undertaken, do not assist the comparative morphologist. The characters on which phylogenetic conclusions may be based increase in value in proportion to the width of their incidence, so that the greater their value for phylogenetic purposes the less do they aid the descriptive worker in discriminating between one plant-type and another. Often they are characters which for practical reasons the descriptive worker must avoid. Organography, then, may not give evidence as to characters whereof cognisance cannot be taken, while for another reason the comparative morphologist may not use characters derived from descriptive sources. The object of the phylogenist is to take his share in advancing our knowledge of taxonomy; to seek from the systematist the evidence on which his results are based would be to vitiate the reasoning of both. All that the phylogenist can ask the descriptive worker to do is to supply the units that require classification.

The comparative morphologist, relying mainly on anatomical and embryological evidence, at first had a hope that his method of study might enable him to supply his own units and thereby render further taxonomic work based on organography unnecessary. This hope remains unfulfilled, and the phylogenist, as a rule, limits his efforts to a narrower field. The organographic systematist realises that in the present state of our knowledge the study of the incidence of selected characters gives more satisfactory results as regards the composition of the higher phyla than repeated aggregation can attain, while the comparative morphologist recognises that, as matters stand, the approximations of organography in respect of types and kinds are more satisfactory than any he can yet offer. Since, however, the progress in one case is outwards, in the other the reverse, a zone of contact is inevitable. This zone, in which the influence of both methods of study is felt, is occupied by those groups immediately higher in value than the natural families of plants, and it is here that discrepancies in the results attained chiefly manifest themselves. These discrepancies take the form of unavoidable differences of opinion as regards the composition of collections of natural families. If a family A possesses ten characters of ordinal import, whereof it shares eight with a family B and only two with a family C, while the characters combined in A are, as regards B and C, mutually exclusive, the organographic systematist is ordinarily induced to group A and B together and to exclude C from that particular aggregation of families. If, on the other hand, the phylogenist finds that the two characters common to the families A and C are met with in other families, D, E, F, he will ordinarily be led to place A, C, D, E, F in the same higher group from which the family B, notwithstanding its greater general agreement with A than any of the others, must be excluded. This source of discrepancy is, however, less potent than might be expected. When the evidence advanced by either is very strong, the other worker readily accepts it; in doubtful cases mutual accommodation takes place, the one worker limiting his groups, the other applying his criteria with less rigidity.

The healthy disregard for formal consistency which admits of adjustments to further practical ends does not, however, alter the fact that a system thus attained can only approximate to the natural arrangement at which both workers aim. Gaps in knowledge may be bridged with histological or teratological aid, or safely crossed with the help of some sudden intuition or happy speculation. But the existence of anomalous types and groups serves as a reminder that much has yet to be learned with regard to living types, while the widest gap in our knowledge of these is a fissure as compared with the chasms that confront the palaeontologist. In this the taxonomist of either type finds the incentive to further effort.

The automatic adjustment of differences due to idiosyncrasy, and the mutual accommodation of those arising from method of work, still leave considerable want of harmony in taxonomic results to be accounted for. What appear to be rival systems of classification compete for recognition. As each such system professes to be the nearest attainable approximation to the natural arrangement, the evidence of a state of dissension and confusion in the taxonomic field appears to those unfamiliar with systematic work to be incontrovertible. Dissension may be admitted; confusion there is none. Pictures of the same subject by different artists may be very unlike, yet equally true; what appear to be rival systems are only manifestations of one.

It is not difficult to form a conception of this system; it is less easy to share the conception with others. Let us imagine a closed space approximately spherical in shape, its surface studded with symbols that mark the relative positions of existing plant-types. Let us imagine the lines of descent of all these types to have been definitely traced and effectively mapped. We find, starting from near the centre of our sphere, a radiating system of lines; we find these lines to be subject to repeated dichotomy and embranchment which may take place at any point; we find the resultant lines departing from the original direction at any angle and in any plane; we find the *nodus* of any individual dichotomy or embranchment capable of serving as the focus of origin for a subsidiary system comparable in everything except age with the centre of our sphere, and conceivably exceeding in the multiplicity of its ramifications the primary system itself. Some only of our lines reach the symbols that stud our spherical surface, though every symbol is the terminal of some such line. Here a terminal is fairly isolated, and the line it limits goes far towards the centre with little or no dichotomy or embranchment. Elsewhere our terminals are closely set, the lines they limit running inwards in company until some proximate *nodus* is reached. Moreover, within our sphere, in the abrupt terminals of various lines we can dimly trace the vestiges of other spheres, not always concentric with our present sphere, once studded with symbols marking the existence of types now extinct. Imagine further the centre of our hypothetical space as not necessarily a primary centre, but merely the *nodus* of some dichotomy or embranchment in a system of which ours is but a residuary fragment.

As we are practically limited to superficial delineation, an intelligible picture of our system is more than the science of perspective and the art of chiaroscuro can be asked to provide. What is unattainable on the flat is still more impossible in sequence. Serial presentation involves a point of departure; convenience, predilection, hazard, may dictate what this shall be, and determine the sequence adopted. The result is not a variety of systems, but a series of variants of one system. Considering how complex the problem is, the number of variants is remarkably small. In any case the differences met with are inconsequent; they do not affect the facts, and the facts alone really count. The trained taxonomist knows that no serial disposition can indicate, even vaguely, the relative position and import of all these facts. Plane presentation, though more adequate than serial by a dimension, falls short of accuracy; the surface on which the bulk of the facts may be displayed can have no lateral boundary. Even if its presentation on a globe be attempted, the diagram must be incomplete; many of the points to be shown lie beneath the surface. Convention might overcome the difficulty involved in the indication of extinct types, but the diagram would still fail by a dimension to demonstrate the descent of the forms superficially represented.

Intercourse with the phylogenist, while directly influencing the relationship of the organographic systematist to taxonomy, has indirectly modified his attitude towards the diagnosis and limitation of plant-types. Taxonomic study based on evidence other than descriptive has stimulated histological research and fired the anatomist with an ambition to replace by his methods those of organography. It is certainly not for want of industry or care that the success of the phylogenist in the taxonomic field has not also attended the diagnostic work of the anatomist. This failure to replace organographic by anatomical methods is due to the fact that the qualities which make histological evidence useful in generalisation lessen its value in discrimination. That anatomical characters may be of great use even in diagnosis has been less fully appreciated than it might by those habituated to organographic methods. On the other hand, anatomists who have not benefited by an apprenticeship in descriptive study at times overlook the fact that the value of histological evidence in diagnostic work is indirect. Codification of the scattered results of systematic anatomy has now shown the descriptive worker how useful histological methods are when skilfully and properly used, and has at the same time made it apparent to the anatomist that, in respect of grades lower than ordinal, his methods are more fitted for proof than for demonstration. Their alliance is now cordial and complete.

While descriptive and anatomical study conjointly make for accurate discrimination, opinion and circumstance combine to prevent uniform delimitation of plant-forms or "species," and no conceivable compromise can overcome this difficulty. With the term "species" is bound up a double controversy—what idea the word conveys, and what entity the word connotes. Into the first we need not enter: we must assume that our ideas are sufficiently uniform to render the term intelligible. The second we cannot take up here; we must accept the position as we find it, and note, in a spirit of detachment, how in actual practice the systematic botanist does delimit his "species." In doing this we have to discriminate between the effect which observed facts produce on different minds, and that which different mental states produce on the records of facts. The results obtained may be essentially identical though arrived at in different ways; as, however, the results are not always uniform, the existence and effect of these two factors must be carefully noted.

It is rather unusual to find that workers whose powers of observation are equal take precisely the same view of every member of a group of nearly allied forms. One, from predisposition or accident, is influenced rather by the characters whereby the forms differ; another is more impressed by those wherein they agree. In monographic work especially the same worker may find himself alternately more alive to the affinities and more struck by the discrepancies among related forms. At one time he feels that his difficulties may be best solved by recognising all these forms as distinct, at another he inclines to the view that they may be but states of one protean species. Where the capacity for detecting differences is naturally strong, the disposition is towards segregation; where there is a keen eye for affinities, the reverse. The facts in both cases are the same; their influence on minds in which the faculty of observation, though equally developed, has a natural bias in a particular direction may thus be different.

This inherent variation in mental quality, of which the observer may personally be unaware, and over which he may have incomplete control, is not, however, so potent a factor as a difference in mental attitude, usually the result of training or tradition. The existence of two distinct attitudes on the part of authors towards their "species" is common knowledge. In the absence of more suitable terms we may speak of them as the "parental" and the "judicial." To the parental worker his species are children, whose appeals, even when *ad misericordiam*, are sympathetically received. To the judicial worker his species are claimants, whose pretentions must be dispassionately weighed. The former treats the recognition of a species as a privilege, the exercise of which reflects honour. The latter views this task as a duty, the performance of which involves responsibility. With amply characterised forms the mental attitude is inconsequent, but when critical forms are reviewed it is all-important. Here the benefit of a doubt is the practical basis of final decision. This benefit in the case of the parentally disposed worker may lead to the recognition of a slenderly endowed species; in the case of the judicially inclined, to the incorporation of an admittedly critical form in some already described species, the conception of which may thereby be unduly modified.

These attitudes do not in practice divide descriptive workers into two definite classes. Some writers display one attitude at one period, the other at another period of their career. Occasionally the two alternate more than once in a writer's history. Cases are known in which one attitude is consistently adopted towards species of one natural family, the other towards species of a different family.

When want of uniformity in delimitation is due to the varying effect of the same facts on different observers there is no room for either praise or blame. Capacity for appreciating affinities is complementary to that for discrimination. The fact that now one, now the other tendency is more highly developed makes for general progress. Workers in whom the two may be more evenly balanced can strike a mean between the discordant results of colleagues more highly endowed than they are in either direction. But those who possess a capacity for compromise do not mistake this for righteousness; they are apt to wish themselves more gifted with the opposing qualities of those whose work they assess.

When cases in which want of uniformity in delimitation due to difference in mental attitude on the part of independent workers are considered, we again find that praise and blame are inappropriate. If both attitudes have defects to be guarded against, both have merits that deserve cultivation. The defects are patent and rarely overlooked; the careful systematist, more critical of his results than anyone else can be, is alive to the risks which attend stereotyped treatment, and on his guard against the excesses to which this may lead. It is more often forgotten that both attitudes have their uses, and that each should be exhibited at appropriate times. Here, however, no middle way is possible; the mean between the two attitudes has the qualities of a base alloy. It is the attitude of indifference, fatal to scientific progress, and productive of results that are useless in technical research.

The ideal arrangement in monographic study is the collaboration of two workers, one highly endowed with the discriminating, the other with the aggregating faculty. But for the statement of their joint results both must adopt the judicial attitude. On the other hand, in floristic work, in isolated systematic contributions, and in all descriptive work undertaken on behalf of economic research, the better because the more useful results are supplied by workers in whom capacity and attitude combine to induce the recognition rather than the reduction of easily characterised forms.

In the present state of our knowledge uniformity in the delimitation of what are termed "species" is unattainable. We are in no danger of forgetting this fact; what we do sometimes overlook is that, circumstanced as we are, such uniformity is undesirable. The wish to be consistent is laudable; when it becomes a craving it blunts the sense of proportion and may lead to verbal agreement being mistaken for actual uniformity. The thoughtful systematist, when he considers this question without prepossession, finds that forms which in one collocation need only be accorded a subordinate position must, under other conditions, receive separate recognition.

The normal effect on specific limitation of the causes that militate against uniformity is easily understood, and the resulting discrepancies can be allowed for in statistical statements. There are, however, cases where the capacity for appreciating differential characters or points of agreement is so highly developed as to obscure or even inhibit the complementary capacity. The effects are then ultranormal; nicety of discrimination exceeds the "fine cutting" allowable in floristic work; aggregation exceeds the limits useful in monography. No common measure is applicable to the results, and the ordinary systematist, who has definite and practical objects in view, expresses his impatient disapproval in unmistakable terms. The work of those addicted to one habit he characterises as "hair-splitting"; that of those who adopt the other he speaks of as "lumping." The industry displayed in elaborating monographs which attribute a thousand species to genera wherein the normal systematist can hardly find a score must often be effort misplaced. The same remark applies to the excessive aggregation that substitutes for a series of quite intelligible forms an intricate hierarchy of subspecies, varieties, subvarieties, and races. Orgies of reduction are moreover open to an objection from which debauches of differentiation are free. Discrimination can only be effected as the result of study; the finer the discrimination, the closer this study must be. Reduction offers fatal facilities for slovenly work, over which it throws the cloak of an erudition that may be specious. When dealing with excessive differentiation the normal systematist is on solid ground; when following extreme reduction he may become entangled in a morass. Yet workers of both classes only exhibit the defects, for ordinary purposes, of striking merits, and there are occasions when the results that each obtains may be of value to science.

Its mnemonic quality renders taxonomic work practically useful. Its application in economic research does the same for specific determination. Economic workers are chiefly interested in useful or harmful species; to others they would be indifferent were these not liable to be mistaken for such as are of direct interest. The identification of economic species and their discrimination from neutral allies is not always simple, because species that are useful or noxious are often those least perfectly known. The qualities that render them important frequently first attract attention; these may be associated with particular organs or tissues, and samples of these parts alone may be available. Ordinarily, when material is incomplete, critical examination has to be postponed. In economic work, however, this may not be possible, and the systematist, just as in dealing with archæological or fossil remains, may here have to make the most of samples and fragments in lieu of specimens. Cultural help and anatomical evidence sometimes lead to approximate conclusions; often, however, as with neutral species, definite determination must await the communication by the field botanist of adequate material. Even then a difficulty, comparable with that frequently met with in archæological and palæobotanical study, may be encountered. As archæological or fossil material may, owing to the conditions to which it has been subjected, look unlike corresponding fresh material of the same or similar plants, so may trade samples, owing to special treatment, bear little outward resemblance to the same organs and tissues when fresh.

When material of economic plants is ample another difficulty may be encountered. Domesticated species often undergo perplexing variation. In studying this variation the systematist may have to seek linguistic and archæological help, and be led into ethnological and historical by-paths. In classifying the forms that such domesticated plants assume he gladly avails himself of aid from those whose capacity for detecting affinities is unusually developed. But even with extraneous assistance the systematist, in this field, sometimes fails to attain final results. He can, however, always pave the way for the student of genetics, whose work involves the study of the "species" as such. As regards forms of economic importance which neither organography nor anatomy can characterise, but which the chemist or biologist can discriminate, physiological methods are required to explain the genesis or elision of qualities evoked or expunged under particular conditions.

A highly developed capacity for aggregation, if properly controlled, is also useful in the study of plant distribution from a physiographical standpoint. The systematist shows his sympathy with phytogeographical needs in two very practical ways. He declines, out of consideration for the geographical botanist, to deal with inadequate material, and for the same reason he refuses, in monographic studies, to be influenced by geographical evidence. The monographer is conscious that if he pronounces two nearly related forms distinct, merely because they inhabit two different areas, he is digging a pit into which the phytogeographer may fall when the latter has to decide for or against a relationship between the floras of these two tracts. But the fact that, with existing knowledge, uniform delimitation of species is impossible, seriously weakens the value of normal systematic results for phytogeographical purposes. The units termed "species" that are most useful in floristic and economic study are often too finely cut to serve distributional ends. When all existing plant-types have been treated on monographic lines the results may with relative safety be used by the phytogeographer, since errors due to personal equation may be regarded as self-eliminating. As matters now stand, however, the geographical botanist obtains his evidence partly from monographs, partly from floras, and is apt to be misled. Yet even in floristic work the systematist sees that the "species" which it is his duty to recognise often arrange themselves in groups of nearly allied forms. These groups, which need not be entitled to sectional rank, while very variable as regards the number of species they contain, are more uniform than species in respect of their mutual relationships. They are therefore more useful than species as units for phytogeographical purposes. In defining these groups the faculty for aggregation is essential, and those in whom this faculty is highly developed may here be profitably employed, even when their discriminating powers show a certain amount of atrophy.

The cases, by no means rare, of workers who, with a comparatively poor eye for species, display great talent in their treatment of genera, afford indirect but striking proof that the faculty for aggregation may be more highly developed than its complement, and that the dominance of this faculty may ensure useful results. But the *a priori* expectation that in dealing with families this dominance should be still more valuable is not borne out by experience, for in this case it is recognised that aggregation has probably been pushed too far. This error has not been attributable to the faculty for aggregation so much as to the evidence at its disposal; the corrective has largely been supplied by the use of anatomical methods as supplementary to organographic data.

The physiologist in studying processes is not always obliged to take account of the identity of the plants which are their theatres of action. He has at hand many readily accessible and stereotyped subjects the identity of which is a matter of common knowledge, and as his experience increases he learns that he may sometimes neglect the identity even of these. If he asks the systematist to determine some type on which his attention is especially focussed, the physiologist only does this in order that he may be in a position to repeat all the conditions of an experiment required to verify or modify a conclusion. A passive attitude towards systematic study has thus been created in the mind of the physiologist; this passivity has been intensified by the fact that the direct help which the physiologist can render to systematic study is limited. Physiological criteria are indeed directly applied for diagnostic purposes in one narrow field, where organography and anatomy are synonymous and inadequate. But if it be true that the diagnostic characters on which the bacteriologist relies belong to some non-corpuscular concomitant of his organism, this attempt to apply physiological characters to systematic ends has failed. In many cases physiological characters do influence taxonomic study. Differences in the alternation of generations, specialised habits connected with nutrition, peculiarities as regards response to stimulation, variation in the matter of protective endowments, admit of application in systematic work, and are constantly so applied in the characterisation of every taxonomic grade. But the evidence as to these characters reaches the systematist through secondary channels, so that the help which physiology renders is indirect, and the passivity of the physiologist remains unaffected.

This passivity has at last been shaken by the development of the study of plant distribution from a physiological standpoint. The practical value of this study has been affected by the employment of a terminology needlessly cumbrous for a subject that lends itself readily to simple statement, and by the neglect to explain the status, or verify the identity, of the units included in its plant associations. A reaction against the use of cryptic terms has now set in, and the physiological passivity which has led workers in this field to ignore systematic canons when identifying the units discussed shows signs of disappearing. The œcologist, it is true, must classify his units in accordance with characters that differ essentially from those on which reliance can be placed by the systematist. But the characters made use of must be possessed by his units, and the œcologist now realises that, in effecting his purpose, he is as immediately dependent on descriptive results as the economic worker or the geographical botanist, and that, if his work is to endure, his determinations must be as precise as those of the monographer, his limitations as uniform as those of the phytogeographer. The needs of the œcologist are, however, peculiar, and his units must be standardised accordingly. Œcological units are not the groups of species, uniform as to relationship, which the geographical botanist requires; nor are they the pragmatical "species" of floristic and economic work. They are the states, now fewer, now more numerous, that these floristic "species" assume in response to various influences; and œcological associations can only be appreciated and explained when all such states have been accurately defined and uniformly delimited. In accomplishing this task the faculty for detecting differences is the first essential, and the physiologist has here provided a field of study wherein workers, whose tendency to nicety of discrimination unfits them for normal systematic study, may find ample scope for their peculiar talent, and accomplish work of real and lasting value.

We find, then, that the taxonomy of the wider and more general groups is now mainly based on phylogenetic study, and is largely scientific in character and application. The taxonomy of the narrower and more particular groups, based on organographic data supplemented by anatomical evidence, is often somewhat empirical in character, and is largely applied for technical purposes. Among the grades chiefly so applied, the "species" is a matter of convenience, variously limited in response to special requirements, while the "family" is a matter of judgment, crystallising slowly into definite form as evidence accumulates. But the "genus" is relatively stable, and, in consequence of its stability, has long been "a thing of dignity." The distinctive air thus imparted to botany is best appreciated when a zoological index is examined.

The use of scientific names, more precise than popular terms and more convenient than descriptive phrases, facilitates the work of reference in applied study. These names are accidents which do not affect the taxonomic status of the units to which they are applied, but do, however, reflect the want of uniformity in the limitation of these units. The non-systematist who has to apply systematic results appreciates that, as knowledge now stands, this is unavoidable, and makes allowance for the state of affairs. But applied workers complain that, in addition to this, descriptive writers show a tendency to care more for names than for the forms they connote, and wantonly alter the designations of familiar forms. The complaint is just, yet the action is not wanton. The tendency in its present form is of recent origin, and, paradoxical as the statement may seem, is the outcome of a wish for uniformity and stability in nomenclature. Of these two qualities the latter is of more importance in applied work, and therefore the more essential. Unfortunately the systematist has given a preponderating attention to the former, and, in his effort to attain a somewhat purposeless consistency, has allowed his science to wait upon the arts of bibliography. He has placed his neck under a galling and fantastic yoke, for nomenclature, though a good and faithful servant, is an exacting and singularly inept master.

To err is human, and the standard of diagnostic work, high as it is, falls short of the standard which the systematic worker desires to attain. It is this fact that explains the remarkable openness of mind, and the great readiness to accept correction, to which systematic study conduces. To this also is attributable the singular freedom of systematic research from the practice of making capital of the fancied shortcomings of fellow-workers. Exhibitions of this commercial spirit are not altogether unknown, and in one narrow field, where systematic results are practically applied, they are sufficiently common to appear characteristic. But they are contrary to the traditional spirit of systematic study, which is uncongenial to the arts of *réclame*.

The subject is by no means exhausted. Time, however, forbids more; but the purpose of this sketch will have been fulfilled if it has helped those whose work lies elsewhere to appreciate more clearly what systematic study tries to accomplish, and to realise the place it fills in the household of our common mistress, the *Scientia amabilis*.

SUB-SECTION OF K.

AGRICULTURE.

OPENING ADDRESS BY MAJOR P. G. CRAIGIE, C.B., F.S.S., CHAIRMAN OF THE SUB-SECTION.

THE occupant of this chair, in the great annual convention of the promoters and appliers of science, cannot fail at the outset of a new session to put on record his emphatic endorsement of the claim, so strongly and so reasonably pressed by his distinguished predecessor at Dublin, that distinctively agricultural problems, instead of being regarded as a subsidiary sub-section of any single division of the Association, should be accorded the full dignity and convenience of a "Section." Specialised research is today one of the governing features of scientific inquiry. It is but fitting, therefore, that those who are trying to equip the agriculturist with all the knowledge which recent speculation and experiment have to offer for the fuller and more economic development of the soil should at least be allotted equal space and sectional rank with the engineer, whose problems are discussed in Section G, or with the schoolmaster, whose educational methods are debated in Section L.

If there were any country in the world where an apology could legitimately be offered for relegating agricultural science to a secondary position, it is certainly not that in which we meet to-day. In this wide Dominion of Canada, in this progressive province of Manitoba, in this great city of Winnipeg, where the agricultural industry must dominate the interests of the people, hardly any subject in the whole range of study can claim a more paramount degree of attention than the utilisation of the land for the use of man.

This is by no means a matter which can be disposed of as an occasional side-issue in the deliberations of any single Section. If we agriculturists have been tardy in coming to be taught by the men of science, we are in earnest now in the application for instruction that we make. Neither is it to any one science we appeal. Even the stern mathematician or physicist of Section A can teach us something, arithmetical and meteorological, for the right conduct of our business and the wiser forecasting of our plans. The chemists of Section B have, in an infinite variety of tasks, to come to the aid of the farmer, and they have doubtless much to tell of the magic they can promise in the direction of fertilising methods. Section C must be raided for the experts who know the contents of the soil itself and its capacities. Section D may have much to pass on to us concerning the live stock and the insect enemies of our farms. Section E may enlighten us on the world-wide distribution of crops and the new regions awaiting the skill of the husbandman. To Section F we look for warnings as to the economic conditions and barriers which—as we are apt to forget—hedge round our industry, and for the statistics which must govern the varying direction which we give to our enterprise from time to time. The mechanical operations of our calling suggest to us the practical assistance which Section G can surely offer. Nor does even Section H lie wholly remote from the inquiries we may need to make as to the resources of the globe and the wants of diverse communities. The physiology of Section I opens regions of research quite germane to many of our daily studies. Under Section K, as an overlord, we rest to-day assured that if every botanist is not a farmer, every farmer must in a sense be a practical botanist, for ever face to face with the plant and its environment. Perhaps also, in common with all the rest of the world, we may have something to our advantage to hear from the pedagogues of Section L, who may advise our scientific counsellors as to the best form in which even the practical farmer may be taught.

Addressing ourselves, however, to the immediate task in the sub-section allotted to us, I suggest to you to-day that, having regard to the place where we meet, I may, as a proper prelude to your debates, invite you to consider, even if only in the broadest way, what are the leading factors that govern the fluctuations of this our industry of agriculture all the world over, and in new countries in particular. The first factor of all is undoubtedly population—its growth, its rapidly varying local distribution, and its changing and diversified needs. It is for man that crops are raised, whether these crops are to furnish food for direct consumption or for the sustenance of live stock, or whether they furnish us with our clothing, like the wool and the cotton of other lands, or with the materials for shelter, as the great timber crops which your vast forests here may bear. When we know what is the demand at any given place and time, we shall be prepared to give a more exact examination to the means of turning out the effective supply at the right moment and in the right place, be it of wheat, of meat, of fruit, of wool, of flax, of cotton, or of timber.

Sir Horace Plunkett told us last summer that he hoped to find in an Agricultural Section "some humanised supplement to the separated milk of statistics." Perhaps he unconsciously reflected in that remark the suspicion that in earlier days the agricultural debates, which, for want of a better place, took place in the Economics and Statistics Section, unduly paraded the bare figures of the position. But I myself confess that, however mortals may shrink from the rigid arbitrament of arithmetic, neither the teaching of the man of science nor the rhetorical advice of the philosopher will lead the agricultural student of the future, even if he have the luxury of a complete Section of his own, to any fertile result, unless he begins by a clear diagnosis of the facts as they stand, on the one hand as regards population, on the other as regards production. We shall by no means waste time if we try to investigate, with some approach to exactness, what are the areas still available for extended cultivation, and who and where are the consumers of our products, and what are their present and future demands.

Obviously, however, in the limits of an Address like this it is impracticable to make, in any detail, a world survey such as this implies, and it is only the most patent of the changes in the world's populations and their agricultural demands which I can put before you. There was a time when the human family lived in self-contained groups, extracting their requirements from the soil which lay around them. So lately as one hundred years ago there was very little of the international trade in food or other agricultural products such as is familiar to our practice to-day. The nations largely lived on their own territories, and the world has wide sections still where production is limited by local needs. But even a hundred years ago or more perpetual questions were emerging as to the time when men should have multiplied more rapidly than food. The transportation revolutions of the nineteenth century may be almost said to have laid that scare by their aid to the mobility alike of the world's populations and of the world's produce. For the migration of men from dense settlements to open lands on the one hand, and the transport of their produce to the cities of the old world on the other, have simplified, and may simplify still further, the solution. It is all a question of distribution.

If the world holds to-day just twice as many souls (as the best demographic authorities seem to assume) as it did only some two generations back, this growth has been by no means uniform, and the development is governed and provoked by the pressure of population on sustenance. Sometimes, I think, we are apt to forget what Prof. Marshall, of Cambridge, has so well laid down, that "man is the centre of the problem of production as well as that of consumption, and also of that further problem of the relation between the two which goes by the name of distribution and exchange." Vastly has the latter problem been simplified by the giant strides the second half of last century has seen in annulling distance and in facilitating transport, until all the world bids fair to become a single community. Whether the present distinguished British Ambassador to the United States was right in looking forward to the gradual unification of the type of the world's inhabitants by the diverse processes of ultimate extinction and absorption of inferior races, I think we will agree with him that the spread into new regions of conquering or colonising races has provoked desires for, and made practicable the supply of, far more varied wants than once were even contemplated, or could indeed have been made available, while the producing areas were sundered widely from the consuming centres.

The sixteen hundred million souls this earth of ours now carries are at present by no means evenly spread over its surface, and a population chart reveals the most extraordinary diversity in the density of the people on the soil. More than one-half are on the continent of Asia, and of these a large section are densely clustered in India, China, and Japan. In Europe, where the average density is double that of Asia, and approximately one-fourth of the world's inhabitants are gathered, many portions are nevertheless still far less thickly peopled than the Eastern States just named. Populations, over any considerable areas, exceeding 500 to the square mile, may be found on the world's map not only in parts of the United Kingdom, in Belgium, or in Saxony, but yet again on the Lower Ganges, on the Chinese coast, and even in portions of the narrow valley of the Nile. But the Indian or the Chinaman are not, broadly speaking, to be ranked among the communities of which we are thinking when we concentrate our attention on the increasing transport of breadstuffs or of meat from the New World to the Old, which has become the prominent feature of the agriculture of our own day, whatever attention may have to be given to the conditions of the Far East at some distant date.

The great movements of agricultural products which have signalised the last half-century are not for the most currents of food supply into Asia, or into Africa, or North America, despite certain limited exceptions which are just beginning to attract attention, as possibly hereafter significant in the case of imports of wheat into Japan or China, of Australian meat into Eastern Asia and South Africa. The Asiatic or the African agriculturist is for the most part content to find the primary necessities of life close at hand. It is mainly Europe, and indeed Western Europe, that calls to-day for the import of breadstuffs or meat or dairy produce. There the growing volume of sea-borne imports has not only materially influenced the agriculture of old settled countries, but at the same time has signalled to the European toiler that space and plenty awaits him oversea, and has stimulated the development of new spheres of cultivation at a rate which the relatively sparse population of the New World, unless largely recruited by immigration, could never accomplish.

I ventured some years ago, from the chair of the Royal Statistical Society, to review the recent changes we have seen in the structure of the world's populations, and urged the greater wisdom of bringing the men to the food rather than the food to the men. The centripetal force which was, in all parts of the earth and not in the oldest countries only, packing more and more together the human family in vast industrial centres, which drew the materials of their handicraft and the food for their maintenance from far distant lands, seemed to my judgment a much less healthy form of development than the older centrifugal impulse which led man to move himself to the newer regions, where the produce was nearer to the mouth of the consumer, and where he could fulfil the oldest obligation of the race to go forth and replenish the earth and subdue it. The vision that meets us here of ample land awaiting man, of possibilities of agricultural production which can only be realised by well-considered and augmented immigration, impresses the visitor from an old and overcrowded country. Before and above all speculations of what transport has done, and may yet do, to carry masses of agricultural produce across the ocean, I must claim, as the better prospect, a steady settlement of these wide acres by a population resting on the soil which this great Dominion offers, and drawing from it, by a more diversified and more general and more wholesome type of farming, a far better, and in the long run a more economic, return than the mere extraction of grain for export can ever promise.

Taking the thirteen States of Western and Central Europe as an example of what I mean, there were added there, in the last seventy years of the nineteenth century, on a comparatively limited surface, something like 100,000,000 new consumers to the 167,000,000 persons previously resident on the 1,700,000 square miles of territory occupied by this group of nations. These numbers, too, take no count of the emigration which has lightened the pressure on the soils of the home lands of Europe. Clearly the maintenance of nearly 70 per cent. more consumers must have meant either a vast development of local agricultural production or a vast demand upon the acreage of the new land of the West, or both. The defective nature of the early statistics obstructs the search one naturally makes into the extent on which these new populations on the old lands have been fed on larger local areas, or from larger yields on non-expansive areas. Adopting, therefore, a much shorter range of view, the lifetime of a single generation has given us 30 per cent. more consumers in Western and Central Europe than were there in 1870, the German element rising apparently by 50 per cent., the Scandinavian, Belgian, and Dutch group of small nationalities by 44 per cent., and the United Kingdom by 40 per cent. in this interval, while these developments were of course reduced in their effect on the total by the slower growth of the South-Western nations and the nearly stationary condition of France.

No larger areas, but rather smaller ones, of the chief food grains are apparent in Great Britain or Scandinavia or North-Western Europe. The German areas of wheat and rye show practically little change, and although, if the Hungarian areas are larger in the centre of Europe, the general movement is not upward in respect of food-producing area. Even in live stock the numbers scarcely keep pace with population, for although the herds and the swine of Western and Central Europe have risen by nearly a fourth in the one case and three-fifths in the other, the sheep, except in Great Britain, are much fewer now.

On the average of the first quinquennium of the present century the home production of wheat represented only about 20 per cent. of the consumption in the United Kingdom or in Holland, 23 per cent. (apparently) in Belgium, 64 per cent. in Germany, and perhaps 80 per cent. in Italy; and the imported grain to fill the deficits was considerably more than 400,000,000 bushels. Nearly half this came, of course, from Eastern Europe, and particularly Russia. Such a mass of produce would require 20,000,000 acres elsewhere, even if the exporters could raise it, as most have certainly *not* done, at twenty bushels per acre, and nearly double that area if the yield was only that of some of our largest exporters to-day.

The actual reductions of area in Western Europe are not in the aggregate extensive, although Belgium has seen her grain area shrink from 30 to 25 per cent. of her total surface, France from 28 to 25·5 per cent., and the United Kingdom from 12 to 10 per cent. The grain-growing capacity of European States varies greatly, and it would be interesting, were the data everywhere available, to see how far we have distinct evidence of an appreciable if not any great advance in the yields extracted from the non-expanding areas under the more recent conditions of scientific knowledge. Nowhere is so large a share of the total surface under grain as in Roumania, an Eastern European State and not inconsiderable wheat exporter, and there, at all events, the total grain acreage developed between 1886 and 1906 by nearly 25 per cent., and the surface under wheat by 72 per cent. The yield there, according to some official reports, was something over fifteen bushels per acre in the five years before 1890, and in those ending 1906 it was more than nineteen bushels—the latest year nearly touching twenty-three bushels; the barley yields of the same State rising from an average in the former quinquennium of thirteen bushels to more than nineteen bushels in the latter.

In Hungary, another European grain exporter, the wheat acreage has been materially developed, rising from more than 7,000,000 acres to 9,500,000 in twenty years to 1906, and but slightly receding since, while the yields are also materially greater.

France, with a drop in wheat acreage of 1,000,000 out of 17,000,000 acres, has between 1884 and 1908 raised the average of her production on a five years' mean from 17·8 bushels to 20·2 bushels, and thus turned out somewhat more produce from a lessened surface.

Germany, on a constant but much smaller wheat area of 4,700,000 acres, with a quinquennial average yield of 20·3 bushels, would seem to have raised this to 27·0 in 1899–1903, touching a still higher level in more recent seasons, when 30 bushels were apparently approached, although some changes in her statistical methods of inquiry may slightly reduce this comparison.

Some effort to feed new mouths from old acres has thus indeed been made. Nevertheless, without disregarding altogether the qualifications which a careful statistician would deem it his duty to admit, one may broadly say Western Europe looks mainly for the growing needs of her consumers to the still exporting States of Eastern Europe, to the New World regions of North and South America, and in a minor degree to Australasia.

Before we quit our session here in Winnipeg we may expect to learn something of scientific interest and of economic guidance respecting the response of Canada to the Old World's call. But it is not for grain alone that densely peopled countries turn to the new fields of the West. Probably the geographical conditions of our place of assembly this year will not lead us at all closely into discussion on the variations in the sources and fluctuations in the volume of the wool supply, or that of cotton, but the possible development of live stock on the territories of newly settled countries may be expected to come well within our purview, and afford us lessons in the development of the export trade in meat and dairy products, and the relation of the Canadian to the surplus of other States. The Royal Statistical Society of London had a paper this summer by an old colleague of mine, Mr. R. H. Hooker, which, although primarily devoted to the supply of Great Britain herself, and the price of meat in her markets, has a world-wide view of what is going on all around us in the conditions of production and of transport in a commodity as important to human life as wheat itself.

Fully a quarter of a century has gone by since, on a former visit to Canadian soil at Montreal in 1884, I raised a debate on this subject of the production and consumption of meat, and the various conditions of its transport. The twenty-five years that have passed since then have not rendered that particular topic a less important one for the consumers of old countries or the farmers of new, but ever-varying factors are presented by the opening of new territories to exploitation and the denser massing of accumulated populations with growing needs, and increasing preference for the most concentrated form of aliment. Among the most recent factors to be remembered as influencing one side of the meat-trade future are the admissions of qualified experts in the United States as to the degree in which the growth of population there was beginning to trench upon the meat surplus of that Republic. On the other hand, the producer will not fail to bear in mind the rapidly advancing importance of partially developed areas and the great advantage of the more economic forms of dead-meat transport now adopted in South America, and will weigh against these the degree in which the herds of the vast prairies of North-Western Canada may be further utilised when questions of handling economically the resultant meat supply may be effectively elaborated.

To-day, however, and here especially, one cannot but be reminded that in whatever direction we look for the aid of science to stimulate the development of Canadian resources, or to help the producers now in these provinces in measuring the probabilities that lie before them, or to summon eager emigrants to the land you have to offer them, there is an intense and ever-engrossing interest in the present and the future of wheat. Alike, therefore, to the statistician and economist on the one hand, and to the experimentalist and investigator on the other, we turn to ask what advice they can give to the farmer of a new country with an area so vast as the North-West of Canada presents, whether and how far and at what rate, with profit to himself and with benefit to the bread consumer across the ocean, he can push the extension of the well-nigh eight million acres of wheat land which the Dominion claims to show her visitors in 1909.

The problem, important as it is to this particular region where we are met, cannot, however, rightly be treated as a purely Canadian question. It is a problem of world-wide interest and of great magnitude and more complexity than has been sometimes recognised, for it is none other than the issue of the race between population and production so far as at least one primary essential of human diet—bread—is concerned.

Within a year of the last visit to this Dominion of the British Association the question was raised by no less an authority than the then President of that body at the Bristol meeting of 1898, whether the possible wheatfields of the globe possessed a potential capacity of expansion sufficient to meet the hypothetical needs of the bread-eaters of even one generation ahead; whether, in fact, a dearth of wheat supply was not already within sight, and by 1931 would be upon us. The suggestion that the wheat-producing soil of the world was already becoming unequal to the strain put upon it by the multiplication of men was not unnaturally met by a vigorous criticism. The mere suspicion that some day, however, there would not be land enough to go round, that famine could be averted only by the beneficial magic of the chemist, is too vital a possibility—even if some of us do not place the date so near or rely so fully on some of the computations made—not to command a very careful examination of the remedy propounded, the promise of the artificial production of nitrate in such a volume and at such a price as would raise the average of the world's production from 12·7 to 20, if not even to 30 bushels of wheat per acre.

The fixation of nitrogen, not as a dream but as a certainty, was, it will be remembered, claimed by Sir William Crookes as the condition on which the great Caucasian race was to retain its prominence in the world, and avoid being squeezed out of existence by races to whom wheaten bread is not the "staff of life."

Personally, I confess I am not so pessimistic as to the surface still available for wheat-growing even without this aid. If we grant that the so-called contributory areas, at a date two or three years before the close of last century, were just what was then stated, that the bread-eating population of that date was rightly guessed at 516,500,000—a much more difficult certainty to reach in the manner adopted by the American statistician whose figures were adopted—and that both the growth of population and of "unit consumption" would proceed exactly in the ratio suggested, it may legitimately be asked, does it nevertheless follow that no such increment of area can be looked for as would satisfy the larger mass of consumers calculated for as likely to be dependent upon wheat in 1911 or 1931 on the scale here laid down?

I should not, in any statistical investigation into these questions, be contented to assume the probability of the exact continuance of previous ratios in the rate of production, or that of individual consumption over such periods, and my experience of very big averages makes me shy of adopting a simple mean of such wide diversities as correctly representing the head-rate consumption of wheat. These are points which might be more fittingly debated elsewhere. I want to narrow the issue now to the actual and more recent course of the wheat-growing surface; for it seems to me that the lesson of such figures as we have in the past, and as those of Mr. Wood Davis's tables, is rather one of irregular than of arrested extension. The periodical opening up of new areas, very often in advance of consumptive requirements of the time, would seem almost invariably to be followed by a pause while prices recover from the over-supply, and that again by new developments and exploitation in new directions, or by better methods on the areas made tributary to the wants of the ever-increasing men.

We may admit that the course of the wheat acreage from 1870 to 1884 and thence onward to 1898 showed—first, a material advance outstripping that of population, then an admitted and serious check, with a subsequent advance, although one below that of the bread consumers of the world.

Let me ask, however, if a later view of the wheat area at the disposal of the world's consumers is not well qualified materially to diminish, if not to dissipate, the "cosmic scare" which, no doubt contrary to the real design of the distinguished chemist who followed Mr. Davis's estimates, was induced by the figures of 1898? My own comparisons of the later growth of acreage covers only the decade from 1897 to 1907, or as nearly to these years as figures permit, and in the form I originally designed it might bring into view something less than 230,000,000 acres as the world's present extent of wheat-field. But, to place matters on a more comparative level, I am willing to omit the large Indian totals and some few of the distant regions which, partly on account of the somewhat uncertain identity of the areas they include at different dates, and partly on account of their relatively small contribution to the bread of the Western world, do not find a place in the estimates with which I am now making a comparison. For the leading groups of other areas the figures stand in millions of acres to a single decimal:—

Groups	1897	1907	Increase in 10 years
Russian Empire	46·6	59·5	12·9
United States	39·5	45·2	5·7
Three chief European Wheat States	37·6	39·8	2·2
The Rest of Europe	20·8	21·4	0·6
Argentina and Uruguay	6·7	15·0	8·3
Canada	3·0	6·6	3·6
Australasia	5·0	6·0	1·0
Total	159·2	193·5	34·3

Now, whatever be the estimated increase in wheat-eating population between these two dates, it cannot in the aggregate be 21½ per cent., as is the growth of the wheat surface in these States. Nor would the result be materially affected if allowance were to be made for the three or four million acres represented by the exports of unnamed States in this table, or even by the inclusion of any minor units of wheat-growing, such as Portugal, or Greece, or Switzerland, for which Mr. Wood Davis estimated from sources not recognised in our official statistics, their totals being well under a single million acres, and the variation, if any, probably insignificant.

If, therefore, the growth of men outstripped the growth of wheat, as we have been warned was the case between 1884 and 1897, the growth of wheatfields has been well over the rate of population increase since that exceptional period, just as it was in the still earlier period between 1871 and 1884. Nor is the check to the rye acreage and its decline by 4 per cent., which seemed to have happened concurrently with the wheat check between 1884–97, continuing; for that, in the aggregate, seems to have returned to, though it has not perhaps much exceeded, the older level.

Comparisons at single terminal points have always a danger which may be avoided by examining more carefully the leading facts year by year. On the diagram which I introduce here I have tried, therefore, roughly to sketch the curves which indicate the growth of wheat acreage, both before and since 1898, in Russia, the United States, Argentina, Australia, and Canada, as typical of the exporting centres, while the acreage in France and Hungary has been added for comparison. The effect is, I think, to bring out the very much greater extension which has been going on during the last decade than could well have been looked for on the basis of the 1884–97 figures.

For the Russian Empire as a whole data are available only since 1895, but I have shown by a separate and steadily mounting line the wheat area of the fifty governments of European Russia, which are comparative for the entire period, and the latter are quite sufficient to establish my conclusion. There is, too, a suggestiveness about the course of prices (in shillings per quarter) in England, the chief recipient of wheat exports, which I have traced by a separate curve across this diagram. This may perhaps aid those who are disposed to make a closer study of the figures. That study may not improbably suggest that in the very latest year—for I have carried the diagram to 1908 where I can—we may be once again nearing another check, or temporary halt, in the course of wheat extension, such as that which puzzled inquirers more than ten years ago, but which proved only a pause in the task of finding all the bread the consumers wanted under the stimulus of better prices. The further leap of prices in 1909 to beyond the 40s. limit in England may effectively encourage extension.

Acreage of Wheat in Million Acres.

Year	Russian Empire	Of which in European Russia	United States	France	Hungary	Argentina	Australasia	Canada	Of which in N.-W.

The exceptional arrest of wheat-growing in the United States between the years 1880–96, when—if we may accept the official statistics as actually representing fact—the rapid rise, which actually doubled the wheat acreage between 1870 to 1880, stopped altogether, was, I believe, the preponderating factor which suggested a general halt in wheat-growing. It should therefore be looked at more closely, and to get rid of the danger of attaching too much importance to the data of single years, the quinquennial average movement in the States over the whole of the last forty years may be summarised as under :—

Five-year Periods	Acreage in U.S.A.	Distinctive Wheat Acreage Levels
1868–72 ...	19,500,000	Extending rapidly up to 1880
1873–77 ...	25,500,000	
1878–82 ...	35,500,000	Nearly stationary from 1880 to 1896
1883–87 ...	37,000,000	
1888–92 ...	38,000,000	
1893–97 ...	35,500,000	Again extending to maxima reached in 1901 and 1903, with a later slight decline in the latest years
1898–1902 ...	45,500,000	
1903–1907 ...	46,800,000	

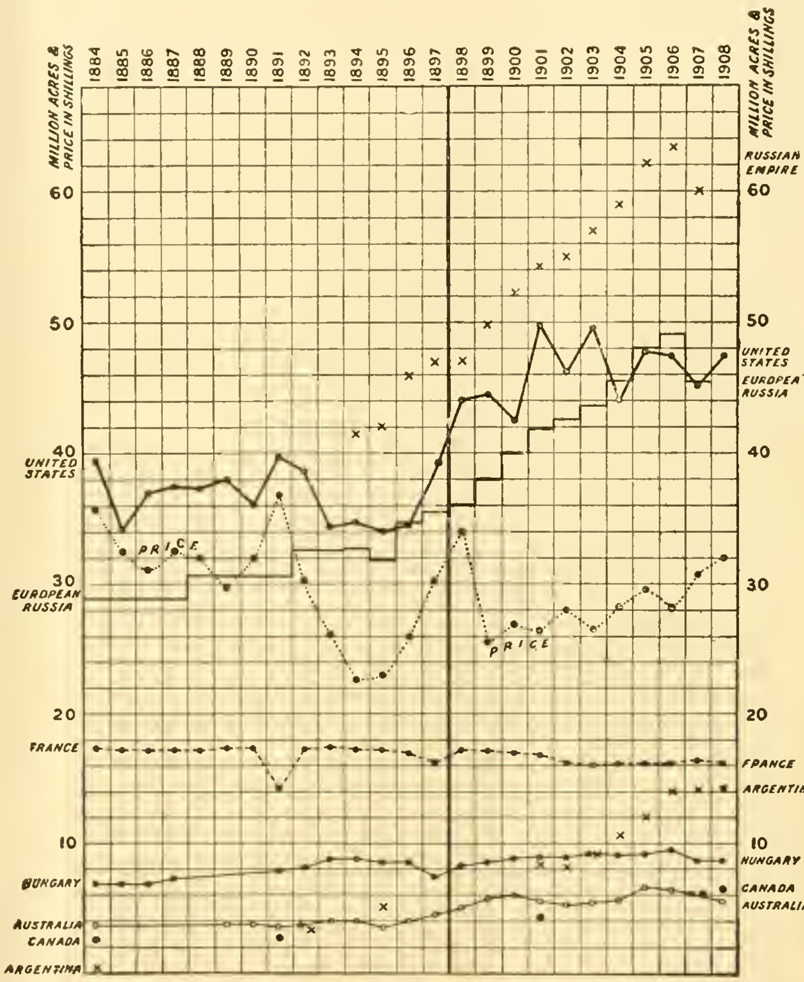
Population in the States has, of course, augmented steadily all over the forty years, from 37,000,000 to 86,000,000, yet all through the stationary years, as well as those of advancing acreage, exports of wheat and flour continued—as much as a third of the crop being shipped abroad in some years—and the transfer of the wheat lands north-westward in the States was doubtless the striking feature of the recovery. Rightly to understand the revolution in the wheat-growing of certain States of the Union would require a treatise for which time could not be given here.

Let me, however, recur again to the general position. In the table already given for the past decade the latest increase to be accounted for is 34,000,000 acres. I ask you to note that the Russian quota forms more than a third of the whole. Now it was Russia that was in a very special degree the subject of unfavourable remark in the wheat problem controversy of ten years ago. She was spoken of, I remember, as having reduced her consumption of bread by 14 per cent., and only by this means continuing her exports in defiance of her true needs, and contributing to the rest of the world therefore a merely provisional and precarious excess. I am not aware how the calculation here alluded to had been arrived at, nor have statisticians perhaps a very robust faith in the estimated numbers of the Russian population before the great census of 1897, but the subsequent history of her apparent wheat surplus is interesting.

The exports of wheat from Russia, which we were warned could not continue, and which had doubtless been unusually large between 1893 and 1898, shrank for three years after that date as if they would realise the prophecy which would relegate Russia from the ranks of exporters to the task of feeding her own population. But that mysterious empire has since then resumed her large supplies, and from 1902 to 1906 the exports ranged higher than before. Although forming only 24 per cent. of her estimated wheat crop, Russia's exports averaged 141,000,000 bushels over the first five years of this century, against 104,000,000 bushels over the whole preceding fifteen years. Quite lately we seem to see some restriction, but the history of the trade forbids a confident opinion that she has reached the end of her contributions to other lands.

So far as the areas under wheat are recorded, the Russian agriculturist keeps on extending his industry, and, low as the yields may frequently be, they are tending upward under, it may be presumed, some reform of the very primitive conditions of production. Within the fifty governments of European Russia alone, and omitting the Polish or Caucasian figures, which do not go so far back, the average area of 29,000,000 acres only in the 'eighties became 40,000,000 at the close of the century, rising to a maximum of 49,000,000 acres in 1906, a point from which a decline was shown in 1907 to 45,600,000 acres. This, however, even taking the latest and lower figure, is an advance of 10,000,000 acres in the last decade, or nearly 30 per cent.—surely considerably in advance of even the Russian growth of population, great as that is.

It has, I think, not been sufficiently realised that in the two decades stretching from 1887 to 1906, European Russia has added 1,000,000 acres of wheat per annum. This is not only a 70 per cent. advance in twenty years, but it is double the absolute area of 10,000,000 acres which the United States added in this interval. From



such official estimates as are furnished, the total produce of these fifty governments, where alone the figures are continuous, increased in a still higher ratio. The average production, which did not exceed 180,000,000 bushels in the five years before 1879, or 226,000,000 bushels in the quinquennium ending 1889, reached what appears to have been a maximum in 1904, and was averaged at 415,000,000 bushels for the whole five years' period then ending. If the later years are again at a lower level, they represent very nearly double the produce before 1879. The yield per acre, which stood below eight bushels to the acre between 1883 and 1892, averaged nine bushels over the next ten years, and has been 10·9, 10·4, and 11·4 bushels respectively in the three seasons ending 1904. In the south-western region, where the yield was just over eleven bushels in the decade ending 1892, it seems to have averaged fifteen in the ten years ending 1902, while more than eighteen and nineteen bushels were reported in 1903–4.

These figures omit the Polish, Caucasian, and Asiatic districts, for which a much smaller retrospect is possible. The acreage in Poland is small—little more than a million—and nearly constant in extent. But the wheat of Northern Caucasia, first accounted for in 1894, has risen from 5,600,000 acres to 8,300,000 in 1906, and the Siberian totals, after increasing, apparently but slightly, from 3,400,000 acres in 1895 to 4,800,000 acres at the close of the century, do not seem much to exceed 5,000,000 acres now. Russian wheat production does not therefore seem a wholly arrested process.

I own I was hardly prepared for this old nation's progress in wheat-growing, and I have no doubt that I shall be told that Russia has been exchanging one form of bread corn for another; in particular, that dependence on rye has decreased as production of wheat has grown. There is some truth undoubtedly in this, for the comparatively stationary character of the rye area indicates that the Russian people, increasing as they are and continuing still an export of rye to Germany and elsewhere, may themselves eat somewhat more wheat and rather less rye, and it is true also that a fluctuating record has attended the surface under the coarser and larger cereal crop. Its "low-water" point—61,900,000 acres—occurs in 1893, while its present figure is 66,000,000 acres. Relatively, therefore, while the rye shows no progress such as wheat, it cannot be said that the rye area has been utilised for the more valuable cereal, and the fact remains that there is more rye grown to-day, even in European Russia, than at any date since the last decade of last century began. Relatively to population, the available data show, the aggregate crops of wheat and rye together, in Russia as a whole, are materially greater than before.

Inquiry shows that the wheat extension in Russia has been made possible by an actual addition to the arable land, and not by deduction from other crops. A recent investigation quoted by a competent American authority informs us that some 23,000,000 acres of new arable land has been accounted for between 1881 and 1904, and, moreover, that a greater surface of this nominally arable area is now actually under cultivation than at the earlier date. These figures stand:—

Year	Total Arable Land acres	Under Crop acres	Wheat acres	Rye acres
1881	288,000,000	174,600,000	28,900,000	64,600,000
1904	310,700,000	205,900,000	45,600,000	65,600,000

It will be noted that this inquiry ends a year or two since, but had it been continued to 1906 the comparison would have been accentuated, and as it stands the additional area cropped in one way or another exceeds 31,000,000 acres.

In Mr. Wood Davis's later memorandum he combats the idea that the expected wheat crops from four relatively new areas of production—Siberia, Argentina, Australasia, and Canada—would meet the shortage he found threatened by his estimate. Not unnaturally he regarded an 8,100,000 addition of acres in these four regions in fifteen years as a very insufficient and unpromising quota to feed more than ten times that number of new bread-eaters on the globe between 1883–4 and 1898–9.

Assuming he rightly gave the increment of wheat between these dates as under, if I add to his table the latest data that I have, these new and gradually opening areas will show a rate of progress much greater in the nine succeeding years than before, even if there was no further increase in Siberia; for as to the areas to be included there I am certain. The figures I give in millions of acres:—

	1883–4	1898–9	Fifteen years increase	1907–8	Nine years increase
Siberia ...	2·0	3·3	1·3	3·3	—
Argentina	1·4	6·1	4·7	14·2	8·1
Australasia	3·2	4·5	1·3	5·6	1·1
Canada ...	2·4	3·2	0·8	6·6	3·4
Total ...	9·0	17·1	8·1	29·7	12·6

In the forecasts offered ten years ago Argentina as a wheat-grower was given a dozen years from 1898 to reach a possible acreage of 12,000,000 acres. She has reached that figure and passed it in less than a decade, and later current official estimates seem to concede to that region a close approximation to 15,000,000 acres to-day. As the actual pace here has bettered so considerably that prophesied, one may legitimately question the further limitations which allowed to Argentina no prospect of ever reaching a wheat area of 30,000,000 acres at any time. That these prophecies by no means coincide with later and probably quite similarly vague forecasts in the other direction goes without saying. In a recent official publication by the U.S.A. Government containing the report of an expert on the resources of Argentina and her farming methods, the competitive prospects of the great grain-exporting Republic of the South were scarcely so lightly treated. For my own part I rather agree with an officer of the Argentine Government there quoted (Señor Tidblom), who candidly admits that it was impossible with any accuracy to forecast the ultimate wheat area of Argentina, although I observe he adds that there were "more than 80,000,000 acres in the Republic that could be *immediately* devoted to successful wheat-farming if we had the farmers to do it." I have seen, though I could not accept, even more sanguine estimates in other quarters, which, with a yield of only ten bushels per acre, promised a crop of 1,238,000,000 bushels at some future date, and would involve an area of wheat land approaching 124,000,000 acres.

No one, I think, can note the strides which Argentina has taken in rapidly augmenting her wheat areas and exports, and that concurrently with the commanding place she is assuming as a meat rearer and exporter to the older peoples of Europe, without some recognition that a great future is possible. On the other hand, apart from climatic conditions, the future must be largely governed by the factor of population; and the nature of the Italian immigrants, their mode of culture, their non-intention in many instances to remain and own the land or identify themselves with the country—preferring to exploit one farm after another and reside on them until they make a small competence wherewith to return to Europe—are all reasons against the extremely favourable prospects which I have here adverted to.

Small relatively to the great extent of surface included in the Commonwealth of Australia is the proportion under wheat, but the Commonwealth is none the less as a rule an exporter. A little more than thirty years ago only about 1,400,000 acres were grown. This seems to have been a good deal more than doubled in the five years 1876–81, when a much smaller rate of increase followed for fifteen years—a check apparently reflecting the same tendency to arrest which we have seen so typically illustrated in the United States. Again, after 1896, just as in the great Western Republic, wheat-growing became again in favour, and the rapid spurt which followed brought the Commonwealth total to 5,700,000 acres as the century closed. Thereafter the rate of growth seemed checked anew, and after passing a maximum of just under 6,300,000 acres, it stands to-day under 6,000,000 acres. Twice during the last twenty years has Australia shown on balance a net importation of wheat, but from 1903 to 1907 the quantity exported has averaged 36,000,000 bushels, and it is not without interest to observe that the Australian exports of the present century have not all been consumed in Britain—South Africa, the western coasts of South America, and even some parts of India sharing in the surplus product of the Antipodean Continent.

The conditions and the future of Australian wheat have been quite recently dealt with in an interesting paper by Mr. A. E. Humphreys, read before the Society of Arts in London. It is here pointed out that the soils on which it is grown are rich in assimilable nitrogen, requiring little manurial expenditure in that direction, but poor in their percentage of phosphoric acid, while the climatic conditions as regards moisture have proved remarkably difficult. Efforts have been made, and apparently, if recent experiences be confirmed, with success, to breed new varieties of the wheat plant adapted to the peculiar climatic conditions of Australia and likely to increase the low average yields hitherto obtained. It is obvious that under Australian conditions the breeding of varieties of the wheat plant which will thrive on a low rainfall would make all the difference to Australia as a source of wheat exports. From 1902–7 the Australian average yield was only half that of Manitoba, or nine bushels per acre; but this included one year of disastrous drought (1902–3), wherein the Commonwealth average fell below 2½ bushels to the acre. In New South Wales and Victoria, wherein more than half the acreage lay, it was even below this according to the official figures. Such instances offer the strongest evidence that could be offered of the extreme variability of Australian conditions, and make one almost hesitate to quote Mr. Humphreys' own cheerful estimate that in the State of New South Wales alone, wherein nearly a third of the Australian acreage is found to-day, or 1,886,000 acres, there was a possible area of good wheat land of nearly ten times this, or 18,000,000 acres.

To the last I have left another sphere of wheat extension, and one that will be most of all familiar to my audience. Yet here again the forecast of the Canadian future made in 1898 was surely unduly pessimistic. The opinion then quoted by Sir William Crookes as that of trustworthy authorities assigned to the Dominion a bare total of 6,000,000 acres under wheat as all that could be expected to be reached within a dozen years. That period has not yet fully come, but I observe that by December 31, 1908, the official figures show an acreage as reached within the decade which exceeds by 10 per cent. the maximum allotted to 1910. If I were to add the figure now ascertained for the 1909 crop, a total of 7,750,000 acres is now reckoned upon, so that here again the forecast has been outstripped. The further proposal to estimate the maximum of the Canadian potential capacity for wheat production by 1923 at no more than 12,000,000 acres will therefore, I imagine, meet severe critics in Winnipeg to-day.

I greatly wish that our contribution to the knowledge of the economic future of Canadian development may be, as the result of discussions here, some approach to an agreement to avoid all exaggeration on the one hand or on the other in these forecasts of future wheat-growing in the North-West; but I am very conscious of the risk of all far-reaching prophecy in a problem where the more or less uncertain growth of the immigrant population plays as great a part as the soil or the climate.

Sir William Crookes, in endorsing the most modest estimates of the capacity of this region, mentions that he had before him calculations which, I think most of us will agree, were, to say the least, exaggerated in an opposite direction, attributing to Canada 500,000,000 acres of profitably utilisable wheat land. Against such inflated prophecies he argued that the whole area employed in both temperate zones of the world for growing all the staple food-crops was not more than 580,000,000 acres, and that in no country had more than 9 per cent. of the area been devoted to wheat culture. But error of estimate in one direction or another is quite inevitable when the available data on which to form a conclusion are so scanty. Replying later to journalistic criticism, Sir William, it must be remembered, acknowledged the undoubted fertility of portions of the North-West provinces; but, basing the conclusion on official meteorological statistics and on supplementary data supplied by Mr. Wood Davis as to the July and August temperatures of these regions, he suggested that "from one-half to one-third only" of Manitoba—the south-west portion already fully occupied—was adapted to wheat. It was doubtless in the light of these climatic records that he inclined to regard 200,000 square miles of the whole 300,000 square miles comprising Assiniboia, Alberta, and Saskatchewan, as these regions were then defined, as lying "outside the districts of profitable wheat-growing," while even of the remainder it was apparently suggested that it would take thirty years from 1898 to place as much as 18,000,000 acres *under all grain crops*. Can we here to-day, with another ten years' experience, reach a somewhat greater accuracy in this search into the possibilities before us?

As illustrating the remarkable discordance of view hitherto existing, it is well to have before us, as a starting point for debate, some specimens of later but still most widely varying estimates of the capabilities of this country. These I quote from the cautious report rendered by Prof. Mavor to the British Board of Trade in 1904, midway through the decade now closing. More or less speculative as it is fully acknowledged all estimates must be which purport to define the area "physically or economically susceptible of wheat production," that painstaking investigator set aside, as of little value, hypothetical curves setting forth the "northern limit of cereal production," trustworthy data for which "were not forthcoming, and if they were they would be constantly changing." After enumerating under fourteen different heads and sub-heads a formidable list of distinct but materially qualifying "conditions" or factors covering questions of soil, of temperature, and meteorology, of moisture, sunshine, and acclimatisation of the plant, Prof. Mavor suggests that, broadly speaking, the cleavage of the areas of different fertility runs obliquely from south-east to north-west through the great quadrilateral of the Canadian North-West. Alike in the north-eastern and in the south-western angle the conditions seemed to him more or less unfavourable. The south-eastern and north-western corners and the belt connecting them, however, presented relatively favourable conditions; an exception qualifying this subdivision was, however, suggested in the extreme north-west.

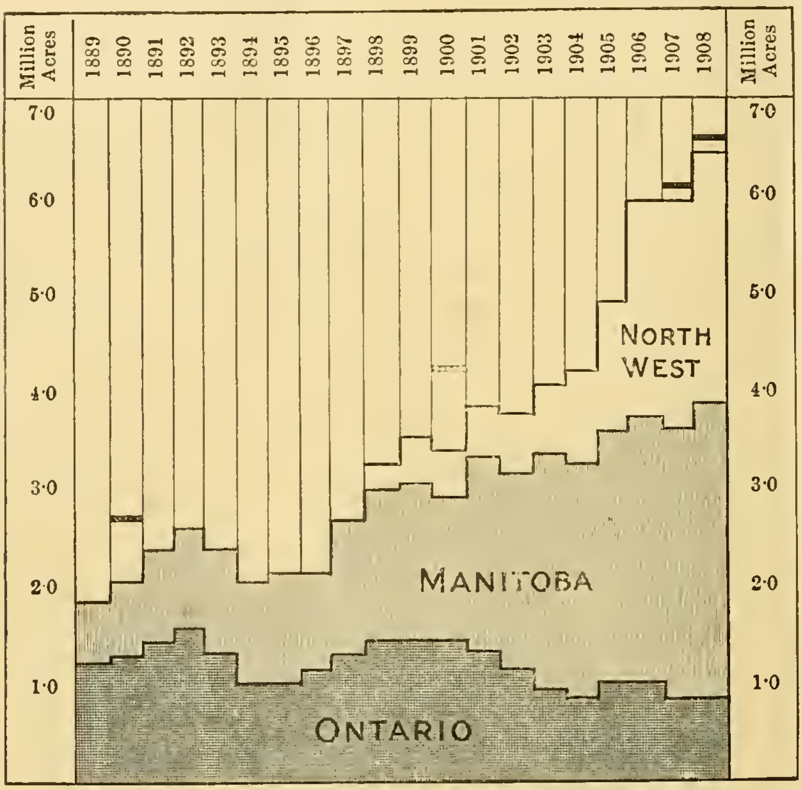
The vagueness of the statistical basis on which any numerical estimate of future wheat areas must rest cannot better be shown than by briefly referring to the results of five independent estimates which are quoted in this report. For the details of these estimates it is necessary to refer any student of the report to the analysis of each, differing as they do materially in their methods and in the classification of the areas comprised within the Manitoba, Assiniboia, Saskatchewan, and Alberta of that date. As regards the total area for settlement and for annual wheat-growing respectively, the first three of these estimates varied in placing the surface fit for settlement or susceptible of cultivation as low as 92,000,000 acres, and as high as 171,000,000, the annual surface available for wheat in these districts ranging from 13,750,000 acres to 42,750,000 acres, and the resultant possible produce from 254,000,000 bushels to 812,000,000 bushels.

It should be added, to make these figures clear, that all the estimators quoted assume as a condition precedent to their accomplishment such an influx of population and settlement of the country as would be adequate to secure the cultivation of the hypothetical cultivable area.

With Prof. Mavor, we may think that both the lower estimates are over-cautious and the third perhaps over-sanguine, while most properly he reminds us that beyond the physical capacity of any region, the question of economic advantage remains to be solved, under what may be conditions prevalent at a distant time, what effect a rise of price might have, and whether the farmers of the future would devote so much of their land as is here suggested, and so much of their working capital, to wheat alone. I ought to add that a fourth estimate referred to in the report takes the graphic form of a map, distinguishing the suggested area where the wheat crop is certain, where less certainty exists from the effect of summer frosts, and where, again, the crop is uncertain from insufficient moisture. Yet another estimate was quoted as made in 1892, but endorsed as not over-stating possibilities of the future in July, 1904, and this classified somewhat more than half the land of Manitoba as "land suitable for farming," or 23,000,000 acres, allotting to the rest of the North-West 52,000,000 acres more, or in all 75,000,000 acres. The same estimator, forecasting the results for 1912 (or three years from the present time), allotted to Manitoba a probable wheat production of 168,340,000 bushels, and to Alberta, Assiniboia, and Saskatchewan 181,600,000 bushels. This crop of 350,000,000 bushels of wheat was in addition to an estimate of a further 200,000,000 bushels of oats and 50,000,000 bushels of barley. I have little hesitation in concluding, with Prof. Mavor, that such widely divergent results, arrived at, as we are told, by competent estimators, illustrated the impossibility at the time of that report of setting out precise limits of cultivation in a region in which so much has yet to be done. To-day I would ask, Has the lapse of another quinquennium, full of interesting movements in both the population and the crops of the North-West, enabled us to reach any greater certainty? If so, the opportunity of this meeting affords an occasion to submit the conclusions, optimistic or pessimistic, practical or theoretical, economic or scientific, to the test of friendly and thorough discussion.

It is a relief to turn from the perplexing variety of these speculations as to the future to the relatively more solid ground afforded by the actual records of wheat extension here. If the progress of the past, and here once again more especially of the very latest decade, is to govern the prospect of the years to come, the wheat area of Canada must still possess a great expansive power.

There are defects of continuous statistics showing from year to year the total acreage of the Dominion, although the recent good work of the Census and Statistics Office promises that this will henceforth be remedied. But outside of the three great wheat-growing sections—Ontario, Manitoba, and the North-West—the surface under this cereal is not material. By the latest figures available the four Eastern Provinces do not now grow 170,000 acres collectively, while the small surface in British Columbia,



not appearing in the last general Bulletin, was only 15,000 acres at the last census. In the roughly sketched diagram I insert here, therefore, the course of wheat-growing on 97 per cent. of the 6,611,000 acres accounted for in 1908 may be conveniently, if only approximately, traced.

The decline in Ontario, where, as in other older settlements, wheat-growing shrinks as more diversified forms of agriculture evolve, is much more than compensated for when the acreage of Manitoba, and in later years the rest of the North-West, is superadded, as in the columns of this diagram, and the rapidity of the recent extension, which—had the 1909 figures reached my hands sooner would have carried the total area far beyond the seven million limit—testifies to the energy in the task of bread-raising which this hopeful section of the British Empire displays.[1]

[1] Were the preliminary estimates for 1909 taken into account, the total acreage would have been given as 7,750,000 acres—a rise of 1,139,000 acres in the latest twelve months. This is indeed the net result, for the West has added 1,402,000 acres—of which 1,289,000 were in Saskatchewan and 113,000 in Alberta—while there are declines in the East and in Ontario of an almost exact equivalent of the last-quoted figure, or 114,000 acres, and likewise a reduction of as much as 149,000 acres in Manitoba since 1908.

But whatever determinations we can reach on the hypothetical questions here propounded, whether we may regard the greater rate of wheat-field extension in the world at large, which has marked the last decade, as disposing of immediate alarm for the bread supply of the next generation, or whether we find in the recent whisper of augmenting prices corroboration of the gain of population on subsistence, it is clear that our statistical records require a further development and a much improved continuity, especially in the new regions of the wheat supply of the future. Nor yet, again, can we dispense with the urgent lesson that science has much to teach us in making more use than we do of the areas acknowledged to be under more or less rudimentary cultivation. If Sir William Crookes was right in adopting the American statistician's average of 12·7 bushels per acre as the mean of the recognisable wheat-fields of the world, the prospect of the extra seven bushels he sought as immediately desirable will make us eager to learn the very latest triumphs of the laboratory in winning for the soil a freer measure of the nitrogen of the air. Even here in Manitoba, where a much higher yield seems on the average to be maintained under existing conditions, and where the cultivators with their 18 bushels average start from a vastly higher level, the promise of such a scientific ally should gladden the heart of the hard-working pioneer.

One caution, however, I feel it my duty to give, as a practical rather than a scientific agriculturist. Whatever wonders are offered in the way of manurial adjuncts or mechanical contrivances, do not let our advisers overlook the paramount consideration of the cost which the newer systems may involve. For the extensive farming of a young country it is above all requisite to remember that expensive methods of cultivation are not as feasible as in the intensive husbandry of old settled regions. Hopefully as we may wait on the chemist's help, I confess that, for my own part, I incline still more confidently to the botanist, under whose ægis of protection agriculture has this year been placed by the decision of the authorities. The producer of new and prolific and yet disease-resisting and frost-defying breeds of wheat plants is to-day more than ever encouraged by what has been done in many lands of late in this direction, to suit the crop to its environment. Nothing could be a greater boon to the wheat farmers, handicapped by a short and irregular supply of summer warmth, and the occasional but often untimely invasion of the frost fiend, than the production of varieties of wheat at once prolific and early ripening, and suited to the relatively scanty moisture of semi-arid regions. What success Canadian investigators, with their renowned experimental system, have had in this direction we hope to hear at Winnipeg, while some of us who have listened to Prof. Biffen, of the Agricultural Department of Cambridge University, look for hopeful results from the application of Mendelian laws to the breeding of wheat.

In closing, let me add that though it is a quarter of a century since I last was here, the message I gave local agriculturists then is one I am tempted to repeat now. It is no use to treat the vast territories you have at your disposal as if they were a mere wheat mine to be exploited in all haste and without regard to its permanence and its future profitable development. It is unwise to proceed as if bread were the only item of food requiring attention at your hands, and to regard a spasmodic rush of grain for a limited number of years from a poorly tilled surface as the only way to profitable returns. The stale maxim of not carrying all your eggs in one basket has a very profound truth to rest upon. The farming of the future must ultimately be one of more careful tillage, more scientific rotations, and of consideration for the changes in the grouping of population and in the world-wide conditions of man and his varying wants. What is going on all over the world has to be learned and studied well, and wheat pioneers of the North-West must not forget the possibility of yet new competitors arising in the single task of wheat-growing, whether they are to be looked for in the still developing sections of the Russian Empire and the still open levels of Argentina, the little-known regions of Manchuria, the basin of the Tigris and Euphrates, the more completely irrigated plains of India, the tablelands of Central Africa, or perhaps under new conditions and a more developed control of the reserves of water supply on the southern shores of the Mediterranean or even in the long tilled valley of the Nile.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—According to the *British Medical Journal*, a movement is on foot for the establishment of university chairs at the Royal Infirmary for the teaching of (1) medicine and clinical medicine; (2) surgery and clinical surgery; (3) midwifery; and (4) pathology. It is proposed that these four professors should form the teaching staff so far as the Royal Infirmary is concerned. Under this arrangement, in place of a complete, there would be a partial medical school at the Royal Infirmary, so that university students, if they preferred, might take their final year at that institution instead of at the Western Infirmary and Gilmorehill. Towards the accomplishment of this object it is understood that the Muirhead trustees are willing to give two sums of 400*l*. a year each to found two of the chairs, that the funds of St. Mungo's College are to be concentrated on one chair, and that the Carnegie trustees are to supply the funds for the fourth chair. The scheme will require to be sanctioned by Parliament, and draft provisional orders for that purpose are being prepared. These will be submitted to the members of the University Court for their approval, probably at a meeting in October.

Dr. G. A. Gibson, professor of mathematics in the Glasgow and West of Scotland Technical College, has been appointed professor of mathematics in the University of Glasgow in succession to Prof. Jack. Prof. Gibson has published a number of original contributions of importance to mathematical science, and is the author of works on the calculus which are acknowledged to be among the best in the English language. His wide knowledge of the history and present state of mathematical science, unusual powers of logical and lucid exposition, and ability as a creative scholar, ensure enthusiasm for mathematical studies at the University and increased activity in scientific investigation.

LONDON.—University College:—The following public introductory lectures will be given as under:—Sir William Ramsay, K.C.B., F.R.S., on "Radium Emanation: one of the Argon Lines of Gases," on Monday (October 4); Prof. H. R. Kenwood, on "What Hygiene demands of School Teachers," on Wednesday (October 6); Prof. J. A. Fleming, F.R.S., on "Electrical Inventions and the Training of Electrical Engineers," on Wednesday (October 6); Prof. Garwood, "The Origin of Scenery" (October 7); Prof. Carveth Read, "The Psychology of Character" (October 7).

MANCHESTER.—The new chemical laboratories of the University will be opened on October 4, when it is expected that the Chancellor, Viscount Morley of Blackburn, will be present and confer honorary degrees on the American Ambassador; Sir Robert Stout, Chancellor of the University of New Zealand; Sir Alfred C. Lyall; and Prof. Otto Wallach, of the University of Göttingen.

MR. JOHN FISHER has been appointed lecturer in biology at the Agricultural College at Cedara, near Maritzburg.

THE prizes and diplomas awarded at the South-eastern Agricultural College will be distributed on October 9 by Principal H. A. Miers, F.R.S.

PROF. W. OSLER, F.R.S., will take as the subject of his address before the London School of Tropical Medicine on October 26 "The Nation and the Tropics."

DR. WALTER MURRAY, of the University of Dalhousie, Halifax, according to *Science*, has been elected president of the new University of Saskatchewan, situated at Saskatoon.

SIR T. CLIFFORD ALLBUTT, K.C.B., F.R.S., will distribute the prizes and deliver an address at the opening of the winter session of Charing Cross Hospital Medical College, instead of Lord Ridley, as was announced.

ACCORDING to a Reuter message, the Czech University of Prague has conferred the honorary degree of Doctor of Philosophy upon the following men of science:—Sir Archibald Geikie, K.C.B., P.R.S., Dr. J. E. Marr, F.R.S., Dr. Francis Darwin, F.R.S., and Prof. T. W. Richards, of Harvard University

MR. WILLIAM BROWN, lecturer in electrotechnology at the Royal College of Science, Dublin, has been appointed to the professorship of physics in the college in succession to Prof. W. F. Barrett, F.R.S., who is to retire on October 1 under the Treasury regulations as to age. Mr. Brown's successor is to be Mr. Felixe Whackett, one of the junior fellows of the Royal University of Ireland.

THE following courses of free Gresham lectures are announced for delivery at the City of London School:—geometry, by Mr. W. H. Wagstaff (beginning on October 5); physic, by Dr. Sandwith (beginning on October 26); astronomy, by Mr. S. A. Saunder (beginning on November 2). This is the first term these lectures will have been delivered other than at Gresham College.

IN connection with the Child Study Society there will be a reception by the president at 90 Buckingham Palace Road on October 7, when short addresses will be delivered by Miss A. Ravenhill, Dr. C. W. Kimmins, and Dr. G. E. Shuttleworth. Succeeding lectures will be by the Right Hon. Sir John Gorst, Dr. W. C. Sullivan, and Dr. A. R. Abelson on, respectively, "The Care of Children under the Poor Law," "The Child Criminal," and "Mental Fatigue."

TWO more calendars of London colleges have reached us, those of the East London College and Birkbeck College. The East London College is a school of the University of London in the faculties of arts, science, and engineering, and a rapid development in its work took place during last session. To the equipment of the school of engineering—civil, mechanical, and electrical—valuable additions have been made, while the botanical department has been reorganised. A considerable sum of money was placed at the disposal of the college committee for these purposes by the Drapers' Company, who specially ear-marked a portion of their benefaction for the improvement of the college library, which is now well housed and possesses a good collection of works dealing with the subjects in the college curriculum. We learn from its calendar that the pressing need of Birkbeck College is for increased space; the usefulness of the college is curtailed by its limited accommodation. New and more spacious college buildings, with more class-rooms and larger laboratories better adapted to modern requirements, would give a great impetus to the work of the college, and it may be hoped, in view of the marked success of the work accomplished in the past, that it will prove possible to secure the money necessary for reorganisation.

AT the meeting of the Chicago section of the American Mathematical Society on January 2 of this year, a committee was appointed for the purpose of investigating the possibility of improving the character of mathematical appointments in colleges and universities. In the July Bulletin Prof. E. J. Wilczynski publishes the proposals submitted by him to the committee. He suggested (1) that vacancies should be announced in the Bulletin in a special column devoted to the purpose; (2) that in the case of major positions, i.e. posts of 400*l.* a year upwards, if a university should desire expert assistance in filling a post, the council should elect a nominating committee for the purpose, the names of the members being published in the Bulletin; (3) in the case of minor positions, Prof. Wilczynski does not consider that much could be done owing to the frequency of vacancies, but, at the same time, an annual standing committee might be appointed. While these suggestions only apply to America, and the report of the committee, which is on somewhat different lines, is to be published elsewhere, the idea suggests itself that reform is none the less needed in Great Britain, and that not for mathematical appointments alone. The present system of sending in printed testimonials is not only a heavy expense to the younger candidates, who can ill afford the money, but in the case of older candidates it involves a serious loss of time that would otherwise be available for research, and debars many from offering themselves for appointments.

Much interesting information as to the provision made for instruction in science and technology in the great provincial centres of population can be gleaned from the calendars and prospectuses issued at this time of the year by the colleges and institutes which have grown up since the Technical Instruction Acts came into force. Among such year-books received we notice those of Armstrong College, Newcastle-upon-Tyne, the Belfast Municipal Technical Institute, and the Bradford Technical College. While at each of these well-equipped institutions the claims of pure science as the foundation of all successful industrial practice are duly recognised, each rightly makes a special effort to suit its classes in technology to the particular manufacturing needs of the area in which it is situated. It is possible only to give a few instances. At Armstrong College there are special courses for miners, and prominence is given to naval architecture. In connection with the latter work it is noteworthy that the B.Sc. degree of the University of Durham, of which this is a constituent college, is awarded in naval architecture. In the Belfast institute day courses have been established to provide a sound training in mechanical and electrical engineering, in the science and technology of the textile industries, and in applied chemistry. Similarly in Bradford, the department of textile industries deals with every aspect of the industry, and diplomas, we observe, are awarded in preparing, combing, and spinning, in weaving and designing, and in chemistry and dyeing.

SOME months ago a committee was formed, with Dr. E. Berl, of Zürich, as secretary, which decided to present to Prof. Georg Lunge, in celebration of his seventieth birthday and the jubilee of his doctorate, a gold medal bearing his portrait, and to collect and hand over to him a sum of money—40,000 francs have already been collected—to be disposed of at his discretion. The formal presentation was made by Prof. Bosshard in the chief chemical lecture theatre of the Zürich Polytechnic on Sunday, September 19, the theatre being crowded with chemists from almost every European country. Following this ceremony congratulatory letters and addresses were delivered by the delegates, Dr. Landolt, speaking for the Swiss Society of Chemical Industry, leading the way. He was followed by Dr. R. Schmidt, director of the famous Elberfeld works, who represented the Verein deutscher Chemiker, and by Geheimrat Bunte, who brought an address from the Karlsruhe Technical College. Dr. Lepetit brought an address from the Società chimica Italiana, and Dr. F. C. Garrett spoke for the Newcastle section of the Society of Chemical Industry, the present-day representative of the Newcastle Chemical Society, of which Dr. Lunge was one of the founders. Chemists who have studied at Zürich are naturally among Prof. Lunge's most devoted admirers, and on behalf of those resident in Great Britain Dr. Richard Seligman presented an address signed by many of Lunge's old students and English friends. Dr. R. Nötzli brought congratulations from Austria, and Herr Bell spoke on behalf of those who still have the good fortune to be working at Zürich. In addition, there were numerous presentations from the various learned societies of Switzerland and Germany, whilst several hundred congratulatory telegrams, including one from the Society of Chemical Industry, were received. In an admirable speech Prof. Lunge thanked the many speakers and the societies they represented, and announced his intention of handing over the money which had been collected to the polytechnic, the interest to be used at the discretion of the professors of chemistry for the assistance of young chemists who would otherwise have difficulty in continuing their studies or investigations for a sufficiently long period.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 20.—M. Bouchard in the chair.—Multiple monochromatic images of the sun given by the large lines of the spectrum: H. **Deslandres** and L. **d'Azambuja**. A historical account of the study of the different layers of the solar atmosphere by means of monochromatic images of the dark lines. In the present paper an account is given of new work, in which the successive layers of iron, calcium, and hydrogen have been distinguished. The upper layers, the most interesting but the most difficult to isolate, have been specially studied, the large spectroheliograph with three slits, built in 1907, having been of great service in this connection.—The earthquake of June 11, 1909: Alfred **Angot**. A map is given of the district affected, showing the zones of equal disturbance.—The action of mineral waters on the striation and form of the valves of diatoms: A. **Lauby**.—The washing of cider apples with an oxidising calcium salt, leading to a pure fermentation: Henri **Alliot** and Gilbert **Gimel**. It has been shown that washing the apples with a weak solution of calcium hypochlorite is very advantageous. The preventive action of normal serum from the sheep on *Trypanosoma duttoni*: A. **Thiroux**.—Calculation of the depth of seismic hypocentres: Comas **Solá**.

THURSDAY, OCTOBER 7, 1909.

TWO BIRD BOOKS.

(1) *Birds of the World: a Popular Account.* By Dr. Frank H. Knowlton. With a chapter on the Anatomy of Birds, by Frederic A. Lucas; The whole edited by Robert Ridgway. Pp. xiii+873. (New York: Henry Holt and Company; London: Constable and Co., Ltd., 1909.) Price 30s. net.

(2) *Birds Useful and Birds Harmful.* By Otto Herman and J. A. Owen. Pp. viii+387. (Manchester: The University Press, 1909.) Price 6s. net.

(1) IT would seem that there is no satisfying the demand for books on birds. Every year places before, not the scientific ornithologist only, but the general reader, in this country, scores of volumes on this group of animals, which must indicate a ready sale for them. The taste for natural-history works has unquestionably been growing in England at a rapid rate during the last decade among all classes of the community, instigated and encouraged largely by the non-technical manner in which so many treatises of the highest scientific authority are being published for the general reader, the majority of them lavishly illustrated, as well as by the issue of so many local faunas, which give an impulse to the study of the species to be found in their own neighbourhood by those into whose hands the books fall.

Imitation is the sincerest flattery, we know. The "Birds of the World," the first of the two volumes on our list, is one of the American Nature series, projected by Holt and Company, of New York, to which the leading scientific men of America are to contribute. This volume, however, compares disadvantageously in one respect with those of the English Nature series, in handiness and comfort in reading or consulting. It is an octavo measuring $10\frac{1}{2}$ inches long by $7\frac{1}{2}$ inches wide, and nearly 3 inches thick. It contains 873 thick pages, and turns the balance at more than 4lb.; it might be termed a bi-manual, or perhaps more appropriately a table-edition. In respect to its contents, the book stands on a high pedestal of excellence.

The demand for books on birds seems to be developing in America as rapidly as it is doing in England, for the Nature series of the United States is due, as the preface assures us,

"to the great awakening of popular interest . . . in recent years in relation to our birds, an interest that has been fostered not only by the admirable work of the Audubon societies and the widespread nature teaching in the schools, but by the deeper, broader sentiment which is leading back to, and nearer to, nature. The increasing number of people yearly turning back to the country, either for recreation or permanent residence, has naturally stimulated a desire to know more intimately their surroundings—the trees, the flowers, the birds."

The three names which appear, as authors or editor, on the title-page are a sufficient guarantee that the desire of the migrant to the country to know more, not only about the birds of the United States, but of those of the globe generally, will be gratified amply, accurately, and in a manner likely to foster personal observation of those species within the reader's reach.

After an introductory chapter dealing with definitions, and such questions as pterylosis and feather structure, nests and eggs, we are presented with clearly, concisely written chapters on the anatomy of birds, their geographical distribution, migration and classification. The various subclasses and orders of birds are then dealt with in twenty-one further chapters. Dr. Knowlton recognises two subclasses—Archæornithes, with unique representation in the Archæopteryx, and Neornithes, containing all other birds, which he divides into twenty-one orders. Had space permitted, we should feel tempted to demur at the position assigned in the avian "tree" to the Hesperornithiformes and Ichthyornithiformes, and to the Palamedeæ and Opisthocomi. Taking the author's brigading as it stands, we find each of the orders discussed in a very interesting manner. The habits and life-history of all the more important species in each are described concisely, as space demanded much condensation; yet nothing essential or really important is omitted to enable the reader to obtain an excellent grasp of each group. The illustrations are very numerous, and, with a few exceptions, excellent. There are 233 black-and-white blocks, many of them full-page; of the latter, some of the best are reproductions of those beautiful life-like groups with scenic backgrounds which form one of the most attractive features of the American Museum in New York. The representation of the young hoatzins is specially instructive. Where the blocks, however, have been made from coloured plates in such works as Schlegel's "Diergaarden" or the Zoological Society of London's publications, the results have proved less satisfactory, inasmuch as the yellows and reds of the originals have come out too dark. The smaller text-figures also leave something to be desired, occasionally, in the clear definition of markings on the plumage. Of the sixteen full-page plates reproduced in the three-colour process, with which the volume is further embellished, specially noteworthy are those of the mandarin-duck, the racket-tailed kingfisher, and the lesser bird of paradise. The figure of the kiwi on p. 29 is taken, we presume, from a drawing of the type which was mounted for Lord Stanley's collection at Knowsley, before the correct attitude and habits of the apteryx were sufficiently known either to scientific men or to taxidermists. Buller's "Birds of New Zealand" would have supplied a better model.

The information contained in the "Birds of the World" is, as already remarked, nearly everywhere up to date, and very accurate; but the omission of any reference to the Phororachidæ is surprising. In regard to the moa, the bird is described as being absolutely wingless. Evidence, however, was obtained from a turbary deposit near Omaru proving that certainly one species of Dinornis possessed a humerus that functioned in its glenoid cavity on the scapulo-coracoid; and, if the writer be not mistaken, a small bone is in existence in New Zealand very similar in form to that described as belonging to the humerus of Œpyornis. The moa had probably, therefore, a diminutive wing like that of the kiwi. With regard to the question whether the Maoris ever saw the moa, it is stated on p. 81 that "it appears that the Maoris have only been in their present location for about ten generations, or some 250 or 300 years, and the moa could hardly have lived within that period, and it is held as probable that their extinction was several centuries earlier than this."

Definite evidence of the contemporaneity of the Maori and the moa was adduced some eighteen years ago, during the exploration of the Sumner Cave, near Christchurch. The mouth of this rock-shelter had been closed by a landslide before the arrival of the Europeans in the South Island, the result, probably, of an earthquake, while a meal was in progress. The occupants succeeded in escaping, but round the fireplace about which they had been sitting were found moa bones and portions of the eggs, with the shell-membrane intact, on which they had been feasting. On the floor near by lay a boat-bailer and other objects with the carving truly characteristic of the Maori upon them.

Of the three specimens of the now extinct *Dromaeus ater* discovered, and brought to Europe by the French expedition under Baudin, all have now been located, as stated in the work before us—two in Paris (a skeleton and mounted specimen), and one (a skeleton) in Florence. A fourth specimen, it might have been mentioned, is now in the Lord Derby Museum, Liverpool, and was exhibited at the International Ornithological Congress in London by the Hon. Walter Rothschild on behalf of the director of that institution. As to the black swan of Australia, it seems extremely probable that it was indigenous to New Zealand as well as to the island-continent. The bones of a species, described under the name of *Chenopis sumnerensis*, hardly differing from those of *Chenopis atrata*, were found among the débris of the disturbed meal referred to above in the Sumner Cave, as well as in an ancient kitchen-midden in the Chatham islands.

A very full index completes this very excellent, succinct, and trustworthy account of the "Birds of the World," and we hope it will, despite is bulkiness and weight, meet in the United States, and in England also, with the appreciation it fully deserves.

(2) The second volume in the list given above is of a very different character, and the reason for its publication in this country is not very apparent.

The book is a translation of portions of the valuable work prepared by the director of the Royal Hungarian Ornithological Bureau to enable landowners, farmers, fruit-growers, and gardeners in that country to discriminate their avian friends and foes, together with a somewhat well-worn account, padded with poetical quotations, by Mr. J. A. Owen, of a selection of our most common English birds, including always the statement whether the species is harmful or useful in England, which seems to be apparently the only excuse for Herr Herman's book (in part) appearing in an English garb. The English co-author believes that amongst the innumerable books on bird-life which have been published of late years "there has been a lack which this little volume may supply."

From a careful reading of the work we can really discover very little not to be found in nearly every book on British birds. It includes also a few species, common in Hungary, which rarely visit England, or are only winter visitors which can trouble the English agriculturist but little. It lacks, moreover, the details "arranged on a regular scientific basis" and "the investigations with regard to the food of birds carried on by a fully qualified entomologist" upon which Herr Herman has proved the various species of Hungary to be useful or harmful, and which would have impressed the corresponding classes of readers in England as those for whom the volume was prepared in Hungary. A more thorough work on the economic value of birds in the English language is to be found in the Bulletins of the U.S. Department of Agriculture, which contain the life-history and the detailed results of the examination of hundreds of individuals of each species, including nearly as many English ones as are given in the volume under review. "Birds Useful and Harmful" may, nevertheless, assist in spreading the knowledge of those birds, persistently persecuted, that deserve protection. F.

A GROUP OF "FLORAS."

(1) *A Tourist's Flora of the West of Ireland.* By R. L. Praeger. Pp. xii+243; with 5 coloured maps, 27 plates, and 17 figures. (Dublin: Hodges, Figgis and Co., Ltd., 1909.) Price 3*s.* 6*d.* net.

(2) *Illustrated Guide to the Trees and Flowers of England and Wales.* By H. G. Jameson. Pp. xi+136. (London: Simpkin, Marshall and Co., Ltd., 1909.) Price 2*s.* 6*d.* net.

(3) *Flora Koreana. Pars Prima.* By T. Makai. (Journal of the College of Science, Imperial University of Tokyo, Japan, vol. xxvi., article i., 1909.)

(4) *The Botany of Worcestershire. An Account of the Flowering Plants, Ferns, Mosses, Hepatics, Lichens, Fungi, and Fresh-water Algae, which grow or have grown spontaneously in the County of Worcester.* By J. Amphlett and Carleton Rea. Pp. xxxiii+654. (Birmingham: Cornish Bros., Ltd., 1909.) Price 25*s.* net.

(1) MR. R. L. PRAEGER'S book is a solid contribution to the subject of phytogeography, and is increased in value by the many beautiful, mostly full-page, photographs of striking species of plants, some of which appear for the first time, as here illustrated. Coloured and uncoloured maps of the districts described or of the distribution of species add to the usefulness of the book, which is well indexed and singularly free from typographical errors. The introduction contains a short account of the physical features of the west of Ireland, of its, mainly edaphic, plant formations, and of the more remarkable features of its flora. The topographical section which follows contains valuable information on the character of the flora of the numerous regions selected for description. This section will appeal to the touring botanist, more especially as the information given is not purely botanical. The author might have expanded this section, with advan-

tage to the inquiring tourist to whom the west is unknown.

The systematic section forms half the book, and follows mainly the classification and nomenclature of the London catalogue. *Pilularia globulifera* is wrongly placed in the Selaginellaceæ. The distribution of each species is recorded, and in many cases it is due to the work of the author that the distribution is now known to be so extensive. First records are duly credited to the discoverers, and many interesting observations are embodied in the text. The Saxifrages and the heaths, *e.g.*, are adequately treated. The book can be well recommended for the sake of its illustrations, and would be worth purchase if it had none. It does justice to the delightful botanical and other attractive features of the west, and is a credit to author and publisher.

(2) The avowed object of the writer of this book is to enable readers, knowing little of botany, by its use to give names to the plants they find, the name being, the writer insists, the first essential. This idea is not at all in keeping with recent views on nature-study. Still, every student of botany should learn to name a plant by the help of a "flora." Teachers know how students, even with the keys in our best floras, fail from time to time to name a plant. In the book under review all flowering plants are divided into ten sections. One section—flowers in heads or umbels—includes the Papilionaceæ. In another section—flower parts in threes or sixes—Rumex occurs between Triglochin and Luzula. The section devoted to aquatic plants will prove useful. Monocotyledons and Dicotyledons are not differentiated. Ruscus is said to have "phyllodes" as leaves. This is one of the few cases in which botanical terms are introduced.

The second part of the book is devoted to a selected number of natural orders, and more especially to the means of identification of the species of different genera, arranged alphabetically. This is the most useful part of the book. The illustrations, though small, are generally good. Misprints are few. There is, however, no index. The book is cheap, and will prove serviceable to the reader who already knows his natural orders fairly well.

(3) Mr. Makai's work is indicative of the line followed by Japan on the absorption of a new province into its empire. Korea was quite recently annexed, and so early as 1906 Makai began his study of its flora. The systematist of Japan is to-day doing as the British systematists did at the time England first acquired and explored her colonies.

This first part of the "Flora Koreana" deals with the Polypetalæ and certain Gamopetalæ, and is well illustrated by fifteen plates (one or two of which are rather crowded) of plants mostly new to science. Though printer's errors are numerous and generally indicated in a list of *errata*, the volume is produced in a form in keeping with the high standard of the other publications of the College of Science of Tokyo. The keys to the genera, and, under each genus, to its species, are useful. Under each species its bibliography, habitat, distribution, and Japanese name are given. New species and varieties are described in Latin, and usually illustrated. The index is inadequate. It is necessary to search the body of the work for the novelties, and there is no general index to the contents of the plates. It is impossible to discuss the contents of the volume in detail. One illustration must suffice for comparison with our flora. The beautiful genus Acer is represented by fifteen species or varieties. Trifolium by one species only.

(4) This work deals in a comprehensive manner with the flowering and flowerless plants of the county of Worcester. In an introduction of twenty pages justice is done to earlier publications, Lees and Mathews being specially noted. The authors follow the London Catalogue in the names of the species, adding useful synonyms. First records are duly credited, and valuable specific distinctions are occasionally added. Some of the notes, now and then amusing, are often loosely worded, and might sometimes have been omitted with advantage. The mosses and liverworts are listed by J. E. Bagnall, and the fungi by C. Rea, both authorities on their groups. It is a little disconcerting to find *Protonema muscicola*, Ag., recorded as a fresh-water alga (crowding about the bases of moss-stems)! Throughout the book derivatives of the Latin names are given. A map showing the botanical areas of the county is an excellent feature. The book is a distinct advance on previous publications on Worcestershire botany, and should stimulate interest in field botany in the county. The price is high for a county flora, but local patriotism will probably rise to the occasion. T. J.

GEOLOGY OF NEW YORK CITY.

Geology of the City of New York. By L. P. Gratacap. Pp. x+232; with 65 figures and 4 maps. Third edition, enlarged. (New York: Henry Holt and Co., 1909.)

THIS general treatise on the underlying structure of the city of New York and its immediate surroundings appears to be the amplification of a shorter work on the same subject, printed privately for the author. Its outlook is local, and, as the interpolated "Class Directions" indicate, it is intended primarily for use in the instruction of the inhabitants of the great city. It is compiled from various sources, which are duly acknowledged, and contains, besides, some original observations, but these are not sufficiently important or numerous to appeal to the wider circle of geologists who have no particular interest in the locality. In many passages it emphasises the transformation wrought by man on the original aspect of the country, in deference, no doubt, to the naïve astonishment with which the average town-dweller receives such information.

New York is one of the few great cities founded upon crystalline schists. Some of the problems of the schists and their entangled igneous intrusions are touched upon by the author, but his grasp is hardly adequate for their unravelling. As in almost every similar region, diverse views are held respecting the age of the different members of the schistose series.

They are supposed by the official geologists of the U.S. Survey and others to include large masses of altered Palæozoic sediments, while the author supports the alternative opinion that most of these rocks are Pre-Cambrian. The Triassic rocks of the western side of the Hudson River, with their intrusive diabase which forms the picturesque Palisades, and the sparingly exposed Cretaceous strata of Staten Island are the only other "solid" formations known in the neighbourhood of New York.

The drift deposits and their associated phenomena, everywhere conspicuous, afford the subject for the final chapter of the book, which the author presents in a strain calculated to impress the uninitiated.

The arrangement of the book is somewhat confusing to the outsider, being based on the municipal divisions of the city. The style of writing is often turgid, over-ornamented, and not particularly accurate. A region is described as of "pene-Saharal loneliness"; there have been "loculicidal slippings" in the gneiss (the botanical adjective looking quite aggressive here); the drifts "tell the singular story which the long, tireless and infinite retinue of glacialists has been engaged in translating these long years"; and so on. Misprints are numerous, even in the preface "carefully" appearing as "carfully"; the so-called "bibliographies" contain few proper references; and there is no index to the volume.

In some appended notes on the archæology of Manhattan Island, some relics of the British army engaged in the Revolution are mentioned; and, considering the recency of the period, it seems curious to read that "the habits and life of the soldiery have been traced by the remains of their food, utensils, pikes, cutlery."

G. W. L.

THE LAWS OF INHERITANCE.

Elemente der exakten Erblichkeitslehre. Deutsche wesentlich Erweiterte Ausgabe in Fünfundzwanzig Vorlesungen. By W. Johannsen. Pp. vi+516. (Jena: Gustav Fischer, 1909.) Price 9 marks.

WITHIN the last few years the output of exact experimental work upon phenomena of heredity has been very large, and the progress made, as compared with that of the previous forty years, has been astounding. In England it has chiefly been produced by investigators who have strictly segregated themselves either to the Mendelian or the biometrical schools, and who as a rule seem unable to realise the merits of the work of their rivals. One may pause in astonishment on reading, in a recent work issued by the head of the Mendelian school, that

"Of the so-called investigations of heredity pursued by extensions of Galton's non-analytical method and promoted by Prof. Pearson and the English biometrical school it is now scarcely necessary to speak. That such work may ultimately contribute to the development of statistical theory cannot be denied, but as applied to the problems of heredity the effort has resulted only in the concealment of that order which it was ostensibly undertaken to reveal. . . . With the discovery of segregation, it became obvious that methods dispensing with individual analysis of the material are useless."

Most biologists, with no axes to grind, are able to appreciate the importance of the work of both schools, though at present it is scarcely possible for them to judge whether the work of the one is destined to be of more permanent value than that of the other. The mutually destructive criticism of the two, though not without value in stimulating healthy competition, has the unfortunate result that the biologist who is wedded to neither school finds it difficult to lay his hands upon an adequate but impartial description of their methods and results. To such we can cordially recommend the work on inheritance, by Prof. Johannsen, now before us. The Danish edition of this book was published in 1905, but the present edition is double the size of the original, and is practically a new work. It consists of twenty-five lectures, in the first eight of which the facts of variation and its statistical study are discussed. The author then describes at some length his own very interesting experiments upon a "pure line" of self-fertilised beans (Phaseolus), which he bred for six generations. He found that selection within such a pure line did not lead to departure from the type, *i.e.* beans grown from a small bean were exactly the same size as those grown from a large bean of the same plant. He designates these non-heritable variations in size as "fluctuations." These results have coloured the author's outlook upon problems of segregation, mutation, and selection, and before accepting his interpretation the criticism of his experimental results by Prof. Pearson and the late Prof. Weldon should be studied ("Biometrika," ii., p. 499).

In subsequent lectures the author discusses discontinuous variation, correlation, regression, and the effects of conditions of life, and then passes on to describe Mendel's law and de Vries's theory of mutation. Darwin's principle of natural selection acting continuously upon small, indefinite variations finds but small favour in his eyes, and he attributes the origin of species to the appearance of mutations and the production of new races by crossing, the new characters being propagated unchanged in accordance with Mendel's law. Selection produces nothing, but extirpates unfavourable mutations, and so leaves room for new and favourable ones. However, the author makes no attempt to explain how mutations, in spite of their extreme rarity, have been able to effect so much. Hence, as is only to be expected, these views on heredity, though worthy of full consideration, must be studied in a critical spirit.

H. M. Vernon.

OUR BOOK SHELF.

A Sketch of the Geography and Geology of the Himalaya Mountains and Tibet. By Col. S. G. Burrard, R.E., F.R.S., and H. H. Hayden. Part iv. The Geology of the Himalaya. (Calcutta: Government Printing Office, 1908.) Price 2 rupees.

The fourth part of the sketch of the geography and geology of the Himalayas is entirely the work of Mr. H. H. Hayden, and is devoted to a review of the present state of our knowledge of the Himalayas. This knowledge is fragmentary; of the Himalayas east of Sikkim only a few small patches, and these close to the southern margin, have been visited, then comes the independent State of Nepal, of which nothing at all is known, and it is only in the British territory and the native States under British control at the north-western extremity of the range that the geology is known, even approximately There is, consequently, a tendency to extend the knowledge of this region to the rest of the range, and to draw conclusions which are only doubtfully applicable.

This tendency has not altogether been avoided, and the lengthy discussion of the age of the unfossiliferous sedimentary rocks of the Simla region seems to give this subject an importance which it does not possess, especially as, in the end, it is left in a state of little less uncertainty than before. The only clue to the age of these rocks is the fact that they contain a series of beds, the Blaini, which is generally acknowledged to present unmistakable signs of glacial origin. At one time this series was regarded as of Permian age, but this explanation is rejected, and the Blaini series is correlated with the pre-Cambrian glaciation which has been studied and described in Africa, China, Australia, and, we may add, in Norway. Mr. Hayden argues with great plausibility that the complete absence of any trace of fossils in a great thickness of rocks, which might well be expected to contain them, and their abundance in the great series of deposits on the other side of the snowy range, is more reasonably explained by a difference in age than in conditions of deposition. This reasoning we may accept, and acknowledge that the Blaini tillites are more probably pre-Cambrian than Permian in age, but the possibility that the rocks of the Simla area are a flysch facies of the fossiliferous sediments of Spiti must be borne in mind, and, until less equivocal evidence is adduced, the problem must remain unsolved.

With this exception the work is a well-balanced summary of the geology of the Himalayas, useful to those who wish to have the leading facts put briefly and clearly, and also, by the copious references to original authorities, invaluable as a guide to more detailed study.

Elementary Physiology for Teachers and Others. By W. B. Drummond. Pp. viii+198; illustrated. (London: Edward Arnold, 1909.) Price 2*s.* 6*d.*

THIS is a useful little book of its kind, elementary, as its title implies, and correct in its details, an element so often lacking in similar works. Like other books of its class, it necessarily contains a good deal of what is anatomy rather than physiology, and it chiefly differs from its competitors in pointing out the applications of physiology in the health, well-being, and training of children. This is by no means an unimportant point, seeing that the work is written for school teachers.

W. D. H.

Evolution: A General Sketch from Nebula to Man. By Joseph McCabe. Pp. vii+128. (London: Milner and Company, Ltd., n.d.) Price 1*s.* net.

THE author of this little book defines his aim as being "chiefly to present a panoramic view of the development of the world—especially the world that lies close about us—by a conscientious use of the results of many sciences, and aided by a personal acquaintance during many years with both telescope and microscope." The style is interesting, and the slight sketch provided may send a few general readers to first-hand authorities for further information. The language is not always precise; for instance, we find "refractory liquid fire," "a lowering of climate," and so on; but on the whole the volume may serve a useful purpose by introducing non-scientific readers to some problems of inorganic and organic evolution.

Magnetic Storms and Solar Eruptions.

REFERRING back to the *Electrician* of nine years ago (December 7, 1900), I find that, following up a suggestion of G. F. FitzGerald made in 1893, I promulgated a view of major magnetic storms which events have confirmed. See, for instance, Mr. Maunder's paper in Mon. Not. R.A.S. for 1904, vol. lxv., p. 33.

What I have to point out is that a stream or beam of electrons ejected from the sun and passing near or over the earth would cause magnetic perturbations of the kind required—positive as it approached, zero as it passed over, negative as it receded; with many minor disturbances superposed due to variations of density, as well as others due to the effect of particles caught by the atmosphere.

Such a beam or stream of electrified particles is essentially a magnetic cyclone, and the changes in magnetic force as it travels past any locality bear a fairly close analogy with the changes in wind-velocity during the passage of an atmospheric cyclone.

The relative speed of such a solar beam, as it overtakes the earth, follows from the sun's angular velocity, and is 210 miles a second.

Earth currents would, in the main, be induced as it approached and checked as it receded.

The rotation of the earth in the magnetic field of such a stream is too slow to be effective: though locally in the neighbourhood of six o'clock an intense ray of the main beam might generate east and west currents.

Now magnetic disturbances recorded during the recent storm, and quoted by Dr. Chree in the *Times* and elsewhere, indicate a declination deflection of $1\frac{1}{2}$ degrees, followed by a reversed deflection of the same amount—all within a quarter of an hour.

This means—on the above theory—that the main beam took this time to traverse the place, so that the breadth of the beam was comparable to twenty times the earth's diameter. No doubt it is diffused, at this distance from the sun, by internal repulsion of the particles.

The intensity of field which would give the above deflection is approximately one-fortieth of that of the earth's horizontal intensity, or, say, 0·004 C.G.S., as the order of magnitude.

Taking these data, together with the known charge and velocity of electrons in kathode rays—say $e=10^{-20}$ electromagnetic C.G.S. units, $u=10^9$ centimetres per second—let us reckon the closeness of the crowd of particles in the beam necessary to account for the observed force.

The magnetic intensity at any place, distant r from the axis of a linear stream of sectional radius a and current density γ, is given by the following expressions:—

$$H=\frac{2C}{r}$$

$$C=\pi a^2\gamma$$

$$\gamma=n_1eu,$$

where n_1 is the number of particles per cubic centimetre of the stream.

This gives

$$n_1=\frac{rH}{2\pi a^2eu},$$

so taking a place just grazed by the beam, so that $r=a=20\times 2/\pi\times 10^9$, and putting in the other data just cited, we get

$$n_1=\frac{0·004}{80\times 10^9\times 10^{-11}}$$

$$=0·005 \text{ per c.c.},$$

or, say, five electrons per litre, on the average, all through the beam. I regard this as a modest and not unlikely estimate of crowdedness. The amount of matter ejected from the sun in this beam is insignificant, being less than a couple of tons per week.

The total current equivalent of such a beam is six hundred thousand amperes—which again is rather surprisingly moderate, and leaves plenty of margin for under-estimate of disturbance and for local perturbations too great for the instruments.

I send this little calculation because some doubt has been expressed as to whether the magnetic effect of a solar stream would be adequate to explain observed facts. It appears to me in general outline to be ample, both in amount and kind.

OLIVER LODGE.

University of Birmingham, October 4.

The Magnetic Storm.

Some details of the magnetic variations during a period including the great magnetic storm of September 25 may be of interest to the readers of NATURE.

From the beginning of the month the magnets were comparatively quiet, disturbed from a state of calm only by small oscillations, increasing somewhat on September 7, 8, and 15 until September 21, when a greater disturbance was recorded between noon and midnight. This was followed by an approximate calm until 8.30 a.m. of September 25, when the coming storm was foreshadowed by a sudden small dip in the curves of the declination and horizontal-force magnets, and a slower fall of vertical-force curve, indicating an eastward movement in declination and a diminution of the two components of force. The preliminary oscillations thus started remained small, averaging about 10′ of arc on both the declination and horizontal-force curves until some time between 11.40 a.m. and noon, whilst the films were being changed. It is, therefore, not clear on which side of the film the spot of light was carried away by the first great deflection; but in declination it remained off the paper until 11.40 a.m., when it was found returning from the east, while the horizontal force had already recovered, and, together with the vertical force, was showing a rapidly increasing intensity.

The general deflection in declination was westward throughout the storm, with many rapid moves off the film, and only two violent throws to the east, one at the commencement and the other at the end of the storm, the latter being a swing across the film from the extreme west edge over the east edge in less than two minutes of time, covering more than $2\frac{3}{4}$ degrees. An equally great and rapid movement on the horizontal-force curve took place at the same time near the close of the storm, with increase of the component force, and the vertical-force balance finally heeled over through loss of force.

The storm seems to have been at its height between 3.30 and 5.30 p.m., when the light spots of all three instruments were, for the most part, off the papers, and ended at 8.30 p.m. It was followed by smaller rapid oscillations of the declination and horizontal-force needles until midnight, when the small after-tremors commenced, and continued until about 6 p.m. of September 27.

The seismologist cannot fail to see in these three phases of oscillation an imitation of the pendular swings produced by a distant earthquake, and the preliminary movements are undoubtedly of the first interest to the student of terrestrial magnetism. The suggestion is very pointed that, whatever be the cause of the magnetic storm, it must be something arriving in our neighbourhood, whether directly from the sun or circulating round it, of which a part travels quicker and has less effect than the slower moving particles which produce the great oscillations; but we are in no position to meet the difficulties which beset any definite supposition as to the nature of these particles, and defend it against the apparent contradictions which assail it.

WALTER SIDGREAVES.

Declination Magnetogram, Stonyhurst College Observatory, September 25, 1909.

THE MEETING OF THE INTERNATIONAL GEODETIC ASSOCIATION IN LONDON AND CAMBRIDGE.

THE meeting which began in London on Tuesday, September 21, and ended in Cambridge on September 30, has been notable in several respects. Great Britain joined the International Geodetic Association only twelve years ago. The triennial meeting has been held this year for the first time in England, and for the first time Greater Britain has been represented by special delegates from the Governments of India, Australia, and Canada; Chili has become a member of the association and sent a representative; and the Egyptian Government has been represented by one of the British officers of the Survey Department. The London meeting marks, then, a broadening of the interests of the association on the political and administrative side; on the scientific side it has been remarkable for the extremely interesting reports upon the special problems of the internal constitution of the earth and the lunar earth-tides.

About fifty delegates, from twenty nations, were appointed to represent their respective Governments, and came to the congress, which held its London meetings in the handsome apartments of the Institution of Civil Engineers, kindly placed at the disposal of the British representative. A large part of the business of the association consists in the reception and adoption of general reports of a highly condensed and technical character, impossible to summarise.

We believe that we shall do better to give an account of the principal discussions only, rather than to attempt to mention the name of every report and its author.

On Tuesday morning, September 21, the chair was taken by Mr. Haldane, Secretary of State for War, who warmly welcomed the association to England on behalf of the British Government. Sir George Darwin, vice-president, welcomed the delegates in the name of the Royal Society, in the absence of Sir Archibald Geikie, prevented by an accident from being present. General Bassot (president of the association) then took the chair and delivered his address; the permanent secretary (Prof. H. G. van de Sande Bakhuyzen) presented his report, and much business of a formal character was taken.

On the Wednesday morning the first business of importance was Prof. Hecker's account of his determination of the lunar earth-tides. Nearly thirty years ago Sir George Darwin and Mr. Horace Darwin tried to observe the lunar earth-tide in the Cavendish Laboratory at Cambridge, but the effect was masked by much larger deviations due to temperature. Prof. Hecker states that the effect of the solar heat was diminished 85 per cent. when his apparatus was transferred from the cellars of the Geodetic Institute to a chamber in a well shaft 25 metres below the surface. Here, in 1902 December, he installed his horizontal pendulums, and observed, with two small interruptions, until 1909 May. Analysis of the resulting curves shows an undoubted periodicity in half a lunar day, and a comparison of the observed with the easily calculated theoretical curve gives the following results:—The yielding is a little larger than would occur if the earth were a ball of steel, and about half the theoretical amount for a perfect fluid; there is little lag, so that the internal friction caused by deformation of the earth must be insignificant; the ratio between the major and minor axes of the elliptical curve does not agree with theory; this is probably not caused by local irregularity, but is, perhaps, due to the position of Potsdam near the western edge of the European-Asiatic continent; an investigation, whether the shape of the surface of the earth is changed by change of barometric pressure, gave inconclusive results. Prof. Hecker concluded that the outstanding questions could be settled only by observations at a number of stations, and he asked the association to stand godfather to these investigations.

In discussion, Sir George Darwin said that the association had in the past devoted much of its funds to the study of the variation of latitude; we may feel quite sure that Newcomb was right in regarding the prolongation of Euler's nutation period as due to the elastic yielding of the earth's mass; and he regarded Hecker's work, therefore, as a second chapter in the variation of latitude investigations. He accepted as worthy of consideration Prof. Hecker's explanation of the remarkable absence of symmetry in the path of the vertical, but suggested an alternative possibility. The curve was much compressed in the N.–S. direction, showing that the earth has much greater rigidity E.–W. than N.–S. It is possible to explain this to some extent by the earth's rotation. Lord Kelvin introduced the idea of gyroscopic rigidity, that is, of greater rigidity E.–W. due to rotation. Whether this is a sufficient explanation cannot be said, because no one has succeeded in solving completely the gravitational problem of a rotating elastic globe. Prof. Hecker's examination of the barometric effect had proved abortive; but he had been pleased to receive lately a letter from Mr. Napier Denison, of the Canadian Meteorological Service, who has succeeded in showing that on the Pacific coast, when the high-pressure system moves towards Alaska, the mean position of the vertical shifts in the same direction.

Dr. Backlund (Russia) suggested that in this matter the International Seismological Association might cooperate with the Geodetic Association in providing funds.

A commission to report on the subject was appointed as follows:—Dr. Backlund (Russia); Sir George Darwin (Great Britain); Baron Eötvös (Hungary); Profs. Haid, Hecker, and Helmert (Germany); M. Poincaré (France); and Prof. Weiss (Austria).

On the Thursday morning Sir David Gill presented his report on the progress of the great African arc of meridian. The British portion has been carried nearly to Tanganyika from the south, and a small section has just recently been measured on the Uganda-Congo frontier. The intervening section belongs to Germany. He understood that Prof. Helmert had already taken active steps to ask for money, and was sorry that for the moment the German Treasury had not responded with its usual alacrity. He could only hope that the little piece just completed to the north will act as a hook to which they will duly rise and be caught in the net of triangulation. We must now think of carrying the arc forward to Egypt, and from Egypt to join Struve's great arc which terminates on the Danube. Captain Lyons had travelled over most of the line in Africa, and Sir David Gill had his authority to say that the completion was only a question of money. There are no real geographical difficulties. Much has been made of the sudd, but this occupies only the valleys, and there are hills on each side. He believed, also, that it is possible to find, away from the river, a line more practicable and closer to the 30th meridian. To complete the whole from Uganda to the Danube would cost about 100,000*l.* He wished the association to adopt a resolution expressive of the importance of the work, and hoped that in time the Governments concerned, helped by private munificence, might be able to provide the money.

Colonel Close (General Staff) said that when it became necessary to send a party to survey the disputed territory on the Congo-Uganda boundary, the Colonial Survey Committee gladly took advantage of the occasion to measure a section of the arc of meridian. The British Government asked the Government of the Congo to approve and cooperate, and the latter appointed a commissioner, who observed all the latitudes. The Royal Society, the Royal Astronomical and Geographical Societies, and the British Association had contributed part of the funds. The whole was an admirable example of cooperation between governments and learned societies.

On the Saturday morning, Prof. Baron Eötvös presented a very encouraging report on the results of his three years' work with his torsion balance. In 1906 he had described the plan of this remarkable apparatus, which gives a rapid means of determining abnormalities in the direction and intensity of gravity. In response to a recommendation of the association, the Hungarian Government placed an annual sum of 60,000 crowns at the disposal of Baron Eötvös, who has been enabled thereby to make many improvements in his apparatus, and to complete a gravity survey over 400 square kilometres in the great plain of Hungary. Simultaneous observations with the torsion balance and with half-second pendulums of the standard Potsdam type, combined with determinations of the deviation of the vertical from astronomical and geodetic latitudes, resulted in a complete accordance, and established the accuracy as well as the extreme handiness of the torsion balance. Baron Eötvös' words give a graphic picture of the operations:—"M. Ch. Oltay followed the traces of the torsion balance and determined by means of his pendulums the differences in gravity between five stations. This voyage into the unknown, far from mountains and from all other irregularity in the distribution of [surface] masses, had a peculiar charm. As we marched over a quite uniform plain, our instruments continually revealed to us something that was hidden below, and we could always direct our steps so as to follow or to cross a series of masses, and in this fashion know them better and better." A bye-product of this work illustrates its remarkable delicacy. Newton had shown that the gravitational attraction upon units of mass of different substances is the same within one part in a thousand; Bessel reduced the limits of possible difference to one in sixty thousand. Baron Eötvös, with his torsion balance, has reduced them to one in a hundred million, and thus set at rest the disturbing doubt whether geodesists might not have to consider more than one geoid.

We have left little space for the other topics that came before the congress. Colonel Bourgeois' report on base measurements revealed a mistrust of invar wires which was not generally shared; the resulting discussion, however, revealed some difference of opinion as to the necessity of standardising these wires in the field, and as to the respective merits of wires and tapes; it was decided to publish an interim report on the subject as soon as possible. Mr. King, Dominion Astronomer, made the gratifying announcement that his Government had authorised the establishment of primary triangulation in Canada upon a strictly geodetic basis. Colonel Burrard, representing India, described the measures which had been taken to discover whether geologists are right in supposing that the Himalayas and Tibet are moving southward and crumpling up the Siwalik range from the alluvial plain. Mr. Keeling described the geodetic operations in Egypt, resumed two years ago by the Government of H.H. the Khedive, "after a regrettable interruption of twenty centuries." Dr. Backlund and Dr. Carlheim-Gyllensköld gave a further account of the geodetic operations in Spitsbergen. Colonel Bourgeois described the re-measurement by the French Academy of the historical "arc of Peru." Prof. Hecker reported on his determinations of gravity over the Black Sea, on a vessel put at his disposal by the Russian Government. There is a somewhat remarkable circumstance connected with these investigations. On his earlier voyages he omitted to take account of the alteration in gravity produced by the E.-W. motion of the ship. Baron Eötvös pointed out the omission, and Prof. Helmert showed from Hecker's observations that the correction appeared to make otherwise concordant observations discordant; hence, he said, the theory appears to be incomplete. Prof. Hecker finds, however, from his Black Sea observations that the correction in question is certainly required. It remains to be explained why the former observations were accordant without it. Prof. Helmert has undertaken that the whole shall be re-reduced.

The somewhat severe and technical labours of the congress were relieved by pleasant social functions, which were, however, kept strictly within bounds, and not allowed to become the burden which the festive side of a congress is too apt to be. On September 22, Sir George Darwin, representing the British Government, gave an official dinner to the principal delegates. On September 23, the president of the Royal Geographical Society took the whole party to Greenwich by water for a visit to the Royal Observatory and the Royal Naval College. On September 24, the Treasurer of the Royal Astronomical Society and Mrs. Hills were "At Home" at 32 Prince's Gardens. On September 25, the delegates and their ladies visited Windsor, on the gracious invitation of the King. On September 26 many of them visited the National Physical Laboratory.

On Monday, September 27, the congress moved to Cambridge, where those unaccompanied by ladies enjoyed the hospitality of Trinity, St. John's, and Caius Colleges, and many others received private hospitality. On September 28, Sir Robert and Lady Ball were "At Home" at the Observatory in the afternoon, and Sir George and Lady Darwin gave an evening party in St. John's College. The final meeting was held on Wednesday, September 29, and in the evening the visitors entertained their Cambridge hosts to dinner. Thus ended an exceedingly valuable, successful, and pleasant meeting.

THE ADMINISTRATION OF AGRICULTURAL EDUCATION.

A MEMORANDUM has just been issued setting out the arrangements which have been made between the Board of Agriculture and the Board of Education in regard to agricultural education. It has been known for some time that a certain amount of controversy existed between the two departments on account of the anomaly arising from the fact that the Board of Agriculture inspected and gave grants to the various agricultural colleges and other institutions for higher agricultural education, whereas agricultural instruction in secondary and primary schools, like all other forms of education, was controlled by the Board of Education. On the one hand it was felt that agricultural education could not thus be dissociated from the general system of the country; on the other hand, there was the danger that so special, and in many respects so weakly supported, a subject would never receive the attention it deserved without the fostering care of its own special department. The situation became more critical as it appeared that the Board of Agriculture, however anxious to retain its connection with the colleges, was unable to obtain the funds either to make adequate grants to existing institutions or to promote the creation of fresh colleges where they were needed. The two Boards appear now to have arrived at a compromise which still leaves the higher educational institutions under the charge of the Board of Agriculture, but also secures an interchange of views by the creation of an inter-departmental committee. The Board of Agriculture is to take charge of advanced schools of agriculture serving, as a rule, more than one local education authority's area, and taking students of an age of seventeen and upwards; under its charge also will be such special institutions as deal only with one branch of agricultural instruction, as dairying, forestry, &c. As before, the Board of Education will be in charge of the agricultural instruction that is provided by the county councils and other local educational authorities, but it is not clear by which board, or in what way, pressure can be brought to bear upon the backward counties that are now doing nothing for organised agricultural education. For example, the East Sussex County Council uses part of its "whisky money" to maintain an agricultural college, which is further assisted by grants from the Board of Agriculture; the West Sussex County Council next door puts the whisky money to the relief of rates, and does nothing for agricultural education. The defect in the Board of Agriculture's administration has been the fact that it has been powerless in such cases; it could neither compel nor bribe such counties to do their duty, and what the public interested in such matters is anxious to know is how the new arrangement will be worked to ensure a provision of higher agricultural education for farmers in all parts of the country, a national system that is not dependent on the caprice or the poverty of any county council.

The novel feature in the memorandum besides the Inter-Departmental Committee is a proposal to create a Rural Education Conference, consisting of representatives of the County Councils' Association, the Agricultural Education Association, and other agricultural organisations, with certain officers of the two Boards. Such a consultative committee seems to smack of the Board of Agriculture's favourite attitude of asking the farmers what it can do for them, but perhaps the influence of the Board of Education, which takes a less humble view of its own expert qualifications and powers to give a lead, will supply the stiffening and find a means of translating the suggestions of the conference into practice.

SCIENCE TEACHING IN GERMAN SCHOOLS.

THE habit of self-depreciation, or at any rate the latest manifestation of it, which is now so prominent a feature of our national life, can be traced to its beginning in a general dissatisfaction with our system of education. At a time when there was no misgiving as to the superiority of our navy, when our commercial supremacy was still unchallenged, and when no foreigner dared to be our rival in the world of sport, it was nevertheless felt that in the science of education we had much to learn from abroad. If our secondary schools, especially the great "public schools," were allowed to have been successful in the formation of character, yet the intellectual equipment of those who passed through them was, and still is, held by many to be miserably inadequate. Germany, on the other hand, is regarded as the land, *par excellence*, where not only the schoolmaster knows and does his business, but where a parental Government has elaborated an almost ideal system of mental training. It is interesting, therefore, to hear that in one important province of school work—the teaching of natural science—there is another side to the picture.

Dr. Erich Leick[1] finds it necessary to bring before the minds of the German public certain points that with us for some years have been received as axiomatic, and are no longer discussed. In England we believe and act on the doctrine that no scheme of education, even for the children of well-to-do classes, should omit all reference to the living world of nature. It is, moreover, generally agreed that courses of practical lessons where common objects are studied by each pupil form the best means whereby the power of observation, clearness of expression, and the inductive methods of science can best be acquired, let alone a general interest and love for living things. Yet in Germany up till now, so we learn from Dr. Leick, natural-history lessons, if given at all in the secondary schools, have been of the old didactic kind, in which the teacher lectures almost entirely for one, or at most two, school hours in the week, and practical work is conspicuous for its absence. This seems to hold good for other branches of science, especially in the classical gymnasia, where, as Dr. Hoppe[2] tells us, practical work in physics is not insisted on, and is done only by "Freiwillige." His pamphlet, in fact, is written to show that some boys will do laboratory work out of school if allowed, and he gives hints as to the best exercises for such volunteers.

[1] "Die biologischen Schülerübungen." By Erich Leick. (Leipzig: Quelle and Meyer, 1909.)

[2] "Freiwillige Schülerübungen in Physik in humanistischen Gymnasien." By Prof. Dr. Edmund Hoppe. (Leipzig: Quelle and Meyer, 1909.)

It need scarcely be said that thoughtful teachers in Germany are dissatisfied with this state of things, and it is gratifying to read in Dr. Leick's account that the example of England is gradually affecting German science teaching. In fact, anyone who has read Mr. O. H. Latter's article on the teaching of science in secondary schools, recently published as an educational pamphlet by the Board of Education (see NATURE, August 12, p. 192), may well rub his eyes with astonishment at the antiquated systems still prevailing in many of the German Gymnasien and Realgymnasien compared to those of our own schools. Is it too much to hope that our improved methods of teaching may bring forth fruit in the next generation, and do much to remove the reproach we are constantly hurling at ourselves that we are an unscientific nation?

The limits of this notice forbid a discussion of either of these interesting pamphlets. Suffice it to say that Dr. Leick, after a review of the gradual introduction of inductive methods into the study of natural science, describes the ups and downs that biological teaching has met with in Germany, and acknowledges the part played by the authorities of Hamburg and Bremen in insisting on natural history being taught in their schools. He shows clearly enough the kind of mental training that biology alone can give, although he is no revolutionary who would sweep away humane letters out of the field. Especially noteworthy is his tactful reference to the problem of sex, how it can best be dealt with by natural-history lessons in the hands of a sympathetic teacher. Doubtless the details of his scheme invite criticism, especially the use of the compound microscope by young pupils, but they offer food for thought to all who have to teach his subjects.

Dr. Hoppe's little work may be well offered to those classical masters in our public schools, if such there be, who still believe, like Darwin's headmaster, that natural science is a waste of time, and have forgotten in their zeal for grammar the true spirit of inquiry of the ancient Greeks. Teachers of practical physics may gain some useful hints from his list of exercises.

But, as has already been suggested, the chief interest to British teachers in these pamphlets lies in the fact that they give us glimpses of what we should not have suspected in so scientific a country as Germany. They confirm the present writer's impression after hearing a science lesson in a German Realschule, that the boys were standing aside and watching rather than taking off their coats and joining in the work themselves.

M. D. H

ANTON DOHRN.

THE whole biological world will feel a pang of grief at the news of the death of Anton Dohrn, the founder and director of the Zoological Station of Naples. It is true that he had accomplished the great work which he set himself forty years ago, and had seen the projects and dreams of his youth fully realised—and more than realised. I met Dohrn first in 1870 at Liverpool, when Huxley was president of the British Association, and in May and June of the next year went, after a winter spent in Leipzig, to join him at Jena, where he was a "privat-docent" in zoology. He was then thirty years of age, and had done some excellent embryological work on the Crustacea, in furtherance of which he had passed some months at Naples and Messina. His father, with whom I later spent some weeks at Naples, was a very remarkable man, one of the iron-willed, somewhat grim type of North Germans, a handsome old gentleman, known throughout Europe as a great collector of Coleoptera, a hobby which brought him into close personal friendship with similar enthusiasts in Italy, Spain, England, and France, whom he visited from time to time. He enjoyed an ample income from a sugar-refining business in Stettin, where he resided, and was anxious that Anton should accept the post of director of the Hamburg Zoological Garden, marry, and settle down there. But when I knew him at Jena, Anton had already made up his mind to do something really large and important for the progress of zoological science. Like others who had visited the Mediterranean in order to study its rich marine life, he had felt the difficulty of carrying on such work in lodgings, without apparatus, without library, and at the mercy of the fishermen whom it was necessary to employ and to conciliate. The French naturalist Coste had, when employed by the Government of the Second Empire to study economic questions connected with the national fisheries, established a laboratory, with aquaria, tanks, and fishing-boats, at Concarneau, on the Brittany coast. Henri de Lacaze-Duthiers had also arranged a permanent marine biological laboratory for himself and his pupils. The plan took shape in Anton Dohrn's mind of establishing a larger and more completely equipped laboratory than these on the Mediterranean coast, and, but for the war between France and Germany, he would probably have carried out his first intention and placed his laboratory on the coast near Marseilles. When I knew him he had already thought out the scheme which he realised, and had determined to try to secure a site at Naples in the Villa Reale, which stretches along the shore. He had succeeded with no little difficulty in securing a certain sum of money from his father—his heritage, in fact—and he intended deliberately to risk this in his enterprise. His plan was to secure the cooperation of all European universities in building and maintaining the Naples laboratory, or "station," as he proposed to call it. This meant, in all cases but that of England, the cooperation of the State Governments. But in order to obtain this support and cooperation he realised that it was necessary, at whatever effort and risk, to make a plunge—to start the "stazione," to erect a fine and imposing building, to demonstrate the convenience and excellence of its organisation, and thus to secure approval and unhesitating financial assistance. His plan was to sink his own fortune in that first step, and he did so. He obtained help from friends both at home and in this country as the building grew, and by tactful appeal and untiring effort—involving years of work given up to persuading statesmen, politicians, associations, professors, millionaires, and emperors of the value and importance of the great Naples "Stazione Zoologica"—he achieved for it a splendid and permanent position.

During the two months which I passed in 1871 at Jena, Dohrn, Kleinenberg, Abbé, and I used to dine in Dohrn's study, our meal being sent in from the Black Bear Hotel. We were usually joined by Willie Preyer, the professor of physiology, in our after-dinner walk in the "Paradise," which resembled Christ Church meadow on a smaller scale. I attended Gegenbaur's lectures, and was kindly given a place by Haeckel in his laboratory, where I was one day visited by the Grand Duke of Saxe-Weimar, who told me that he was a cousin of my Queen, and kissed Haeckel on both cheeks, much to my astonishment. I was working at the embryology of Mollusca, and especially at that of Pisidium, a minute bivalve, the haunt of which Kleinenberg showed to me. He himself was preparing his celebrated work on Hydra. Abbé was experimenting and applying mathematical knowledge in the optical workshop of Zeiss, which led later to the splendid result which all the world knows. Those delightful men, with the exception of the veteran Haeckel, are all dead now. Haeckel remains not only alive and active, but faithful to Jena. In those days Jena was a singularly beautiful place. The nearest railway station was at a distance of seven miles. It was a very small town. I had a room overlooking the "Prinzessen-garten," and was kept awake by the nightingales. Dohrn and I took long walks in the wooded hills of the Thuringer Wald, and I learnt and discussed fully with Dohrn his plans for the Naples "station." He adopted the name "station" because he hoped that, in the course of time, other thoroughly equipped marine zoological laboratories would be set up elsewhere on the same sort of international cooperative basis as that which he intended to adopt at Naples Port Jackson was one point which we selected for a future station, and some favoured spot on the Japanese coast another. Already, before we left Jena, and before he had opened any negotiations with the Neapolitan municipality, Dohrn had planned the series of monographs of the fauna and flora of the Gulf of Naples which has been so splendidly realised. Dohrn was a profound student of Goethe, and had a saying of the great teacher for every occasion. He was what appeared to me, with my English upbringing, singularly introspective, and he puzzled, even occasionally alarmed, me by his self-conscious and systematic cultivation of his will-power. I have no doubt that he was fully endowed with this power, as his remarkable accomplishment of what he set out to do proves, and I do not suppose his anxiety to keep it at a high pitch of activity was really of any effect in the end. When we were at Jena he did not smoke and drank very little. It was not, I think, until he was past forty that he took to tobacco. I left him at the end of June, 1871, promising to join him at Naples in October. He arranged to take an unfurnished flat in the Palazzo Torlonia, where we were to have ample space, and to take down with him plans for the projected laboratory, and an architect. Whilst he negotiated with the municipality and the Italian Government, I was to set up a temporary laboratory in our flat and pursue embryological work. This plan was carried out. Dohrn had succeeded in obtaining the definite and effective support of the new German Imperial Government, and his path with the Naples municipality was smoothed. But there was a good deal of haggling and putting forward of the palm of the hand (which Dohrn ignored) before the site to be occupied by the "Stazione" in the Villa Reale (or Nazionale, as it is now called) was made over, with many queer and strenuous conditions, to Dohrn, and so to the building contractor. When I left Naples in May, 1872, after an attack of typhoid fever, the walls of the laboratory were a couple of feet above ground. An example of the innumerable difficulties which Dohrn had to surmount is the challenge to a duel brought to him by the representative of the Neapolitan architect whom he had agreed (in order to conciliate the Neapolitans) to employ for the design of the elevation. This gentleman considered himself insulted because Dohrn refused to promise him a ten per cent. commission instead of the five per cent. which is usual in northern Europe. I had to act as Dohrn's second, and conferred with the Neapolitan architect's friend. On my insisting that Dohrn was a soldier of the German Emperor, and a very deadly man with the sabre—and determined not to yield to any nonsense—the challenge was withdrawn, and the insulted architect completed his task very satisfactorily. On another occasion, in my presence, Dohrn was deliberately threatened with assassination by a Neapolitan who could not get his own way. "You forget," the Neapolitan said, "that the night is dark and that for a few francs I can get a couple of men to deal with you." Another very awkward thing was that the young German architect who had come to Naples with Dohrn, and was living with us in the Palazzo Torlonia, suddenly went quite mad, and had to be sent home under escort. Happily he completely recovered. A great feature in our life at the Palazzo Torlonia was the occupation of one of the chief "flats" (ours was high up in a building against the Posilippo cliff) by the Baranowski family. Dohrn had made their friendship in Sicily a year before, and we spent nearly every evening with them. Baranowski had been governor of the Russian province of Orenburg, and was now employed by the Russian Government on important missions in China. His wife, a Polish lady, her sister, two daughters, and a son, took up their residence in the chief "suite" of our Palazzo, and in the late winter were joined by Baranowski himself, whose official business did not allow him to remain for long. All those dear friends of the Palazzo Torlonia are now dead and gone, with the exception of the elder of the two sisters, who three or four years later married Anton Dohrn, and is the mother of his four now grown-up sons: She nursed him in his last illness during the past six months at Munich. In 1874, when the Naples laboratory was built and its machinery at work, its rooms filled with professors and investigators from all parts of Europe, including the wonderfully gifted and beloved Frank Balfour and his friend Dew-Smith, I again spent three months at Naples. Dohrn was suffering from the labours he had gone through in securing the position of the laboratory, and also from the climate of Naples. He was engaged, but his marriage was delayed and his future wife's family were no longer at Naples. A very remarkable Englishman, Grant by name, who had been lecturer in English literature and a close friend of Dohrn's at Jena, was with him, and remained for some years in Naples. His delightful book, "Stories of Naples and the Camorra," is the memorial of the work Grant did there. He died some years ago. Later I made two short visits to Naples, and saw my friend with his family growing up around him. In the 'nineties he visited Oxford and received an honorary degree. For some years the University, following the example of Cambridge, had rented a table at the Naples station, and provided the travelling expenses of a graduate selected to pursue investigation there.

During the thirty-six years of its existence, the Naples station has increased vastly in size and the perfection of its organisation. Its biological library is one of the best in the world, its staff of servants, assistants, and skilled workers of all kinds unrivalled. Having secured capable assistants in all departments and the funds for carrying on the now large and celebrated institution, Dohrn was able to pursue some of the problems of vertebrate morphology which had occupied his mind already in Jena days. I think that the most important of the general ideas which he had arrived at in those early times was, first, that degeneration or simplification of organic structure is a result of evolution as well as increase of complexity, and that the relatively simple or less complicated members of a group are not necessarily more primitive or archaic than the more elaborately structured members. Also of great value was his determination to take a free and unprejudiced view as to the lines of the animal pedigree, and he particularly objected to being tied in any way to the conclusions of Haeckel on this subject. He successfully resisted the notion that either Amphioxus or the Ascidians represent in any definite or complete way the lower phases of vertebrate ancestry. He held that they were specialised, and, in the sense of being simplified, degenerate. He sought himself to connect the vertebrate stock with that of the chætopod worms, but though this hypothesis led him into many interesting discoveries of detail—which are published in a series of papers in the *Mittheilungen* of the Zoological Station of Naples—it cannot be said to have been placed on a secure footing, and we are still speculating, with very little assurance, as to the nature and structure of the pre-vertebrate ancestors of Vertebrata.

Dohrn was a great lover of classical music, like his father, and I think that music and philosophy were his chief relaxations from the severe labour of business correspondence and scientific discussion. He was very fortunate in having the opportunity, some fourteen years ago, of receiving the German Emperor at the Naples laboratory. He was able thoroughly to interest that able man in the work of the institution, who recognised that it was a real honour and glory to the German name, and accordingly gave to it his warm friendship and support. From that time forward large assistance has been given to the Naples laboratory from Berlin, and I believe that some definite responsibility in regard to the institution—involving possibly its ownership—now passes to certain authorities in Berlin.

It is a great and satisfactory thing which I have had to record here—the success of a noble effort. Dohrn's example in founding a "station" for marine zoology has been followed in a modest way elsewhere. The Marine Biological Laboratory at Plymouth, which I joined with others in founding some twenty-five years ago, was, confessedly, an attempt to provide on our English coast an institution similar to, if less spacious than, that established by Anton Dohrn at Naples. The Plymouth laboratory has done good service to science and to fishery interests, but London is not Berlin, nor are the ways of British departments of Government in regard to science in any way similar to those of the German Imperial Government. The former are ignorant, envious, and destructive; the latter are intelligent, friendly, and helpful.

E. RAY LANKESTER.

NOTES.

IN reply to a question asked in the House of Commons on Thursday last, the Postmaster-General stated that arrangements have been completed with the Marconi Company for the transfer to the Post Office of all their coast stations for communication with ships, including all plant, machinery, buildings, land, and leases, &c., and for the surrender of the rights which they enjoy under their agreement with the Post Office of August, 1904, for licences or facilities in respect of coast stations intended for such communication. In addition, the Post Office secures the right of using, free of royalty, the existing Marconi patents and any future patents or improvements, for a term of fourteen years, for the following purposes:—communication for all purposes between stations in the United Kingdom and ships, and between stations on the mainland of Great Britain and Ireland on the one hand and outlying islands on the other, or between any two outlying islands; and (except for the transmission of public telegrams) between any two stations on the mainland; and on board Post Office cable ships. All the stations will, under the International Radio-telegraphic Convention, be open for communication equally to all ships, whatever system of wireless telegraphy they may carry, and the Post Office will be free to use or to experiment with any system of wireless telegraphy at its discretion. All inland communication of messages by wireless telegraphy will be entirely under the control of the Post Office. Arrangements have also been made with Lloyd's for the transfer to the Post Office of their wireless stations for communication with ships, and for the surrender of all claims to licences for such communication.

AN Italian National League against malaria has recently been formed, and the first meeting is now taking place at Milan. The inaugural address is being delivered by Prof. Baccelli, and the following communications have been promised:—the present state of knowledge in regard to malaria, by Prof. Bordoni-Uffreduzzi; prophylaxis against malaria, by Prof. Castellino; the pathology of malaria, by Prof. Golgi; some questions relating to the pathology and treatment of malaria, by Prof. Grassi; little known abortive forms of malaria, by Prof. Queirolo.

THE programme of the second International Congress for the Repression of Adulteration in Food, Chemical Products, Drugs, Essential Oils, Aromatic Substances, Mineral Waters, &c. (to be held in Paris on October 17–24), has now been issued. The discussion of the various subjects will be classified in the following sections:—(1) wines, alcohols, syrups, liqueurs, beer, cider; (2) farinaceous foods, baking, pastries, meat and other pastes, spiced confectionery; (3) cocoa, chocolate, confectionery, honey, sugar, and sugar candy; (4) vinegar, mustard, pepper, spices, tea, coffee, chicory; (5) butter, milk, cheese, eggs; (6) lard and edible fats, margarine, provisions preserved in oil, bacon, sausages and pork products, salted provisions, and canned and bottled goods; (7) drugs, chemical products, essential oils, &c.; (8) mineral water (medicinal), aërated waters, ice.

IN opening the *Nimrod* Antarctic Expedition last week, the Lord Mayor of London stated that he intended to call a meeting at the Mansion House to initiate a fund towards the expenses of the forthcoming expedition under Captain Scott to the south polar regions.

IT is stated in the *Times* that a telegram has been received from Dr. T. G. Longstaff to the effect that he has arrived at Leh, in Ladak, after having connected the Tarim river with the Saichar glacier, making it about fifty miles long. This would appear to mean that the Tarim or Yarkand Darya river, which flows north from the Himalayas towards the Taklamakan desert, and had hitherto been supposed to rise near the Karakoram Pass, originates much further to the west in the Saichar glacier. On existing maps, what was supposed to be a branch of the river is shown to originate in the Saichar glacier, and it is that branch, apparently, which Dr. Longstaff makes out to be the main river.

THE Ottawa correspondent of the *Times* states that a telegram has been received by the Canadian Marine Department from Captain Bernier, of the Canadian Government steamer *Arctic*, which left Quebec fourteen months ago to cruise in the Arctic region, announcing his arrival at Point Amour, Labrador. Captain Bernier says that he has accomplished his mission, which was to report upon the ice conditions in Hudson's Straits in 1908 and then to proceed north and take possession of Banks Land and other Arctic lands for Canada; he also states that he discovered the record left at Winter Bay in 1819–20 by Lieut. (afterwards Sir E.) Parry.

PROF. J. v. HEPPERGER has been appointed director, and Dr. J. Palisa vice-director, of the Imperial University Observatory, Vienna.

MR. PHILLIP FOX, formerly of the Yerkes Observatory, has now assumed the directorship of the Dearborn Observatory, Evanston, Illinois, in succession to the late Prof. G. W. Hough.

WE learn with regret that M. J. A. Fraissinet, secretary of the Paris Observatory, died, in his sixty-third year, on August 29.

THE Denny gold medal has been awarded by the Institute of Marine Engineers to Mr. W. P. Durtnall, for his paper on the generation and electrical transmission of power for main marine propulsion and speed regulation, which was read at the Franco-British Exhibition in July, 1908.

As was announced in NATURE of July 15, a model engineering exhibition will be held at the Royal Horticultural Hall, Westminster, on October 15–23. We learn from the promoters that the exhibition will contain a number of exhibits of exceptional interest, *e.g.* model aëroplanes, working model steam and electric railways, electric clocks, light machine tools, model motor-boats, a model engineer's workshop in operation, and a working demonstration of wireless telegraphy by the latest Marconi apparatus.

SIR WILLIAM MACGREGOR, who is shortly to take up his duties as Governor of Queensland, was entertained at luncheon last week at Liverpool, and, speaking in reply to the toast of his health, said he had known the Liverpool School of Tropical Medicine from its inception. He had spent thirty-one years in the service of the country in the tropics, and he thought that few people had had a better opportunity than he had of seeing how much an institution of this kind was wanted in the world. Few men could better appreciate the amount of good it had been able to do. He had had the opportunity of renewing his studies at the school, and what he had been able to learn had been of considerable use to him and would be of great value to others. It was a great school, not on account of its size, but because it was the nucleus which was going to scatter broadcast tropical schools all over the Empire. The beginning of the Liverpool School of Tropical Medicine they owed from a scientific point of view to Major Ross, but to Sir Alfred Jones they were almost equally indebted. He looked upon the school as being the pioneer of all other schools of this kind that were to follow.

A COURSE of twelve free lectures under the Swiney trust will be begun in the lecture theatre of the Victoria and Albert Museum, South Kensington, on Saturday, November 6, by Dr. T. J. Jehu, who will take as his subject "The history of north-west Europe during Tertiary times."

THE new session of the Royal Geographical Society will open on November 8, when a paper entitled "Two Journeys in Bhutan" will be read by Mr. J. Claude White. The other papers expected to be delivered at meetings before Christmas are:—journey into northern Arabia, by Mr. Douglas Carruthers; explorations in the Hispar region, by Dr. Hunter Workman and Mrs. Bullock Workman; and a naturalist's travels on the Congo-Zambezi watershed, by Mr. S. A. Neave. The papers expected after Christmas are:—an expedition to the North Pole, by Commander Peary; explorations in and around Lake Chad, by Captain J. Tilho; explorations in Fernando Po and the Cameroons, by Lieut. Boyd Alexander; explorations in southern Nigeria, by Mr. P. A. Talbot; explorations in and around Magellan Straits, by Dr. K. Skottsberg; a journey from Uganda by Lake Rudolf to Abyssinia, by Captain C. H. Stigand; explorations in the Aldabras, by Mr. J. C. F. Fryer; climbing and exploring in Central Asia, by Dr. T. G. Longstaff; boundary-making and exploration in Bolivia and Brazil, by Major P. H. Fawcett; exploration in the Kasai region of the Congo, by Mr. E. Torday; a journey in South-west Africa, by Prof. Pearson; geographical conditions affecting the development of Australia, by Prof. J. W. Gregory, F.R.S.; and geographical conditions affecting the development of Canada, by Mr. W. L. Grant.

ARRANGEMENTS have been completed whereby a standard clock at the Hamburg Observatory, Bergedorf, is connected to the trunk telephone system. A sounder automatically emits a siren-like note from the fifty-fifth to the sixtieth second of each minute—mid-European time—and this goes automatically to all the receivers connected, at that time, with the special exchange number which has been allotted to the time signal. Thus Hamburg and neighbourhood and other towns of east Germany are supplied with a ready means of ascertaining the standard time.

THE past summer was characterised by cool and unsettled weather, and, with the exception of about a fortnight at the commencement of August, there was a peculiar absence of warm days. For the six months April to September the observations at Greenwich show that there were in all only fifty-three days with a temperature of 70° or above; of these, twenty occurred in August and eighteen in July, whilst there was only one instance in September. During the last quarter of a century the only years with as few warm days are 1888, 1894, and 1903. On the average of the last fifty years, there are seventy-four such warm days. There were nine days with a temperature of 80° or above, and in the last five years the number varies from two in 1907 to twenty in 1906. The absolutely highest temperature during the summer was 80°, on August 12 and 15. The aggregate rainfall at Greenwich for the six months is 14·04 inches, which is 1·75 inches more than the average summer fall of the last fifty years, the mean being 12·29 inches. With the exception of the summer of 1903, when the aggregate rainfall was 22·21 inches, there has been no summer as wet since 1888. There was an excess of rain in all the summer months except May and August, and the wettest month was June, with a total of 3·65 inches, which is 1·65 inches above the average. The early summer months were exceptionally bright, and a record duration of sunshine for any month was established in May, with 326 hours, but most of the subsequent months had a deficiency of bright sunshine.

SOME remarkable experiments on the reproductive apparatus of insects have recently been conducted by Prof. J. Meisenheimer, and are recorded by him in a treatise ("Experimentelle Studien zur Soma- und Geschlechts-Differenzierung") published by Fischer at Jena. The results of this investigation have been summarised by the author in the *Naturwissenschaftliche Wochenschrift* for August 29. The species selected for experiment was the well-known "gipsy moth," *Lymantria dispar*. The reproductive glands were removed from larvæ of both sexes, in some cases immediately after emergence from the egg. The difficulty of operating upon larvæ barely three millimetres long must have been great; it was, however, successfully overcome by aid of the galvanic cautery. In larvæ of a larger growth an actual transplantation was effected of testis into the female and ovary into the male. Details of much interest are given in the original paper; the main result is that, in strong contrast to the conditions obtaining in vertebrates, the removal of the primary sexual organs has no effect upon the development of the remainder of the sexual apparatus, or of the secondary sexual characters whether somatic or psychic. This takes its normal course even in the presence of a successfully transplanted primary organ of the opposite sex.

To the August number of the *National Geographic Magazine* Mr. H. M. Smith, U.S. Deputy Commissioner of Fisheries, communicates a very graphic and interesting account of the herring-fisheries of the world, in which stress is laid on the importance and value of this industry, which has determined the position of cities and influenced the destiny of nations. In America large numbers of the smaller-sized herrings are tinned and sold as sardines. In place of the methods adopted on this side of the Atlantic, weirs of stakes and brushwood play an important part in the American herring-fishery. As the average tidal rise and fall is 20 feet, and in spring nearly 30 feet, the weirs are necessarily large and strongly built structures. These weirs are fished at low water, when the fishermen enter in boats, set a seine and haul its ends together, and proceed to take out the fish in huge dip-nets. Sometimes, however, the herring are left high and dry by the falling tide, when they are collected by hand or with pitchforks.

IN No. 29 of the "North American Fauna," published by the Biological Division of the U.S. Department of Agriculture, Mr. E. W. Nelson gives an exhaustive account of the Leporidæ of North America, of which no fewer than ninety-seven species and races are recognised, against eighteen in 1887. Although in America all the members of the family are commonly termed rabbits, the author suggests that the name rabbit should be restricted to the so-called "cotton-tails," which produce blind and naked young in burrows or other concealed cavities, while the species related to the typical Lepus of the Old World should be designated hares. The fact that the cotton-tails resemble the European rabbit in the matter of habits and the condition of the young at birth goes far to justify their separation as Sylvilagus, although that term might perhaps be preferably employed in a subgeneric rather than in a generic sense. It is pointed out that both "jack-rabbits" and "cotton-tails" are serious pests to the agriculturist and horticulturist in the United States, although the former are considerably the worse of the two. On the other hand, these rodents form a valuable asset to the country as a source of food and of fur.

IN the annual report of the Natural History Section of the Indian Museum for 1908–9 the director states that the Museum Conference at Calcutta has done much to facilitate the interchange of opinions and specimens between the various museums of the country. At that conference it was agreed that the Calcutta establishment was to be the depository for all type-specimens, except such as, for climatic reasons, would be safer in London. Among recent additions attention is directed to a skeleton of the Mishmi takin (*Budorcas taxicolor*), which is alleged to be the only one in existence. If those of the living individuals of the species be excluded, this statement may be literally true, although it might have been added that the British Museum possesses skeletons of the Bhutan race (*B. t. whitei*) and of the Sze-chuen *B. tibetanus*.

IN the September number of the *Zoologist* Mr. G. B. Corbin states that the smooth snake (*Coluber laevis*, or *austriaca*) is still to be found in the New Forest and on the heath-lands on the opposite side of the Avon, where it was first recognised as a British species. Unfortunately, a portion of its habitat is slowly but steadily coming under the hand of the builder.

WE have received three parts (Nos. 1, 4, and 5) of a new Bulletin of Economic Biology, issued by the Department of Agriculture of the Federated Malay States, and published at Kuala Lumpur. No. 1, by Mr. H. C. Pratt, the Government entomologist, deals with termites found in rubber-plantations; No. 4, by the same author, is devoted to a zygænid moth (*Brachartona catoxantha*), the larva of which infests cocoanuts; while in No. 5 Mr. W. J. Gallagher discusses the best means of destroying the rats, which do serious damage to rice-fields.

MR. H. M. LEAKE has followed up his first paper on the experimental breeding of Indian cottons by a second, published in the Journal and Proceedings, Asiatic Society of Bengal (vol. v., No. 1). The author's object is to discover characters which behave as units under artificial crossing. In the present paper he records the constancy for Indian cotton plants of the position of the accessory bud on the main stem, *i.e.* certain plants regularly produce the accessory bud to the right, others to the left, of the main bud, but this character does not follow the Mendelian laws. Similarly, the main stem is always a monopodium, but the subsequent branching may be monopodial or sympodial; these are two distinct types, of which the sympodial is dominant. Further, it was observed that early flowering is a feature of the sympodial type, and herein lies the importance attached to a differentiation of Indian cottons according to their mode of branching.

THE thirty-fourth series of contributions to the flora of Africa, published under the direction of Dr. Engler, occupies the bulk of Engler's *Botanische Jahrbücher* (vol. xlii., parts i. and ii.). An important revision of African species of the genus Impatiens is supplied by Dr. E. Gilg, and Dr. Engler contributes descriptions of several new species, notably of the genus Mesembrianthemum. The classification of African species of the polymorphic genus Senecio is discussed by Dr. R. Muschler. Five subgenera, comprising about 500 African species, are demarcated. The subgenus Eusenecio is further divided into many sections, of which twenty are added by the author. The sections *crassuli* and *kleinioidei* are succulents, similar in this respect to the subgenus Kleinia; the section *tuberosi* is based on the production of large tubers; a large group is that of climbing plants, *scandentes*; other sections are the *pinifolii*, *rhizomatosi*, and *arborei*, the latter being represented by *Senecio Johnstonii*, a tree attaining a height of 45 feet.

A SECOND set of studies of tropical American ferns, by Mr. W. R. Maxon, is published in the Contributions from the United States National Herbarium (vol. xiii., part i.). The first paper deals with ferns collected in Guatemala by Baron von Türckheim, principally in the humid mountainous region of Alta Verapaz. The determinations include several new species, notably an interesting Campyloneuron and an epiphytic Lycopodium, also the species *Diplazium ternatum*, formerly recorded from Mexico. The author also supplies a revision of the West Indian species of Polystichum, with a key for determination. Diagnostic characters are sought in the presence or absence of a proliferous bud upon the rachis. Where present, it may arise immediately above the uppermost pinna, as in the species *heterolepis*, or on a whip-like prolongation, as in *P. decoratum*.

THE Cambridge Scientific Instrument Company, Ltd., has recently issued a new catalogue explanatory of its microtomes and accessory apparatus. The ingenious rocking microtome is, of course, universally known; the present-day instrument shows several improvements on the original pattern, notably in the fitting of the rocking arms. A second type of microtome, also a rocker, cuts flat sections, and is suitable for objects up to a diameter of 30 mm., while a larger microtome has been recently designed which will take objects up to 40 mm. diameter, and with which hard substances, such as bone or cartilage, can be manipulated.

THE Bulletin of the Johns Hopkins Hospital for August (xx., No. 221) is devoted to tuberculosis. The subjects dealt with are tuberculin treatment of dispensary patients, report of the work of the Phipps Dispensary for Tuberculosis, Marmorek's serum in the treatment of pulmonary tuberculosis, and the kind of employment suited to arrested cases of the disease. In the last it is concluded that farm-colonies are the best possible means for the after-care of consumptives.

THE July number of the *Journal of Comparative Neurology and Psychology* consists of a monograph, by Mr. M. E. Haggerty, on imitation in monkeys. To the lay mind there will appear no question as to the power of monkeys to learn by imitation. The experimental evidence, on the other hand, has not always been on the side of popular opinion. It is true that Hobhouse obtained experimental evidence of the imitation of human behaviour by monkeys, and that Kinnaman observed two cases in which one monkey, after watching another monkey that had learnt to get food by manipulating a mechanical device, itself repeated the performance; but Thorndike was unable to find any such imitation of one monkey by another, and in neither of the two monkeys studied by Watson was there evidence that the watching animal learnt to get its food by seeing how the other animal got it. Mr. Haggerty bases his observations on no fewer than eleven monkeys. Following previous workers, he places the animals "in the presence of simple mechanical devices, the manipulation of which opened doors, disclosed openings, or dropped food into the experiment cage." The important feature of his paper consists in the extraordinarily detailed record of the movements of the monkeys while under experimental conditions. The seven mechanical devices with which the monkeys were at various times confronted yielded sixteen cases of successful imitation (three of which were immediate), five cases of practically successful imitation, and five failures. Seven of the monkeys imitated in every form of test, two failed absolutely, while two succeeded in some tests but failed in others. The statistical results, however, are of less interest than the valuable description of the facts of behaviour, inasmuch as there is doubt as to what shall be allowed to count as imitation. In the present state of the subject it is observation that is needed, and this Mr. Haggerty's paper supplies in abundance.

THE June number of *Petermann's Mitteilungen* contains a short paper on the climate of Siam, by Dr. W. Gerbing, which deals specially with the observations made by Dr. Hosseus during journeys in 1904 and 1905. Little is known of the meteorology of the mountainous regions of the Laos States, where Dr. Hosseus spent most of his time, and the observations are therefore of considerable value. They consist chiefly of seven months' records kept at the mission station at Djeng Mai by Dr. Harris, and temperature observations made *en route* and during halts in climbing expeditions on the Dai Sutep.

THE Bulletin of the American Geographical Society (vol. xli., No. 8) contains an article on the Stonington Antarctic explorers, by Mr. E. S. Balch. The article is based on letters and papers belonging to Mrs. Richard Fanning Loper, of Stonington, Connecticut, who inherited them from her father, Captain Alexander Smith Palmer. These papers are few in number, as most of the Antarctic records of the Palmers were destroyed by fire in 1850, but they afford much valuable fresh information about four very fruitful exploring voyages, and throw many new side-lights on the formerly important sealing industry in the South Seas.

THE August and September numbers of the *Bollettino* of the Italian Geographical Society contain a report on the Messina earthquake of December 28, 1908, by Dr. Mario Baratta. The author gives the results of a full examination of the scene of the earthquake and a comparison of its effects with those of the earthquake of 1783. A number of illustrations and detailed maps accompany the report.

A SUPPOSED ancient canoe was recently discovered, embedded in sand below water (not in peat) near Lochmaben. It is formed of a single oaken trunk, and is about 13 feet long and 2 feet broad, with sides which can hardly have been 1 foot in height. The bottom is flat and smooth. On the inside there are two rows of neatly drilled holes, in which were wooden pegs. These holes are at intervals of 18, 21, 24, and 27 inches, and lie in shallow grooves close to the sides of the canoe. The bow has a distinct resemblance to that of a dug-out canoe, and it is of course possible that this may be an ancient boat with ribs to which rough planks were tied, but the evidence for this theory is hardly convincing. It differs greatly from the dug-out canoes found at Lochrutton and Friarscarse, which were probably used by the dwellers in the crannoges which existed in those lochs. We have to thank Mr. Thomas Henderson, of Lockerbie, for the measurements given above, which would seem to show that the people who made the holes used a foot rule divided into 12 inches. It is very likely, however, that a flat-bottomed boat of this kind might have been used in the loch at almost any period from 1200 A.D. to 1600 A.D.

ACCORDING to the *Jewish World*, the French expedition has made further notable discoveries at Susa, the Shushan of the Bible, the ancient Elamite capital. In the Acropolis the explorers found, superimposed one above the other, the remains of three cities dating back to B.C. 4000, and beneath these other settlements of the prehistoric period. The most important discoveries were three black stone pillars, on which was inscribed the law code of King Hammurabi of Babylon. The site appears to have been occupied by the Babylonians earlier than B.C. 2800. Subsequently the Elamites regained their independence, and retained possession of the city until B.C. 649, when it was sacked by Assurbanipal, King of Assyria.

PHYSICAL anthropologists in search of a new test of race to supplement that of the cephalic index, which no longer commands the authority once attributed to it, will welcome the essay, reprinted from the fourth volume of the *Philippine Journal of Science*, by Mr. R. B. Bean, entitled "Filipino Ears, a Classification of Ear Types." The author claims that he established for the first time a seriation of human ears, and that each ear type is associated with a physical variety of man. Most of the Filipino ears, except those of some long-term convicts, agree with the European type, and those varying from this standard are of an older morphological class. The Spanish population of Manila has ears closely agreeing with the European types among the Filipinos. In this, as in other characteristics, Chinese influence is apparent. He concludes that prehistoric Europeans have probably to some extent affected this ear type, and that Chinese ears are longer than those of Europeans, Filipinos, or Indians, because the Chinese population is composed more largely of the long-eared European types (northern, sub-northern, and Cro-Magnon). Ear type he believes to be to some extent independent of pigmentation, because the same type of ear is found in blonde and brunette Europeans, in dark- and light-skinned Filipinos, in dark-skinned Indians and light-skinned Chinese. It is improbable that his views of the permanence of ear type as a test of race will be accepted without criticism, but, at any rate, this monograph, with its large selection of photographs, raises a new and interesting problem.

AN interesting article on the climatic features of Wyoming and their relation to "dry-farming," by Mr. W. S. Palmer, section director, is published in the *U.S. Monthly Weather Review* of February last. From systematic data collected during the last seventeen years, it appears that the average annual rainfall of the State is 13·7 inches; in some parts the amounts vary from about 5 inches to 20 inches, and crops are now being successfully produced by the dry-farming method in semi-arid regions where a few years ago it was considered that the precipitation was not sufficient for the purpose. Prof. C. Abbe explains that the expression dry-farming may be considered as an abbreviation of dry-land-farming, and that the method consists in giving up the attempt to raise crops every year, and attempting instead so to conserve and utilise the moisture as to secure a crop every two or three years. Success depends essentially upon the annual quantity rather than upon the seasonal distribution of precipitation and evaporation.

IN the valuable meteorological charts of the Atlantic and Indian Oceans issued by the Meteorological Office for October, 1909, it is pointed out that the Southern Ocean has been remarkably free from icebergs and drift-ice throughout the first seven months of this year. Icebergs were frequently passed in 1908, and during the first five months of 1909 some were seen between latitude 52° and 59° S. and longitude 90° and 130° W., the loftiest being 300 feet high; but not a single berg has been sighted in the vicinity of Cape Horn. During the past quarter of a century many icebergs having an altitude of not less than 1000 feet have been met with in the Southern Ocean.

THE use of light filters in spectroscopic work whenever it is necessary to shut out all but a particular portion of the spectrum is so simple an expedient that we venture to direct attention to a list of Wratten light filters which has recently been issued. They consist of thin films of gelatin coloured with organic dyes, and the list gives the spectrum of the light transmitted in each case. One of the most useful for spectroscopic work appears to be the mercury green line filter, which is transparent for the mercury green line, but opaque for all the other mercury lines.

A DETAILED study of the lengths of the waves emitted by many of the ordinary forms of generators of short electric waves has been carried out by Messrs. H. W. Webb and L. E. Woodman at Columbia University, and the results are given in the August number of the *Physical Review*. The object of the authors was to establish such definite relations between the dimensions and electrical properties of the generators and receivers of the waves as to enable future workers to calculate the wave-length with certainty from the dimensions of the apparatus used. The method employed was Boltzmann's, the beam sent out by the generator being reflected at two mirrors, and the two half-beams brought together to produce interference. Rod, cylinder, Righi, and other generators were tested, and the wave-length measured in each case, a non-selective receiver being used. For apparatus of the same type, but of different size, the wave-length is proportional to the linear dimensions of the apparatus.

An interesting paper on sparks as indicators of the different kinds of steel was contributed by Mr. Max Bermann, Budapest, at the meetings of the International Association for Testing Materials, held in Copenhagen early in September. An abstract appears in *Engineering* for September 17, from which we learn that the author stated that the influence of the emery-wheel on the nature of the sparks was far outweighed by that of the quality of the steel. It seems from the author's experiments that the spark ray gives a precise indication of the quality of the metal, and may be so applied in practice. Pointed branching lines denote carbon steel (Siemens-Martin); leafy ends of the branching lines indicate Siemens-Martin steel containing a high percentage of carbon; spark pictures, with a blossom-branch-like appearance, are obtained from ordinary tool steel, and so forth. The author states that the spark test is so sensitive that it gives clear indication of a difference of 0·01 per cent. of carbon, and could be resorted to in the course of the Siemens-Martin process for testing the bath and also for the inspection of the finished material.

Among other interesting articles in the August number of *The Central*, the organ of the Old Students' Association of the Central Technical College, City and Guilds, is one on pipes for use underground, by Mr. H. A. Humphrey. In this article the writer emphasises the great value of a proper covering for steel pipes. Thin bituminous coatings, obtained by dipping in hot mixtures, is liable to be destroyed in places by the subsequent handling of the pipe. What is wanted is a coating which has elasticity and offers greater mechanical protection. The South Staffordshire Mond Gas Company followed the recommendation of the author for its mains, extending over an area of 120 square miles, a great portion of which lay in the "Black Country," thus rendering the mains liable to subsidences and to attacks from sulphur and acid compounds. The steel pipes were coated once with asphaltum, then wrapped round with Hessian or canvas, and afterwards again coated with asphaltum, the result giving a thick, tenacious coating of sufficient elasticity and strength. Five years' experience is now available, and has proved that even under the worst conditions such a coating, when properly applied, is an absolute preservative against corrosion.

OUR ASTRONOMICAL COLUMN.

Observations of Mars.—Further results of his observations of Mars are published by M. Jarry-Desloges in No. 4358 of the *Astronomische Nachrichten* (p. 224, September 24).

Changes are becoming more numerous, and the canals more visible. The observations made at the Massegros Observatory (Causse de Sauveterre) showed a new canal on Libya, but the Hellespontus was no longer visible. The Indus was seen to be intercepted at the estuary of the Oxus, and Syrtis Major and the Baie du Méridien were intersected. Since September 3, both at the Revard and the Massegros stations, a clear band traversing the Auroræ Sinus was recorded. The Revard plateau observing station is being dismantled before it becomes snowbound, and the instruments are to be remounted on the plains of the Beauce.

Having occasion to examine some of Prof. Lowell's 1907 photographs of Mars, M. Antoniadi was struck by the absence of the dark band which, according to visual observations, is circumjacent to the polar snows. Whilst recognising the possibility that this may be due to the photographic encroachment of the neighbouring bright area, M. Antoniadi does not think that this is the probable explanation; he would rather believe that in the visual observations the phenomenon is a subjective one, the appearance of a dark band being produced by contrast with the bright cap.

Some interesting letters, describing the observed phenomena, and drawings, communicated by MM. Jarry-Desloges and Antoniadi to Signor Schiaparelli, are published by the latter in No. 9, vol. iii., of the *Rivista di Astronomia* (Turin).

The Recent Magnetic Storm and Aurora.—From Mr. Basil T. Rowswell we have received an account of an auroral display observed by him, at St. Martin's, Guernsey, on the night of September 25, the date of the magnetic storm described in Nature for September 30 (p. 395). On going into the garden at 8 p.m. (G.M.T.) Mr. Rowswell was struck by the appearance of a rosy glow, at an altitude of about 60°, in the E.N.E. sky. This glow brightened and then faded away, or was obscured by misty clouds and, possibly, moonlight, until at 8.10 p.m. no trace of it was to be seen; nor could it be discerned at 9 p.m. when the sky was partially clear. That it was a true auroral display which he observed Mr. Rowswell has no doubt, and he suggests that, had the sky been clear, a good, if brief, display might have been seen at Guernsey.

Elements and Ephemeris for Halley's Comet (1909c).—A set of elements, computed by the Russian Astronomical Society, for Halley's comet is published in No. 4358 of the *Astronomische Nachrichten*. The perturbations for the period November 15·9, 1835, to December 13, 1909, were computed by the method of mechanical quadratures, and the time of perihelion passage is given as 1910 April 23. An ephemeris which accompanies the elements gives positions for every tenth day from September 4 to December 23, and agrees fairly well with the position determined, for September 11, from Prof. Wolf's photograph.

Double-star Observations.—In No. 4350 of the *Astronomische Nachrichten* Prof. Doberck compares the observations of a number of double stars, made by various observers, with the data deduced from the published orbits. For twenty-three objects he gives the places where the orbits were published, the years in which observations were made, and the differences, for each observer, in angle and distance. The names of the observers are given in abbreviated form in accordance with a comprehensive list published by Prof. Doberck in No. 4346 of the same journal.

A Newly discovered Nebula Cluster in Cetus.—In No. 4352 of the *Astronomische Nachrichten* Prof. Wolf announces the discovery of a small cluster of nebulæ in the constellation Cetus. The position of the cluster is $\alpha = 2h.\ 50m.$, $\delta = +5{\cdot}4°$ (1855·0), in a region which is generally very barren in these objects. The new object is very faint, with a central condensation, and has a filamentous appearance.

Observations of Variable Stars.—No. 4352 of the *Astronomische Nachrichten* is devoted to the discussion of twenty stars of which the variability is doubtful or small. The observations were made, photometrically, at Potsdam, by Herr W. Münch, during the period September, 1908, to March, 1909, and are discussed at some length.

Terrestrial Refraction in Egypt.—No. 33, vol. iii., of the *Cairo Scientific Journal* contains an interesting discussion of some observations of vertical refraction made by Mr. Xydis at Alexandria. The observer found a well-marked diurnal variation which, in November, 1908, gave for k, the coefficient of refraction, values ranging from 0·0497 (at 9h.) to 0·1186 (at 17h.); frequently the value, which is usually positive, was found to be negative. The observations are also discussed by Messrs. Craig and Keeling, the latter pointing out the difficulties inherent to observations of vertical refraction, especially when settings are made on a sea horizon. Observations made at Helwan Observatory in November, 1908, showed the refraction to vary between 0·781 and 0·101, and, when compared with others made in June, showed that k is much smaller in summer than in winter, the values ranging, in June, from 0·368 to 0·076. It also appears that the refraction in Egypt varies much more than in European countries.

THE IRON AND STEEL INSTITUTE.

THE autumn session of the Iron and Steel Institute commenced on Tuesday, September 28. Meetings for the reading and discussion of papers were held on Tuesday, Wednesday, and Thursday at the Institution of Civil Engineers, and were attended by a large number of members. In the absence of the president, the chair was taken by Lord Airedale, supported by the Duke of Devonshire, who presented the Carnegie gold medal to M. A. Portevin, in recognition of his researches on steel alloys.

A short paper on the production of iron and steel by the electric smelting process, by E. J. Ljungberg, gives information regarding some experiments made in Sweden at the works at Domnarfvet. The latest form of furnace employed resembles a common blast-furnace having three carbon electrodes fed by three-phase alternating current at about 40 volts, 60 cycles, and 9500 amperes. These electrodes take the place of tuyeres. The furnace has been running for 1903 hours, and has produced 280 tons of iron containing from 0·95 per cent. to 3·09 per cent. of carbon. In producing this quantity there was used 442 tons of ore, 24 tons of lime, 41 tons of coke, 58 tons of charcoal, 6·5 tons of electrodes, and 891,623 kilowatt-hours of current. No air whatever is used in the process. The manufacture of iron and steel direct from ore by electrical means is of importance in a country like Sweden, possessing practically no coal mines, but having numerous waterfalls available for the generation of electricity. A commercial start has been made by the installation of three large furnaces in Canada at Sault Ste. Marie.

The difficulties encountered in tests for determining the economy of steam engines used in driving reversing rolling-mill engines are explained in a paper by Mr. C. A. Ablett. Such tests are usually carried out by indicating the engine, and so estimating the steam consumption per indicated horse-power, or by measuring the feed water or coal consumption in cases where the boilers supplying the engine can be isolated. In the latter case the result can be expressed in pounds of steam or coal per ton rolled, provided a record is kept of the total weight of steel passed through the mill during the test. The author also describes how the power consumed in electrically driven mills may be obtained by means of an ordinary integrating wattmeter. The results of such tests are expressed easily in kilowatt-hours per ton. Five steelworks have decided to adopt electrical driving since the last autumn session of the institute, making more than twenty firms in all which have come to this decision. The author gives some results of electrically driven rolling mills, from which we quote the highest and the lowest. In rolling flange rails, 100 lb. per yard, from 2-ton ingots, output 30 tons per hour, 48·0 kilowatt-hours per ton were required. In producing 32-inch by 9-inch slabs from 6-ton ingots measuring 36 inches by 19½ inches, output 40 tons per hour, 4·3 kilowatt-hours were required.

An interesting paper on the growth of cast irons after repeated heatings was contributed by Profs. H. F. Rugan, of Louisiana, and H. C. H. Carpenter, of Victoria University, Manchester. The fact that certain types of cast iron grow after repeated heatings has long been familiar to engineers. Cast iron annealing ovens 8 feet in length, 3 feet in diameter, and 1½ inches in thickness, kept red hot for prolonged periods, sometimes grow to 9 feet in length in the course of use. The conditions under which the maximum growth occurs were first investigated, and, as a result, a period of four hours at 900° C. was chosen for the experiments. For growth to take place, repeated heating and cooling are required. In the tests, three commercial cast irons were examined, the test bars being heated in a cast-iron muffle protected by another muffle of fire-clay. The bars grew at different rates and to different extents, constant volume being reached after ninety-four heats. The growth in volume varied from 35·21 per cent. to 37·50 per cent. An increase in weight of from 7·82 per cent. to 8·60 per cent. was observed. The connection of growth and chemical composition was investigated on a series of iron-carbon alloys containing no graphite. An alloy was found the volume of which remains constant even after repeated heatings at about 900° C. This alloy is a white cast iron having about 3 per cent. of carbon and only small quantities of other constituents, of which silicon is the most important, and this should not exceed 0·2 per cent. to 0·3 per cent. The influence of silicon was examined in a series of iron-carbon-silicon alloys. The growth was found to be roughly proportional to the silicon present. In grey irons there are alloys the growth of which in air on heating is due entirely to oxidising gases penetrating their interior; in others, originally dissolved gases contribute to some extent to the growth.

Some experiments carried out at the Clarence Ironworks, Middlesbrough, are described in a paper by Mr. Greville Jones. These experiments had for their object the determination of whether the principal saving in fuel in blast-furnaces using dry air blast was due to the uniformity of the blast or to its dryness. Two furnaces were used, both of the same size and carrying the same load. For comparison, one of these was run with dry blast, and the other was supplied with blast in which the moisture was gradually increased up to 4 grains per cubic foot during the first of the four weeks over which the experiments extended. No appreciable difference was found in the working of the two furnaces.

Mr. R. S. Moore dealt with the fuel economy of dry blast in a subsequent paper. The author was associated with Mr. Jones in the tests at the Clarence Ironworks, and believes that the results of these tests point strongly to the fact that the great heat saving of the Gayley dry blast must be due to its dryness.

In another paper Mr. F. J. R. Carulla considers the development of the process of manufacturing artificial magnetic oxide of iron. Dr. William Gregory, of Edinburgh, first observed that when a solution of protosulphate of iron is divided into two equal parts, one of which is peroxidised, then mixed with the other, and precipitated by ammonia at a boiling heat, a black oxide is obtained which does not attract oxygen in drying, and is highly magnetic. Its composition must be $2FeO + Fe_2O_3$, as the two solutions contain equal quantities of iron, and Gregory suggests that it may occur native as a variety of magnetic iron ore. Dr. Wülffing first worked out its industrial manufacture from waste liquors. Notwithstanding difficulties, the product is difficult to spoil in the making, and the great protective value of the Gregory-Wülffing magnetic oxide of iron paint is acknowledged by all who have had any experience of it.

The serviceable life and cost of renewals of permanent way of British railways were dealt with in a paper by Mr. R. Price-Williams. The total annual cost of the maintenance and renewal of the permanent way and works now amounts to 15 per cent. of the entire working expenses, which for some years past have reached the high figure of 63 per cent. of the entire railway gross receipts. The wear and tear of permanent way during the last ten years amounts to 5039 miles of railway, which have become worn out and have been replaced in most, if not all, cases with stronger and better materials.

Dr. J. Newton Friend, in a paper on the corrosion of iron, points out that the ionisation of water, which forms the base of the electrolytic theory of corrosion, is purely an assumption of which we have no definite proof. Kohlrausch showed that water offers the greater resistance to the passage of an electric current the more carefully it is purified. Not a few chemists maintain that if absolutely pure water could be obtained it would be found to be incapable of conducting an electric current—in other words, that it would not be capable of ionisation. Leduc has directed attention to the extreme difficulty of removing every trace of dissolved gases from water by boiling. The author points out that the results obtained by Kohlrausch and Heydweiller may be simply a measure of the extent to which the dissolved gases remain in solution under the special conditions of the experiments. If such is really the case, the electrolytic theory of corrosion becomes a myth, whereas the acid theory is unaffected by it.

Dr. Friend read another paper on the action of air and steam on pure iron. His experiments show that pure iron combines with ordinary air and with air dried over phosphorus pentoxide with increasing readiness as the temperature rises. Below 150° C. the oxidation proceeds too slowly to be readily detected. Pure iron becomes tarnished when heated in pure steam at temperatures ranging from 350° C. upwards. The author concludes that the action of steam on iron takes place in two stages, first, the dissociation of the steam, second, the combination of the dissociated oxygen with the iron and the consequent liberation of free hydrogen gas. If this conclusion is correct, the dissociation pressure of the oxide of iron produced at 350° C. is of the order of $1 \cdot 02 \times 10^{-12}$ atmospheres.

A paper on tests of cast iron was read by Mr. E. Adamson. The general results were as follows. The best tensile and transverse tests are obtained from bars which have been machined. Transverse test bars cast on edge and tested with the "fin" in compression give the best results in testing. The transverse test is not so trustworthy or helpful as that of the moment of resistance. The use of high-grade ferro-silicon in the foundry is of no commercial value. Cast iron gives the best results when poured as hot as possible.

Mr. T. Swinden contributed a paper on the constitution of carbon-tungsten steels. This paper is a continuation of the author's earlier researches on the same subject. His hardness tests and exhaustive microscopic examination support in every respect the conclusions previously recorded upon the cooling-curve work, namely, that the "lowering temperature" marks a definite reaction in which the tungsten is involved, and that the rate of cooling from above the lowering temperature is without influence on the low point. It is suggested that the hypothesis of Edwards, that the lowering of the point is due to the formation of a carbide tungsten, is untenable. The theory of a double carbide formation is difficult to account for with the cooling curve and microscopic facts observed. A tentative hypothesis is given, wherein the lowering of the recalescence point is attributed to the solution of a tungsten compound, probably Fe_3W, at the lowering temperature. The tungsten is re-precipitated at the low point, and the Fe_3C immediately separates also.

THE OPENING OF THE LONDON MEDICAL SESSION.

ALTHOUGH under the present five-years' curriculum of medical study it is perhaps preferable for the student to commence his studies in the summer session, by a time-honoured ordinance the medical year in London always dates from October 1 or thereabouts, and is in many of the schools made the occasion for the distribution of prizes and the delivery of addresses of welcome and advice.

At University College Hospital Sir John Tweedy opened the session, and in his address dealt particularly with the importance of the experimental method in medicine. He pointed out that failure to appreciate the difference between the dissemination of knowledge and the advance of knowledge had given rise to much confusion of thought and not a little waste of endeavour. Perhaps the crudest manifestation of this confusion was the belief, real or feigned, by some persons that inquisitorial experiments are performed in hospitals on men, or on animals, or both. Less crude—nay, even creditable in a sense—was the notion that by establishing sanatoria or endowing special hospitals for the treatment of particular classes of general diseases it was possible to solve the problem of the nature and origin of these diseases and to hasten the discovery of the means of prevention and cure. He proceeded to give examples of the value of research in combating disease, instancing the discoveries relating to malaria, Malta and yellow fevers, and the arrest of hæmorrhage by the ligature of arteries, the last-named being the outcome of experiments on horses performed by Dr. J. F. D. Jones at the beginning of the last century.

At St. Mary's Hospital, the principal of the University of London, Dr. Miers, gave an address to the students on the importance of "theories." Dr. Miers said that for all people there was a certain period of life when they were ready and anxious to invent and to produce something original. It was in the period including the close of school life and the beginning of university life, or whatever came after school, that most people had been guilty of attempts to write poetry, or had endeavoured to construct a tale, or had believed themselves to be on the brink of a discovery or invention, or had taken up some new idea or theory of life which was for them, at least, a new thing of their own making and a piece of their own philosophy. It had been too much the fashion to decry youthful efforts, and to endeavour to persuade ourselves that knowledge and experience were required before anything good came out of a man unless he were a heaven-born genius.

After referring to the instances of Pasteur, Darwin, and other great workers in research, the lecturer went on to draw a distinction between the pleasure of merely acquiring knowledge or making observations, and that more intellectual pleasure of scientific discovery. He contended that after school days were over all the preparatory and educational work that they had to do should be taught and learnt in a new spirit, no longer as an exercise or a preparation, but as real active living research guided by the light of theory and inspired with the hope of discovery. He counselled medical students in all their work to adopt a theory and stick to it so long as they were able, and then, if necessary, to invent a new one, to work in the spirit of investigation in the light of their theories, and to regard all their work as belonging to medical science and illustrating the general principles of that science.

At the Middlesex Hospital, after Dr. Goodall, the sub-dean, had addressed the students on "walking the hospitals," in which he emphasised the importance of the ground-work of chemistry, biology, anatomy, and physiology for the intelligent study of clinical medicine, Lieut. Shackleton distributed the prizes and gave a sketch of some of his experiences in the Antarctic. The temperature of the explorers on the plateau went down to 94° F. or 93° F.—four or five degrees below normal—without ill effect. The members of the expedition did not suffer from colds, though on one occasion when a bale of clothing packed in England was opened they caught cold, but it disappeared when they went out, while those who remained in the hut still suffered.

"St. George's and the Progress of Physic" was the title of Dr. Rolleston's opening address at St. George's Hospital. The lecturer detailed many interesting facts in the lives of Matthew Baillie (physician to the hospital, 1787–1800), who did much for the study of anatomy; Thomas Young (physician, 1811–29), best known as the discoverer of the undulatory theory of light; John Hunter, the great anatomist and physiologist; Sir Benjamin Brodie, the well-known surgeon; and Edward Jenner, the discoverer of vaccination.

At the London School of Medicine for Women, Mrs. Garrett Anderson, M.D., in opening the proceedings, referred to the admission of Miss Woodward to the membership of the Royal College of Physicians.

Mrs. Henry Fawcett, LL.D., gave an address on "pioneering," in which she pointed out the courage and self-sacrifice displayed by the pioneer in every branch of human endeavour. The pioneers cleared away difficulties, made the road for those who followed safe and easy. If they really wished to recognise with gratitude the work which had been done for them by the great pioneers, she would wish nothing better for them than that they might be able to claim, even though they might not receive, the gratitude of those who followed after them in the noble profession to which they were devoting their lives.

FORTHCOMING BOOKS OF SCIENCE.

AGRICULTURE.

Constable and Co., Ltd.—Soils and Manures, J. A. Murray, illustrated.

ANTHROPOLOGY.

Wm. Blackwood and Sons.—The Life and Times of Akhnaton, Pharaoh of Egypt, A. E. P. Weigall, illustrated. *Constable and Co., Ltd.*—The Tomb of Queen Tiyi (Theodore M. Davis's Excavations), illustrated. *Macmillan and Co., Ltd.*—Totemism and Exogamy: a Treatise on Certain Ancient Forms of Superstition and Society, Dr. J. G. Frazer, 3 vols. *Swan Sonnenschein and Co., Ltd.*—Bushman Folk-lore, Miss L. C. Lloyd, edited by Dr. G. M. Theal, illustrated; History and Ethnography of South Africa, 1505–1795, 3 vols., Dr. G. M. Theal: vol. ii., Formation of the Cape Colony by the Dutch; vol. iii., Account of the Dutch, Portuguese, Hottentots and Bantu.

Biology.

F. Alcan (Paris).—La Critique du Darwinisme social, J. Novicow.—*John Bale, Sons and Danielsson, Ltd.*—Household Pests and Household Remedies, W. R. Boelter; Handbook of Animal Parasites of Men and of Animals, Drs. Braun and M. Luhe, translated; Biological Excursions: being an easily understood Introduction to Biology, Dr. C. Thesing, translated by W. R. Boelter, illustrated. *George Bell and Sons.*—A new edition of Hayward's Botanist's Pocket-book, containing, in a tabulated form, the chief characteristics of British plants, with the botanical names, soil, or situation, colour, growth, and time of flowering of every plant, arranged under its own order, with a copious index, G. C. Druce. *A. and C. Black.*—Egyptian Birds, C. Whymper, illustrated. *Blackie and Son, Ltd.*—Ancient Plants: a Simple Account of the Past Vegetation of the Earth and of Recent important Discoveries in that Realm of Nature-study, Dr. Marie C. Stopes, illustrated. *W. and R. Chambers, Ltd.*—British Flowering Plants, W. F. Kirby, illustrated; Mammals of the World, W. F. Kirby, illustrated; A Book of Birds, W. P. Pycraft, illustrated. *Chapman and Hall, Ltd.*—The Craftsman's Plant-book, or Figures of Plants selected from the Old Herbals, arranged with Notes and Additional Drawings, and an Essay on the Use of Plants in Decorative Design, R. G. Hatton. *Constable and Co., Ltd.*—The Biography of a Silver Fox, E. Thompson Seton, illustrated. *J. M. Dent and Co.*—Physiology, Prof. C. S. Sherrington, F.R.S., illustrated (Scientific Primers); Zoology, Prof. W. A. Herdman, F.R.S., illustrated (Scientific Primers); Nature Photography for Beginners, E. J. Bedford, illustrated; Nature Stalking for Boys through Stereoscope and Camera, W. P. Westell. *Duckworth and Co.*—Diseases of Cultivated Plants and Trees, G. Massee, illustrated. *Gustav Fischer (Jena).*—Handbuch der Anatomie des Menschen, Dritter Band, Vierte Abteilung, Lymphgefässe, Dr. P. Bartels, illustrated; Allgemeine Biologie, Prof. O. Hertwig, new edition, illustrated; Die Säugetierontogenese, Prof. A. A. W. Hubrecht; Vorträge über botanische Stammesgeschichte, Dr. J. P. Lotsy, Zweiter Band, illustrated; Studien über die Bestimmung des weiblichen Geschlechts, Prof. A. Russo, illustrated; Zoologische und Anthropologische Ergebnisse einer Forschungsreise im westlichen und zentralen Südafrika, Prof. L. Schultze, Dritter Band, illustrated; Lehrbuch der Botanik für Hochschulen, Profs. Strasburger and Jost, new edition, illustrated; Technik und Methodik des biologischen Eiweissdifferenzierungsverfahrens mit besonderer Berücksichtigung der forensischen Blut- und Fleischuntersuchung, Prof. Uhlenhuth and Dr. Weidanz, illustrated. *C. Griffin and Co., Ltd.*—The Plant Cell: its Vital Processes and Modifications, H. A. Haig, illustrated. *Harper and Brothers.*—Ant Communities, Dr. H. C. McCook. *T. C. and E. C. Jack.*—The British Bird Book, edited by F. B. Kirkman, in twelve sections, illustrated. *John Lane.*—The Book of Fern Culture, A. Hemsley; The Book of the Cottage Garden; The Book of the Sweet Pea, D. B. Crewe. *Longmans and Co.*—Beasts and Men, C. Hagenbeck, translated by H. Elliot and A. G. Thacker, with introduction by Dr. P. Chalmers Mitchell, F.R.S., illustrated; The Natural History of British Game Birds, J. G. Millais, illustrated; Field and Woodland Plants, W. S. Furneaux, illustrated; Spring Flowers at Belvoir Castle, with Directions for Cultivation and Notes on Gardening, W. H. Divers, illustrated. *Macmillan and Co., Ltd.*—Improvement of Wheat and other Cereals, Prof. R. H. Biffen. *A. Melrose.*—Darwin and Modern Science, Prof. J. A. Thomson; A First Book of Wild Flowers, M. M. Rankin, illustrated. *Methuen and Co.*—Bird Life, W. P. Pycraft, illustrated; Fungi and how to Know Them, E. W. Swanton, illustrated. *The Methodist Publishing House.*—Nature through the Microscope: Rambles and Studies of a Microscopist, Rev. W. Spiers, illustrated. *John Murray.*—Ornamental Bulbous and Tuberous Plants for the Open Air, Greenhouse and Hothouse, with Details as to Descriptions, Culture, and Propagation, J. Weathers.—*The Oxford University Press.*—History of Botany, Prof. J. Reynolds Green, F.R.S.; The Face of the Earth, Prof. E. Suess, translated by Hertha B. C. Sollas, edited by Prof. W. J. Sollas, F.R.S., vol. iv.; Knuth's Handbook of Floral Pollination, translated by Prof. J. R. Ainsworth Davies, vol. iii. *Sir Isaac Pitman and Son, Ltd.*—The Teacher's Course of Elementary Science, part ii., The Plant and its Life, F. Belton. *Smith, Elder and Co.*—The Book of Flowers, Mrs. Hinkson and Miss F. Maitland; The Small Garden Useful, A. C. Curtis, illustrated; The Small Garden Beautiful: and How to Make it so, A. C. Curtis; Common Weeds of the Farm and Garden: including the Weeds of Chief Importance both of Arable and Grass Land, and Weed Seeds, H. C. Long and J. Percival, illustrated. *The S.P.C.K.*—British Wild Flowers in their Natural Colours and Form, Prof. Henslow, illustrated. *Swan Sonnenschein and Co., Ltd.*—Plant Life: a Manual of Botany for Schools, Prof. E. Warming, translated by M. Rehling and E. M. Thomas, illustrated. *The University Tutorial Press, Ltd.*—The Senior Botany, Prof. F. Cavers. *T. Fisher Unwin.*—Leisure Hours with Nature, E. P. Larken, illustrated. *Witherby and Co.*—History of the Birds of Kent, N. F. Ticehurst, illustrated; The Vertebrate Fauna of Cheshire and Liverpool Bay, edited by T. A. Coward, 2 vols., illustrated (Mammals, Birds, Reptiles, Batrachians, T. A. Coward and C. Oldham; Fishes of Cheshire and Liverpool Bay, J. Johnstone, with a chapter on The Dee as a Wildfowl Resort, J. A. Dockray); A Monograph of the Petrels, Dr. F. Du Cane Godman, F.R.S., the fifth and concluding part, illustrated; The Adventures of Tommy, Sir Digby Pigott, C.B.; a nature-story book for boys and girls, describing further adventures of the hero of "The Changeling."

Chemistry.

D. Appleton and Co.—The Story of Sugar, G. T. Surface. *Baillière, Tindall and Cox.*—The Poisons and Pharmacy Act, 1908, with Notes, H. W. Gadd; and new editions of Aids to the Analysis of Food and Drugs, C. G. Moor and W. Partridge; Chemical Notes and Equations, G. H. Gemmell. *The Cambridge University Press.*—Outlines of Chemistry, with Practical Work, Dr. H. J. H. Fenton, F.R.S., first part. *J. and A. Churchill.*—A Course of Practical Chemistry, A. B. Ryley. *Constable and Co., Ltd.*—Van Nostrand's Chemical Annual, 1909, edited by Prof. J. C. Olsen. *Henry Frowde and Hodder and Stoughton.*—Practical Chemistry, Dr. A. M. Kellas. *C. Griffin and Co., Ltd.*—Physico-chemical Tables, J. Castell-Evans, vol. ii., Chemical Physics, Pure and Analytical Chemistry; Technical Mycology: the Utilisation of Micro-organisms in the Arts and Manufactures, Dr. F. Lafar, translated by C. T. C. Salter, vol. ii., Eumycetic Fermentation. *Macmillan and Co., Ltd.*—Chemical Constitution and Crystalline Structure, Dr. A. E. H. Tutton, F.R.S. *Williams and Norgate.*—A History of Hindu Chemistry: from the Earliest Times to the Middle of the Sixteenth Century A.D., with Sanskrit Texts, Variants, Translation and Illustrations, Prof. Praphulla Chandra Ray, vol. ii.; Introduction to the Preparation of Organic Compounds, Prof. Emil Fischer, translated by R. V. Stanford.

Engineering.

Edward Arnold.—The Theory of Structures, R. J. Woods, illustrated; Steel Roof and Bridge Design, W. H. Kerr; and a new edition of A Text-book of Electrical Engineering, Dr. A. Thomälen, translated by G. W. O. Howe, illustrated. *Blackie and Son, Ltd.*—Elementary Principles of Alternating Current Dynamo Design, A. G. Ellis. *Constable and Co., Ltd.*—A new volume of the Deinhardt-Schlomann Technical Dictionaries: Railway Construction and Operation, including Electric Traction, A. Boshart, illustrated; The Encyclopædia of Municipal and Sanitary Engineering, edited by W. H. Maxwell and J. T. Brown; Tables and Diagrams for obtaining the Resisting Moments of Eccentric Riveted Connections, E. A. Rexford, illustrated; Waterproofing: an Engineering Problem, M. H. Lewis, illustrated; Concrete Steel Construction, E. Mörsch, translated by E. P. Goodrich, illustrated; and a new edition of Bridge and Structural Design,

W. C. Thomson. *C. Griffin and Co., Ltd.*—Experimental Investigations on the Power Required to Drive Rolling Mills, translated from the German of J. Puppé; Transformers, Prof. H. Bohle, edited by D. Robertson, illustrated; Stresses in Masonry, Prof. H. Chatley, illustrated; The Design and Construction of Ships, Prof. J. H. Biles, vol. ii., illustrated; Sea-water Distillation, F. Normandy, illustrated; and new editions of Principles and Practice of Dock Engineering, Brysson Cunningham, illustrated; The Theory of the Steam Turbine: a Treatise on the Principles of Construction of the Steam Turbine, with Historical Notes on its Development, A. Jude, illustrated; A Pocket-book of Marine Engineering Rules and Tables, for the Use of Marine Engineers, Naval Architects, Designers, Draughtsmen, Superintendents and Others, A. E. Seaton and H. M. Rounthwaite. *Longmans and Co.*—Tables and Diagrams of the Thermal Properties of Saturated and Superheated Steam, L. S. Marks and Dr. H. N. Davis; Domestic Sanitary Engineering and Plumbing: dealing with Domestic Water Supplies, Pump and Hydraulic Ram Work, Hydraulics, Sanitary Work, Heating by Low Pressure, Hot Water, and External Plumbing Work, F. W. Raynes, illustrated. *E. and F. N. Spon, Ltd.*—Electric Cables: their Construction and Cost, D. Coyle and F. J. O. Howe.

Geography and Travel.

Edward Arnold.—Sikhim and Bhutan: Experiences of Twenty Years on the North-eastern Frontier of India, J. C. White, illustrated; With a Prehistoric People: the A-ki-ku-yu of British East Africa, W. S. and K. Routledge, illustrated. *A. and C. Black.*—Kashmir, Sir Francis E. Younghusband, K.C.I.E., illustrated; National Geography of Africa and Australasia, J. B. Reynolds, illustrated; Geographical Diagrams and Land Forms: Senior, H. J. Snape, three books; Descriptive Geography of the British Isles, F. D. Herbertson, illustrated; Geographical Pictures: Land Forms and how They are Made, in packets of six cards. *The Cambridge University Press.*—Cambridge County Geographies, illustrated: Dorset, A. L. Salmon; Gloucestershire, H. A. Evans. *Constable and Co., Ltd.*—Peaks and Glaciers of Nun Kun: a Record of Pioneer Exploration and Mountaineering in the Punjab Himalaya, Fanny Bullock Workman and W. H. Workman, illustrated. *W. Heinemann.*—The Heart of the Antarctic: the Story of the British Antarctic Expedition, 1907–9, E. H. Shackleton, C.V.O., 2 vols., illustrated; With a Camera in East Africa, A. R. Dugmore, illustrated. *John Lane.*—Lake Victoria to Khartoum with Rifle and Camera, Captain F. A. Dickinson, illustrated. *Longmans and Co.*—Mighty Hunters: being an Account of Some of the Adventures of Richard and Helen Cuthbertson in the Forests and on the Plains of Chiapas in Mexico, A. Russan, illustrated. *Macmillan and Co., Ltd.*—Trans-Himalaya: Discoveries and Adventures in Tibet, Dr. Sven Hedin, 2 vols., illustrated; In the Grip of the Nyika: further Adventures in British East Africa, Lieut.-Colonel J. H. Patterson, D.S.O., illustrated; The Gates of India, Colonel Sir Thomas H. Holdich, K.C.M.G., K.C.I.E., C.B., with maps and plans. *John Murray.*—Zambezia: a General Description of the Valley of the Zambezi River, from its Delta to the River Aroangwa, with its History, Agriculture, Flora, Fauna, and Ethnography, R. C. F. Maugham, illustrated; The Great Wall of China, Dr. W. E. Geil, illustrated. *Sir Isaac Pitman and Son, Ltd.*—Notes of Lessons on Geography, L. Marsh, vol. ii. *Alston Rivers, Ltd.*—Labrador: its Discovery, Exploration and Development, W. G. Gosling, illustrated. *Witherby and Co.*—Across Papua, Colonel the Hon. J. A. K. Mackay, C.B., illustrated; Savage Home-life in Southern Seas, H. W. Walker; and a new edition of Three Voyages of a Naturalist, M. J. Nicoll.

Geology.

F. Alcan (Paris).—La Géologie générale, Prof. S. Meunier, new edition. *Edward Arnold.*—The Geology of Building Materials, J. Allen Howe, illustrated. *J. M. Dent and Co.*—Geology, Prof. J. W. Gregory, F.R.S., illustrated (Scientific Primers). *C. Griffin and Co., Ltd.*—A new edition of Ore and Stone Mining, Sir C. Le Neve Foster, revised by Prof. S. H. Cox, illustrated. *Longmans and Co.*—A new edition of An Introduction to the Geology of Cape Colony, Dr. A. W. Rogers and A. L. Du Toit, with a chapter on the Fossil Reptiles of the Karroo Formation by Dr. R. Broom, illustrated. *Macmillan and Co., Ltd.*—The Origin of Ore Deposits and the Extent of Future Supplies, Prof. J. W. Gregory, F.R.S. *Milner and Co., Ltd.*—Geology, G. Hickling, illustrated.

Mathematical and Physical Science.

Edward Arnold.—An Introduction to the Theory of Optics, Prof. A. Schuster, F.R.S., illustrated. *A. and C. Black.*—Primer of Statistics, W. Palin Elderton and Ethel M. Elderton, with a preface by Sir Francis Galton, F.R.S. *The Cambridge University Press.*—Elements of the Differential and Integral Calculus, Prof. A. E. H. Love, F.R.S. *Cassell and Co., Ltd.*—New editions of The Earth's Beginning, Sir R. Ball, F.R.S., illustrated; The Story of the Heavens, Sir R. Ball, F.R.S., illustrated. *W. and R. Chambers, Ltd.*—Light, E. J. Houston; Magnetism, E. J. Houston. *Chatto and Windus.*—Astronomical Curiosities: Facts and Fallacies, J. Ellard Gore, illustrated. *Constable and Co., Ltd.*—History of the Slide Rule, Prof. F. Cajori, illustrated; Electricity, H. M. Hobart, illustrated. *J. M. Dent and Co.*—Astronomy, Prof. F. W. Dyson, F.R.S., illustrated (Scientific Primers). *Gauthier-Villars (Paris).*—Leçons élémentaires sur la Théorie des Fonctions analytiques, Ier Partie, Tome ii.: Les Fonctions algébraiques, les Séries simples et multiples, Foüet, new edition; Savants du Jour: Henri Poincaré, Biographie et Bibliographie analytique des Écrits, E. Lebon; Nouvelles Méthodes de Prévision du Temps, Guilbert; Leçons sur la Théorie de la Croissance, Borel; Principes de la Théorie des Fonctions entières d'Ordre infini, Blumenthal; Précis de Mécanique, Appell and Dantheville; Des Notations mathématiques, Enumeration, Choix et Usage, André. *C. Griffin and Co., Ltd.*—Electrical Theory and the Problem of the Universe, G. W. de Tunzelmann; Hydrographic Surveying: for the Use of Beginners, Amateurs, and Port and Harbour Masters, Commander S. Messum, illustrated; An Elementary Text-book of Physics, Dr. R. Wallace Stewart, vol. i., Matter, vol. iv., Heat, illustrated; Applied Mechanics and Mechanical Engineering, Prof. A. Jamieson, vol. v., Theory of Machines. *Harper and Brothers.*—Curiosities of the Sky, G. P. Serviss. *W. Heinemann.*—The Conquest of the Air, A. Berget, illustrated. *T. Werner Laurie.*—Chats on Electricity, F. Broadbent, illustrated; Chats on Astronomy, H. P. Hollis, illustrated. *Crosby Lockwood and Son.*—Wireless Telephony, Dr. J. E. Murray; Electric Power Conductors, W. A. Del Mar, illustrated; and a new edition of Alternating Current Machines: being the second volume of Dynamo Electric Machinery: its Construction, Design, and Operation, Dr. S. Sheldon, H. Mason, and E. Hausmann, illustrated. *Longmans and Co.*—Physical, Chemical, and Mathematical Tables, Dr. G. W. C. Kaye and Prof. T. H. Laby; The Apprentices' Course of Experimental Physics and Mechanics for Preliminary Technical Students and Secondary School Pupils, J. L. Maxim. *Macmillan and Co., Ltd.*—The Life of William Thomson, Baron Kelvin of Largs, Prof. Silvanus P. Thompson, F.R.S., 2 vols., illustrated; Lord Kelvin's Early Home: being the Recollections of his Sister, the late Mrs. Elizabeth King, illustrated; Aviation, Prof. G. H. Bryan, F.R.S.; Ancient Eclipses, and the Lengths of the Day, Month, and Year, P. H. Cowell, F.R.S.; Solar Researches, Dr. G. E. Hale, For.Mem.R.S.; Researches in Magneto-optics, Prof. P. Zeeman; The Shape of the Earth, Prof. A. E. H. Love, F.R.S.; Climates of British Possessions, Dr. W. N. Shaw, F.R.S.; Wind Pressure, Dr. T. E. Stanton; Physical Science in the Time of Nero: being a Translation of Seneca's "Quæstiones Naturales," J. Clarke, with notes on the subject-matter by Sir Archibald Geikie, K.C.B., P.R.S. *The Oxford University Press.*—The Story of the Comets, simply told for General Readers, G. F. Chambers. *Sir Isaac Pitman and Son, Ltd.*—Notes of Lessons in Arithmetic, C. W. Crook, vol. ii. *G. P. Putnam's Sons.*—Nautical Science in its Relation to Practical Navigation, together with a Study of the Tides and Tidal Currents, Prof. C. L. Poor, illustrated; In Starland with a Three-inch Telescope, W. T. Olcott, illustrated. *Alston Rivers, Ltd.*—Problem Papers for Upper

Middle Forms, H. L. Reed. *The University Tutorial Press, Ltd.*—The School Geometry, W. P. Workman and A. G. Cracknell, in 1 vol. and in 2 parts; Introduction to the School Geometry, by the same authors. *T. Fisher Unwin.*—A new edition of Wireless Telegraphy and Wireless Telephony, Prof. A. E. Kennelly, illustrated.

Medical Science.

F. Alcan (Paris).—Traité international de Psychologie pathologique et de thérapeutique des Maladies mentales, Dr. A. Marie, Tome premier. *Appleton and Co.*—Legal Medicine and Toxicology, R. L. Emerson; Minor Surgery, E. M. Foote; Preparation of the Patient and Treatment after Operation, H. A. Haubold; Diseases of Children, Dr. A. Jacobi; Surgical Diagnosis, A. B. Johnson, 3 vols.; Orthopedic Surgery, H. L. Taylor; Medical Sociology, J. P. Warbasse. *Baillière, Tindall and Cox.*—Cowhouses and the Milk Supply, G. Mayall; Incidents of Sex and Age on Diseases, G. Andrews; and a new edition of Aids to Mathematics of Hygiene, Dr. R. B. Ferguson. *John Bale, Sons and Danielsson, Ltd.*—The Stomach, Pancreas and Intestines, Dr. W. C. Bosanquet and H. S. Clogg. *George Bell and Sons.*—A new edition of Hoblyn's Dictionary of Terms Used in Medicine, and the Collateral Sciences, J. A. P. Price. *A. and C. Black.*—New editions of Text-book of Operative Surgery, Dr. Th. Kocher, translated by Dr. H. J. Stiles, illustrated; Black's Medical Dictionary, edited by Dr. J. D. Comrie, illustrated. *J. and A. Churchill.*—A Text-book of Nervous Diseases, Drs. W. A. Turner and T. G. Stewart, illustrated; A Text-book of Experimental Physiology, Drs. N. H. Alcock and F. O'Brien Ellison, with an introduction by Prof. E. H. Starling, F.R.S., illustrated; Sight-testing Made Easy, Dr. W. W. Hardwicke, illustrated; and a new edition of A Guide to the Paris Medical School, Dr. A. A. Warden. *Constable and Co., Ltd.*—Preventable Diseases, Dr. W. Hutchinson. *Gustav Fischer (Jena).*—Lehrbuch der Protozoenkunde, Zweite Auflage der "Protozoen als Parasiten und Krankheitserreger," Prof. F. Doflein, illustrated; Elektrizität und Licht in der Medizin, Prof. R. Kutner, illustrated; Entwicklung und Fortschritte der Chirurgie, Prof. R. Kutner, illustrated; Vorlesungen über chirurgische Infektionskrankheiten, Profs. Kocher and Tavel, Teil 1, illustrated; Das Virulenzproblem der pathogenen Bakterien, Dr. Laurent; Die Pathologie und Therapie der plötzlich das Leben gefährdenden Krankheitszustände, R. Lenzmann, new edition; J. v. Mering's Lehrbuch der inneren Medizin, illustrated, new edition; Grundzüge der internen Arbeiter versicherungs-Medizin, J. Rubin; Einführung in die Hydro- und Thermotherapie, Prof. J. Strasburger, illustrated; Atlas der menschlichen Blutzellen, Dr. A. Pappenheim, Zweite Lieferung, illustrated. *Henry Frowde and Hodder and Stoughton.*—The third and last volume of A System of Operative Surgery, edited by F. F. Burghard; Practical Pathology, Prof. Sims Woodhead, illustrated; History of Medicine, Prof. Max von Neuburger, translated, 2 vols.; Gallstones, Drs. M. Robson and Cammidge; Constipation, A. F. Hertz; Andrology, E. M. Corner; Infectious Diseases, C. Buchanan Ker, illustrated; Emergencies in General Practice, both Medical and Surgical, Sargent and Russell; Pathology in General Practice, Dr. T. J. Horder. *John Lane.*—The Medical Diseases of Children, R. Miller. *Longmans and Co.*—New editions of Quain's Elements of Anatomy, vol. iii., Neurology, by Profs. E. A. Schäfer, F.R.S., and J. Symington; part ii., containing the descriptive anatomy of the peripheral nerves and of the organs of special sense, illustrated; Anatomy, Descriptive and Applied, H. Gray, edited by R. Howden, Notes on Applied Anatomy revised by A. J. Jex-Blake and W. F. Fedden, illustrated. *Macmillan and Co., Ltd.*—Chronicles of Pharmacy, A. C. Wootton, illustrated; A System of Medicine, by Many Writers, edited by Sir T. Clifford Allbutt, K.C.B., F.R.S., and Dr. H. D. Wundt, a translation of the fifth and wholly re-written German edition by Prof. E. B. Titchener, in 3 vols., vol. ii., illustrated. *The University Tutorial Press, Ltd.*—Hygiene for Training Colleges, Dr. R. A. Lyster. *T. Fisher Unwin.*—Psychotherapy, Dr. H. Münsterberg. *Williams and Norgate.*—Science, Matter and Immortality, R. C. Macfie.

THE BRITISH ASSOCIATION AT WINNIPEG.

SECTION L.

EDUCATIONAL SCIENCE.

Opening Address by the Rev. H. B. Gray, D.D., Warden of Bradfield College, Berkshire, President of the Section.

The Educational Factors of Imperialism.

Among all civilised races and in all epochs of the world's history there has existed an inveterate belief that the particular age in which men live is fundamentally distinct from those that have preceded it.

Even in the most stagnant periods the illusion has prevailed that *the present day* is a period of flux and movement more or less organic, and as such either to be welcomed or to be deplored.

Notoriously difficult, however, as it is to gauge the temper of an age while we live in its midst, yet the phenomena in England at the beginning of the twentieth century seem so unmistakably marked that even a superficial thinker can hardly fail to recognise the spheres in which the symptoms of change and unrest are clearly operating. They are surely in these two—the sphere of education and the sphere of Imperial sentiment.

It may not appear inapposite, therefore, if, meeting as we do in this city of phenomenal growth and infinite enterprise, our thoughts were to be directed in my inaugural address on the science of education towards discovering what may be either called the Imperial factors in education, or conversely, and perhaps more properly, the educational factors in Imperialism.

It may be perhaps safely said in this great Dominion what might possibly be disputed in the academic groves of our ancient English universities, that there was no width of educational outlook within our own little island until the last thirty years of the nineteenth century.

The only strongholds of learning which presumed to give the lead to English secondary education were to be found on the banks of the Isis and the Cam. In these antique, I hesitate to say antiquated, fastnesses, the "grand old fortifying classical curriculum" was, until lately, regarded as the main, if not the only, highroad to educational salvation. They preserved, indeed they preserve to this day, almost the same entrance bars against admission to their thresholds as existed in pre-Reformation days. And, conformably with the pursuit of these ideal studies, the vast mass of their emoluments were, and still are, appropriated to the pursuit of the ancient models of education.

The result of this monopoly on the lower rungs of the educational ladder has been obvious, and, to a scientific thinker, lamentable. The curricula of the public secondary schools have been narrowed, or rather have never been widened coincidently with the development of new spheres of knowledge and enterprise. The students in those institutions have been dominated from above, for just as "where the carcase is, there will the eagles be gathered together," so where the emoluments have been, thither do the cleverest students concentrate their intellectual forces.

The ambition of the ablest boys has been inevitably and exclusively concentrated on a single line of study, and (as often happens in the minds of the young) other no less humane but entirely unendowed departments of human knowledge have been laughed down and despised. Opprobrious epithets, even, have been bestowed on the study of the natural sciences, while those modern linguistic achievements which opened the door to the treasures of French and German literature are still nothing accounted of in the great schools of England.

But (more marvellous than all) even the scientific acquisition of and familiarity with the literature of the mother tongue have been entirely neglected, because no room could be found for it in a time-table, three-quarters of which is confined for the great mass of boy students in the historic schools of England (whatever their tastes and capabilities) to the exclusive study of the grammar, literature, and composition in the languages of ancient Greece and Rome. And the particular methods pursued in this confined curriculum have rendered the course more straitened still. The acquisition of the literatures of the two dead languages and of the great thoughts buried with them has given place to a meticulous study of the subtleties of scholarship, and students are taught to wanton in the abnormalities of the words and phrases in which those literatures were enshrined, so that in the mind of the classical scholar the form has become, or at any rate became until quite lately, more important than the substance.

Nor is this all. Those who cannot find any stomach for such drenching doses of mediæval learning are actually driven away prematurely as lost souls from those moss-grown seats of learning, which we acclaim as the great public schools of England; and, with moral characters only half-fledged, have either been condemned to the limbo of private tuition or sent as "submerged tenths" to find, or lose, their fortunes in the great dependencies and dominions of the Empire like that in which I am speaking to-day. There has been no serious attempt made until the twentieth century by the leaders of our best-known places of secondary education to discover the bents and aptitudes of the boys committed to their charge and to give them any educational chance if they have not possessed that particular kind of perception which could find its way through the subtleties of a Euripides or a Horace. Boys have been entirely denied the opportunity of showing their mental powers in any other sphere of learning. How many unsung Hampdens or mute, inglorious Miltons of mechanical genius have been lost to the world by the non-elastic systems prevailing (even now) in our best-known educational institutions, is a tremendous responsibility for conscientious trainers of the young to contemplate and atone for.

In how many, or rather how few, places of learning in England, at the present time, can the establishment of scientifically equipped carpentering and engineering shops be found in which a young mind which finds it impossible to digest the crude morsels of Latin and Greek grammar can find resource and development? In how few schools has the connection between mind and hand and eye been scientifically trained? Such establishments, even in the first decade of the twentieth century, can be counted on the fingers of one hand.

And yet, in spite of it all, the surprising fact remains—a fact which speaks volumes for the innate vigour and originality of the English race—that, out of the stream of young men which flows out annually from our public schools[1] and colleges, so many accommodate themselves as happily as they do to the startlingly new conditions which confront them when they pass over the seas and swell the tide of population in great centres of industry and enterprise such as that in which we stand to-day. Their educational vision, however, has had such a narrow and limited horizon that no wonder a large proportion are not very adaptable to the practical life of the prairie and the forest, or even of the counting-house and the office stool. Am I, or am I not, correct in hazarding the conjecture that many specimens of this really fine English breed from the old country come to you here in this Dominion without an elementary knowledge of the

[1] It should be noted in the forefront of this address that the expression "public schools" is used throughout in its English (not in its more proper and American) sense—*i.e.*, as the educational centres of the upper classes.

laws of the world in which they live, full of antiquated prejudice and tradition, derived principally from the straitened area of their island-home experience, so that not seldom they put their hand to the plough (either literally or metaphorically) and look back, becoming wastrels instead of forceful citizens in this ever-widening Empire? "No English need apply" has been, if I mistake not, written as a memorandum inside the breast of more than one leader of industry in this great continent, and small wonder is it when the cramping character of the ultra-mediæval training which our young men have received at some of our historical public secondary schools in England is taken into account.

What remedy (you may ask) have I to propose? My answer is this: I want to force upon the attention of English educationists certain Imperial factors which should occupy an indispensable place in the educational curricula of the great schools in the Mother Country.

I would give a prominent place to the scientific teaching of geography, and particularly to historical geography, with special reference, of course, to the origin, growth, and progress of the British Empire. Such a volume as the "Sketch of a Historical Geography," by Keith Johnston, should be placed in the hands of every boy, and be known by him from cover to cover. It can hardly be realised that in many of our great classical schools to this day not more than one, or at most two, hours a week are devoted to this subject, and that it is often not taught at all beyond the middle classes in a school.

Again, I would enforce an elementary knowledge of science on every boy who passes through the stage of secondary education.

I am aware that many hard things have been said about the teaching of science in secondary education. A learned professor, who is the president of another section of the association, has passed his opinion that, as taught in our schools, it has proved of little practical or educational value. But because the methods employed have been halting, insufficient, and unscientific, it by no means follows that it should be left out of the category of school subjects. On the contrary, it appears astounding that two-thirds of the public-school boys of England should grow to man's estate without even an elementary knowledge of the laws of the world in which they live.

Lord Avebury, in his presidential address at the International Moral Education meeting held in London last autumn, told his audience an amusing story of how, walking back one beautiful summer night from the House of Commons arm-in-arm with a leading luminary on the Government benches, his companion, who had been at Eton and Oxford, gazing at the great luminary in the heavens, pensively observed: "I wonder, my dear Lubbock, whether we shall ever know why the moon changes her shape once a week at least?"

To one who aspires to seek his fortune in the wide and half-unexplored continents of Greater Britain the value of the knowledge of chemistry, geology, botany, and arboriculture can hardly be overestimated. And yet many present here could bear critical witness to the fact that a large proportion of young men go out to the North-West totally unequipped, after their public-school training, with even the most elementary knowledge of those departments of science to which I have alluded. No wonder, again, "No English need apply." Every youth we export to you ought educationally to bear this label on his back: "Every seed tested before being sent out."

But above and beyond all there should be brought into the foreground a co-ordinated study of English language and English literature. Nothing impressed me more in my visit to the United States in 1903 as one of the Mosely Commission than to observe how greatly the cultivated classes in the Federation outstripped our island-bred people in the facility and power with which they manipulated the English tongue. Awkwardness, poverty of expression, and stammering utterance mark many Englishmen of high academic distinction. But the American who, on account of the incessant tide of immigration, has to assimilate the congeries of all the nations of the earth in the shortest possible space of time, has so co-ordinated the study of his ancestral tongue in the schools of his country, that the pupil emerges completely equipped for the use of persuasive and oratorical language wherein to express his thoughts and wherewith to gain his ends.

In connection with this, may I add that it was indeed a happy augury that, at the eve of the meeting of the British Association in this great Dominion, there should have been a gathering of delegates of the Imperial Press in the centre of our small island home? "Little they know of England who only England know." The phenomenal, or rather abysmal, ignorance of the geography and of the vastness of the productive power of the British Empire which exists among the upper and middle classes in England would be ludicrous if it were not so deplorable. The loyalty and devotion of the Colonies, right unto the utmost corners of the earth, admit of no dispute. It is observable on every hand and in every national crisis. The doubt is of the loyalty of the centre of the Empire towards its extremities, through the crass ignorance which exists as to the geographical and political meaning of that Empire. I would annihilate that ignorance, as aforesaid, by putting political, historical, and physical geography in the forefront of our educational system; by lectures from your able men in Canada, or Australia, and South Africa, vivified by lantern-slides, and encouraged and endowed by the Mother Country. I would bring all visible means of presentment to bear on the education of childhood, boyhood, and youth in the Motherland.

Let me touch on one further educational factor of Imperialism. The sentiment of patriotism, unlike that of charity, is not equally capable of indefinite intension and extension. The peculiar system of education which finds vogue in England in most of our greatest institutions—the institutions from which are drawn the future leaders of the nation—is, as everyone knows, the barrack system, otherwise called the boarding system. It is not the time or place here to enlarge on the obvious advantages of that system, its unique characteristics, its power of moulding character and developing enterprise. But it has its cramping and confining side—it has a tendency to localise patriotism, to narrow a young man's mental horizon, and to ignore whatever lies outside its immediate survey. Hence the abnormal and gladiatorial devotion to games and comparatively selfish amusements, which absorb, and, in my opinion, not seldom paralyse and stifle wider, more generous, more enlightened—in fine, more Imperial instincts. However much in the field of sports the individual youth may subordinate his own self-regarding impulses to the welfare of the tiny community for which he is exercising his energies, his horizon is not wide enough to bid him rise to a sentiment of self-sacrifice and self-abandonment on behalf of a greater and more abstract ideal—love of Fatherland and loyalty to Empire.

But it is a welcome thing to be able to point to a larger sentiment lately awakened in this direction. There is no doubt that the patriotic spirit in our schools and colleges has, from whatever cause, received a great impetus in the last two years, and that the general principles of an intelligent defence of our shores from foreign aggression have been taught and construed into terms of scientific training and co-operative action with a rapidity equally surprising and welcome to those who, a few years ago, looked with something more than apprehension on the supineness of the youth of England in all patriotic regards.

"The flannelled fool and muddied oaf,"

though they have not yet received their quietus, have been less rampant lately in our educational institutions, and something like an Imperial instinct, born of increasing knowledge both of the glory and dangers of our vast Empire, has, at least in the more cultured classes, taken the place of apathy, disregard, and ignorance. In hours formerly lavished to an abnormal extent on trivial amusements, and even in hours hitherto devoted to more academically intellectual training, we find young men in our schools and colleges now with arms in their hands, shooting, signalling, scouting, and studying scientifically the art of defensive warfare. This, at least, is "a beam in darkness, of which we pray that it may grow."

Time and your patience will not allow me to touch on more than the fringe of the great educational problems which have to be solved before we can approach in English education to what I venture to call the ideal of Imperial responsibility.

In criticising the old mediæval system of education which prevailed in England until comparatively recent years, and which still has far too great a hold on the more venerable and important institutions of our island home, I would not have you suppose that I am an advocate of a complete, or even approximately complete, basis of utilitarian education. It is an easy charge for those who desire *stare super antiquas vias* to throw in one's teeth. I have little hesitation in expressing my belief that the time has come (and I speak as one whose training was that of a classical scholar, for I was brought up in the straitest sect of academical Pharisees)—I say I have no hesitation in expressing my belief that the time has come, not only that the study of the two ancient languages should be reduced to one for all except scholastic specialists, but also that both should yield pride of place in our educational system to the claims of English, modern languages, mathematics, natural science, and, not least, manual training, so that our young men should be fitly equipped to put their hand to any work which may confront them amid all the complex problems and critical situations to be found within the world-wide boundaries of the British Empire.

Germany, France, and the United States have been beforehand with us in the working out of such a reformed system of education. I am by no means one of those who believe that we should be wise in copying the methods in their entirety of any of these three peoples in their educational methods. Undoubtedly in all three there has been a more organised connection between the actual teaching given in their respective schools and the industrial, social, and political needs of the respective peoples. But no one nation is exactly like another nation in its temper and genius, and I should be sorry to advocate, for instance, the highly organised system of State education in Germany, under which it could be predicted to a certainty that boys and girls in every secondary or primary school on any given Friday morning should be studying (say) the geographical importance of Natal or the outlines of the coast of Lincolnshire. There must be many educational differences, because the idiosyncrasies of each nation differ from those of another, and I do not think we need ever fear that our intrinsic individuality will be crushed into any Teutonic cast-iron mould or ground down beneath the heel of some bureaucratic educational despotism. But that we ought to change our ways still more than we have, and adopt saner educational models, many searchings of heart through a long educational career have gradually, but overwhelmingly, convinced me. If we are apt to think, speak, and act Imperially, our education must take form from a strong Imperial sentiment, and must aim at instilling Imperial instincts in the young lives which that education is meant to control and develop.

I have spoken hitherto of this subject mainly from the point of view of secondary education, with which I am the most conversant; not only for that reason, however, but because most of those who are destined to proceed to the distant outlying parts of the British Empire, and, when there, to take prominent parts in the development of that Empire, obtain their educational equipment from the secondary schools of England. It is, therefore, on curricula offered or desiderated in them that I have exclusively dwelt. But I do not blink the fact that the proper educational organisation of our elementary schools on the one hand, and of our universities on the other, exercises a large influence on the solution of Imperial problems.

On elementary education, however, I do not propose to touch in this address, mainly because I look forward to experts in primary schools directing the thoughts of this association more directly to them. But I will touch with great brevity on the subject of university education.

Whether Oxford and Cambridge—particularly Oxford—will ever so reform themselves as to contribute largely to such solution remains to be seen. Personally, I look with far greater confidence to the more recently organised universities—those of London, Leeds, Sheffield, Manchester, and the like—to equip men educationally with those moral, physical, and intellectual qualities which are most in requisition in our great dependencies and commonwealths.

Such institutions, from their newness, their eagerness, their freedom from antiquated prejudices and vested interests, are more likely to be counted upon for many years to come to send forth a stream of young men who have learned in the school of hardness to face the difficulties and to adapt themselves to the austere conditions which are inseparable from life in unworked regions and half-discovered continents. And it is at once a hopeful and inspiring thought that the great Dominion of Canada will welcome such to herself as sufficient and efficient citizens of her all but boundless territories, that she will recognise in them "bone of her bone and flesh of her flesh," physically, mentally, and morally capable, in company with those of her own sons who have long settled in the land, of extending the borders of the Empire by enlarging its resources, and of lifting, securing, and consolidating thereby the destinies of the Anglo-Saxon race.

There is still one more educational factor on which I would ask attention before I close this address. It is this—the necessity of a closer touch educationally (in the sense of "academically") between the secondary schools and colleges of the Mother Country and similar institutions in the great Dominion and commonwealths which own her parentage. How this can be effected without great modification of our existing English system it is hard to see. But one point is quite clear. We must give up that part of our system which insists on choking the passage of the student from point to point in his education to the privileges of further education, if such examination on entrance and throughout his academical course. It would be of incalculable advantage to the Empire at large if an extension of educational intercommunion, such as was inaugurated by the noble benefactions of the late Cecil Rhodes, could be secured throughout the Empire. Undoubtedly examination would be the surest test for determining the question of the admission of a student to the privileges of further education if such examination could be conducted within a limited geographical area. But it is quite an impossible system if adopted as between the outlying parts of a great empire. The United States of America have taught us a better way. For instance, in the State of Minnesota, the university has legislated that if and when the principal of a high school of recognised position certifies that a student has successfully pursued for a specified length of time those studies in that high school that would entitle him to admission to the university, he should be admitted thereto without further delay or hindrance. What a paralysing curse the Charybdis of examination has been to all true learning only those who have suffered from it for thirty years can bear adequate testimony. It would be one of the most fertilising sources from which to secure good and progressive citizens if, instead of admitting within her borders all or any who came of their own spontaneity or from compulsion (leaving their country, perchance, for their country's good), the Government authorities in the Dominion could get into closer touch with the educational authorities of the Mother Country, who would act as guarantee that the material sent out by the Mother Country should be of an approved and first-rate quality. This might be worked on the American "accredited school" system, under which the authorities of the school sending the pupil should feel the *maximum* of responsibility in recommending his admission to the academical, or the technical, or the industrial organisations existing in the Dominion.

Since penning the first sentences of the above paragraph last June my eye has been caught by a notice which appeared in the columns of the *Times* on the 28th day of that month while I was engaged in the very act of correcting the proofs of this address; but I prefer to leave the paragraph written as it stands, as the notice in question is an eloquent commentary on my suggestion of educational intercommunion.

I may, perhaps, be allowed to read the extract from the *Times verbatim*, though it may be familiar to some at least among my audience. It is headed "International Interchange of Students—a New Movement."

"We have received," says the *Times*, "the following interesting particulars of a new educational movement to provide for the interchange of University students among the English-speaking peoples.

"The object is to provide opportunities for as many as possible of the educated youth of the United Kingdom, Canada, and the United States (who, it is reasonable to suppose, will become leaders in thought, action, civic and national government in the future) to obtain some real insight into the life, customs, and progress of other nations at a time when their own opinions are forming, with a *minimum* of inconvenience to their academic work and the least possible expense, with a view to broadening their conceptions and rendering them of greater economic and social value, such knowledge being, it is believed, essential for effectual leadership.

. . . .

"The additional objects of the movement are to increase the value and efficiency of, as well as to extend, present University training by the provision of certain Travelling Scholarships for practical observation in other countries under suitable guidance. These scholarships will enable those students to benefit who might otherwise be unable to do so through financial restrictions. It also enables the administration to exercise greater power of direction in the form the travel is to take. In addition to academic qualifications, the selected candidate should be what is popularly known as an 'all-round' man; the selection to be along the lines of the Rhodes Scholarships.

"The further objects are to extend the influence of such education indirectly among the men who are not selected as scholars (through intercourse with those who have travelled) by systematic arrangements of the periods' eligibility while they are still undergraduates.

"To promote interest in imperial, international, and domestic relations, civic and social problems, and to foster a mutual sympathy and understanding imperially and internationally among students.

"To afford technical and industrial students facilities to examine into questions of particular interest to them in manufactures, &c., by observation in other countries and by providing them with introductions to leaders in industrial activity.

"To promote interest in travel as an educational factor among the authorities of Universities, with a view to the possibility of some kind of such training being included in the regular curricula.

"To promote interest in other Universities, their aims and student life, the compulsory physical training, and methods of working their ways through college, for example, being valuable points for investigation.

"To promote international interchange for academic work among English-speaking Universities; and, in the case of the British Empire, to afford facilities for students of one division to gain, under favourable circumstances, information relative to the needs, development, and potentialities of other divisions; and to promote an academic interchange of students among the Universities of the Empire.

"As already indicated, there is a widespread interest in the movements so far as the United Kingdom is concerned; while in Canada and the United States there is also a widespread recognition of the value of the scheme; and although committees have not been actually organised there as in this country, a very large body of the most prominent educationists are strongly in favour of the plan, and have promised their co-operation if the scheme is financed.

"It is proposed to establish two students' travelling bureaux, one in New York and one in London; an American secretary (resident in New York) and a British secretary (resident in London), both of whom shall be college men appointed to afford every facility to any graduate or undergraduate of any University who wishes to visit the United States, Canada, or the United Kingdom for the purpose of obtaining an insight into the student, national, and industrial life of those countries. The bureaux will undertake the work of providing information relating to United States, Canadian, British, and other English-speaking Universities for the use of students, undergraduates, and others. They will also provide information relating to educational tours of any description in English-speaking countries, and the arrangement of tours suitable to the needs of the inquirer with a view to his obtaining the greatest facilities for education with a *minimum* of expense. Furthermore it will be their duty to provide information as to the best places for the study of educational, governmental, industrial, and social problems in the United States, Canada, the United Kingdom, and other parts of the Empire, as well as to provide introductions to leaders in the above-named spheres of activity, besides undertaking the organisation and conduct of special tours for educational purposes, if necessary.

"It is proposed to provide 28 travelling scholarships, 14 of these being available for Universities in the United Kingdom, 10 for Universities in America, and four for Universities in Canada. The arrangements will be controlled by general committees, one for the United Kingdom and one for Canada and the United States, unless it is found necessary to inaugurate a separate committee for each of the latter."

You will observe, then, that a scheme which I had ventured to suggest as being "of incalculable advantage to the Empire" had, before I wrote the words quoted, been advocated entirely without my knowledge by a body of influential educational leaders in England, whose names were appended to the notice which I have read; and I need only add that it is quite certain that I am interpreting the sentiments of all here assembled in wishing God-speed to the development of the scheme, which seems likely to prove, if carried into effect, a great, if not the greatest, educational factor of Imperialism.

But it may be objected here, Is not your own horizon circumscribed? Why should educational ideals be limited, even by so extended a conception as Imperialism? Should not the ultimate aim of all education be, not the federation of one race only, but the federation of the world at large—the brotherhood of man?

I am not concerned to deny that such a lofty conception is the true end of all physical, moral, and mental training.

But if the master mind of a Milton was content to define true education to be "that which fits a man to perform justly, skilfully and magnanimously all the offices, both public and private, of peace and war," it may well suffice us if we extend our (at present) too narrow conceptions (the aim of which seems to be the cultivation of a mere island patriotism) to a sphere which has for its end the imperialistic sentiment of a whole race.

It may, indeed, be well doubted whether a race-sentiment is not an ultimate factor beyond which it is impossible in an imperfect world to go. Universal philanthropy in its most catholic sense is a sentiment which the limited conditions of the earth's surface seem to render impossible. So long as men's ambitions are an unlimited quantity, and so long as the habitable globe remains, as it ever must remain, a limited quantity, so long will the populations of the world be continually liable to shifting movements and frequent dislocations. Practical educationists, then, must inevitably confine the scientific consideration of aims and methods in education to the development of the highest interests of their race rather than of mankind at large.

And that being so, the last point on which I would insist in dealing with the educational factors of Imperialism is to emphasise the importance of what the educationists of the United States call "civics" as the binding power which should fasten together all the separate educational faggots in any Imperial scheme of education—the duty of personal service to the State, the positive obligation which makes us all members incorporate in one Imperial system. In our love of individual freedom, in our jealousy of interference with our individual liberty of action, in our insular disregard and depreciation of intellectual forces working in our sister communities beyond the seas, we have lost sight of this civic responsibility which has ever lain on our shoulders and from which we can never dissociate ourselves, so long as our Empire remains as part of our ancestral heritage.

It is this positive duty towards each other and our race beyond the seas which those who live in our island home have been slow in realising, and it has been a real blot on our educational system that such ideas as Imperial responsibility and Imperial necessities have not been inculcated in the young people in our schools and colleges. As an illustration, I may observe that it has been even debated and doubted in some responsible quarters in England whether the Union Jack should wave over our educational institutions on the days of national festivity and national observance.

To sum up. By these and other kindred means I would urge a closer educational touch between the Mother Country and the Empire at large.

Long ago a great Minister was able to say: "Our hold of the Colonies is in the close affection which grows from common names, from kindred blood, and from similar privileges. These are ties which, though light as air, are strong as links of iron."

But times have changed. To-day we are confronted with the problems of a vast and complicated Empire—great commonwealths, great dominions, sundered from each other by long seas and half a world, and however closely science has geographically brought them together, we cannot in soul and sympathy, nor ultimately in destiny, remain attached, affiliated as mother and children should be, unless we grapple to each other and understand each other in the greatest of all interests—the educational training which we give to our children in the one part of our Empire to make them suitable citizens in another.

In suggesting reforms and modifications in which this educational unity may best be expressed, forgive me if I have but touched, and touched inadequately, on the fringe of a great subject, the transcendent importance of which it requires no elaboration of mine to impress on the earnest attention of the people of this great Dominion —which great Dominion may I be allowed to salute, without flattery or favour, as the most favoured by natural beauty and by virgin wealth of all the children of our common Motherland? May I salute her in terms which formed the old toast with which the two greatest of our English public schools, Winchester and Eton, pledged each other when we met in our annual cricket contest: *Mater pulchra, filia pulchrior!*

GEOLOGY AT THE BRITISH ASSOCIATION.

If the number of geologists from the British Isles who attended the meeting of Section C was somewhat limited, the number from the American continent was considerable, and it was greatly to them, and especially to those from Canada, that the markedly successful character of the sectional meetings was due. The Canadian geologists not only contributed a particularly interesting series of papers, but also arranged two excursions, which were largely attended.

The papers read before the section may be classified in four groups.

(1) *Stratigraphical Geology.*

Mr. J. B. Tyrrell's account of the geology of Western Canada, which followed the president's address, afforded an excellent introduction to the succeeding series of papers on local geology. *Pre-Cambrian geology* naturally occupied a good deal of the attention of the section, which had the advantage of hearing papers by Prof. A. P. Coleman on the bearing of pre-Cambrian geology on uniformitarianism, and by Prof. W. G. Miller on the pre-Cambrian rocks of Canada. Prof. Coleman described the somewhat complicated subdivision which Canadian geologists recognise in the pre-Cambrian rocks, and pointed out the varied nature of their origin, including as they do quartzites, sandstones sometimes passing into arkose, carbonaceous shale, limestone, igneous rocks both volcanic and intrusive, and metamorphic rocks in great variety. The most interesting point about Prof. Coleman's paper was the evidence he brought forward for the existence of glacial conditions in pre-Cambrian (Huronian) times, and the bearing of this on uniformitarianism. He exhibited stones which he had extracted from the pre-Cambrian conglomerate of the Cobalt district, the upper surface of which was scratched by the Pleistocene glaciation, while the lower (embedded) surface after extraction, also showed striæ which it was difficult to distinguish from those produced by the Pleistocene ice. In the subsequent discussion Drs. Fairchild, Strahan, Warren Upham, and Dwerryhouse expressed the opinion that Prof. Coleman had established his contention.

Prof. Miller's paper was chiefly directed to bringing into prominence the almost limitless mining possibilities of the Canadian pre-Cambrian rocks. He pointed out that although they have as yet been very imperfectly explored, they are already, in the Cobalt and Sudbury districts, the chief, or among the chief, world's source of nickel, cobalt, silver, and arsenic, while in the Michigan district their yield of copper and iron is one of the most important in the world. The same may be said with regard to the mica mines of Ontario.

The stratigraphy of the Palæozoic rocks of the British Isles was represented by the reports of several of the association's committees, including the following:—(1) Mr. E. S. Cobbold, on the Cambrian rocks of Comley, Shropshire; (2) Prof. S. H. Reynolds, on the igneous and associated rocks of the Glensaul district, Co. Galway; and (3) Dr. A. Vaughan, on the faunal succession of the Lower Carboniferous (Avonian) of the British Isles. The latter report included an important series of tables embodying Dr. Vaughan's latest views on the subdivision of the Lower Carboniferous rocks, and the correlation of the sequence in various parts of the British Isles. With the view of helping to bring Dr. Vaughan's work to the notice of Canadian geologists, Prof. S. H. Reynolds exhibited a series of lantern-slides of the two principal sections of the Bristol district, those of the Avon and of Burrington. He also contributed a paper on the lithology of the Burrington section. Another stratigraphical paper having reference to the Carboniferous rocks of the south-west of England was that by Mr. H. Bolton, on new faunal horizons in the Bristol coalfield, in which further evidence was brought forward of the occurrence of marine episodes in the Coal-measures of this part of the country. The only remaining stratigraphical paper was one by Dr. D. Woolacott, on the classification of the Permian rocks of the north-east of England.

(2) *Glacial Geology.*

Glacial geology naturally had much attention paid to it by the section when meeting in Canada, and the members were to be congratulated on hearing from Dr. Warren Upham an account of the glacial Lake Agassiz, in connection with which his name is so well known. At its maximum extent, according to Dr. Upham, it covered an area of about 110,000 square miles, exceeding the combined areas of the five great lakes tributary to the St. Lawrence. Lake Winnipeg forms its reduced representative at the present day. Dr. Upham's paper was followed by an interesting discussion, in which many leading Canadian and American geologists took part. Members of the section had, further, the opportunity of seeing some of the glacial and other deposits of Lake Agassiz on excursions which were made to Stony Mountain and Bird's Hill.

Prof. A. P. Coleman, in a paper on the extent of the ice sheets in the Great Plains, pointed out that while boulders from the Archæan region to the east are spread over the great plains as far west as Calgary, further to the west an older drift, derived from the Rocky Mountain region, is met with, this sometimes passing below the eastern drift. In places boulders from the eastern drift are found stranded 5000 feet up on the sides of the Rocky Mountains. These Prof. Coleman believes were stranded from ice-dammed lakes at a time when the Rocky Mountain region stood at a lower level than it does at present.

Glacial geology was further represented by a paper by Dr. A. Strahan, on the glacial geology of South Wales; by a lantern lecture by Dr. A. R. Dwerryhouse, on the glacial geology of Britain, as illustrative of the work of the committee on erratic blocks, and by the report of the committee for the investigation of the fossiliferous drift at Kirmington, Lincolnshire, and elsewhere.

(3) *Economic Geology.*

This subject, as might have been expected, was well to the fore, a series of most interesting papers on the ore deposits of Canada being given by Canadian geologists, Prof. W. G. Miller dealing with the gold, silver, and iron ores, Prof. A. P. Coleman with copper and nickel, Mr. J. B. Tyrrell with placer mining, and Prof. T. L. Waller with the rare metals. Prof. Miller prefaced his description of the gold and silver mining with a general account of mining in Canada. He pointed out that, until a few years ago, the central part of Canada was regarded as purely agricultural. The discovery of the rich ore deposits of Sudbury and Cobalt in 1908 completely changed this, and the value of the mineral produce rose from about a million dollars in 1901 to eighty-seven million dollars in 1908. The most interesting feature of the mineral wealth of Canada is its great variety. Canada is now the largest producer in the world of nickel, cobalt, asbestos, and corundum. As regards the immediate subject of his paper, Prof. Miller stated that the output of gold from the Archæan districts was not great, but it was found in British Columbia and the Yukon, the latter district standing third in the world's output. Gold is found also in Nova Scotia, and has recently been discovered at Prince Albert, in Saskatchewan. The great silver-producing region is Cobalt. The Canadian production of iron is as yet comparatively unimportant.

Prof. Coleman pointed out that copper is found in many parts of Canada, and in British Columbia some very low-grade ores are worked to a profit. Most of the copper of Ontario is found associated with nickel, the great locality for these substances being Sudbury, where the deposits occur in the marginal portion of a laccolitic mass of norite intruded between the Upper Huronian and the Animikie.

In dealing with placer mining, Mr. J. B. Tyrrell pointed out that it was almost confined to the mountainous region of the west, and that the industry had gradually spread along the river valleys from California northwards until eventually the Klondyke deposits were met with. These owed their value rather to exceptional conditions of erosion than to special richness. Mr. Tyrrell estimated that the Yukon district had yielded hitherto about six million ounces of gold, and might yield another four million.

Prof. T. L. Waller concluded the series of papers on the mineral resources of Canada with a description of the rare metals. Platinum and palladium are found in small quantities in the native state in placer workings at various points. Platinum has also been found combined with arsenic in the decomposed superficial deposits of the Sudbury district. Canada is also rich in undeveloped deposits of molybdenum and tungsten.

(4) *Palaeontology and other Subjects.*

In addition to the president's masterly address on the evolution of vertebrate life as shown by fossils, vertebrate palæontology was represented by two short papers, also by the president, recording the discovery of dinosaurian remains in the Cretaceous rocks of Australia and the Trias of Brazil, and by the report of the committee appointed to investigate the footprints of the Trias of Great Britain.

Other papers read before the section were by Mr. E. Dixon, on unconformities on limestone and their contemporaneous pipes and swallow-holes; by Prof. E. F. Chandler, on the rainfall run-off ratio in the prairies of Central North America; and by Dr. Tempest Anderson, on the volcano of Metavanu, in the Samoa Islands. The eruptive phenomena of this volcano closely resemble those of Kilauea, in the Sandwich Islands; but while the latter volcano, according to Dr. Anderson, is in its old age, the former shows the same phenomena with the exuberance of youth. A further interesting point in Dr. Anderson's paper was his confirmation by actual observation of the subaqueous production of the "pillow" structure in lavas.

The reports of the following committees were also presented:—on South African strata, by Prof. J. W. Gregory; on topographical and geological terms in South Africa; on geological photographs, this taking the form of an exhibition of lantern-slides illustrating certain aspects of British scenery; on the crystalline rocks of Anglesey; on the composition of the Charnwood rocks; on further excavations on Neolithic sites in north Greece; and on the salt lakes of Biskra. This latter report, which was represented merely by the title, refers to the work upon which the late recorder of Section C, Mr. Joseph Lomas, was engaged at the time of his lamented death.

ENGINEERING AT THE BRITISH ASSOCIATION.

THE proceedings in Section G consisted largely of papers by Canadian engineers on a closely related group of subjects, determined by the conditions of Winnipeg. Winnipeg occupies a peculiar geographical position, similar in some respects to Singapore or Buenos Ayres, as the gate of a great productive area. This position, and the bearing on it of the communications to the section, are most easily explained by recalling the geography of the country. Canada consists roughly of five sections.

(1) The Laurentian area, the so-called shield of Canada, is defined by the St. Lawrence and the chain of lakes which extends through Winnipeg, Athabasca, and the Great Slave and Bear Lakes to the polar regions. This vast district lying round Hudson's Bay is in the main a wilderness of lakes, rocks, and forests, swept clean of all cultivable soil by Glacial ice, except in certain areas where later Palæozoic rocks have been left over the Laurentian.

(2) The rich agricultural country between the Laurentian area and the Rocky Mountains. This, the modern provinces of Manitoba, Saskatchewan, and Alberta, is the northern section, reaching to 60° N. lat., of that geographical area of which the southern section is the basin of the Mississippi.

(3) The mountain region between the eastern foothills of the Rockies and the Pacific, a strip 400 miles wide extending up the whole coast.

(4) The fertile lands along the south of the St. Lawrence, New Brunswick, Nova Scotia, and the peninsula between Erie and Huron.

(5) The Arctic regions of tundra and ice.

To these five sections must be added for administrative purposes another of equal importance.

(6) The navigable route of St. Lawrence and the lakes.

Winnipeg is the gate between (2) and (6).

This section (2), 1200 miles long from north-west to south-east, and from 300 to 500 miles wide, is of extraordinary fertility, and especially adapted for growing wheat. The isothermals take a strong bend upwards in this region, and wheat has been ripened as far north as the Great Slave Lake, in 62° N. lat. The fertility of the soil is such that wheat can be grown remuneratively for many years in succession, and where the practice has obtained of allowing the land to be fallow one year in four to prevent exhaustion, it has to be sparsely tilled in the seasons following the fallow years to prevent the crops choking themselves by their own exuberance. Of this area, only 5 per cent. is yet cultivated, but in 1908 this produced 30 million quarters of grain, and carried nearly 4 million head of stock.

So long as the United States grows enough wheat for her own consumption, and until a new route is opened to the Atlantic by the Nelson or Churchill rivers on Hudson's Bay, the main trade of the provinces must pass east between Lake Winnipeg and Lake of the Woods. Here on the Red River, where the fertile lands end and the Laurentian wilderness begins, is Winnipeg, on the site of an old Hudson Bay Co.'s fort, Upper Fort Garry. A better site would have been at Selkirk or Lower Fort Garry, lower down the river and nearer the lake, but the site of the great depôt was ultimately fixed by the Canadian Pacific Railway for indirect reasons.

The great engineering questions of the city are to find the best means to develop the agricultural industry of the north-west, and to improve the trade routes, especially to the Atlantic. The papers presented to the Engineering Section dealt largely with these two subjects. Two papers on the grain industry, each of considerable length, were contributed by Mr. John Miller, an official at the experimental farm at Indian Head, Saskatchewan, and by Mr. George Harcourt, Deputy Minister of Agriculture of the Province of Alberta. The latter of these, especially, was a paper of exceptional ability and interest, the author being intimately acquainted with his subject and an admirable lecturer. He exhibited a map showing some of the extreme points in which wheat has been successfully ripened, and the area of potential grain-growing country. The subjects of these papers were not strictly those of engineers, but the urgent need for improved communications with which other papers dealt could hardly have been realised without them. These other papers fell into two groups, viz. deep water and railway communications. The problems of wheat transport are (1) to bring ocean steamers to the nearest possible point to the wheat fields, and (2) to handle and transport the grain to the ports as efficiently as possible. At present ocean-going steamers drawing not more than 27½ feet of water can reach Montreal at all tides, and this depth is being increased to 30 feet. Ships drawing 14 feet of water can pass between Montreal and Lake Erie by the lower Ottawa river, the Lachine and Rideau canals, Lake Ontario, and the Welland canal. Erie, Huron, Michigan, and Superior can be navigated by vessels drawing 20 feet of water, the depth of water in the Soo locks. If the depth of water in the lower Ottawa river, and in the Lachine, Rideau, and Welland canals, in all of which the depth is now 14 feet, could be increased to 22 feet, ocean steamers of, say, 7000 tons, by taking in or discharging the last 1000 tons at Montreal, could reach Lake Superior and charge or discharge cargo at Port Arthur, the nearest point to Winnipeg. Thus, subject to a small proportion being transhipped at Montreal, cargoes could be carried in bulk by ocean steamers of the size of ordinary tramps between Port Arthur, in the very heart of the continent, and any Atlantic port.

This route, however, is open to serious objection in that it lies through the Detroit River, and is liable to interruption by political difficulties with the United States. A new canal route which is not subject to this objection has been surveyed. The scheme, which is called the Georgian Bay Canal Scheme, provides for a canal between Montreal and Lake Superior by way of the Ottawa River, Lake Nipissing, and the Pickerel and French rivers, having a minimum depth of 22 feet and locks 650 feet long, at a cost of 20 millions sterling. This canal would accommodate ships of the type now used to carry ore and coal between Cleveland and Lake Superior, as well as ordinary ocean-going tramp steamers. As a set-off to the cost, the water-powers that would become available are put at one million horse-power, and the value of the country that would be opened up would be very large. It seems probable that the work will be started before long.

On this side of the subject three considerable papers were read. Colonel Anderson described the navigation works on the St. Lawrence up to Montreal, and showed maps of all the lights and buoys, and of the dredging accomplished and still to be done. Mr. St. Laurent placed in the president's hands copies of the Government reports and plans of the Georgian Bay Canal surveys, and the latter read a paper to the section on the subject. In addition, Major George Stephens contributed an admirable paper on the St. Lawrence River as an imperial highway, and on the importance of Montreal as a central port of distribution.

The Hudson Bay route is not likely to be developed in the immediate future, and little reference was made to it. The Canadian Northern Railway has surveyed a route to Churchill, on the Hudson Bay, though the mouth of the Nelson may ultimately be preferred, as it is said that this river, draining lands far to the south, even beyond the U.S. frontier, is very free from shore ice. In the future Canadians look to the Nelson River being made navigable up to Lake Winnipeg, and from there the Saskatchewan may carry ships to the foothills of the Rockies.

Mr. T. E. Schwitzer, assistant chief engineer of the Canadian Pacific Railway, contributed a paper on some important works on that railway. The Lethbridge Viaduct is an immense structure, more than a mile long and more than 300 feet high, and the mode of construction was strikingly bold and effective. The revision of the grades in Kicking Horse Pass, involving the construction of two long spiral tunnels in the rock, was also described, and the great increase obtained in the loads hauled by a given engine-power. Careful grading on lines where the heavy loads of grain and other material usual in Canada are hauled is of extreme importance, and much was said on the cost of rail transport both in this paper and in two others by Mr. Macpherson and Mr. Lanigan. Mr. Duncan Macpherson described the organisation of the surveying parties for the new line between Monckton and Winnipeg, to be continued to the Pacific coast as the Grand Trunk Pacific. It is this line which is interrupted near Quebec by the failure of the great cantilever bridge while under construction. Mr. H. W. Lanigan wrote on the organisation for the collection and transport of grain in the wheat area. As assistant manager of freight traffic on the Canadian Pacific Railway at Winnipeg he has an intimate knowledge of that subject. The policy of the Canadian Government is to forbid the owners of elevators to trade in wheat and to restrict them to the duties of collecting and despatching, much as railways are restricted to the work of carriers. The Government undertakes the inspection and grading of the wheat, and performs this work with extreme care, so that the wheat is sold by the farmer and bought by the ultimate purchaser strictly by grade, not by sample. That is to say, the quality of the wheat having been determined by the Government inspector, the price paid per bushel is the current price for that quality. The system is too complex for more than reference here, but the advantage both to farmer and purchaser of an authoritative determination of quality is obvious.

Besides the papers we have referred to, which are all mainly of Canadian interest, three electrical papers were contributed by Prof. Marchant, Prof. Thornton, and Mr. E. A. Watson respectively, all dealing with three-phase transmission lines. Other papers were by Sir John Thornycroft, on skimming boats; by Colonel Ruttan, the city engineer of Winnipeg, on the high-pressure water plant of the city; by Mr. C. B. Smith, on a new hydro-electric power plant now being erected by the city authorities; by Mr. C. E. Larard, on torsional tests on materials—a very elaborate and detailed paper; by Prof. Coker, on an optical method of exhibiting strain; by Mr. Dugald Clerk, on the work of the gaseous explosions committee; and by Prof. Foster, on a systematic examination of the properties of the different coals of Canada now being carried out at McGill University. We have left to the last a paper on the Panama Canal by Colonel Goethals and Sir William White's address. Colonel Goethals is engineer-in-chief and president of the Isthmian Canal Commission. The paper was a long one, and very fully illustrated by lantern-slides. Colonel Goethals himself was unable to come to Winnipeg to deliver it, but Lieut. Goethals, of the United States Army, who has been engaged on the canal under his father, gave an account of it and exhibited the illustrations. It will be remembered that the failure of the French operations was largely due to two causes, one of which was the excessive mortality among the labourers and staff from tropical fevers, and the other the violent floods of the Chagres river. Since that time the cause of tropical fevers has been traced to the mosquito, and the American engineers, with characteristic thoroughness, have extirpated the mosquito over the whole of the canal zone, thereby bringing the rate of mortality to the figure of a well-organised town in a temperate climate. The measures which have enabled them to do this are of extraordinary interest, and the results are almost romantic. The engineering difficulties, which were mainly the floods of the Chagres, mentioned above, and the enormous excavation of the Culebra ridge, have been met by a design which promises to be quite successful. The Culebra ridge is much nearer to the Pacific than to the Atlantic shore, and deep valleys run down from the divide to the Caribbean Sea, one of which carries the Chagres river. Across this an immense earthwork dam, the Gatun dam, is being constructed, forming a great lake 160 square miles in area in the centre of the isthmus. The floods of the Chagres and of the other rivers, its tributaries, flowing down these mountain valleys, can discharge themselves into this large body of water without doing any damage to the canal works, however violent the floods may be. The level of the water in the lake is regulated by a spillway, built in a natural hill which forms part of the Gatun dam, discharging below the dam into the old bed of the Chagres. The surface of the lake is 85 feet above the mean sea-level, and is reached by three locks on each side. The lake is amply sufficient to provide the necessary water for lockage and waste during the dry seasons. Lastly, this high summit-level has reduced very largely the necessary amount of excavation in the Culebra cut. Even then, however, this amounted to 150 million cubic yards. Besides photographic views of the works and machinery, there were exhibited copies of some of the working plans and surveys, and it is much to be hoped that the whole paper may be published in full. A recommendation to this effect was made by the committee.

Sir William White was expected to deal in his presidential address with problems of naval organisation and construction, peculiarly interesting at a time when the Imperial Naval Conference was sitting in London. His address was, however, an admirable preface to the series of papers on questions of water and railway transport which followed it, and was a masterly review of the position of Canadian commerce.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—Prof. Jordan Lloyd has accepted the invitation of the council to succeed Prof. Bennett May in the chair of surgery.

Prof. Peter Thompson, of King's College, London, has been appointed professor of anatomy in the place of Prof. Arthur Robinson.

The chair of zoology, rendered vacant by the death of Prof. T. W. Bridge, F.R.S., has been filled by the election of Dr. Frederick William Gamble, F.R.S.

The following appointments have been also made:—Dr. Jessie S. Bayliss, as lecturer in botany; Messrs. F. W. Aston and H. B. Keene, as demonstrators in physics; Mr. T. F. Wall, as assistant lecturer and demonstrator in electrical engineering; and Mr. Cyril S. Fox, as demonstrator in coal mining and lecturer in mine surveying.

Cambridge.—The professorship of zoology and comparative anatomy is vacant by the resignation of Prof. Sedgwick. The electors will meet for the purpose of electing a professor on Friday, October 29. Candidates are requested to send in their names to the Vice-Chancellor on or before October 22.

Notice is given that the Quick professorship of biology is vacant, as the period of three years for which Dr. Nuttall was appointed has now ended. The election will take place on Friday, October 29. Candidates are requested to send in their applications to the Vice-Chancellor on or before Friday, October 22.

Mr. F. A. Potts, of Trinity Hall, has been appointed demonstrator of comparative anatomy for one year from Michaelmas, 1909. Mr. L. A. Borradaile, of Selwyn College, has been appointed demonstrator of animal morphology for one year from Michaelmas, 1909. Mr. F. T. Brooks, of Emmanuel College, has been appointed senior demonstrator of botany for two years ending September 30, 1911, and Mr. D. Thoday, of Trinity College, has been appointed junior demonstrator of botany for the same period.

An anonymous benefactor has promised the sum of 100*l.* towards the construction of a field laboratory in the vicinity of Cambridge, in connection with the Quick Biological Laboratory. The sum of 100*l.* has been granted by the advisory committee of the tropical diseases research fund towards the expenses of the Quick Laboratory in the present year.

Glasgow.—The University is to benefit to the extent of 10,000*l.* from the estate of the late Dr. Robert Pollok. The amount in question is given for the endowment of a university lectureship for original research in materia medica.

Manchester.—The new chemical laboratories (to be known as the John Morley Chemical Laboratories, after the Chancellor of the University) were opened on Monday last by Sir Henry Roscoe, F.R.S., professor emeritus of chemistry in the University.

Oxford.—It is proposed to confer the degree of D.C.L., *honoris causa*, upon his Excellency Osman Hamdy Bey, director-general of the Imperial Ottoman Museum of Antiquities, Constantinople.

Mr. John Finnigan has been appointed secretary to the Senate of Queen's University, Belfast.

The new laboratories for physiology, chemistry, and physics of the London Hospital Medical College are to be opened on Friday of next week by Prof. W. Osler, F.R.S., who will afterwards deliver the Schorstein lecture.

Courses of lectures on the fermentation industries are announced for delivery at the Sir John Cass Technical Institute, Aldgate. The inaugural lecture (on chemistry in relation to brewing and malting) was given by Mr. A. R. Ling on Tuesday last.

Mr. H. A. S. Wortley, of Downing College, Cambridge, has been appointed assistant lecturer in the day training department of the University College of North Wales, Bangor. The inaugural lecture of the present session was delivered on Tuesday last by Prof. W. M. Flinders Petrie, F.R.S., who spoke on recent excavations in Egypt.

A course of ten lectures on economics, by Mr. Alfred Milnes, has been arranged for delivery at Bedford College for Women in connection with the course of scientific instruction in hygiene at the institution. The lectures are specially designed for women preparing to be factory inspectors or desiring to take part in other public work. They will be delivered on Mondays, beginning on October 11.

The new chemical laboratory of the Pharmaceutical Society's School of Pharmacy was opened on Wednesday of last week. On the same day began the new session of the school, when the opening address was delivered by Prof. Alexander Tschirch, of the University of Bern, who took as his subject "The Future of Pharmacognosy." At the conclusion of the address the Hanbury gold medal was presented to Prof. Tschirch.

The Leathersellers' Technical College, which has been erected at a cost of nearly 20,000*l.* in the Tower Bridge Road, was opened by the Lord Mayor of London on Friday last. In declaring the college open, Sir G. Wyatt Truscott said that no subject was of greater interest than the development of technical education and the splendid part which the city guilds had played in that development. The city companies had found, in assisting technical education, an opportunity of re-associating themselves with the interests of the trades that they represented. In the leather trade, unfortunately, the system of apprenticeship had somewhat died out, but he hoped that it might be revived.

In opening a new wing of the Leicester Technical and Art Schools on Thursday last, Prof. Silvanus P. Thompson, F.R.S., said the conclusion he came to after a tour of the industrial centres of Europe was that the most successful technical schools were those which carefully studied the needs of their own special industries. The disastrous tale of the manufacture of dyes from coal-tar products was not without its warning to this country. The trained brains sent out by German universities and technical colleges profited by the inventions of English chemists, and we paid 2,000,000*l.* a year for dyes manufactured abroad from coal-tar products. Thanks largely to technical education, a similar disaster was averted when the electrical engineering industry was developed.

According to a note in the *Engineer*, arrangements have been made with several of the leading engineering firms in Glasgow and elsewhere by which students of the South-western Polytechnic Institute are allowed to enter their apprenticeship. Students who satisfactorily perform the work in the mechanical engineering department in the first year may proceed at once and continue their work at one of the firms arranged for, and students who have satisfactorily finished the second-year course are allowed to proceed with their apprenticeship and return to the college and continue their third session. Furthermore, students who obtain the diploma of their college will have their apprenticeship reduced. Under these conditions a student can obtain a first-class training as an engineer, and apprentices who perform satisfactorily in the workshop are allowed to enter the drawing-office.

Attention has often been directed in these columns to the complete equipment and excellent arrangements of the London polytechnics. Among these institutions, the Battersea Polytechnic takes a prominent place. The calendar for the session which has just commenced shows that for this winter entirely new classes have been started in engineering estimates, electrochemistry, chemical engineering, dyeing and cleaning, analysis of foods and drugs, and sanitation. In addition to this, it is of interest to notice that new accommodation, in the form of laboratories, workshops, and equipment, is being provided in mechanical, electrical, and motor engineering, chemistry, natural science, art, and domestic economy, these extensions having been rendered possible by the assistance of the London County Council, and it is expected that they will be to some extent ready for use during the current session.

The following free courses of advanced science lectures are announced by the University of London:—the geographical distribution of plants, by Prof. Percy Groom and Mr. A. W. Hill; evolutionary aspects of palæobotany, by Mr. E. A. N. Arber; fertilisation, by Prof. J. B. Farmer, F.R.S.; the anatomy of plants in relation to external conditions, by Mr. L. A. Boodle; geology and evolution, by Prof. J. W. Judd, C.B., F.R.S.; the geology and physiography of Arctic Europe, by Prof. E. J. Garwood; a course by Prof. W. W. Watts, F.R.S.; dynamical meteorology, with special reference to the forecasting of weather, by Dr. W. N. Shaw, F.R.S.; recent researches on chloroform anæsthesia, by Prof. G. A. Buckmaster and Mr. J. A. Gardner; a course by Mr. W. B. Hardy, F.R.S.; the physiology of the peripheral nerves, by Dr. N. H. Alcock; protozoan parasites, with special reference to those of man, by Prof. E. A. Minchin; the distribution of the Oligochæta, by Mr. F. E. Beddard, F.R.S.; the phylogeny of calcareous sponges, by Prof. A. Dendy, F.R.S.; symbiosis, by Dr. F. W. Keeble; the Marsipobranchii, by Mr. F. G. Cole; Amphioxus, by Prof. E. W. MacBride, F.R.S.; the morphology of swim bladders, by Dr. W. N. F. Woodland.

The two universities created by the Irish Universities Act of 1908 came into existence on October 1. The *Times* Dublin correspondent last Friday described the state of preparation of the new universities. The commissions appointed under the Act to draft statutes and lay the foundation for the two new universities were given a period of two years for their work. They have sat often and worked hard, with the result that they are now well in advance of schedule time. The National University consists of a Senate and officers with large powers, but with no buildings of its own. The University has its concrete embodiment in the new University Colleges, formerly Queen's Colleges, at Cork and Galway. University College, Dublin, is so far only concrete in the sense that its governing body has been called into existence. At the present time it has no teaching and no college buildings. The commissioners will meet shortly to appoint a teaching staff, and the college will open early next month. As regards staffs, the Dublin College is differently situated from those at Cork and Galway, where teaching staffs exist in the staffs of the old Queen's Colleges, which are to be taken over in accordance with the provisions of the Act. Only a very few chairs remain to be filled. In University College, Dublin, it is taken for granted that most of the old staff will be translated to corresponding chairs in the new college. In this case, however, the commissioners will have also to fill a number of new chairs. Nothing has yet been done in connection with the buildings of the new college in Dublin, though various sites have been suggested. Meanwhile, the college will probably begin its work in the Royal University buildings, and will solve the immediate problem of class-rooms by renting the Roman Catholic University College and the buildings of the Roman Catholic Medical School. The cases of Queen's University, Belfast, and of the University Colleges at Cork and Galway present no difficulties. These institutions will have teaching staffs within a couple of weeks, and all their buildings and class-rooms are in going order. It may be taken for granted that by the middle of November, at latest, the work of the two new Irish universities in all its departments will have been organised and practically initiated.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 27.—M. Bouchard in the chair.—The existence of intrusive Pliocene rocks in the volcanic *massif* of Cantal: A. **Lacroix.**—Aniline antimonyl tartrate in the treatment of trypanosomiasis: A. **Laveran.** Experiments on experimentally infected guinea-pigs having given favourable results on treatment with this drug, M. Thiroux has tried it in Senegal on natives suffering with sleeping sickness. The immediate results were very satisfactory, the intra-venous injection of 15 centigrams causing the disappearance of the trypanosomes from the blood of an adult man. The action is more rapid than when atoxyl is used, two patients who had commenced to sleep recovering after the injection of 15 centigrams. It has still to be proved that the cure is permanent.—The Brownian movement of rotation: Jean **Perrin.** Einstein has deduced a formula for the rotation of a spherical particle in a fluid of a given viscosity. The author has succeeded in measuring the velocity of rotation experimentally, the result being in complete agreement with Einstein's theory. It appears probable that the molecular kinetic hypothesis affords a safe basis in the study of Brownian motion.—The electro-diapason: A. **Guillet.**—Thermochemistry of some phosphorus compounds: P. **Lemoult.**

THURSDAY, OCTOBER 14, 1909.

SOME BOTANICAL BOOKS.

(1) *Die Pflanzenwelt Deutschlands*. By Dr. P. Graebner, mit Zoologischen Beiträgen von F. G. Meyer. Pp. xi+374. (Leipzig: Quelle und Meyer, 1909.) Price 7 marks.

(2) *Pflanzenbiologie. Schilderungen aus dem Leben der Pflanzen*. By Dr. W. Migula. Pp. viii+352. (Leipzig: Quelle und Meyer, 1909.) Price 8 marks.

(3) *Unsere Zierpflanzen. Eine zwanglose Auswahl biologischer Betrachtungen von Garten und Zimmerpflanzen sowie von Parkgeholzen*. By P. F. F. Schulz. Pp. viii+216. (Leipzig: Quelle und Meyer, 1909.) Price 4.40 marks.

(4) *Phanerogamen. Blütenpflanzen*. By Prof. E. Gilg and Dr. R. Muschler. Pp. 172. (Leipzig: Quelle und Meyer, 1909.) Price 1.25 marks.

(5) *Kryptogamen*. By Dr. M. Möbius. Pp. iv+164. (Leipzig: Quelle und Meyer, 1908.) Price 1.25 marks.

(6) *Zimmer- und Balkonpflanzen*. By P. Dannenberg. Pp. vi+160. (Leipzig: Quelle und Meyer, 1908.) Price 1.25 marks.

(7) *Clay's Successful Gardening*. Fourth Edition. Pp. 275. (London: Clay and Son, Stratford, n.d.) Price 9*d*. net.

(8) *Botany for Matriculation*. By Dr. F. Cavers. Pp. viii+568. (Cambridge: University Tutorial Press, Ltd., 1909.) Price 5*s*. 6*d*.

(9) *Beginners' Botany*. By Prof. L. H. Bailey. Pp. ix+208. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1909.) Price 3*s*. 6*d*.

(10) *Elementary Practical Botany*. By W. E. Clarke. Pp. xii+311. (London: The Normal Press, Ltd., n.d.) Price 3*s*. 6*d*. net.

(1) DR. GRAEBNER deals with the plant-world of Germany from an ecological standpoint, and thereby provides one of the first works on ecology confined to the limits of a single country. The subject of ecology is still in its infancy, and it is probable that it may gain stability when it is considered from a national rather than an international outlook. The difficulty in reducing ecological facts to a system, as the author points out, arises from the complexity of factors which influence the being of a plant. Dr. Warming bases his classification on soil conditions, but Dr. Graebner selects a more arbitrary standard, as his main divisions depend primarily upon the favourable or unfavourable characters of natural conditions, and, secondarily, on the modifications produced by special agencies, such as seasons or man. The arrangement works out better than might be expected. The first section is that of tropophilous formations found on sunny hills, on rocks and inland dunes. The second comprises formations on cultivated land. The succeeding sections refer to meadows, woods, river banks, plankton and aquatic vegetation. Finally, the author relegates heath and halophytic formations to separate categories. The two most prominent sections are those devoted to formations on cultivated land and to woods or forests. Under the former are gathered the vegetation of waste places (*Ruderalstellen*), fields and gardens, lawns and roadside trees. The importance of this section is extremely great, not only because of its extent, but because it lies immediately at our doors. Obviously the effect of human influence does not stop here, but the limit is that of man's most determined struggle to turn nature to his immediate purpose.

Under each section the author discusses the predominant factors, also any well-marked modifications, and describes the typical plant-formations with reference to their adaptations for nutrition and reproduction. The notes on animal life contributed by Mr. F. G. Meyer are added as postscripta to the sections. The book is a very desirable acquisition to the scanty literature on ecology, and can be recommended both for the philosophic argument of principles and causes, and also for the details. It also suggests the thought that there is a good opportunity for preparing a book on similar lines dealing with vegetation in the British Isles.

(2) The scope of Dr. Migula's "Plant Biology" is considerably wider than the preceding. It treats of bionomics as exemplified by reproduction and dissemination of plants, protective modifications and adaptations to external conditions; this leads to plant associations, and biology of nutrition precedes the description of federations between different plants, or plants and animals. It is, of course, impossible to deal comprehensively with these various subjects, and the author has merely endeavoured to present interesting sketches of plant-life. There is no striking originality in the early sections, but the author imparts his information in a clear and effective manner, notably in the introduction dealing with development, or, to put it more popularly, Darwinism. The chapters on adaptations of plants to climate and soil are in some respects the most attractive, as the author has elaborated these themes more fully. Plant communities are described under the divisions of forest, grass vegetation, heath and moor. Reference should also be made to the succinct accounts of root tubercles in the leguminous family, and the relationship between plants and ants.

(3) The horticulturist who is a deep thinker must often be puzzled to understand the idiosyncrasies of many plants that come under his care, even of stock plants in cultivation. For instance, how many can offer an opinion on variegation in a begonia-leaf and say how far it can be modified, or can explain why a pelargonium thrown on the dust-heap will retain its vitality for a long time? Further, there are the manifold variations in stem and leaf, the devices for pollination, and many other biological features which are not readily explicable even by those who have received technical training. To those who are anxious to gain an insight into these problems the book by Mr. P. F. F. Schulz will certainly appeal. He has wisely limited his notes to about fifty kinds. Plants in general cultivation are represented by begonias, the dahlia, perennial lupines, Aspidistra, sunflowers, and common ferns. Sauromatum, Aristolochia, and

various cacti are included because of their peculiar character, while the tulip tree and tree of heaven recall the plantations which beautify so many German towns.

(4, 5, 6) The next three volumes of which the titles appear above are units in a series of neat brochures dealing with all branches of knowledge. The publishers are entitled to great credit for bringing out such a series at the modest price of one mark per volume, as they have enlisted competent authors to deal with the various subjects. It may, however, be suggested that some of the volumes deal with subjects of too extensive a nature to be satisfactorily compressed within the limits permitted. The account of phanerogams, a systematic compendium, prepared by Drs. E. Gilg and R. Muschler, provides a case in point. About 120 families are dealt with in as many pages, with the result that there is only a bare reference to the botanical characters of each family, while the space is occupied by a mere enumeration of the more important plants and their properties. The same criticism applies to the volume on cryptogams, in which Dr. Möbius has made good use of the space at his disposal, but it is evident that each of the four groups of algæ, fungi, mosses, or ferns might with advantage have been taken separately. The cultivation of plants in living rooms and on balconies is a subject better suited to these small volumes, on which Mr. P. Dannenberg provides an interesting and useful book, essentially German as regards the minuteness of detail. Advice is given on methods of arrangement, ornamental pots, watering, pruning, transplanting, and propagation; also a useful list is supplied of plants suitable for growing at different seasons and under different conditions. Precise, accurate, and well arranged, the book admirably fulfils its purpose.

(7) A different type of floricultural book is that issued by Messrs. Clay and Son, primarily intended to advertise their special manures. The list of contributors includes Messrs. J. Hudson, J. Douglas, J. Udale, H. J. Wright, and E. H. Jenkins, who contribute articles on fruit-culture, carnations, begonias, sweet-peas, daffodils, and lilies. Sections are devoted to vegetable cultivation, indoor gardening, rock gardens, and garden pests. The volume contains much practical information for the cultivator, and more particularly for the grower of produce.

(8) It is not very long since Dr. Cavers produced a very successful elementary botanical text-book under the title of "Plant Biology," in which he indicated the methods adopted with his classes, and outlined a large number of experiments intended to instruct the student by his own personal observation and experiment. The success of this book and of "Life-histories of Common Plants" has presumably led to the compilation of the volume now under notice, which in many respects resembles the earlier books. Physiology is made the groundwork of preliminary study and explanatory of morphology; classification is dealt with in the descriptions of selected families, and a chapter is devoted to ecology. The range of the book is very much wider than is necessary for a matriculation course, although this is no disadvantage, as a teacher can select the portions immediately necessary. At the same time, many of the chemical and physical paragraphs might have been omitted, also the final chapter on the uses of plants. Apart from these criticisms, the book deserves the highest commendation, chiefly because the author conveys his information in a precise and well-ordered manner. The numerous experiments scattered through the text are admirably chosen to illustrate the points under discussion or observation, and for the most part require only simple apparatus.

(9) There is always a fund of originality in any book written by Prof. L. H. Bailey, and teachers will meet with not a few fresh ideas in his latest production. The opening is original, although Darwinian, that no two plants or parts are alike, that there is a struggle for life, and that the fittest survive; then follow chapters on plant societies and the plant body, after which ensues the ordinary gamut of elementary morphology, but treated in a fresh and inviting fashion. Another essential feature, also characteristic of the author's style, is the concise method of indicating facts or points without superfluous details; and finally it will be observed that the author introduces practical examples, so far as possible, as in the excellent chapter on bud propagation. The illustrations are bold, practical, and artistic. The studies in cryptogams, forming almost an appendix, do not make a very desirable addition, as they are perforce scrappy and introduce facts altogether beyond the scope of a beginner.

(10) The elementary practical book prepared by Mr. Clarke begins with external morphology and passes on to physiology, with the inclusion of chapters on soil, garden vegetation, distribution and cell structure. The experiments are collated in a separate part, and some account is given of selected flowering plants. Appendices are devoted to hints on the microscope and certain principles of chemistry and physics. It is apparent that the author has attempted to compress too much material into the book, more especially as he does not display that happy faculty of expression which combines conciseness with brevity; further, the information is somewhat ill-assorted, and there is a tendency to introduce ideas which are only partially relevant to the subject under discussion. There are also some inaccuracies, as in the use or explanation of various terms, such as pollarding, block, sucker, ivy root-tendrils and monosexual.

CLAYWORKING IN THE UNITED STATES.

History of the Clayworking Industry in the United States. By Dr. H. Ries and H. Leighton. Pp. ix+270. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 10*s*. 6*d*. net.

FEW realise the important *rôle* played by clay in the industries. It certainly ranks not lower than fourth in the value of its production in the mineral industries of the world, and it is only exceeded by iron and coal, and possibly copper. Very few industries, too, are not dependent in some way upon clay products. Every advance in the quality of these products has been followed by advances in other industries. The raising of the refractory qualities of fire-bricks, for example, gives the metallurgist greater power and scope, and the success of the electro-chemical industries is to a large extent dependent upon the capability of the potter.

Considering the importance of the subject, the list of books with trustworthy information is surprisingly small. We therefore turn with pleasure to the present work, which is a history of the various branches of the clayworking industry in the United States, from the building of the brick houses by the early colonists up to the close of 1907. Consequently, there is no more than a passing reference to the very curious pottery fashioned by the aboriginal Indians. The book is compiled from statistics collected in the main by the United States Census Bureau and the United States Geological Survey. The first portion of the history is a general *résumé* of the various stages in the development of the industry through the manufacture of common bricks, glazed bricks, terracotta, tiles, and pottery. In the second portion of the work, these stages are discussed State by State.

The author can seldom be charged with diminishing the value of his facts by entangling them in the meshes of hypothesis. Statistics are given showing the yearly value of the products made in the United States, and also imported. Using the word "consumption" with its broadest connotation, it is possible to calculate from the authors' tables the approximate proportion of the total yearly consumption of "pottery" which is actually manufactured in the States. We thus obtain 57 per cent. for 1870, and 68 per cent. for 1907. The influence of the ceramic schools is said to be a "strong factor" (pp. 6–7) in the evolution of the industry. The first of these was started in Ohio in 1894, under the capable hands of Prof. E. Orton; the fifth, in Iowa, in 1907. Quoting from Mr. J. Moses' "One Hundred Years of American Commerce" (p. 53), the authors state that it was not, indeed, until the first real protection by the tariff ever accorded the potters was enacted, as a war measure, that the American maker found himself able to enter the field against the English potter. The influence of imported workmen, on whom there is no tariff, is not indicated, although we find some curious evidence pointing in that direction from Messrs. Ries and Leighton's tables. In 1897, 41 per cent. of the total china clay consumed in the States was mined there, and in 1907, 68 per cent. The remainder was imported. This might be attributed to the dearth of china clay, but the Americans have splendid clays, better, indeed, than our own. The greater probability is that the "secret" recipes of the imported workmen are compounded with raw materials from Cornwall, &c., and a mysterious virtue is supposed to reside in a recipe for an "English" body or glaze. The workmen have not always the courage and skill to adapt imported recipes to local materials. The recipe is thus master of the situation.

J. W. Mellor.

A JOURNEY ACROSS VENEZUELA AND COLOMBIA.

The Journal of an Expedition across Venezuela and Colombia, 1906–7. An Exploration of the Route of Bolivar's Celebrated March of 1819, and of the Battlefields of Boyaca and Carabobo. By Dr. Hiram Bingham. Pp. viii+287. (New Haven, Conn.: Yale Publishing Association; London: T. Fisher Unwin, 1909.) Price 10*s*. net.

THE expulsion of Spanish power from the present State of Colombia was effected by Bolivar, who in the year 1819 conducted an army from near Caracas to Bogotá, across country that had been deemed to be impassable. All the saddle and pack animals, and many of the soldiers, succumbed to the hardships of the march, a distance of about 700 miles, traversed in about seven weeks. Spanish-American historians have compared this feat with the marches of Hannibal and Napoleon. Dr. Bingham, lecturer on Latin-American history at Yale, wanted to form a proper estimate of the actual obstacles that were overcome by the army of liberators, the backbone of which was the foreign legion of British veterans from the campaign of Waterloo. He therefore undertook the spirited and difficult task of following up the route of Bolivar through regions not easily visited and scantily known.

There is a regular overland route from Caracas to Bogotá which leads over the high plateau between the Central and the Eastern Cordilleras. The author and his companion, Dr. Hamilton Rice, however, went, like Bolivar, broadly speaking, parallel with this road, along the foothills of the Eastern Sierras, where they join the vast Llanos, at an average altitude of 600 feet to 700 feet above sea-level. The greater part of this route has been scantily described by but few travellers, and some districts were known locally only.

The travellers left Caracas at the beginning of January, 1906, and crossed the great Llanos with mules, and an ox-cart for the baggage. In time the cart had to be discarded. There were many rivers to cross, tropical forests, and the Llanos. These, never pleasant to traverse, were rendered more than difficult by the rains which set in about the middle of March, and continued with increasing force. The stiffest part of the journey began with the ascent to the plateau, to gain which the Paramo, a pass of 13,000 feet elevation, had to be negotiated.

For reasons only known to themselves, the travellers did not carry a tent. Consequently the diary is full of the troubles of getting accommodation in the wretched villages or occasional so-called towns, in rest houses kept by suspicious Indians or disobliging white men, often without sufficient food. The Western Venezolanos (why are they persistently called Venezuelans in the book?), white, mixed, and brown alike, are apparently not a very prepossessing people, and local officials were, of course, worse. The Colombians seemed to be more amenable, as being less beyond the reach of civilisation.

The whole journey took 115 days, more than twice the time required by Bolivar's army. The book is adorned with numerous photographs of characteristic scenery and scenes, *e.g.* Yaruro Indians between the Apure and Araura rivers. Although the travellers do not profess to be naturalists, they mention a good many birds and beasts which they came across. There are also some most interesting pictures of Iabiru storks on their nest, and of half-a-dozen Capybaras on the bank of a stream.

The reader will get a very good idea of the kind of country and its inhabitants.

A STUDY OF CHILD-LIFE.

Children in Health and Disease. A Study of Child-life. By Dr. David Forsyth. Pp. xix+362. (London: John Murray, 1909.) Price 10*s.* 6*d.* net.

THIS volume should appeal to a large number of readers, medical and lay, and its publication at the present time is opportune, for it brings a sane and experienced judgment to the assistance of those who in a public or private capacity are striving to solve the problems with which it deals. The vitality of the country depends on the health and training of the children, and while the duty of supervision rests with the physician, success can only be obtained through intelligent cooperation of parents and teachers.

The early chapters deal with the physiology of childhood. The food consumption of the infant, relatively to body weight, is considerably greater than that of the adult, but only one-fifth of the ingesta is used for purposes of growth, while the rest serves to maintain the temperature of the body. In proportion to bulk, the surface area is greater in a small child than in a man, hence increased loss of heat and more need for heat production. In early life appetite waits on surface area, and in the recognition of this fact lies the clue to the proper feeding of children. The amount of food should be determined by the weighing-machine rather than the calendar, and it should contain plenty of carbohydrate, the heat-producing ingredient in diet.

By the end of the second year a child's mind has acquired, in an elementary form, most of its principal faculties, so that its further progress consists in perfecting them rather than in the acquisition of new ones. Habit clusters round the lines of least resistance, and education is an attack on natural indolence. From the medical point of view school-life stands by itself. Opportunities for the transmission of infectious and contagious diseases are greatly increased, and the problem of class-room hygiene offers special difficulties. The evils of the examination system, defective ventilation, bad feeding arrangements, and insufficient hours of sleep exist in many higher-grade schools, as they do in elementary schools. The hygiene and curriculum of both require supervision. Medical inspection of schools is now recognised as a branch of public-health work. It has shown the prevalence of ill-health, much of which is preventable. The author notes with approval the value of invalid and "open-air" schools, and he also discusses the difficult question of the training and care of the mentally deficient.

Not the least interesting section of the book is that which deals with the causes of infant mortality. Most diseases of childhood are preventable, and yet 20 per cent. of children die before their fifth birthday. Infancy must always remain a critical period of life, but it should be relieved of many dangers which now decimate it. The statistical value of death certificates will not be great until they become confidential and cease to be framed so as to meet the susceptibilities of parents. Syphilis is scarcely mentioned in death certificates, although it is recognised as a potent cause of premature birth and death in early childhood.

The value of the volume is enhanced by the index, which is well arranged and adequate.

OUR BOOK SHELF.

Lehrbuch der Pharmakognosie. By Dr. George Karsten and Dr. Friedrich Oltmanns. Second edition. Pp. vi+358. (Jena: Gustav Fischer, 1909.) Price 9 marks.

IN the first edition of this work, published in 1903, Prof. Karsten explained his object to be the provision of a text-book that should treat pharmacognosy from a botanical point of view, and, considered in this light, it must be admitted that his object was successfully attained. But the second edition has more ambitious pretensions; it is intended to present a "clear survey of pharmacognosy and to introduce the young pharmacist to the varied provinces of that science."

The arrangement and treatment of the subject-matter are similar to those that were adopted in the first edition. The classification is on strictly botanical lines. Each drug is separately described, the description including the botanical and geographical sources, the morphology, anatomy, and constituents. In almost all instances the lion's share has fallen to the morphology and anatomy, these usually occupying some three-fourths of the entire description, but occasionally more, as with white hellebore rhizome, where only twenty lines out of six pages are devoted to the other points. This part of the descriptions is excellent, and doubtless many pharmacognosists will frequently refer to the very complete, detailed, and well-illustrated accounts of the morphology and anatomy of the drugs.

This, however, is all that can be said in favour of the work. The constituents of the drugs, for the young pharmacist a most important branch, are dismissed in three or four lines, in which sins of omission and commission are frequent and great. Take, for instance, gentian root and chamomile flowers, in which the bitter principles are entirely forgotten; opium, ipecacuanha, aconite, hydrastis, colchicum, and conium, all of them most important drugs, in which the proportion of the constituents is sadly inaccurate; ergot, liquorice, senna, euphorbium, in which they are not brought up to date. Indian and Turkey opiums are said to be made into balls about the size of the fist, and covered with Rumex fruits, while Persian opium is usually made into sticks! Seldom is any sufficient account given of the diagnostic characters of the genuine drug, of the adulterants, changes on keeping, preservation, preparation for the market, commerce, &c. Such a work fails to give a "clear survey of pharmacognosy," and cannot be recommended as a means of introducing the young pharmacist "to the varied provinces of pharmacognosy." It relegates that science to the position of a subordinate department of botany, and shows once more that the author of a work on pharmacognosy should be a trained pharmacognosist. As an account of the morphology and anatomy of drugs it might have been successful; as a text-book of pharmacognosy it is a failure.

Henry G. Greenish.

Catalogue of the Lepidoptera Phalaenae in the British Museum. Vol. viii., Catalogue of the Noctuidæ. By Sir George F. Hampson, Bart. Pp. xiv+583; pls. cxxiii–cxxxvi, and 162 text-figures. (London: British Museum, Natural History, 1909.) Text, price 15*s*.; plates, price 12*s*.

We have again to congratulate Sir George F. Hampson and the Trustees of the British Museum on the completion of another volume of the great catalogue of moths, which bids fair to surpass even the catalogue of birds in extent and importance. Vol. viii., now before us, is the fifth volume devoted to the Noctuidæ, and the second of the great subfamily Acronyctinæ, which it will require a third volume to complete. Fifteen subfamilies of Noctuidæ were indicated by the author at the commencement of his work; possibly he may find it necessary to increase the number before its completion. The Acronyctinæ, occupying three volumes, is only the fourth subfamily out of the fifteen, but, in the sense in which the author employs it, it is, perhaps, the most extensive of all. The remaining subfamilies, with three or four exceptions, appear likely to be of very much smaller dimensions.

Works of this character are far too costly to be undertaken by private enterprise, and though the price at which they are published by the museum cannot be remunerative, the cost of an extensive work issued in successive volumes soon becomes prohibitive to private students.

Hence we would urge on the librarians of public libraries and museums at home and abroad to secure sets of such publications as those of the British Museum before the volumes become too numerous, and before any of the earlier ones go out of print. Many of the earlier publications of the Museum were issued in comparatively small numbers, and several are now scarce and difficult to obtain. Sometimes early volumes have been exhausted even before the whole series has been completed. This is another reason why public libraries, to which they will always be valuable, should not neglect to add them to their shelves as soon as they appear.

The Geology of South Africa. By Dr. F. H. Hatch and Dr. G. S. Corstorphine. Second Edition. Pp. xvi+389. (London: Macmillan and Co., Ltd., 1909.) Price 21*s*. net.

The general scheme of the book remains the same as in the first edition, but the authors have skilfully rearranged portions of the original subject-matter and have made those additions which the rapid advance of geological investigation in South Africa since 1905 has rendered necessary.

To digest and sift the numerous official and unofficial reports dealing with the geology of South Africa is no easy task, and with respect to the stratigraphy of these regions, the authors have evidently spared no pains to bring the book up to date. They, however, almost entirely ignore the many interesting problems connected with the origin and development of the present physical features, of which striking examples have been illustrated and described in the reports of the surveys of Cape Colony, of the Transvaal, and of Natal, as well as in other publications. This is an obvious omission in a work entitled "The Geology of South Africa."

In dealing with the correlation of the widely scattered formations, the authors speak in a guarded manner, but their suggested correlation of the older formations will not pass unchallenged.

The illustrations, of which many are new, retain a high standard of excellence. The figures illustrating the fossils of the Karroo are the least attractive, and are hardly representative, especially with respect to the well-known and interesting reptilian remains. The general index is far too meagre, and the index of place-names is overburdened by a superfluity of mere page references of more annoyance than assistance to the general reader.

Handbook for Field Geologists. By Dr. C. W. Hayes. Pp. ix+159. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 6*s*. 6*d*. net.

The preface states that this work originated in a handbook printed in 1908 for distribution to members of the United States Geological Survey. Requests for copies of this were so numerous that it was rewritten, omitting those instructions which apply only to members of the Government Geological Survey, and enlarging upon certain features which will be of service to students preparing for work in field geology. In spite of this declaration the book still contains much which is only applicable to members of a Government Survey in the United States, but is, besides, a very practical little handbook, the treatment of the problems connected with the determination of dip, thickness, and depth of beds being perhaps the least satisfactory part. These problems, if properly put, are of great simplicity; but the beginner, trusting to Dr. Hayes, might well conclude that there was some subtle difference between the dip of a fault plane and the dip of a stratum, and that problems which may be tackled in the one case are insoluble in the other.

An attempt has been made to get over the difficulty of making the same work at once a beginner's guide and an expert's *vade mecum* by dividing it into two sections, and of the two the latter seems better done. The schedules of subjects to be noticed in special investigations have their use in refreshing the memory whenever a fresh piece of work is entered on, but the ideal geologist's pocket-book is yet unpublished. Engineers and architects have their little books crammed with information cut up into pieces, each complete in itself, so that temporary lapse of memory on any particular point can be rectified, or reference made to figures which the human brain cannot carry, but which must be accurately known if required at all. Geologists, on the other hand, whether on account of the smallness of their number or their supposed addiction to dilettante methods, are condemned to wade through a mass of matter, with which they are familiar, to obtain the particular piece of information of which they are in search.

Physiology: a Popular Account of the Functions of the Human Body. By Dr. Andrew Wilson. Pp. vii+128. (London: Milner and Co., Ltd., n.d.) Price 1*s*. net.

As a contribution to scientific literature this book is negligible; as a popular exposition of the elementary principles of physiology it is untrustworthy. It is no part of a reviewer's duty to enumerate the errors scattered through it; it will be sufficient to take one as a sample. "The red blood corpuscles are also carriers of carbonic acid gas to the lungs . . . and the darker colour of impure or venous blood is explained by the fact that when carbonic acid gas unites with the hæmoglobin a darker hue is produced" (p. 64). A first year's student knows better than this. It would be better to leave the writing of physiological text-books to those who know something of physiology.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Magnetic Storms.

IN supplement to my letter in the last issue of NATURE I may add that if a solar outburst, acting in the way supposed, causes a magnetic storm which lasts eight hours, the effective influence of the whole group of electric streams at the distance of the earth must extend over a breadth of about six million miles; so that if simply conical, with vertex at the sun's centre, the angle of the cone would be four degrees. Projected back to the surface of the sun, this would correspond to what we may call a "spot" about one-thirtieth of the visible disc in diameter; but, inasmuch as the trajectory of the particles in the beam would be slightly curved, the size of the actual solar eruption could be much less.

Until the main outlines of the view advocated are approved by those most competent to judge, it is useless to enter into further details.

I regret to notice a numerical slip—fortunately unimportant, since it affects nothing else—in the top line of my letter on p. 426, where the current equivalent should be expressed, not in hundred thousands, but in hundred millions of amperes—an order of magnitude which is "reasonable" rather than "surprisingly moderate."

October 9. OLIVER LODGE.

Magnetic Storms and Solar Eruptions.

I HAVE read Sir Oliver Lodge's letter (NATURE, October 7, p. 425) on the above subject with some surprise. The emission theory which he supports, and which he claims to have originated, regards kathode rays from the sun as the electric carriers, and so is presumably the same as has been actively advocated by Prof. Kr. Birkeland for a number of years. He seems, however, to be unaware of the existence of Birkeland's volumes [1] on the subject, and of the numerous numerical calculations therein contained. He also makes no reference to the important mathematical work of Prof. Störmer, which cannot, I think, be disregarded by anyone whose theory postulates the introduction of charged particles from without into the earth's magnetic field. The general idea that magnetic storms are due to some action arising in the sun goes back to at least the time of Broun and Balfour Stewart, and different forms of the emission theory have naturally presented themselves to various minds independently, as Röntgen, kathode, and other rays came successively under our ken. It is when we come to details that real troubles arise. Most people, I take it, have little difficulty in believing in a general way that the changes of declination experienced at a single magnetic observatory, say Kew, during a magnetic storm can be accounted for by a stream of electrons in the magnetic meridian, provided it is possible for the direction and intensity of the stream to be altered at frequent intervals. One doubts this just as little as that the motion of the magnet of the declination magnetograph at Kew on September 25 could be reproduced with the aid of a copper wire, a single battery cell, a commutator, and a resistance box. Those who have seen Störmer's calculations and studied Birkeland's volumes will realise, however, that to be regarded as an advance of knowledge at the present day, a theory must afford an explanation, not merely of what is taking place in a single magnetic element at a single station, but of what is taking place in all three elements at a number of stations. Coming, now, to Sir Oliver Lodge's own calculation, it seems based on an inadequate idea of the phenomena of the late storm, derived from a description of one or two of the more striking changes at Kew as recorded in your columns and those of the *Times*. It is rare for a disturbance to be limited to the declination, *i.e.* for the disturbing force to be wholly perpendicular to the magnetic meridian. The component in the magnetic meridian is, as a matter of fact, usually the larger. A vertical component is also usually present. A magnetic storm does not usually consist of a disturbing force in a fixed or nearly fixed direction, waxing and waning. Each of the three elements usually exhibits values both above and below the normal, and not infrequently there are many excursions on both sides of the mean. This will, I think, be readily recognised by anyone who consults the reproduction of the Stonyhurst curve of September 25 in your columns and of the Kew curves in the *Electrician*. After inspecting these curves it will, I think, be recognised that it is quite out of the question to limit the passage of the imaginary solar jet, as Sir Oliver Lodge does, to the fifteen minutes near the end of the storm, when there occurred the prominent declination oscillation to which he has confined his attention. Even whilst this oscillation took place, it was far from representing the total disturbance. Simultaneously with it, but partly overlapping, as is often the case, there was a very large change in progress in the horizontal force. Those looking at the curves will, I think, agree that if there was a jet such as Sir Oliver Lodge supposes, its time of transit took, not fifteen minutes, but at least nine hours. His estimate of the diameter of the cone thus requires multiplication by 36, with a consequent multiplication of the cross-section, if it were circular, by 1296. Large as this may appear, the jet theory requires it to be often exceeded, as the storm of September 25 was an unusually short one. The average duration of the storms in Mr. Maunder's Greenwich list, from 1882 to 1903, was almost exactly thirty hours, so that the cross-section of the average storm-jet would be naturally fully 14,000 times that given by the calculation in your columns. The really crucial thing is that the magnetic disturbances which occur simultaneously at different stations are inter-related. It is in accounting satisfactorily for these inter-relations that Birkeland, who has given years of thought to the subject, encounters his main difficulties.

In pointing out these facts, I am not expressing any opinion for or against any or all of the emission theories. What I think is really called for at the present moment is a reservation of judgment as to theories, and a more minute study and inter-comparison of the records from different observatories with a mind as unbiased as possible by preconceived ideas. C. CHREE.

Fireball in Sunshine.

WITH the sun shining in a beautifully clear sky on October 6, at about 9.40 a.m. a large meteorite passed over central England, and was well observed from many widely distant stations. People noticed it in Norfolk, Suffolk, Gloucester, Somerset, and other counties, but the observations, owing to the absence of visible sky marks, are not very definite.

The meteor was brilliant; it had a slow motion, traversing a long path in about four seconds, and it left a luminous trail of short duration. An observer at Bristol says it burst with rocket-like effect at the finish. The meteor had a radiant in the south or south-east sky, but the place is uncertain. At the time of the observation Leo was on the meridian and Virgo and Boötes near.

At Cottesbrook, Northamptonshire, a loud detonation followed the meteor in four minutes, which corresponds to a distance of fifty miles. At East Haddon, Holdenby, and other small towns and villages north-west of Northampton the noise of an explosion was heard, doors creaked, windows rattled, and people ran out of their houses in terror, thinking that an earthquake had occurred. The final disruption of the meteor evidently took place over the region ten or fifteen miles north-west of Northampton, and its direction of flight was from S.S.E., so it must have passed over, or nearly over, London.

Further observations will be exceedingly useful if they are sufficiently exact to be utilised. W. F. DENNING.

The Mansfield Automatic Water Finder.

CAN any reader of NATURE supply the names of the "leading scientists" who are stated to have "thoroughly investigated" this instrument "and vouch for the successful application of the invention"?

As stated by the makers, "the principle on which the instrument works is the measuring of the strength of the electrical currents which are constantly flowing between earth and atmosphere, and which are always strongest in the vicinity of subterranean water courses." It would be interesting to know whether there is any scientific basis for this statement.

The writer has applied to the makers of the instrument for particulars relating to it, but beyond sending him a circular embodying the above quotations, he has been unable to obtain from them much information.

A. A. Campbell Swinton.

66 Victoria Street, London, S.W., October 7.

MOVEMENTS OF THE EARTH'S SURFACE.

In the *Revue scientifique* of August 28 is an interesting address delivered by M. Ch. Lallemand to the Association française pour l'Avancement des Sciences. The address deals with two subjects:—(1) Tides in the solid earth; (2) gradual changes of level in large tracts of the earth's surface.

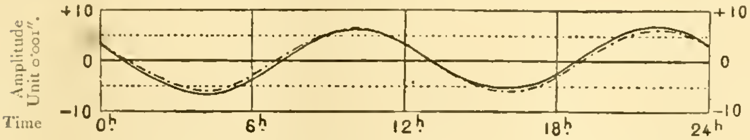

Fig. 1.—Semi-diurnal oscillation of a pendulum under the action of the moon.

—— Observed wave. - · - · - Calculated wave reduced in amplitude.

The first subject is introduced by a short historical account of the attempts made in the past thirty years to discover alterations in the position of the vertical relative to the earth's surface accompanying the changes of direction of the sun and moon. This is followed by a detailed account of the recent work of Dr. Hecker, of Berlin. An illustration of his apparatus is given, and an interesting account of the manner in which, by a mechanical and optical device, a horizontal pendulum, 0·25 m. in length, is made to produce effects such as could only be produced directly by a vertical pendulum of length equal to the height of Mont Blanc.

Dr. Hecker's apparatus was placed in a chamber, which was situated at a depth of 25 m. below the surface of the earth, and kept at constant temperature and humidity. The motions of the pendulum, greatly magnified, were registered continuously on a revolving drum. Roughly speaking, they amounted to a daily oscillation of the vertical of about 0·02″ north and south. The greater part of this oscillation was thermal in origin, being caused by the heating of the upper layers of the earth's surface by the sun's rays. It was possible to remove this term, and there was left as a residual effect a semi-diurnal oscillation, which could be traced to the varying attraction of the sun. More important, because it was more free from thermal disturbance and greater in magnitude, was the semi-diurnal oscillation of the pendulum, which Dr. Hecker found corresponding to half a lunar day. The close agreement between this observed oscillation and a theoretical curve for the deviation is shown in Fig. 1.

Whereas the phase and direction of the changes in the vertical agree closely with theory, the amplitude of the observed change is much less than that which theory indicates. Or, rather, we should say that the amplitude is about 2/3 of that which would be observed if the earth were perfectly rigid. The difference between this factor 2/3 and unity is a measure of the extent to which the earth's surface yields to the tidal force of the moon, and thus masks the deviation of the pendulum. It is interesting to note that in 1884 Sir George Darwin, from analysis of tidal records, found this factor to be 0·676, also that his and Lord Kelvin's earlier estimate of the rigidity of the earth accord closely with that now determined by Dr. Hecker, namely, 5/6 of the rigidity of steel. The difference between observation and theory is shown in Fig. 2.

One interesting fact is illustrated in Fig. 2. The reduction of amplitude from one curve to the other is different in different azimuths. Dr. Hecker has discussed this point, and shown it is in no way to be accounted for as an indirect effect of accompanying changes in the sea-level or the atmosphere. Whether it is due to local surface conditions at Potsdam, or whether it bears some relation to large structural deformations of the earth, these are questions which further research will alone elucidate.

The second question discussed by M. Lallemand is the examination of permanent or gradual deformations of the earth's crust. A short account of changes, which have been shown to have been caused by recent earthquakes, is followed by a discussion of attempts made in France to ascertain gradual changes of level. Accurate work of recent date has discredited Bourdaloue's result that the sea-level at Brest and Marseilles differs by a metre, that result being ascribed to systematic errors in the observations. The difficulty of ascertaining permanent changes of level is increased by secular alterations in the mean sea-level at the base of a level-line. Added to this are the errors of the actual work of levelling. M. Lallemand's estimate of the error that would probably be introduced in ascertaining the height of a hill-top 2000 m. above sea-level, at a distance of 600 kilom. from the sea-shore, is 12 cm. to 17 cm. even when the levelling is done by the most accurate methods at present available. In view of the slowness with which changes of level take place, an interval of at least thirty years ought to elapse between successive levellings undertaken to show changes of level.

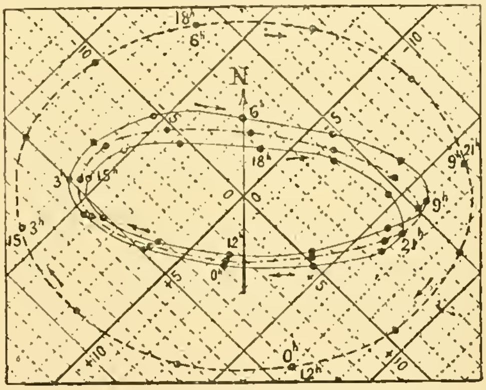

Fig. 2.—Daily apparent motion of the pendulum due to the action of the moon.

—— Observed oscillation.

· - · - Observed semi-diurnal oscillation.

- - - - Semi-diurnal oscillation calculated for a rigid earth.

In time we may hope to ascertain by repeated geodetical researches in what way countries, or even whole continents, are rising and sinking. In such work the geodesists will have the fullest support of all men of science. In particular they may expect sympathy from the astronomical world, which will soon be faced by an allied problem. The question must, before many years, come up for decision as to when a repetition of the chart of the heavens, which is slowly nearing completion, will be justified by the conclusions to be drawn from it.

SCIENTIFIC STUDIES OF DEW-PONDS.

An endeavour to solve the so-called mystery of the dew-pond has recently been made by Mr. E. A. Martin, and the results of some of his observations are shown in a paper which appears in the *Geographical Journal* for August. The paper was read before the Research Department of the Royal Geographical Society on April 22. Attempts were made by direct experiment to ascertain how the replenishment of such ponds takes place. During the autumn of 1908, Mr. Martin spent many nights and days on the Clayton downs, in Sussex, and thus was on the spot during the hours when, according to theory, the ponds should be receiving dew. The result of a large number of thermometrical observations went to show that very rarely does the temperature of the water of the ponds sink below that of the air above it, or below dew-point.

The term "dew" is widely used to mean any kind of condensation which does not fall as rain, hence "dew-ponds," "mist-ponds," and "cloud-ponds" are terms which are used for one and the same kind of pond. On the Sussex Downs no overhanging tree to condense moisture out of the air is found, as a rule. The bare down is all around, whilst in the water there is, as a rule, pond-weed, or reeds, sometimes projecting above the surface of the water. Where this happens, dew is undoubtedly precipitated on the reeds, and this helps to replenish the pond. But many ponds have no projecting vegetation, and yet do not suffer greatly in times of drought. It is pointed out that the measurements of some ponds and their surrounding basins give a receiving area sometimes double the area of the water. In one case the pond-area was 4120 square feet, whereas the shelving margin gave an area of 5795 square feet. Other similar examples are given, and it is this width of margin which has caused many observers to conclude that rainfall is the chief factor in filling the ponds; but not the only factor, as Mr. Martin points out, otherwise there would be little reason why the lowland ponds should dry up in times of drought, and leave the upland ponds fairly full.

Thermometrical observations show that the depth of a pond at the commencement of a drought has much to do with its continuance. A shallow pond was found rapidly to dry up by evaporation, the high temperature gained during the day being well maintained during the night. On the other hand, a deep pond will but slowly be heated, and may well be saved excessive evaporation until a break in the weather comes, and normal conditions again prevail. One pond which was but a foot deep was found so late as 8.20 p.m. in July to show no differences of temperature at 1 inch, 6 inches, and 9 inches, the thermometer registering 67·5° F., whilst that on the bank showed a reduction to 58·5° F. The water lost heat but slowly, and no doubt evaporation went on well into the night. Three weeks later it was dry. Another pond, 3 feet deep, showed, at 6 p.m., 76° F. at 1 inch, 74° F. at 6 inches, and 71° F. at 9 inches, and two hours later the 1-inch temperature had been reduced to 70¾° F., whilst the 6-inch and 9-inch temperatures were uniform at 71° F., the surface temperature showing a considerable loss. There was in this pond a large quantity of rushes, and the loss by evaporation was almost compensated for by the deposition of dew upon their exposed surfaces. This pond did not dry up.

Attention was given to the alleged chilling of the water below dew-point, but it was found that although such a circumstance rarely happened, it sometimes was seen that the temperature of the air resting on the water was below dew-point. Further observations in this direction are to be made. Numerous experiments were made to determine whether straw, wood, and woodwool were likely to effect a chilling of the water of a pond resting on a foundation of these materials, and the evidence pointed to these acting in the desired direction. A series of experiments showed that both "downward" and "upward" dew would be found on different nights according to certain atmospheric conditions, and it is pointed out that if a pond were to depend on the latter only for its replenishment, it would simply receive what it had previously lost by evaporation. The chilling effect of grass on the moisture-sodden lowest stratum of the atmosphere results in dew on the grass, but there is no such chilling of the air by the pond-water, and if dew is there deposited there must be some other cause at work.

It is found that out of seven localities quoted where straw has been used in the foundations of dew-ponds, in no case has it been used with the idea of inducing dew-deposition in the pond. Sections of dew-ponds are given in the paper, constructed according to various authorities. The most remarkable case seems to be that in Wiltshire, where foundations are laid in the form of six layers of straw and clay alternately, but here again the reason given is that the straw prevents the clay from cracking. Incidentally, Mr. Martin refers to the danger to clay-puddled ponds from the small red-worm, swarms of which were met with in some ponds. An estimate of dew-fall on grass was made, giving 0·77376 inch per annum.

So far as rainfall is concerned, it was found that in thirty-two days the amount measured on the downland was 2·57 inches, but a gauge placed in a hollow dug for an experimental pond measured 3·51 inches. This seems to show that a pond-depression on the downs would draw into it, by setting up currents and eddies of the wind, a greater quantity of rainfall. By experimenting with a gauge in the rim of which had been placed some straw and grass, in imitation of conditions which obtain in some ponds, it was found that when 0·37 inch was measured on the down, 0·54 inch was measured in the gauge; when the former showed 0·32 inch, the latter showed 0·69; when the former showed 0·46 inch, the latter showed 0·80 inch. The gauge with the straw and grass was placed in the hollow.

In order to determine whether the chemical composition of pond-waters would give any clue to their origin, a number of analyses of such waters was made at the South-Western Polytechnic, and the results are given in the paper. These seem to show that there is too much sodium chloride contained in the ponds to have come from rain-water, and in normal conditions dew certainly contains no common salt. The sea-mists may reasonably be held to be responsible for the saline qualities of the waters.

So far as the antiquity of the name and the idea of the dew-pond is concerned, Mr. Martin seems to think that puddling by cattle-trampling by accident may have caused artificial ponds first to have been made, and although proof must be lacking, it is possible that some may be of very ancient date. Wells are so rare in ancient camps on the downs that ponds were probably the chief source of water supply. Why straw was first used, and how it was first used, are likely to remain unanswered satisfactorily. A description is given of a small experimental pond which the author made. The foundations were composed of wood-wool resting on a chalk base, followed by straw and wooden planks, with puddled clay thereon. Further investigations are promised, and no doubt the success or otherwise of the pond will form the subject of a future paper.

In the discussion which followed the reading of the paper, Dr. H. R. Mill claimed that rain is the principal factor in filling the downland ponds, and suggested that the reason why the lowland ponds the more quickly dry up may be that they are not so carefully made watertight as those on the higher ground.

ARTIFICIAL PARTHENOGENESIS.[1]

THE development of biology into an experimental science is nowhere better illustrated than in the important researches on artificial parthenogenesis which we owe largely to Jacques Loeb, and biologists will welcome heartily the little book in which this distinguished author gives an account of the subject. Prof. Loeb informs us that the object of his investigations was to transfer the problem of the fertilisation (Entwicklungserregung) of the animal egg from the domain of morphology to that of physical chemistry. He recalls the fact that it is only about sixty years since it was first firmly established that the animal egg—with the exception of a few cases—can only develop into an embryo after fertilisation by the entrance of a spermatozoon. Various interpretations have been placed upon this process. O. Hertwig maintained that the essential feature of fertilisation was the union of the male and female pronuclei in the egg-cell, and the observation of this union was undoubtedly of the greatest importance, especially from the point of view of the theory of heredity, but it gave us no real insight into the nature of the stimulus which evokes as its response the segmentation of the egg. Boveri, indeed, maintained that the union of the two pronuclei had nothing to do with providing this stimulus, and was able to show that an enucleated egg may develop after fertilisation by a spermatozoon. According to Boveri the centrosome is the organ of cell-division, and the unfertilised egg cannot develop because the centrosome is wanting. A new centrosome is introduced by the spermatozoon, and then cell-division or segmentation commences.

Loeb, however, maintains that the development of the egg is a chemical process, depending mainly on oxidation, in which there takes place a synthesis of nuclear material from constituents of the cytoplasm. He accordingly regards the Boverian hypothesis, in which a purely mechanical *rôle* is assigned to the centrosome, as inadequate to explain the nature of fertilisation. His earliest experiments consisted in treating the eggs of a sea-urchin with sea-water, the alkalinity of which had been increased by the addition of soda-lye. In such water the eggs segmented once or twice, but did not develop further. On the other hand it was found possible to cause the unfertilised eggs to develop into larvæ by placing them for a couple of hours in hypertonic sea-water—sea-water, that is, the osmotic pressure of which had been raised about 60 per cent. by the addition of some kind of salt or sugar. This apparently purely osmotic stimulation of the egg was subsequently found to comprise two factors, viz., the loss of water by the egg, and the concentration of the hydroxyl-ions of the hypertonic solution. It was also found that the hypertonic solution can only stimulate the egg to development if it contains free oxygen in sufficient quantity.

The author next succeeded in producing larvæ from unfertilised eggs of Chætopterus by means of potash and acids without raising the osmotic pressure of the sea-water.

It has long been known that the eggs of many animals, immediately after the entrance of the spermatozoon, form a "fertilisation membrane" on the surface. We used to be told that this membrane served to prevent the entrance of additional spermatozoa. Loeb attributes to it a much deeper significance. He finds that in the case of osmotically "fertilised" eggs no membrane-formation takes place, but a short treatment with a monobasic fatty acid causes the formation of a typical "fertilisation-membrane" in all the eggs of Strongylocentrotus. If such eggs are then placed for a short time in hypertonic sea-water they all develop into larvæ. The artificial membrane-formation by itself, however, in this case only causes the eggs to commence their development without being able to continue it.

The membrane-formation is regarded as the most important factor in fertilisation. It has also, however, a deleterious effect, a tendency to cytolysis, which requires to be counteracted by treatment with a hypertonic solution, or in some other way. In some species the artificial membrane-formation alone is sufficient to bring about the development of the eggs to normal larvæ, the injurious cytolytic effects being less marked than in the sea-urchin. That it is the membrane-formation and not any other action of the fatty acid which brings about the development of the egg is evident from the fact that membranes produced in any other way have the same effect.

The author attributes a like importance to membrane-formation as the essential factor in the normal fertilisation of the egg by the spermatozoon, and proceeds to inquire what substances and agencies determine such formation. Membrane-formation may be regarded as a stage in the cytolysis of the egg, and all cytolytic agents will cause membrane-formation. Clearly the cytolysis must be arrested in some way after the membrane has been formed, otherwise it will lead to the destruction of the egg. Loeb maintains that in the natural fertilisation of the egg the formation of the fertilisation membrane is brought about by a "lysin," carried by the spermatozoon, which also brings with it a second substance which serves to counteract the evil effects of membrane-formation.

Such is the essence of the "Lysin Theory" of fertilisation. As an attempt to interpret biological phenomena in terms of chemistry and physics, it is of the greatest interest, though the point of view from which its author regards the phenomena of fertilisation may not be the one which appeals most strongly to students of biology.

We do not doubt that a new edition of this extremely interesting work will shortly be called for, and we hope that it may be found possible to publish it simultaneously in German and English. Not the least valuable feature of the book is, to our mind, the introduction of twenty-one pages, in which a concise *résumé* of the entire subject is given.

[1] "Die chemische Entwicklungserregung des tierischen Eies (Künstliche Parthenogenese)." By Jacques Loeb. (Berlin: Julius Springer, 1909.) Price 9 marks.

NOTES.

A MEETING to further the interests of the forthcoming expedition, under Captain Scott, to the South Polar regions, was held at the Mansion House on Tuesday last, the Lord Mayor presiding. Captain Scott laid the plans and objects of the expedition before the meeting, and stated that 40,000*l*. was required for the estimated cost of the first year's work. He further said that if that sum was contributed by this country he hoped that, with the cooperation of the over-seas dominions, they might raise a sum sufficient to carry on the work until it was finished, that was to say, if necessary, for a second and possibly a third season. He would prefer a request for support to the Government of the Commonwealth of Australia, because the scientific work of an expedition of that kind —its meteorological and magnetic observations—was possibly of greater use to the countries which lay adjacent to the region of research than it was to the homeland. A resolution in support of the expedition was passed.

ACCORDING to a Reuter telegram from Washington, the National Geographic Society has passed a resolution requesting Dr. Ira Remsen, president of the U.S. National Academy of Sciences, to appoint a commission to examine the records and observations of Dr. Cook and Commander Peary. This action is based on a proposal made by the Peary Arctic Club.

AT a meeting of the executive committee of the Zeppelin Polar Expedition, held at Friedrichshaven last week, it was decided that a preliminary expedition should be sent next summer to Spitsbergen in order to investigate the polar ice and determine the conditions affecting the management of airships in those regions. The committee laid great stress upon the importance of promoting the development of Zeppelin airships for long journeys, especially over the sea, for the purpose of scientific investigation. Plans are to be drawn up immediately for the construction of a suitable airship, which is to be ready at the beginning of 1911.

IT is stated by a *Times* correspondent that Mr. Evelyn Baldwin, the leader of the Baldwin-Ziegler expedition of 1901–2, announces his intention to make an attempt to reach the North Pole by drifting with the ice eastward on a parallel course to that taken by the *Fram*. He calculates that the voyage will last four years.

LIEUT. SHACKLETON delivered a lecture before the Danish Geographical Society on Saturday last on the work of his late expedition, and received from the president the gold medal of the society. He also had conferred upon him, by the King, the Commandership of the Dannebrog Order of the Second Class. It is the intention of the explorer to present a small collection of specimens of Antarctic rocks to each of the principal geological museums.

A SEVERE shock of earthquake was experienced in the island of Shetland at about two o'clock on Saturday morning last. The shock was accompanied by a dull rumbling sound, which many fishermen mistook for the sudden outbreak of a hurricane.

ACCORDING to a Reuter message, a severe earthquake shock was experienced at Reggio di Calabria in the morning of October 7.

A STORM of unusual violence broke over Havana and the coast of Florida on Monday last. The damage to property at Key West is estimated at 400,000*l*. At Havana five persons were killed and many injured.

WE note with regret the death, on Saturday last, of Dr. Hugh Blackburn, emeritus professor of mathematics at the University of Glasgow. Prof. Blackburn was born on July 2, 1823, and filled the chair of mathematics in the University from 1849 until 1879, when he was succeeded by Prof. Jack.

MR. RICHARD BANNISTER, whose death occurred at his residence in South Kensington on September 27, had held the position of deputy principal chemist in the Government laboratory for about twenty-five years. He attended the Royal College of Chemistry in 1862–3, obtaining full marks at the final examination of the students, and was attached to the small chemical staff then at Somerset House. Eleven years later he was promoted to the post of deputy principal, and continued to hold this office until his retirement from the public service in 1898. On such analytical matters as the detection of adulterations in tobacco or of methyl alcohol in spirituous liquors, Mr. Bannister in the earlier stages of his career was often required to give expert testimony. Later, however, in accordance with what his duties demanded, it was chiefly as an administrator and a shrewd man of business that his capabilities were shown. He gave evidence before several Royal Commissions, notably upon the questions of the materials used in brewing beer and the adulteration of food products. His knowledge, judgment, and sound common sense were also recognised outside strictly official circles. He was a Cantor lecturer on certain food-stuffs, such as tea and coffee, the lectures containing much useful technical information of a kind not easily found at that time in text-books. He acted as juror at the Paris and Chicago exhibitions, where his combined chemical and business experience—for he was a director of the Civil Service Stores, as well as an analytical chemist—was no doubt of exceptional value. Mr. Bannister, who was in his seventy-fifth year, was a member of the council of the Institute of Chemistry.

MR. JAMES BRITTEN has just retired from the botanical department of the British Museum after a period of service of thirty-eight years. Previously to joining the staff of the British Museum he was for two years an assistant in the Kew Herbarium, and has therefore completed forty years in the service of the State. Mr. Britten has recently been engaged in the preparation of a catalogue of the Sloane Herbarium, which will shortly be published by the trustees. The collections of Sir Hans Sloane, it will be remembered, were the foundation of the British Museum, and his herbarium contains some of the earliest botanical collections from many parts of the world, and is of great importance in connection with the systematic works of Linnæus and other botanists of the eighteenth and early nineteenth centuries.

ACCORDING to a *Times* correspondent, a further fossil human skeleton has just been discovered in the department of the Dordogne at Ferrassie, 5 kilometres from Bugue, in a layer belonging to the lower middle post-Tertiary period.

A CORRESPONDENT of the *Globe* states that the remains of a lake-dwelling (reputed to be 4000 years old) have just been discovered by Dr. Otto Froodis while excavating the hilly region near Lake Vettern, in Sweden. Weapons and primitive household utensils were found in stone, flint, bone, and horn.

THE demonstrations in connection with the museum of the Royal College of Surgeons of England, which were inaugurated last year, are to be continued by Profs. A.

Keith and S. G. Shattock. This year's course is to begin to-morrow. It will be open to all practitioners and medical students on presentation of their cards.

THE first monthly general meeting of the new session of the Institution of Mechanical Engineers will be held to-morrow, when a paper will be read by Prof. W. E. Dalby entitled "Heat Transmission." It will be remembered that in 1906 the members of the institution decided, by vote, that the subject of heat transmission was suitable for further research, and Prof. Dalby has therefore, at the request of the council, collated in an appendix to his paper information already published relating to the transfer of heat across metallic surfaces in contact with water and with gases.

THE syllabus of the first half of the 137th session of the Medical Society of London has reached us, from which we learn that on October 25 a paper is to be read by Dr. F. W. Hewitt on the need for legislation in regard to anæsthetics, and the lines upon which it should take place. Subsequent papers will be read by Prof. Arthur Keith and Dr. James MacKenzie. The Lettsomian lectures will be delivered on February 7 and 21 and March 7 by Dr. J. S. Risien Russell, on the cerebellum and its affections.

ACCORDING to the *Lancet*, a new edition of the catalogue of the pathological section of the Museum of the Royal College of Surgeons of England is to be prepared by Prof. S. G. Shattock, with the assistance of Mr. Alban Doran; a new edition of the catalogue of the Entozoa, by Dr. R. T. Leiper, is also in preparation.

NOTICE is given of the holding, in June and July, 1910, of an International Agricultural Exhibition at Buenos Aires. Communications respecting the exhibition should be addressed to the secretary, 316 Florida, Buenos Aires.

THE inaugural meeting of the China Philosophical Society was held at Tientsin on September 18, under the presidency of the president of the Pei Yang University (Mr. Wang Shoh Lian), who, in the course of his address, pointed out the importance of the existence of such a society in the present stage of China's development, when western learning is being spread over the Empire. The possibilities before the society are unlimited, as all branches of science and art present practically untouched ground, and it can do much to build up the new learning, to foster and organise research, to unite Chinese and foreign students in a common cause, and help these to understand each other better; to assist in the introduction of foreign methods and in the adaptation of these, and yet to protect and retain those older methods which are threatened with extinction. After the delivery of the address referred to, papers were read by Dr. G. Purves Smith, on agricultural possibilities of North China, and Dr. Wu Lien Teh, on a striking example of scientific farming in Chihli.

WE learn from the *Times* of October 11 that the shipments of salmon ova to New Zealand in the early part of this year have, so far, proved highly successful. Of the first consignment of some half-million eggs from Scotland and Ireland, only about 5·6 per cent. died on the voyage out. The second consignment consisted partly of English and partly of German eggs; the latter had to be re-packed in London, and about 7·8 per cent. of them perished on the voyage to New Zealand, while of the former only about 1·7 per cent. failed to reach their destination in safety. On their arrival in New Zealand the eggs were immediately sent to the hatcheries, where they commenced hatching out within a few hours of their arrival. There is clearly no difficulty about transporting salmon eggs to New Zealand in good condition. The difficulty is to rear the young fish after hatching. Hitherto all attempts to do this have failed in New Zealand, and we shall be much interested to hear what happens in the present instance. If they can once get established, there seems no reason why the salmon should not thrive in New Zealand as well as the trout, the acclimatisation of which has long since been successfully accomplished.

THE exploration of the fauna and flora of the waters of Lake Tanganyika has been carried out with important results during the last ten years owing to the efforts of Sir Ray Lankester. He obtained funds from the Government grant committee of the Royal Society, in the first instance, in 1895, which were employed in sending Mr. J. E. S. Moore on a preliminary expedition. The results obtained were so promising that in 1899 Sir Ray Lankester collected from those interested in the great lake and in African natural history a special fund amounting to more than 4700*l*. for further exploration, and obtained the assistance of a committee of naturalists in its administration. Mr. Moore was sent on a second expedition, well equipped and furnished with funds for the hiring of a steamer which had been placed on the lake by some enterprising pioneers. On Mr. Moore's return a third expedition was entrusted to Dr. W. A. Cunnington, of Christ's College, Cambridge, who has given special attention to the algæ and the smaller invertebrates of the lake. The money collected by Sir Ray Lankester has now been all spent, and an account rendered to the subscribers, together with a list (a copy of which we have received) of the numerous important publications on the fauna and flora of Lake Tanganyika, written by various experts who have undertaken the study of the collections brought home by Mr. Moore and by Dr. Cunnington. The most extensive results are those published by Mr. Boulenger, in five separate memoirs, on the fishes, which include a vast number of new species and genera; Mr. Moore's publications on the new gastropod molluscs and the anatomy of many of them, and on the reproduction of the fresh-water jelly-fish, Limnocnida; papers on the Crustacea, by Messrs. Cunnington, Calman, G. O. Sars, and Stebbing, and on the botanical collections by Dr. Rendle and Prof. G. S. West. All the collections have been placed in the Natural History Museum, although the trustees did not in any way contribute to the expenses of the expedition, which was a purely individual enterprise carried out by Sir Ray Lankester when director of the natural-history departments. It now remains for Dr. Cunnington to give a clear and concise illustrated account of the natural history of Lake Tanganyika so as to embody the results of all this recent investigation in a readable form, with indication to the reader as to where he may find the various scattered memoirs in which the detailed descriptions are published.

PART iii. (June) of the Ceylon Marine Biological Reports is devoted to an account, by Messrs. T. Southwell and J. C. Kerkham, of an inspection of certain pearl-banks situated between Dutch Bay Point and Negombo, which are at present under the control of the Ceylon Government. The inquiry was conducted by the Ceylon Company of Pearl Fisheries, Ltd., which at present holds the main fisheries in Ceylon; and the chief results seem to be that these southern banks are exposed to the continuous influence of adverse surface-currents, and that the nature of the sea-bed is less well adapted for oyster-culture than is the case in the leased beds. Further, the close proximity of the southern banks to the "overfalls" renders them unsafe as oyster-beds, although the actual *modus operandi* by which this is brought about is not at present understood.

In a note communicated to vol. xxxiii., No. 3, of the *Tropical Agriculturist*, Mr. E. E. Green states that an attempt is to be made to check the ravages on tea-plants in Ceylon of the beetle known as the "shot-hole borer" by introducing a predaceous beetle (*Clerus formicarius*), which is already well known as an enemy of pine-boring Scolytidæ. Mr. Green decided to try this beetle as an exterminator on account of the good reports of its value as a pest-ridder received from the United States. The experiment can, however, only be of a tentative nature, as the Clerus is an inhabitant of the temperate zone, and it remains to be seen whether it will thrive in the tropics. In a second note the Government entomologist states that in the Ambawella district of Ceylon camphor-plants are attacked by a scolytid allied to the shot-hole borer.

Several interesting additions to the British insect-fauna are recorded in the October number of the *Entomologists' Monthly Magazine*. Many years ago, it appears that Dr. David Sharp received from Chobham a water-beetle which he was unable to identify; this year he took a second example at Brockenhurst, and he finds both to belong to the continental *Laccobius scutellaris*. In the next article Mr. J. Edwards describes a new beetle from Horning, under the name of *Dryops anglicus*; later on, Mr. E. R. Speyer records the occurrence in Sussex of a number of specimens of the continental dragon-fly *Somatochlora metallica*, a species already known from Scotland, but not hitherto definitely identified in England. Finally, Mr. K. J. Morton mentions the occurrence in the west of Ireland of the trichopterid *Limnophilus fuscinervis*, which is quite new to the fauna of the British Isles.

C. Dawydoff contributes to the *Zeitschrift für wissenschaftliche Zoologie* (Bd. 93, Heft 2) a very elaborate memoir on the process of regeneration in the Enteropneusta. He considers that this group of animals, about which so much has been written recently from the morphological and phylogenetic points of view, affords an uncommonly convincing example of the untenability of Weismann's view that the power of regeneration is the result of natural selection. He states that when dredging for Ptychodera only the anterior portion of the body is usually obtained, the hinder end being commonly torn away, and concludes that under normal conditions the animal may lose its hinder end but hardly ever loses its head. He thinks that, according to Weismann's views, the animal should accordingly be able to regenerate the hinder end, but not the head end, while his own experiments show exactly the contrary to be the case, the anterior extremity being very readily regenerated after amputation, but not the posterior. The author's argument in this respect does not appear to us to be very convincing. The facts as stated suggest the possibility that anterior ends are cut off and collected by the dredge because they protrude, while the posterior ends remain buried, and that for the same reason the head ends are likely to be bitten off by fishes. If this be so, the fact that the anterior ends and not the posterior are regenerated fits in exactly with Weismann's views. We need to know something definite about the habits of the living animal before coming to a conclusion on this question. It will interest morphologists to know that Dawydoff finds in the mode of regeneration of the proboscis pores evidence in favour of Schimkewitsch's view that these organs are homologous with the "metanephridia" of annelids, consisting each of a mesodermal funnel and an ectodermal canal, the latter of which he regards as of more recent origin than the former.

Dr. W. F. Purcell contributes to the September number of the *Quarterly Journal of Microscopical Science* (vol. liv., part i.) a very interesting memoir on the development and origin of the respiratory organs in Araneæ. He finds that the first "leaves" of the "lung-books" in spiders appear on the free posterior side of the provisional abdominal appendages, quite outside of the pulmonary invagination, and deduces from this fact that the lung-books are derived from gill-books similar to those of Limulus. The tracheal system is supposed to have a two-fold origin, the pair of lateral tracheæ of dipneumonous spiders having been derived from the second pair of lung-books of tetrapneumonous forms, while the medial trunks of the tracheæ are equivalent in their entirety to metamorphosed entapophyses, *i.e.* to the invaginated ectodermal areas, lined by cuticle, which serve for the attachment of the ventral longitudinal muscles. Dr. Purcell's observations and conclusions should be of great value in settling the much-discussed question of the classification of the Arthropoda—if it ever is settled. The same number contains a further instalment of Mr. Goodrich's work on nephridia, dealing with these organs in Dinophilus and in the larvæ of Polygordius, Echiurus, and Phoronis, and some further notes on a trypanosome found in the alimentary tract of *Pontobdella muricata*, by Miss Muriel Robertson.

Among the shikar and natural-history notes contributed to the *Indian Forester* (August) is a note on the Burma mole rat, which, according to the writer, is a serious depredator of Para rubber trees, especially in young plantations, and is also reported to attack seedlings of teak, mango and jack trees. The animal, which is not definitely identified, but may be *Nesocia hardwickei*, is apparently confined to Burma and western Siam.

An important collation of the genus Cereus and its allies in North America, based upon observations in the field in Mexico and elsewhere, also of living material in the greenhouse in addition to herbarium species, is presented by Prof. N. L. Britton and Dr. J. N. Rose in the final part (No. 10) of the twelfth volume of Contributions from the United States National Herbarium. Following to a considerable extent the revision by Mr. A. Berger, except that they raise several of his subgenera to generic rank, the authors distinguish twenty-three genera, of which Cephalocereus, Echinocereus, and Lemaireocereus are the chief. The plant originally named *Cereus greggii*, that has a curious turnip-shaped root, is made the type of one of the new genera, Peniocereus. The same part contains descriptions of five new Mexican Crassulaceæ communicated by Mr. J. N. Rose, and a supplement to the monograph of North American Umbelliferæ by Drs. J. M. Coulter and J. N. Rose.

As might be expected, the officials of the Department of Agriculture in the Federated Malay States have been called upon for advice regarding pests of Para rubber trees. Mr. H. C. Pratt has collected further information on the ravages of the ants identified by him as *Termes gestroi*, which is published in Bulletin No. 3, together with methods of treatment. No insecticides can be recommended, but eradication of old tree stumps and carefully devised fumigation with arsenic and sulphur of the burrows leading to hollow stems have proved efficacious. Mr. W. J. Gallagher discusses in Bulletins Nos. 2 and 6 the root disease caused by *Fomes semitostus*, and a branch and stem disease which has not yet been traced to a specific fungus. The Fomes spreads from the old stumps of jungle trees, so that eradication of these is the only remedy, while excision of infected parts and treatment with Bordeaux mixture have proved effectual against the less dangerous stem disease.

A VARIED selection of microscopic accessories, apparatus for bacteriological and hæmatological investigation, and instruments for collecting natural-history specimens, is kept by Messrs. H. F. Angus and Co., 83 Wigmore Street, who have recently issued a well-illustrated catalogue of this part of their stock. The firm acts as agent for Messrs. Swift, Leitz and Zeiss, also for Dr. G. Grübler, of Leipzig. Another feature of the catalogue is the list of mounted specimens for the microscope, physiological, pathological, and botanical.

THE Francis Galton Eugenics Laboratory has published a lecture by its research scholar, Miss Ethel M. Elderton, entitled "The Relative Strength of Nurture and Nature," which was recently delivered in a course of lectures on national eugenics at the laboratory. By the method of correlation used by the lecturer and her colleagues, she claims to establish the fact that "overcrowding, bad economic conditions, bad physical and moral conditions of the parents, have practically no effect on the intelligence, eyesight, glands and hearing of the children." The results, indeed, show that the children of drunken parents are somewhat healthier and more intelligent than those of sober parents, and generally that the influence of environment is almost negligible compared with that of heredity. As the author admits, some of "these results are certainly startling and rather upset one's preconceived ideas."

IN a work entitled "Die Härte der festen Körper und ihre physikalisch-chemische Bedeutung" (Dresden: Theodor Steinkopff) Dr. Viktor Pöschl makes a valuable contribution to the study of an important physical character of solid substances, which has as yet scarcely received adequate attention from crystallographers and others interested in such matters. He describes a new form of sclerometer recently devised by him; in it the section under test is placed on a carriage and drawn under a diamond point, which may be lightly loaded, and the width of the resulting scratch is measured by means of a high-powered microscope. He gives the results of a series of experiments made upon various minerals and metals. It is interesting to note that the apparently wider scratch made perpendicular to the trace of the cleavage plane is due to incipient cleavage cracks, and that the direction parallel to the trace is really the one of least hardness. Dr. Pöschl discusses with considerable acumen the connection between hardness and solubility, chemical composition, crystal form, and density.

PROF. ECKERT publishes a new "isochronic" chart of the world in the September number of *Petermann's Mitteilungen*. The first part of an article on the construction of such maps, dealing with the history of their development and with modern methods of arranging and reducing the *data* upon which they are based, accompanies the chart.

THE October number of *Travel and Exploration* contains the first part of a paper, by Dr. M. A. Stein, on his journey through the Taklamakan Desert, entitled "Across the 'Sea of Sand.'" The paper gives a graphic account of the incidents of the journey, and is illustrated by excellent photographs.

MR. ELLSWORTH HUNTINGDON contributes an article on the Russo-Afghan frontier region to the September number of the *National Geographic Magazine*. The paper forms the first part of an account of the "Afghan Borderland," based chiefly on journeys made by the author in recent years. Speaking of eastern Persia, Mr. Huntingdon remarks that "the inhabitants stagnate and play no part in the present history of the country except as pawns to be harried by the Afghans, cowed by the Russians, or cajoled by the English."

THE British School of Archæology at Athens has made further important discoveries on the site of the city of Sparta. The great temple of Artemis Orthia has been now completely cleared. The site known as the Menelaion, at Therapne, about two miles south-east of Sparta, has been partially examined. The sanctuary of Menelaus and Helen, mentioned by Herodotus, Livy, Pausanias, and Polybius, was a favourite resort of the Spartan ladies, where the goddess was believed to confer the gift of beauty on her worshippers. The discovery of Mycenæan remains on this site suggests that this was the famous palace of Menelaus, and this provisional identification is corroborated by finds of bronzes, votive double-axes, lead figurines, and terra-cottas.

IN the fourth Bulletin of the Archæological Survey of Nubia for the current year Dr. G. A. Reisner continues his account of a group of prehistoric cemeteries at Koshtamna, in Nubia. The excavations disclosed two remarkable sets of graves, one simple archaic pits with contracted burials, and the second mud-cut chambers with mummies deposited in an extended position. Unfortunately, many of the former have been destroyed by cultivators in search of fertilising matter for their fields, but those which remain extend from the middle pre-dynastic period down to that of the late Empire. The mud-cut graves represent the period from the earliest Ptolemaic down to Christian times. Drs. G. Elliot Smith and D. E. Derry have, as usual, reported upon the physical characters of the human remains. These show a considerable intermixture of the Negroid with the indigenous type, which has resulted in a progressive shortening of the cranium. Three distinct negro types were observed—one small and relatively short-headed, the second taller and dolichocephalic, the third a big, massive, broad-faced, large-headed variety. The occurrence of spinal tuberculosis in this region is now definitely established, and the present investigations have pushed back the diagnosis of this disease another thousand years, as far back as the period of the Ancient Empire.

THE Transactions of the Royal Society of South Africa for July last contain a useful paper by Mr. R. T. A. Innes, in which he endeavours to show what reductions applied to the Transvaal air-temperatures will in the mean for the whole country reproduce the assumed temperatures at sea-level. On squared paper points were placed for the actual temperatures recorded at different altitudes; a curve drawn through these to the point at sea-level approximated closely to a parabolic form, and from this curve the reductions to sea-level were taken, the figures below 2500 and above 6000 feet being mostly derived by extrapolation. Three maps are given showing the distribution of sea-level temperatures during the warmest and coldest months of the year and for the mean of the year. The isotherms differ considerably from those drawn by Dr. Buchan; in the warmest month, for instance, Dr. Buchan gives the sea-level temperature of the western border as about $92\frac{1}{2}°$, whereas Mr. Innes gives it as $85°$. The author remarks that, in the absence of data, Dr. Buchan must have relied on the analogy with other continental areas, but that the effects of the South African plateau and of the great wind movement alter the circumstances. The present tables, based on data for two years, are, however, only considered as a first approximation.

With reference to suggested reforms in meteorological methods, we referred in a recent issue to a proposal made by Prof. A. G. McAdie in the *U.S. Monthly Weather Review* of November, 1908, to adopt the centigrade (not Celsius) scale and the metric system for temperature, wind, rain, &c., and 1000 on an arbitrary scale of units as the equivalent of the normal atmospheric pressure of 760 mm. This proposal has led to several interesting communications on the subject in the *Monthly Weather Review* of March last. Mr. M. E. J. Gheury (Eltham) prefers, for reasons given, the units at present generally adopted for meteorological observations in this country. Mr. H. H. Clayton (Blue Hill, U.S.) prefers the metric system, but with regard to temperature he renews a suggestion, made in Nature in 1899 (vol. lx., p. 491), that the Kelvin thermometer scale (freezing point 273°, boiling point 373°) should be used, and he points out that the adoption of this scale with the metric system was recommended by a committee of the British Association in 1904. Prof. Köppen (Hamburg) approves of the use of the metric and centigrade systems by England and America, but would express all barometric measurements by ordinary general units of force, taking as unit the product gram × acceleration of gravity. In connection with the above notes it may be stated that from the commencement of this year the Meteorological Office has adopted centigrade degrees on the absolute scale (from $-273°$) and pressure in C.G.S. units, or megadynes per square centimetre, as most suitable for the publication of values in the investigation of the upper air.

No. 15 of the *Verhandlungen der deutschen physikalischen Gesellschaft* contains two contributions from Prof. W. Nernst and his pupil, Dr. H. Levy, dealing with the physical properties of water from the thermodynamic point of view. Assuming that the deviations of water vapour from the "perfect gas" laws are due to the formation of a certain proportion of double molecules in the vapour, they show that it is possible to give expressions for the density and pressure of the vapour and the latent heat of evaporation of the liquid, within the interval 0° C. to 100° C., the latent heat of fusion of ice, and even for the variation of the specific heat of water with temperature, which show an accuracy far greater than has been attainable with the help of any previous theory.

Some experiments by Prof. Rateau on fluid pressure on inclined planes are discussed in an article in *Engineering* for September 17. The mathematical solution for an ideal fluid shows that a portion of the fluid is always deviated so as to pass over the leading edge, whatever may be the inclination of the plane. Rateau's experiments show that, for considerable angles of incidence, the fluid actually spills over both edges, whilst for smaller angles the flow takes place wholly past the trailing edge. Using a rectangular plane 30 by 50 centimetres by 1·25 millimetres thick, from 0 to 29 degrees the flow is solely over the trailing edge; from 29 to 36 degrees the conditions are absolutely unstable; afterwards a proportion regularly escapes past the leading edge. Further, the smaller the angle of inclination the nearer does the centre of pressure lie to the leading edge of the plane, the limiting value for the above plane being 0·236 of the width of the plane for zero inclination. A plate having a flat ship-shaped section shows a very marked retrogression of the centre of pressure at inclinations less than 7 degrees, the centre of pressure moving rapidly towards the trailing edge. A blast of air was used in these experiments, and results were also obtained for the total pressure and for the friction.

From an article on the Paris Aviation Exhibition in *Engineering* for October 1 we note a point which may possibly require more attention than it has hitherto received. In the case of an engine running with no fly-wheel except the propeller, the blades near the root may be subject to a considerable stress alternating with every revolution of the engine. The amount of this stress will depend on the number of cylinders the engine has, and it may be necessary to make the propeller-blades considerably stronger with two- and three-cylinder engines having no fly-wheel than with others having a more even turning moment. Wooden propellers seem more in favour than those of metal, and probably are more suitable, as wood is well able to withstand the above-mentioned stresses, and it is easy to make the blade strong at the root without excessive weight. The wreck of the dirigible *République* and the death of four men composing her crew, owing to a broken propeller, shows that danger from this cause is not imaginary, and the results in an aëroplane would probably be at least equally disastrous. We also note from the same article that although the cross-Channel flight and the record for distance have been performed with air-cooled motors, the water-cooled engines are in a very large majority at the exhibition. Weights per horse-power range from 2·2 lb. in the Gnome to 7·5 lb. in the Renault, both being air-cooled. The water-cooled engines range from 4 lb. in the Darracq to 6·1 lb. in the Bayard, excluding radiator and water.

The Carnegie Institute of Washington has now published the eighth volume of the "Index of Economic Material in Documents of the States of the United States." It deals with the State of Illinois, and covers the years 1809–1904. This index has been prepared by Adelaide R. Hasse, of the Librarian Department of Public Documents in the New York Public Library, and deals only with the printed reports of administrative officers, legislative committees, special commissions, and governors' messages. The term "economic" has been given a liberal interpretation, and the index will constitute a useful addition to the resources of students of American history.

We are asked to state that a new edition (the third) of "A List of Official Chemical Appointments" is being prepared by the registrar and secretary of the Institute of Chemistry, and that corrections and additions should be sent as soon as possible to the registrar of the institute, 30 Bloomsbury Square, W.C. Suggestions which may increase the usefulness of the list will be carefully considered.

Since the appearance in the last number of Nature of particulars as to forthcoming books of science, information has reached us of the following additional works:—In *Agriculture*.—"Principles of Agriculture: a Text-book for Lecturers on Agriculture, Rural Schoolmasters, Young Farmers, and Students of Agriculture," J. M'Cutcheon, illustrated (E. and S. Livingstone). In *Biology*.—"Window and Indoor Gardening," T. W. Sanders; "Mushrooms and their Cultivation," T. W. Sanders; "Bees for Profit and Pleasure," H. Geary (W. H. and L. Collingridge); "The Mammals of Somaliland: a Book for Naturalists and Sportsmen," R. E. Drake-Brockman, illustrated (Hurst and Blackett, Ltd.); "The Mutation Theory," Dr. H. de Vries, 2 vols., illustrated (Kegan Paul and Co., Ltd.).

In *Geography and Travel*.—"The Basutos: the Mountaineers and their Country," Sir Godfrey Lagden, 2 vols., illustrated (Hutchinson and Co.); "Mediæval Researches from Eastern Asiatic Sources: Fragments towards the Knowledge of the Geography and History of Central and Western Asia, from the Thirteenth to the Seventeenth Century," E. Bretschneider, 2 vols. (Kegan Paul and Co., Ltd.). In *Mathematics and Physical Science*.—New volumes of the International Scientific Series:—"Music: its Laws and Evolution," J. Combarieu; and new editions of "Light and Photography," Dr. H. Vogel and A. E. Garrett; and "Colour-blindness and Colour-perception," C. W. Edridge-Green, illustrated; also "An Easy and Concise Guide to the Starry Heavens," D. M'Ewan, illustrated (Kegan Paul and Co., Ltd.).

OUR ASTRONOMICAL COLUMN.

EPHEMERIS FOR HALLEY'S COMET, 1909*c*.—A corrected ephemeris for Halley's comet is published by Mr. Crommelin in No. 4359 of the *Astronomische Nachrichten* (p. 249, September 28). This ephemeris, like that published in No. 4330 of the same journal, is based on the elements published, for the Astronomische Gesellschaft prize, under the pseudonym "Isti mirantur stellum," Messrs. Cowell and Crommelin, it transpires, being the calculators. The new observations do not yet cover a sufficiently long arc to permit of an independent determination of the orbit, but they do show that the previously published elements are correct except that the date of perihelion passage must be advanced 3·4 days, thereby making it 1910 April 20·0 (G.M.T.); this modification has been taken into account in preparing the present ephemeris, which covers the period August 28 to December 26 in five-day steps. An extract follows:—

Ephemeris.

Berlin M.T	R.A. (1910·0) h. m.	(decl. 1910·0) ° ′	log *r*	log Δ	Magnitude
Oct. 17·4	6 9·7	+16 57	0·4785	0·3982	14 7
,, 22·4	6 5·1	+16 56			
,, 27·4	5 59·1	+16 54	0·4608	0·3447	14·2
Nov. 1·4	5 51·7	+16 52			

From this we see that the comet is at present in the northern limits of Orion, and is some 280 and 230 million miles from the sun and earth respectively; also that it is approaching the sun and the earth at the respective rates of about 1·12 and 2·7 million miles per day. The accompanying chart shows its positions in relation to the constellations so far as Mr. Crommelin's ephemeris gives them.

CHANGES ON MARS.—In No. 4359 of the *Astronomische Nachrichten*, M. R. Jonckheere, of the Observatoire d'Hem (Roubaix), gives a drawing of the south polar cap of Mars, executed on September 2, showing the new "land" which he discovered in longitude 120°. He points out that the crevasse and greyish region observed by M. Jarry Desloges are produced by the emersion of the two "lands," Argyre II. (longitude 60°) and the new one, from the polar snows. For the newly discovered area in longitude 120° he proposes the name "Stella," suggested by its brilliant appearance.

In the same journal M. Antoniadi records his observations, on September 19, of the Mer du Sablier, which to him appeared as Dawes recorded it in 1864. As Prof. Lowell's observations and photographs show it of a very different form during the period 1894–1907, M. Antoniadi suggests that periodic changes of form, probably irregular, may take place in this feature.

A number of interesting observations of the planet are recorded in No. 22 of the *Gazette Astronomique*, by M. P. L. Dupont, of Hoboken, Antwerp.

REMARKABLE METEORS.—No. 22 of the *Gazette Astronomique* contains the records of three remarkable meteors seen in Denmark during August. The first was at 9h. 25m. (C.E.T.) on August 19, and it was bright enough to illuminate the surrounding landscape. Apparently its actual path was from 128 km. above the town of Sorö, in Zealand, to 30 km. above a point on the coast about 22 km. west of Sorö; thus the path was nearly vertical, and the velocity was about 33 km. per second. The other two meteors were seen on the same night at 9h. 17m. and 9h. 38m. respectively. The former was attended by a noise similar to that made by escaping steam, whilst the second one was extraordinarily slow, and was seen for fifteen seconds, during which it passed, nearly horizontally, from 190°, +23° to 152°, +32°.

THE URSA-MAJOR SYSTEM OF STARS.—Following up Dr. Ludendorff's conclusion that the stars β, γ, δ, ϵ, and ζ Ursæ Majoris belong to a definite system of stars moving along parallel lines in space, Mr. Ejnar Hertzsprung has investigated the conditions for other stars having similar proper motions, and finds that a number of other stars probably belong to the same system. Among these may be noted β Aurigæ, Sirius, α Coronæ, 78 Ursæ Majoris, and Groombridge 1930, while κ Boötis is suspected. A number of the stars, nine out of fifteen given, are double, and a tabulation of the magnitudes and spectral classes suggests a development of spectrum, from one star to another, with an attendant decrease of brightness (*Astrophysical Journal*, vol. xxx., No. 2, p. 135).

SEARCH-EPHEMERIS FOR WINNECKE'S COMET.—A continuation of the search-ephemeris for Winnecke's comet is published by Herr C. Hillebrand in No. 4360 of the *Astronomische Nachrichten*. As the present southerly declination (−20°) is increasing, it is not likely that the comet will be generally observed in the northern hemisphere.

THE NATURE OF SOLAR FACULÆ.—An important result concerning the nature of bright faculæ seen on the sun's disc is published by M. Deslandres in No. 11 of the *Comptes rendus* (p. 493, September 13). The main conclusion is that the vapours in the bright faculic areas are, relatively to the surrounding dark areas, descending. This result has been deduced from the measures of the motion-displacements shown on negatives taken with the Meudon spectro-register of radial velocities, the pure K_3 line being employed.

Exhaustive measures of the absolute velocities have not been made, because to measure completely the whole disc on one negative would entail some 36,000 settings, and the Meudon staff is not sufficiently large for such an enterprise. But the measures of a number of displacements on bright areas near the centre of the disc, where the line-of-sight motions are independent of the solar rotation, indicate that the result is general. A diagram which accompanies the paper shows this result for a faculic area photographed on June 4.

M. Deslandres discusses this result in comparison with atmospheric movements on the earth, and suggests that it is in accordance with theory. When a mass of vapour descends it becomes compressed, and therefore brighter; when ascending, its pressure is decreased, and consequently the vapour becomes cooled and less bright.

The investigation of the nature of spots, on the same lines, has not yet been undertaken, M. Deslandres looking upon spots as a secondary phenomenon following the production of faculæ.

PERCY SLADEN MEMORIAL EXPEDITION IN SOUTH-WEST AFRICA, 1908–9.

I.

The Percy Sladen Memorial Expedition was the outcome of a recent study of Welwitschia, that most remarkable of West African plants. Its primary object was the investigation of the biology and morphology of *Gnetum africanum*, the only immediate relative of Welwitschia known to occur south of the Congo. It was further proposed to examine, so far as circumstances would allow, the flora of the desert-belt and of the regions adjacent to it. The expedition was under the auspices of the trustees of the Percy Sladen Memorial Fund, and was assisted by a grant of 200*l.* from the Royal Society. During the first section of the journey (Cape Town to Lüderitzbucht) I was fortunately able to travel in company with the magnetic survey expedition of the Carnegie Institute under my colleague, Dr. J. C. Beattie. A saving of half the ordinary cost of transport was thus effected. The route followed was very largely determined by the distribution of the usually widely separated water-holes. What would certainly have proved a very interesting part of the journey (viz. from Keetmanshoep to Windhuk) had to be abandoned owing to the necessity of arriving in central Angola before the end of the season in which suitable stages of the ovules of Gnetum were likely to be obtainable.

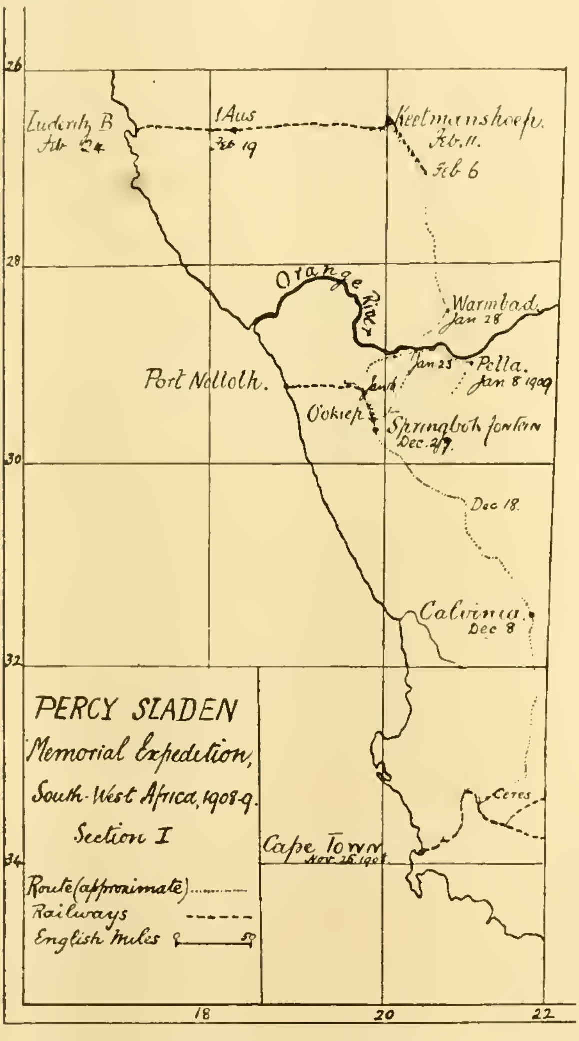
Fig. 1.—A view across the Orange River near Raman's Drift, looking North. The river itself is concealed by the lowest zone of vegetation.

Leaving Ceres Road Station on November 26 with a waggon drawn by twenty oxen, we ascended to the Ceres Plateau (1100 feet) through Mitchell's Pass in the Langeberge Range, and travelled for four days over an undulating tableland rising to 2500 feet, the flora of which is closely related to that of the mountainous districts of south-western Cape Colony. Unfortunately, most of this country was suffering from drought, and the botanical results were poor. At Karoo Poort we suddenly emerged upon the western tongue of the Karoo (November 30), which was crossed in six days. Here also the ground was parched; in some districts, it was stated, no rain had fallen for four years, and many of the farmers had migrated with their families and flocks into Bushmanland and other more favoured localities leaving their homesteads unoccupied. Over large areas all the non-succulent vegetation had disappeared and the flora consisted almost entirely of *Augea capensis* with a few species of Mesembrianthemum. Ascending the Blauwkrantz Pass in a spur of the Roggeveld Range on December 6, we came upon a plateau the flora of which is closely related to that of the Nieuveldt Mountains in the neighbourhood of Beaufort West. On December 10 a somewhat sudden descent to 1600 feet brought us again into a karoid region, in which species characteristic of the dry, low-lying plateaux of Great Namaqualand were encountered for the first time. Prominent among these were *Tamarix articulata*, *Aloe dichotoma*, *Statice scabra*, *Galenia articulata*, *Didelta annua*, *Exomis albicans*, and *Vogelia africana*. This southern extension of the flora of tropical and subtropical Namaqualand seems to be confined to sheltered valleys at elevations not exceeding 2000 feet.

From O'okiep a detour to the north-east across the sandy plains of Bushmanland was rewarded by an unexpectedly rich collection, for unusually heavy rains had recently fallen. The plains were gay with the flowers of *Hoodia Gordoni*, *Rhigozum sp.*, and a tall bushy Hermannia. A shrubby Aristida and some smaller species of the same genus were also very abundantly represented, while trees of *Aloe dichotoma* and large symmetrical bushes of species of Euphorbia were conspicuous on the "kopjes." The natural vegetation along the banks of the Orange River forms a narrow belt, in which a distinct arrangement in subordinate zones can usually be traced. The lowest zone (Fig. 1) consists of a dense scrub of *Salix capensis*, *Acacia horrida*, *Zizyphus mucronata*, and a few other bushes, with some grasses, reeds, and sedges. Above the primary bank of the river the mountains rise steep, rugged and barren, or, between them and the stream, are stony flats (Fig. 1) all but devoid of vegetation. Having returned to O'okiep to refit, we arrived at Raman's Drift for the second time on January 22, and crossed to the German side on January 24. The river at this time was in flood, and its muddy waters were some 600 yards wide at the drift. A few hours of heavy travelling brought us upon a plateau (2300–4000 feet)

Fig. 2.—Great Namaqualand south of Warmbad, *Aloe dichotoma*, *Euphorbia sp.* The native is a Bondelzwaart.

where the vegetation proved to be richer than any hitherto met with. It was said that the rains which had fallen a few months earlier were more copious than any experienced during the previous fifteen or twenty years. It was no doubt a consequence of this that the annual constituents of the flora were unexpectedly abundant. Warmbad is noted for a number of warm springs (35° C.) the waters of which—like so many of the natural waters of the south-west coast—are impregnated with sulphuretted hydrogen. The railway between Keetmanshoep (3300 feet) and the sea ascends to nearly 5000 feet at !Aus, where the vegetation presents many karoid features. From !Aus the descent—at first gradual, later more rapid—is uninterrupted. About 30 km. west of !Aus (110 km. from the coast) the desert commences very abruptly at 2700



feet. In this latitude there appear to be few forms peculiar to the desert itself and its flora consists very largely of the more resistant of the species found at higher levels and under less arid conditions. Nevertheless, the eastern boundary of the desert is remarkably sharp, and approximately coincides with the western limit of precipitation from clouds condensed upon the neighbouring highlands. Within 50 km. of the sea the sharp, bare mountain peaks and ridges are frequently more or less buried in sand-dunes, the materials of which are blown up from the lower-lying flats, leaving behind the worn gravels from which diamonds are now being obtained over an extensive area. Nearer the coast the scenery is remarkably gaunt and rugged and the wind-swept surface is frequently quite bare of vegetation.

Leaving Lüderitzbucht by sea on February 26, I arrived in Swakopmund eighteen hours later, and on March 2 reached Welwitsch (lat. 22°), a Welwitschia locality previously visited in 1907 in company with Mr. E. E. Galpin.[1] The object of this visit was to obtain later stages of the Welwitschia embryo than were present in material collected in 1907. The flora in general was this year very much poorer than two years earlier. Not only were many of the smaller plants then collected not found at all, but woody species formerly obtained in flower or fruit now showed no signs of reproductive activity; this also applies to some extent to Welwitschia itself, for only a small proportion of the plants had coned. The explanation of this very striking difference seems to be contained in the meteorological records. Between[2] November 1, 1906, and January 31, 1907, 12·8 mm. of rain were measured at Welwitsch; in the corresponding period of 1908–9 the rainfall was 5·9 mm. In December, 1906, the fall was 12·5 mm., an amount very much in excess of that recorded for the whole of each of the years 1907 and 1908. We have here, then, another example of the remarkable influence of a small additional rainfall upon both the annual and perennial constituents of a desert flora.

A large number of the Welwitschia plants present in 1907 in this easily accessible locality have been removed in the interval, and, at the same rate, a few years would probably have seen the complete disappearance of all plants from the vicinity of the railway, for there is here no sign of seed-reproduction. It is therefore very satisfactory to note that His Excellency the Acting Governor has issued instructions for the protection of the plants that remain.

H. H. W. Pearson.

RESEARCHES ON THE ACTION CENTRES OF THE ATMOSPHERE.[3]

In the domain of world meteorology, that is, the comparison and discussion of meteorological data of widely distributed stations over the earth's surface, Prof. H. Hildebrand Hildebrandsson has, during the last decade or so, been making some very important communications. He has clearly emphasised the fact that the laws which rule the general movements of our atmosphere will never be found if observations are only made in civilised countries on the earth's surface. Our atmosphere is a mass of air resting both on the continents and the oceans, and modern researches have shown that a large perturbation at one time in one area may be intimately associated with a perturbation of an opposite nature in the antipodal part of the world. Although several workers many years ago intimated the positions of isolated areas which behaved in a reverse or see-saw manner meteorologically, it was Prof. Hildebrandsson who first directed attention to a great number of such areas. In more recent times these isolated instances of barometric see-saws have been found to be part of really one general law applying to the movements of our atmosphere. This general law has yet to be more minutely investigated, for it is, as Prof. Hildebrandsson states, "une verité avec des grandes modifications." There is little doubt, nevertheless, that world meteorology has made a considerable advance since the discovery of these simultaneous reverse-pressure changes, and one is now in a much better position to state where on the earth's surface observations should be made.

Every attempt should therefore be made to utilise islands in the large oceans, even if the sole occupants of the islands are the meteorological observers themselves, for until the air movements over the oceans are carefully observed and recorded we shall still be left to a great extent in the dark.

Prof. Hildebrandsson's most recent memoir deals chiefly with the northern latitudes of the northern hemisphere, and is devoted to a discussion of data with respect to the simultaneous compensation between types of seasons in different regions. The meteorological data here dealt with relate mainly to certain regions between the east coast of

[1] Nature, vol. lxxv., p. 536.

[2] Meteorological observations at this station were commenced in November, 1906.

[3] Kungl. Svenska Vetenskapsakademiens Handlingar, Band 45, No. 2. III. "Sur la Compensation entre les Types des Saisons simultanés en différentes Régions de la Terre." By H. Hildebrand Hildebrandsson.

North America and Siberia, but some more southern stations are included.

Without going into any great detail, the investigation may be summarised as follows. Prof. Hildebrandsson regards the state of the ice of the polar sea as being the principal cause of the different types of the seasons of different years. Thus a high summer temperature in the arctic sea to the north of Europe will set free a large amount of ice, and consequently the polar current arriving on the north coast of Iceland in February and March, and a branch of which, after skirting the east coast, is directed towards the North Sea, will bring much ice and will be surrounded by a layer of cold water. This current will cool the air in its neighbourhood. The result of the movement southward of these specially cold currents is that the land areas around the Arctic Circle and North Atlantic Ocean suffer *successively* from them by the lowering of their air temperatures. Prof. Hildebrandsson accompanies his statements with tables and an excellent series of curves, which are very convincing. He specially refers to the investigation of M. Peterson, who showed that a variation of 2° or 3° in the surface temperature of the sea is sufficient to create changes of considerable magnitude in the air temperature over very large areas.

The main result of this research is to indicate that in certain cases a means is afforded of making forecasts for seasons. Thus, to take an example, he shows that, with two or three exceptions, in twenty-five years the temperature of the summer at the North Cape was in the following spring in opposition to that of Europe, represented by Debreezin.

THE NATURE AND EXTENT OF AIR POLLUTION BY SMOKE.[1]

IN a former paper read at the Congress of the Sanitary Institute held at Leeds in 1897 an account was given of the quantity of soot suspended in and deposited from the atmosphere of Leeds. It was then shown that, on the average working day, 20 tons of soot are sent into the air of Leeds, of which half a ton falls on an area of four square miles, and of the latter from 20 lb. to 25 lb. stick, that is, are not removable by rain. The present paper contains a record of the atmospheric impurities carried down by rain and the effect of this rain water on vegetation. It also contains an inquiry into the diminution of daylight caused by suspended particles of soot.

Ten representative stations were selected in Leeds and one at Garforth, about $7\frac{1}{2}$ miles due east of Leeds. The impurities, in the form of suspended matter, consist of soot, tar, sand, mineral substances, and, in solution, of sulphurous and sulphuric acids or their salts, chlorides, largely in the form of hydrochloric acid or common salt, and nitrogenous matter, in the form of nitrates or free and albuminoid ammonia. The results are embodied in the following table:—

ANALYSES OF RAIN WATER, LEEDS AND GARFORTH.

Total for Year, expressed in Pounds per Acre.

	Collecting station	Suspended matter	Tarry matter	Mineral matter	Free acidity as H_2SO_4	SO_3	SO_2	Chlorine	Nitrogen as NH_3	Nitrogen as N_2O_5	Nitrogen as albuminoid ammonia	Total nitrogen

[1] Abstract of a paper by Prof. J. B. Cohen and Mr. A. G. Ruston read at the Health Congress held at Leeds on July 17.

The solid impurities were found to diminish rapidly in passing northwards from the centre of the town. Within the distance of a mile the quantity fell to less than half, and at $2\frac{1}{2}$ miles to less than one-fifth.

The influence of the industrial centres upon the solid impurities stands out most conspicuously, as a glance at the table will show, *i.e.* in the chief industrial centres the solid impurities are roughly twenty times as great as in the purer atmosphere of Roundhay, about three miles north-east of the centre of the town (Fig. 1).

The quantity is also determined by the prevailing winds, which are west, south-west, and north-east, and the drift of the impurities is consequently more towards the east than the west. Of the three constituents of the total suspended matter, the one which is least injurious is the mineral matter. This is abnormally high at the Leeds Forge, and consists principally of oxides of iron, lime, alumina, and silica, either escaping with the fumes from the furnace or thrown out mechanically.

In a former series of experiments the amount of soot deposited was determined by collecting daily from a fresh surface a square yard of snow (which lay for several days), melting, filtering, and weighing the soot. The total deposit on the first day represented 16 cwt. to the square mile, and the daily increase was, on the average, 4 cwt. Taking a four-square-mile area covered by the town, and

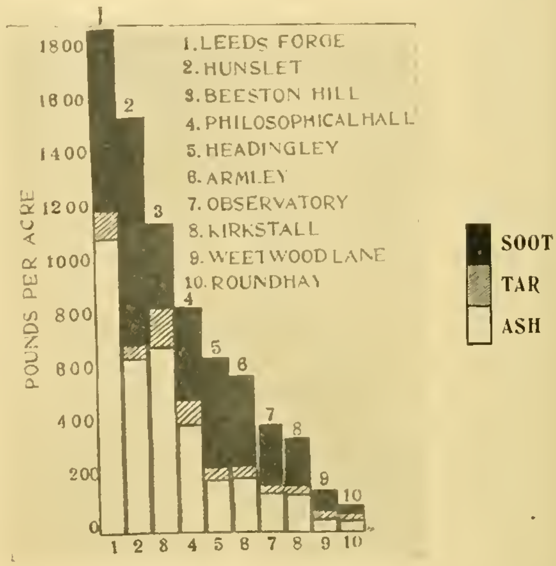

FIG. 1.—Suspended Matter.

allowing for a diminishing fall on the fringe of the area, the amount carried down by the first fall of snow may be represented roughly by 10 cwt. to the square mile, and the daily increase as one quarter of this amount. Later results, as determined from the soot deposited with the rain water, are in close agreement with these figures. The analyses of the total deposit for the whole year show that at Hunslet (industrial centre) the soot amounts to 300 tons per square mile, at the Leeds Forge (industrial centre) to 250 tons, whereas at Woodhouse Moor (one mile north-west of the centre) it dropped to 80 tons. Taking the average of the stations which lie within the central four-square-mile area, we get 190 tons per square mile per year, or roughly half a ton per square mile per day.

The amount of tar deposited with the soot was previously demonstrated by exposing glass plates 1 foot square at different points situated in and at distances from the town. These plates at intervals were washed under running water, and the residual deposit analysed. The amount of soot thus remaining, as determined from its carbon content, was found to be twenty-four times greater in the town than at a distance of nine miles. In the present experiments the tarry matter was estimated by extraction with ether. The quantity dropped from 80 lb. per acre per annum in the centre to 14 lb. per acre at a distance of three miles north-east of the town. The waste of fuel in the form of unburnt coal passing into the atmosphere is represented each year by about 300 tons per square mile in the centre of the town, or, over the whole area of four miles square, about 100 tons per square mile. The effect of these suspended impurities in diminishing the amount of sunlight in Leeds may be gathered from the fact that in 1907 the number of hours of bright sunshine was 1167 in the town, whilst four miles north-west it reached 1402 hours. The amount of daylight has also been recorded at two different periods by the quantity of iodine liberated from an acid solution of potassium iodide. On the first occasion, over a period of four winter months, it was shown that the smoke in an industrial centre absorbed one-quarter of the daylight as compared with a station one mile to the north-west. In the present investigation, carried out during the month of June of this year, the amount of daylight often fell to one-half in the centre of the town as compared with Garforth several miles away. The relation of soot deposit (black column) to daylight (light column) is shown in the diagram (Fig. 2).

It is the tarry matter in the soot which causes the latter to adhere to and blacken buildings and vegetation. It is sometimes stated that it is the domestic smoke rather than industrial smoke which is injurious to plant life, on

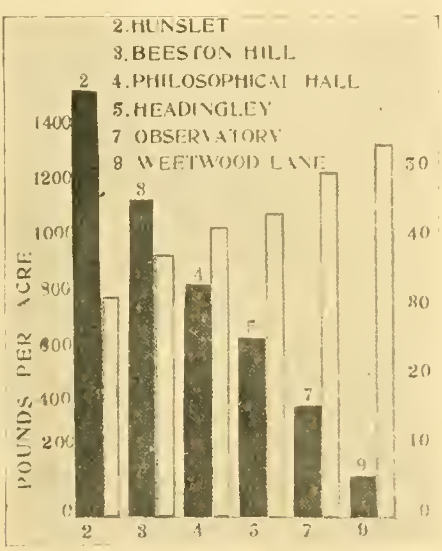

FIG. 2.—Influence of Suspended Matter on Intensity of Light.

account of its higher content of tar. There is a certain justification for this statement, for the percentage of tarry matter in the total solid impurities is highest in the residential and lowest in the industrial areas, varying from 18 per cent. in the former to 4 per cent. in the latter. When, however, account is taken of the total tarry matter deposited each year, the industrial centres are responsible for the greater quantity, which reaches in some cases ten times the amount in the residential districts. The total sulphur, either as sulphurous or sulphuric acid, is everywhere high, but particularly in and near the chief manufacturing areas. A large portion of the free acids is neutralised either by the alkaline fumes of the blast furnaces or by the ammonia of the burnt coal. Still, free acid is present in considerable quantity, and in Hunslet (industrial centre) represents an annual deposit of 90 lb. per acre, or 25–30 tons per square mile.

It is the sulphurous acid which imparts to town fog its choky and irritating effects. The large amount of this acid present in fogs may be gauged from the fact that the hoar-frost collected during the dense fog of January 27 contained acid corresponding to 10·29 parts per 100,000, or more than ten times the average acidity of the same station.

To demonstrate the detrimental effect of sulphuric acid upon vegetation, Timothy grass was sown on May 12, 1908, in boxes 1 foot square, the soil being uniform. The seed was watered at a rate corresponding to the average rainfall of 25 inches with water containing different amounts of sulphuric acid. In addition to this, three other samples were watered with Garforth rain water in which the acidity was neutralised, the second with ordinary Garforth rain water, and the third with Leeds rain water. The results were very instructive. In the case of Leeds rain water and of those waters containing a higher degree of acidity, germination was distinctly checked, and the delicate green of the young grass quickly changed to yellow or brown. Grasses watered with water containing 32 parts per 100,000 were killed in a little more than three months, and with 16 parts per 100,000 in less than a year.

Chlorides are found in large quantities, especially in the industrial centres, where, expressed as common salt, they sometimes reach as much as 3 or 4 cwt. per acre, a quantity which must be distinctly prejudicial to vegetation.

The nitrogenous impurities, on the other hand, would be beneficial by acting either as direct stimulants and fertilisers or by neutralising the acidity of the sulphur and chlorine compounds.

MATHEMATICS AND PHYSICS AT THE BRITISH ASSOCIATION.

THE proceedings of Section A began on Thursday, August 26, with the address of its president, Prof. E. Rutherford, F.R.S., which has already been printed in full in these columns (NATURE, August 26, p. 257).

A paper followed, by Prof. J. H. Poynting and Mr. Guy Barlow, on the pressure of radiation against the source. The authors employ thin slips of material which become heated by incident radiation. Those black on both sides experience a pressure equal to the energy-density, P, of the incident radiation; those black on the incident side and brightly silvered on the other experience a pressure 1·67 times as great, the excess being due to the radiation which is emitted by one side only of the plate. Plates which are bright both sides experience a pressure 2P, because they do not become heated. Experiments, which are in progress, give good accord with theory. In a short discussion which followed, Prof. Hull intimated that he was alive to the possibility of this reaction when making his experiments on the pressure of incident radiation, but his experiments had been devised carefully so as to prevent its occurrence.

Prof. T. Lyman then gave a summary of the ascertained properties of light of very short wave-lengths ("Schumann rays"), including their ionising and photoelectric effects. To these Prof. Bumstead added that one of his students had shown that the velocity of the electrons emitted photoelectrically increases directly as the frequency of the light up to a wave-length $\lambda = 1250$—a result which Ladenburg had previously shown to hold good for ordinary light.

Prof. Percival Lowell followed with an account of the photographs of Jupiter taken at the Lowell Observatory. The slides exhibited showed a wonderful amount of detail, the most noteworthy features being faint wisps that criss-cross the several belts, particularly the bright equatorial one. He explained the belts and wisps as gaps in the clouds formed by condensing of uprising vapours from Jupiter's heated interior (he being still a semi-sun), and strung out by his rotation. Prof. Larmor added greatly to the interest of the paper by exhibiting some early drawings of Jupiter made by Sir W. Huggins, and stated that Sir William's opinion from the first was that the wisps were the edges of cumulus clouds. He noted that the high albedo of Jupiter (72) indicates that the Jovian atmosphere acts like a bright cloud; it follows that very little of the meteorology of Jupiter can be due to the sun if heat is only absorbed like light. Other planets with a low albedo would have surface markings more like terrestrial ones. The day's proceedings concluded with a paper, by Prof. E. E. Barnard (read by Prof. E. W. Brown), on the motion of some of the small stars in Messier 92 (Herculis). Two of the stars in this cluster are shown to have proper motion; the first (No. 11 of Schultz's list) is moving away from the centre of the cluster; the second one is moving towards the centre. Several others in the cluster appear to have a slight motion.

On Friday, August 27, owing to the large number of papers presented to the section, it was divided into three departments, which met concurrently. In the mathematical department, Prof. E. H. Moore dealt with fundamental analogies existing in diverse branches of mathematics, and proposed a method for unifying these branches in a more general theory embracing all such analogous branches. Further information with regard to Prof. Moore's theory will be found in a paper by him on a form of general analysis with applications to linear differential and integral equations (*Atti del IV. Congresso Internationale dei Mathematici*, vol. ii., pp. 98–114), and in a memoir entitled "Introduction to a Form of General Analysis," which will shortly be published by the Yale University Press. Prof. E. H. Hobson, in a paper on the present state of the theory of aggregates, considered a number of points in connection with the theory, and indicated the desirability of a new and more adequate definition of an aggregate of a more restricted character than the one due to G. Cantor, and of such a character that no difficulties would arise from the ascription of a cardinal number to each such aggregate, and also of an ordinal type in case the aggregate is an ordered one. Prof. G. A. Miller, in a paper on generalisations of the icosahedral group, considered the group the two generating operators of which satisfy one of the following three sets of conditions:—

$$t_1{}^2=t_2{}^5, \quad (t_1t_2)^3=(t_2t_1)^3;$$
$$t_1{}^2=t_2{}^3, \quad (t_1t_2)^5=(t_2t_1)^5;$$
$$t_1{}^3=t_2{}^3, \quad (t_1t_2)^2=(t_2t_1)^2.$$

Amongst other theorems, Prof. Miller proves the following:—There is an infinite number of groups each of which may be generated by two operators satisfying one of these conditions. Each of the possible groups generated by t_1t_2 contains either the icosahedral group or the group of order 120, which is insoluble and does not contain a subgroup of order 6n, and it must have one of these groups for its commutator subgroup. Prof. G. A. Bliss followed with a new proof of a theorem of Weierstrass concerning the factorisation of power series which states that any convergent series in $p+1$ variables, $F(x_1, x_2, x_3, \ldots x, y_n)$ in which the lowest term in y alone is of degree n, can be expressed as a product

$$(y^n+a_1y^{n-1}+\ldots+a_{n-1}y+a_n)\,\Phi\,(x_1\ldots x_p, y),$$

where $a_1, a_2 \ldots a_n$ are convergent series in $x_1, x_2 \ldots x_p$, which vanish with these arguments, while Φ is a convergent series in all $p+1$ variables with a constant term different from zero. The author also gave formulæ by which the coefficients in the different series may be computed. Mr. J. H. Grace read a paper in which a treatment was given of ideals in a quadratic field, and Prof. W. H. Metzler one on a continuant of order $n+1$ which is expressible as the product of $n+1$ factors. Prof. Ellery W. Davis gave a complete representation of the elements of the central conic the axes of which are non-similar complex quantities. In a paper on the invention of the slide rule, Prof. F. Cajori sifted the evidence in connection with this subject bearing on the rival claims of Gunter, Oughtred, and Wingate. His conclusion is that the slide rule was undoubtedly invented by William Oughtred in 1832. Papers by Major P. A. MacMahon on a correspondence in the theory of the partition of numbers, and by Mr. J. W. Nicholson on the asymptotic expansion of Legendre's functions, were read in title only in the absence of the authors. The like fate overtook the report of the committee on the further tabulation of Bessel functions. This committee has made further progress during the year. Using the notation of previous reports, values of $Q_n(x)$ have been calculated for integral values of n from $n=1$ to $n=6$. From these the values of $\sin^{-1}(Q/R)$ have been computed for the same values of n, and the values for $n=\frac{1}{2}, 1\frac{1}{2}, \ldots 6\frac{1}{2}$ have been added. From the tables of the present report and those of the 1907 report, the values of $J_n(x)$ for values of n from 0 to $6\frac{1}{2}$ at intervals of $\frac{1}{2}$, and for values of x greater than 10, can be computed to six places without sensible error. The Neumann function $Y_n(x)$ can be calculated from the same data.

Meanwhile, the department of general physics was holding a joint meeting with Section B (Chemistry). The papers of more particularly chemical interest will be referred to in the report of the proceedings of that section. Prof. E. Goldstein led off the physical papers with one on the three-fold emission spectra of solid organic compounds, which the council has ordered to be printed *in extenso*. Prof. Goldstein finds that aromatic substances solidified by liquid air can emit three discontinuous spectra, which are quite different from one another, when they are exposed to kathode rays. First, the *initial* spectra are observed at the beginning of the luminescence; when these become fainter the *chief* spectra, which are very characteristic for each substance, appear; the *solution* spectra are observed when the aromatic substance is dissolved in another medium and the frozen mixture is exposed to kathode rays. All three spectra commence in the red; the initial spectra extend to the ultra-violet; the chief spectra are shorter. Very characteristic solution spectra are given by naphthalene and its derivatives. The solution spectrum varies with the solvent medium. Very small quantities of aromatic bodies are sufficient to give marked solution spectra; on the other hand, the phenomenon gives a very sensitive method of detecting slight impurities. In this way it may be stated that until now no aromatic substance has been prepared in a really pure state. In the consequent discussion Sir J. J. Thomson pointed out that the results would have been clearer if kathodic rays of only one velocity had been employed. Changes come in very abruptly as the energy of the rays passes a certain value. Experiments are in progress in the Cavendish Laboratory upon lithium chloride. With ordinary kathode rays ($v=10^9$ to 6×10^9) the chloride exhibits a steely-blue appearance, and gives a continuous spectrum; but with positive ions the spectrum shows the lithium red line and very little continuous background. As to the origin of these phosphorescent spectra, he emphasised the fact that phosphorescence is not so much a question of ionisation as of the breaking up of complex aggregates, *e.g.* iodine vapour phosphoresces without showing any sign of ionisation. You can freeze out the phosphorescence, thereby making these complexes stable. Prof. H. E. Armstrong raised the point as to whether something of the same sort as Goldstein had brought forward goes on in a Welsbach mantle. Experiment shows that you can obtain phosphorescent spectra by inserting traces of rare earths. The next paper was by Mr. E. F. Burton, on the influence of electrolytes on colloidal ferric oxide solutions. A commercial ferric oxide solution was dialysed in conductivity water, and the velocity with which the particles moved in a unit electric field was observed from time to time. As the purification continued the velocity at first increased, but afterwards decreased in almost linear relation with the amount of chlorine found. A comparison of the coagulating powers of monovalent, divalent, and trivalent ions on the colloidal particles indicates that the Linder-Picton-Hardy law holds good. This paper was followed by one by Dr. Otto Hahn, on methods of separation of radioactive products. These methods are based on the working hypothesis that single radio-active products emit only one type of radiation, either homogeneous α particles or homogeneous β particles. This hypothesis requires that thorium C and actinium B be complex. Also, radium C must be complex, and consist of three products, one emitting α particles and two emitting different β particles. Experiments using a "recoil" method seem to support these conclusions. The author also has found that radium itself emits β as well as α particles; it also must be complex; and experiment seems to show that the β particles come from radium itself, the well-known α particles being due to a new body, radium X. Prof. Rutherford, in commenting upon the paper, pressed the bearing of the results upon the supposed purity of ordinary "chemically pure" bodies. Sir J. Larmor asked for an explanation of the well-known difficulty in connection with the emanation being positively charged after emitting a positively charged body, and in reply Dr. Hahn expressed his belief that δ particles are simultaneously expelled. In answer to a question of Prof. Bumstead's, Dr. Hahn replied that he had not made any magnetic experiments to test the homogeneity of his various rays. Prof. J. C. McLennan then read a paper on the secondary rays excited in different metals by α rays. He finds that the secondary rays emitted by a selected metal when bombarded by the α particles from polonium deposited on copper are proportional to the α radiation, but that different metals are not equally active, the secondary radiation varying from 62 for platinum to 47 for aluminium. δ radiation excited by polonium appears to be independent of the metal which carries the polonium, and is probably produced by and accompanies the α particle in the course of its expulsion from the polonium atom. Prof. McLennan continued with a paper by Mr. V. E. Pound, on some phenomena associated with the radiations from polonium. By measuring the electrical charge acquired by an insulated metal plate B placed close to and facing an insulated copper plate A bearing a deposit of polonium, it was made clear with the aid of moderate electric and magnetic fields that there are present (1) α rays emitted by the plate A; (2) an easily absorbed secondary negative radiation emitted by B; and (3) an easily absorbed δ radiation emitted by A. An additional negative stream seemed to arise from the polonium in stronger fields; from its behaviour it is considered to consist of streams of rest-atoms from the active product RaG or polonium. Dr. O. Reichenheim followed with an important paper, ordered to be printed *in extenso*, on anode rays and their spectra. He explained that the conditions for the production of anode rays, or striction-anode rays, are:—(1) the presence of positive ions, produced by heated salts of the alkalis or alkaline earths serving as anode; (2) a high fall of potential at the anode, which is produced by the presence of halogen vapours in the tube, and is the origin of the high velocity acquired by the ions, so that they appear as rays in the tube. A new kind of positive rays passes through a perforated anode under a high gradient of potential. These are called A_1 rays, because they are analogous to the K_1 rays or retrograde rays which leave the kathode. The spectra of anode rays are very simple, often simpler than the arc or spark spectra. The rays show the Doppler effect; in the case of the earth-alkaline rays shifted lines only were found, without any line in the unshifted position. This seems to arise from the fact that we have here to deal with moving particles which emit other lines than the surrounding luminescent gas. A paper by Dr. H. L. Bronson and Mr. A. N. Shaw, on Clark and Weston standard cells, was taken as read owing to lack of time. It dealt with the accuracy and reproducibility of these cells. The mean of five set up in the National Physical Laboratory differs from the mean of the cells set up in Montreal by 5 microvolts. The maximum deviation of their own cells from their mean was only 31 microvolts. The ingredient of main importance is the mercurous sulphate. The ratio of their Weston cells to their Clark cells is 0·716953 as against the value 0·716958 determined by Wolff and Waters. Prof. Rutherford concluded with a paper on the action of α rays upon glass, in which he detailed results analogous to the naturally occurring action due to specks of beryl in rock which had been microscopically detected by Prof. Joly.

In the department of cosmical physics, which met simultaneously, Dr. L. A. Bauer gave a *résumé* of some of the chief results of interest obtained in the magnetic work of the past ten years carried out under his direction by the U.S. Coast and Geodetic Survey and the Carnegie Institute of Washington.

From the detailed magnetic survey of the United States he found that it would not be possible to represent the observed quantities satisfactorily by a general series of spherical harmonics without using a prohibitive number of terms. He found, moreover, by calculating the line integral of the magnetic force around closed circuits, one of which enclosed the whole of the United States, that a part of the magnetic force, 1/300 to 1/500, must be due to non-potential systems, *e.g.* vertical electric currents. Further calculations to test the existence of such currents are being made with the data obtained by the Carnegie Institute in the Pacific, 1905–8, and with the recent resumption of the ocean magnetic work by the *Carnegie* it will soon be possible to make some circuits completely round the earth.

Various types of magnetic disturbances recorded at the five coast and geodetic survey observatories were briefly discussed. An investigation of the relation between solar activity and terrestrial magnetism, carried on in cooperation with Prof. G. E. Hale, showed that the absolute magnetic effect, connected apparently with an *increase* in solar activity, is equivalent in general to a *diminution* in the earth's mean intensity of magnetisation. Between February 1, 1907, and February 1, 1908, this amounted to about 1/1000th part.

The author emphasised the need in such researches of including all the magnetic elements and of differentiating between effects resulting from internal and external magnetic systems.

Mr. R. F. Stupart read a paper on the distribution of pressure over Canada. He pointed out that the world charts of pressure distribution give an inadequate and even inaccurate representation of the pressure conditions in the dominion. He found that relatively high pressure in the north-west at Dawson City is accompanied by relatively mild winters, and low pressure by severe winters, a fact which is directly contrary to the prevailing idea that in winter the higher the pressure the lower the temperature over continental areas. Dr. Shaw read a paper, by Mr. J. I. Craig, on the surface motion of air in certain circular storms. The paths of the air in travelling storms were obtained from theoretical considerations, and compared with the paths found by actual observation.

Mr. J. W. Shipley showed photographs of large hailstones observed in western Canada shortly before the meeting. In the centre of one of the stones he discovered a small fly which had apparently been carried upwards and had formed a nucleus of condensation.

Dr. A. A. Rambaut detailed some of the results of stellar parallax observations carried out at the Radcliffe Observatory, Oxford, with the equatorial instrument acquired about six years ago employing Kapteyn's photographic method. The immediate object of the research was to demonstrate the feasibility of a photographic "Durchmusterung" for parallax extending to stars of the thirteenth and fourteenth magnitude. A paper by Messrs. Plaskett and Harper on two curiously similar spectroscopic binaries concluded the sitting.

On Monday, August 30, the section met in undivided sessions, which began with a discussion on positive electricity, opened by the president of the association, Sir J. J. Thomson. The questions he asked were:—(1) Is there a definite unit of positive electricity? (2) What is its size? The same negative units are obtainable from both oxygen and hydrogen; is the same true for positive electricity? Attention is concentrated on kanalstrahlen and on the motion of positive ions through mixed gases. Sir Joseph Thomson outlined the evidence afforded by the magnetic and electric behaviour of the kanalstrahlen. He concludes that the ratio e/m is the same for the positive rays of all gases and vapours (including uranium chloride) at very low pressures, although at high pressures it does depend upon the nature of the gas, and that therefore there is a positive unit of electricity. This is confirmed by Wellisch's experiments on the velocity of the positive ions through mixed gases; their velocity is the same whether they arise from hydrogen or from methyl-iodide. The value of e/m is of the order of 10^4; no evidence of smaller particles has been obtained. Some observers, on the other hand, find easily deflected positive rays. It must be remembered that the magnetic field may alter the conditions of the starting of rays, and, secondly, that deflection depends, not only upon e/m, but also upon the velocity; the easily deflected rays are probably secondary rays. In the discussion which followed many points were raised dealing with side-issues, but the main question did not receive much fresh elucidation, and in the end the predominant feeling was probably that we are still a long way from obtaining as definite experimental knowledge of positive electricity as we at present possess of negative.

Mr. A. S. Eddington next read a paper on the law of distribution of stellar motions, in which he obtains the constants of Schwarzschild's velocity ellipsoid by making use of the mean proper motions of stars instead of the numbers of stars moving in the various directions as the observed data. The following sufficiently exact result is stated. The radius of the velocity ellipse in the direction

θ is the geometric mean between the mean P.M. of stars moving in the direction θ and the mean P.M. of stars moving in the direction $\theta+180$. A paper by Prof. H. T. Barnes dealt with the variation of the specific heat of mercury at high temperatures. Prof. Barnes, employing the continuous-flow method, has now determined the specific heat up to a temperature of 268° C. with an error (for the higher temperatures) of not more than one or two parts per thousand. The results are specially interesting inasmuch as they show that the specific heat of mercury passes through a minimum at about 140° C., and then increases fairly rapidly up to the boiling point. The minimum for water occurs at about the same relative position between the freezing and boiling points. During the discussion on the paper Prof. Perry emphasised the great need there is for an accurate determination of the specific heat of superheated steam. Dr. T. Proctor Hall exhibited an apparatus for making enlarged tracings of sound waves from a cylindrical graphophone record, and showed some of the results obtained with it. Prof. A. W. Porter exhibited some transparencies of electric discharges upon photographic plates. A paper by T. Kinoshita was read in his absence by Prof. Rutherford, on the photographic action of α rays, and Prof. A. S. Eve contributed one on secondary radiation by γ rays on different metals. Prof. J. C. McLennan then read one by Mr. W. T. Kennedy, on the active deposits from actinium in uniform electric fields. The deposits were obtained on both of two plates 2 mm. apart, under a field of 250 volts at various atmospheric pressures. As the pressure is decreased from atmospheric the amount of active deposit on both electrodes gradually increases, passes through a maximum value, and then rapidly decreases. The maximum on the kathode is about 2·7 times that for the anode, and is formed at a different pressure. The total deposit is independent of the electric field until potentials higher than the sparking ones are applied. The coefficients of diffusion of the emanation from actinium into CO_2, air, and hydrogen are in the proportion 1/1·3/4·2. On Dr. O. Hahn stating that in the case of actinium emanation it is difficult to know what we are dealing with, the reply was elicited that in all probability a number of products are concerned in the experiments described. A paper by Mr. F. W. Bates, on the effect of light on sulphur insulation, was read by Prof. A. S. Eve. The author concludes from some electroscope experiments that sulphur in the presence of light becomes to a slight degree a conductor of electricity to an extent depending upon the intensity of the incident light. In the discussion the resemblance to selenium was pointed out. Dr. Hahn elicited the statement that the effect exhibits no time-lag. Dr. P. Pringsheim mentioned that Röntgen had found a similar effect for paraffin. A paper followed by Dr. T. Franck and Dr. W. Westphal on the charge upon gaseous ions. The authors consider from their experiments that Townsend's doubly charged ions are only a small part of the total ionisation, and that generation in an electric field, contrary to Townsend's view, has nothing to do with their formation. The two kinds can be separated by fractional diffusion if a piece of wire gauze be interposed in their path. The coefficient of diffusion of the double ions is found to be half that of the single ones. With α, β, γ rays and point discharge no doubly charged ions were found, though in the last case big charged clusters, due to chemical processes, were proved to occur. A paper on the re-combination of ions in air at different temperatures, by Dr. P. Phillips, was read by the recorder. In the experiments outlined in this paper Langevin's method is adopted. The rays produced by a single discharge in a Röntgen bulb ionise a layer of air between two parallel electrodes, one of which is connected to a Dolezalek electrometer and the other raised to any desired potential. These plates are 3 cm. apart, and the layer of ionised air is 1·5 cm. thick; in these circumstances diffusion is probably negligible. The whole is surrounded by a vapour jacket. The experiment consists in measuring the charges received by the electrometer with different electric fields and temperatures. The following values for α, the coefficient of re-combination, were obtained, and are put alongside Prof. Erikson's values recently obtained (*Phil. Mag.*, August) for ions produced by radium:—

Temperature	α	Erickson
15° C.	1·00	1·00
100	0·50	0·51
155	0·40	0·405
178	0·36	0·38 (extrapolated).

The day's session was concluded with a paper by Prof. John Zeleny and Mr. L. A. McKeehan, on the terminal velocity of fall of small spheres in air. Experimenting with spherical spores, the authors find divergences from Stokes's law for the limiting velocity as follows:—

Substance	Radius	Velocity	Theoretical
Lycoperdon	0·000207 cm.	0·0465 cm./sec.	0·0757
Polytricum	0·000478	0·228	0·417
Lycopodium	0·00158	1·77	3·52

These experiments have an important bearing upon determinations of the numbers of nuclei in cloud condensations. Sir Joseph Larmor attributed the divergences to the inapplicability of the usual theory to particles comparable with the length of the mean free path, and recommended that experiments be made in air of different densities. Prof. Hull agreed that the theory must fail, but expected that the divergences should tend the other way. In answer to Prof. E. W. Brown, it was stated that no Brownian motion or rotation was visible, and the fall was quite steady.

On Tuesday, August 31, the section began with a discussion on earth tides, opened by Prof. A. E. H. Love. Prof. Love stated that Lord Kelvin had shown (1863) that if the earth could be regarded as homogeneous and absolutely incompressible, and possessed of the same degree of rigidity as steel, the oceanic tides of long period would be reduced, owing to the yielding of the earth, to about two-thirds of the theoretical heights which they would have if the substance were absolutely rigid. Sir G. Darwin (1881) estimated the actual height of the fortnightly tide as about two-thirds the theoretical height. Attempts to measure directly the lunar disturbance of gravity were made by several observers; and recently Dr. O. Hecker, by using two horizontal pendulums mounted in an underground chamber, has demonstrated the existence of the corporeal tide, and has shown that the deflection of such pendulums is about two-thirds what it would be if the earth were absolutely rigid. This means that, besides the tide-raising force, F, of the moon, there act on the pendulum other forces arising from the deformation of the earth. These forces are (1) the component of undisturbed gravity tangential to the deformed surface, denoted by hF; (2) a genuine disturbance of gravity, consisting in the attraction of the tidal protuberances and other related changes of the attraction of the mass of the earth, denoted by kF. The results obtained by Darwin and Hecker, and confirmed by Schweydar, show that the two numbers h and k are connected by the equation $h-k=1/3$. To find h and k separately we must have recourse to hypothesis or to new observations. If we adopt Kelvin's hypothesis we find $k=3h/5$, and thence $h=5/6$, $k=1/2$, and the corresponding estimated height of the corporeal lunar tide is about 46 cm. If, however, we bring in the fact of observation, discovered by Dr. S. C. Chandler, viz. that the period of variation of latitude (about ten months if the earth were absolutely rigid) is actually about fourteen months, we can determine k in terms of known quantities. Variations of latitude imply an adjustment of the earth's figure to rotation about an instantaneous axis which does not quite coincide with a principal axis. The corresponding inequality of "centrifugal force" has the same effect as a certain external force producing a deformation of the earth and a genuine disturbance of gravity. If the force in question is denoted by F, the genuine disturbance may be denoted by kF, where the coefficient k is necessarily the same as in the tidal problem. It has been proved independently by Sir J. Larmor and Prof. Love that k is about 4/15. It thence appears that $h=3/5$ approximately, and that the height of the corporeal lunar tide is about 33 cm. The earth would therefore appear to be more rigid than Lord Kelvin estimated it to be, a result confirmed by the interpretation of seismographic records. In the discussion which followed Sir J. Larmor asked whether there was any evidence for Wiechert's theory of the constitution of the earth, viz.

a central metal nucleus surrounded by a viscous layer and an outer shell of rock. On Clairaut's ellipsoidal theory the internal structure is not determinable from outside effects. Observation of the propagation of earthquakes is a direct experiment on the interior; but even here you cannot go far, because of ignorance of the properties of materials under enormous stresses. The phenomena of terrestrial magnetism are also concerned with the interior. He asked how the weight of mountain chains is supported. To avoid crushing, the basal material must have the strength of steel. A rival theory is based on the survey of India, viz. that the mass of a mountain is compensated by less dense material underneath; but Burrard's recent researches show that the defect underneath is not nearly so great as was thought. He pointed out that there was room for a fresh calculation. The presence of a mountain chain supported without collapsing necessitates also that the supporting material shall not have any fluidity at all, or else the mountain chains would gradually settle down. He asked if the necessary calculation had been made. He pointed out that Hecker's curve, being of the right shape though of the wrong size, was in conflict with a supposition of unequal rigidities in different directions. Finally, he propounded a conundrum of Lord Kelvin's: It is possible for any person in this room, if he lived long enough, to turn the earth upside down! Dr. L. A. Bauer directed attention to the semi-diurnal variation of the earth's magnetism, which has so far not been explained. In reference to Wiechert's theory, Prof. Love stated in reply that if it be adopted the rigidities of the supposed metal nucleus and rocky shell required to satisfy the two conditions $h-k=1/3$ and $k=4/15$ are respectively about three times and about one-tenth the rigidity of steel. Attention was also directed to the scooped-out beds of the ocean as being much more important than mountains. More than half the surface is 2000 fathoms below the sea-level. The earth is not an ellipsoid; it is the ocean that is so approximately. At the close of the discussion the section again divided.

In the department of general physics two papers were given by Prof. Poynting:—(1) on the lengthening of loaded wires when twisted; (2) the angular momentum in a beam of polarised light. These have appeared in a recent number of the Royal Society Proceedings. Prof. Frank Allen followed, dealing with the effect on the persistence of vision of fatiguing the eye with red, orange, and yellow. The persistence is measured by finding the speed at which flickering ceases when a sectored disc is rotated in front of a source, and a curve is drawn representing the whole spectrum. This persistence is measured when the eye has been fatigued with light of definite wave-length. When fatigued with light of 680 μ and 670 μ, only the red part of the curve is affected; fatigued with green only the green part; but when the fatiguing colour lies between 577 μ and 650 μ, the curves differ in both red and green. With wave-length 660 μ the two curves coincide completely. This means that the fundamental red sensation is at least beyond wave-length 660, and that yellow and orange cannot be simple primary sensations. Prof. Allen also contributed a paper on a new method of measuring the luminosity of the spectrum. The principle of the method is that the persistence of a colour sensation is a function of the luminosity only. The next paper was by Profs. E. L. Nichols and E. Merritt, on the effect of low temperature on fluorescence spectra. The measurements consisted in comparing the brightness of the fluorescent spectra of natural willemite, commercial anthracene, an alcoholic solution of fluorescein, and one of resorufin at various temperatures from 20° C. to −185° C., these being excited by a quartz-mercury lamp any portion of the spectrum of which, dispersed through quartz, could be focussed upon the fluorescent body. The results were shown by means of curves. In response to a query by Prof. Rutherford, Prof. Nichols stated that the fluorescent bands tend to become narrow as the temperature is diminished. Sir J. Larmor expressed his opinion that fluorescence was due to molecular creeping, but Prof. Nichols replied that though there *is* hysteresis (thermoluminescence), his experiments were all conducted slowly so as to eliminate it. A paper on an analogous subject, the absorption and fluorescence of canary glass at low temperatures, was contributed by Mr. R. C. Gibbs. The glass, of known composition, exhibited a main fluorescence band extending from 0·48 μ to 0·59 μ. With decreasing temperature the fluorescence for the most part increases, the maximum increase being about 100 per cent. The band, which at ordinary temperature shows a faint indication of two maxima between 0·51 μ and 0·535 μ, shows at the lowest temperature (−175° C.) two narrow overlapping bands with maxima at 0·514 μ and 0·533 μ.

In the cosmical physics department, which was sitting simultaneously, Prof. W. J. Humphreys communicated some results he had obtained from a consideration of European *ballons-sondes* observations, while Mr. E. Gold presented the report on the present state of our knowledge of the upper air drawn up by Mr. Harwood and himself. One of the most interesting facts was that both Prof. Humphreys and Mr. Gold found that in areas of high pressure (above 770 mm.) the temperature up to 9–10 km. was greater than in areas of low pressure (below 750 mm.), while at greater heights the conditions became reversed. So long as this condition holds and the isothermal or advective region exists, it appears impossible that there should be anything in the nature of circulatory interchange between cyclones and anticyclones, and the intensity of these systems cannot be maintained.

Gold and Harwood found remarkable minima in the height at which the advective region begins in March and September, and an attempt was made to connect these minima with the general circulation of the atmosphere.

On Wednesday, September 1, the section again bifurcated. In the department of cosmical physics Prof. A. L. Rotch gave an account of the highest balloon ascent in America. He found a remarkable result, which occurred in at least two ascents, that the temperature *increased* in a cumulus cloud in passing from the base upwards. Considerable discussion took place, and doubt was expressed as to the reality of the phenomenon, but Prof. Rotch stated that the observations were unexceptionable. The fact adds further difficulties to the explanation of cloud-formation and its connection with atmospheric motion.

Dr. Shaw showed photographs of models illustrating the temperature distribution in the free atmosphere over the British Isles in the international week in July, 1908. The models show the gradual production or pushing forward of a wedge of cold air at a height greater than 10 km. The wedge had just reached Limerick on the first day, but two days later extended well over England. It may be noted that the construction of the models was only made possible by the observations obtained near Limerick, in Ireland.

Mr. Gold read a paper by Mr. A. Harwood on the results of hourly observations with registering balloons, June 2–3, 1909. At heights above 10 km. there was a diurnal variation of 6° C. to 8° C., with the maximum in the middle of the day, but the values were irregularly distributed, and it was impossible to say how far the variations were real or instrumental.

Prof. W. J. Humphreys described an arrangement for obtaining a record of the ultra-violet part of the solar spectrum (below 0·2 μ) at very great altitudes.

Mr. Stupart read a paper by F. Napier Denison on the connection between atmospheric pressure and the motion of the horizontal pendulum of a Milne seismograph.

Simultaneously, in the department of general physics, a paper was given by Mr. R. F. Earhart on the effect of temperature variations on the luminous discharge in gases for low pressures. The potentials were measured which are required to produce, and also those required to maintain, a luminous discharge for pressures varying from 0·2 mm. to 5 mm., and for temperatures from −78° C. to 325° C. Up to 300° C. Paschen's law holds good for air; for higher temperatures it does not hold even approximately. Prof. Rutherford considered the paper important, because it raises the whole question as to the dependence of ionisation upon temperature. Prof. H. M. MacDonald gave the results of his calculations on the diffraction of electric waves round spherical obstacles. Prof. Love inquired whether the propagation of Marconi waves round the earth could, in the light of these calculations, be attributed simply to the great length of wave employed. Sir J. Larmor reminded the meeting of the effect of conduction, which probably played a considerable part in the Marconi system. In Lodge's method the antennæ are not earthed, and the result is that much better resonance is obtained. Prof. MacDonald did not think his results would account for Transatlantic transmission, and pointed out that Lodge's method differed also in the use of shorter wave-lengths and antennæ with a much less distance above the surface. In a paper by Dr. T. H. Havelock, on the instantaneous propagation of a disturbance in a dispersive medium, an attempt was made to remove an apparent anomaly in the results obtained by Lord Rayleigh in a recent paper in the *Philosophical Magazine*. A paper followed by C. W. Chamberlain, on the relative motion of the earth and æther and the FitzGerald-Lorentz effect. Analysis shows that the total effect of the relative motion is a displacement of the interfering rays in the line of sight, and one at right angles to it. In the interferometer the former should be detected (in the absence of shrinkage); the latter should not. The author suggested an arrangement, called a diffractometer, which he considered should detect the transverse change. Interference is to be produced between two rays travelling at right angles to one another, and the effect will be analysed by a diffraction grating. A change in the length of the path of one of the interfering systems will produce interference bands either in the spectra to the right or to the left. A shift of a whole band is expected for the length of path used in the Morley-Miller experiments and a grating of 30,000 lines to the inch if the apparatus is rotated through ninety degrees. The failure of many experimentalists to find any effect depending upon the earth's motion through the æther has served so much to strengthen the belief of those who hold that it is undetectable that the meeting seemed inclined to receive the proposal with reserve. Prof. Hull pointed out what he considered a flaw in the reasoning. We must therefore await the results of the actual performance of the experiment or a thorough examination of the calculations upon which the belief in its suitability is based. In a somewhat technical paper Prof. E. W. Brown outlined some new methods under trial for tables of the moon's motion. Lieut.-Colonel J. W. Gifford followed with a description of a new cemented triple devised by him for spectroscopic use, the peculiarity being the possession of a ratio of 7·5 of focal length to effective aperture and great freedom from tertiary colour-aberration. Dr. H. G. Dorsey, in an interesting paper on magnetostriction, said that he finds from experiments on eight steel rods of known composition that the maximum elongation due to magnetisation is a function of the carbon content, the curve being similar to a curve in the iron-carbon phase diagram; there is also a relation between it and the maximum susceptibility of a specimen. The maximum retraction bears an inverse relation to Young's modulus. The results tend to straighten out the somewhat chaotic data obtained by other observers. One more paper now remained on the programme, but the inexorable clock pointed out that the time had arrived for the compulsory closing of the sessions. So the final rites were performed, and then an interested group informally examined some remarkable vibration curves of speech exhibited by Prof. D. C. Miller.

CHEMISTRY AT THE BRITISH ASSOCIATION.

Bearing in mind the special local conditions attaching to a meeting of the association out of England, the work of the section was organised so as to include the consideration of broad problems of general and local interest rather than the reading of specialised papers. Accordingly, the section sat jointly with the physicists for one session, with the physiologists and agriculturists for another, and with the botanists and agriculturists for a third. These joint discussions were all exceedingly successful and attracted large audiences.

It was regretted that a larger number of the younger English chemists did not make the journey to Canada, and still more that so few of the chemists from eastern Canada were present, though the section was particularly indebted to Mr. F. T. Shutt, of Ottawa, for his contributions to the discussions. The section was strengthened by the presence of a number of American guests, in particular Prof. W. A. Noyes, Prof. G. B. Frankforter, and Dr. A. Springer.

Stress was laid throughout the meeting on the importance and necessity of Winnipeg and the province of Manitoba possessing a university fully up-to-date in every respect. In particular, attention should be devoted in Winnipeg to agricultural chemical research and to the higher training of agriculturists. Wheat must always be a pioneer crop, as it requires less capital, less labour, and less skill than most other types of farming. With fuller development or with some change in the world's requirements a change will come in the farming, and wheat may become a by-product, as often in England now. Such a change comes very quickly, and the farmer will go under unless he is prepared for it and has the highest scientific advice.

In the United States the farmer has realised very definitely the benefits he has obtained by following the results of the experimental stations; in consequence he supports the State universities, and has the greatest belief in the schools. On the western excursion there was abundant opportunity of remarking that the Canadian is equally far-sighted in regard to the schools, but it is none the less necessary to urge that the university work, and above all university research, be not neglected.

Following the president's address, which was delivered at such an hour that members of the section could also attend the addresses delivered by the presidents of Sections A and G, the work of the section was opened by a short paper from Prof. W. A. Noyes dealing with his recent work in connection with camphor. A very full report on combustion, by Prof. W. A. Bone, was taken as read. Prof. E. H. Archibald outlined the method followed by him in a new determination of the atomic weight of iridium. Potassium chloroiridate was analysed by weighing the dry salt, reducing it in hydrogen, and estimating the hydrochloric acid formed, the potassium chloride and the metallic iridium set free. The results show a value of 192·9 for the atomic weight. His further paper, contributed jointly with Mr. W. A. Patrick, dealt with the electrical conductivity of solutions of iodine and platinum tetraiodide in ethyl alcohol. The conductivity of solutions of iodine in ethyl alcohol increases rapidly with time, reaching a maximum in about twenty-five hours at 25°. Platinum tetraiodide forms good conducting solutions with alcohol.

A paper of very considerable interest, on the anti-putrescent effects of copper salts, in particular towards the bacteria of milk, was contributed by Dr. Alfred Springer. Copper salts are selective in their action, greatly retarding or inhibiting the putrefactive bacteria such as *Proteus vulgaris*, *P. mirabilis*, *P. Zenkeri*, and *Clostridium foetidum*, but having little effect on the lactic bacteria. Consequently, milk treated with copper salts retains its sweet odour even when the acidity becomes sufficiently high to curd it. On the other hand, moulds such as *Penicillium glaucum*, *Aspergillus niger*, *Eurotium repens*, and others, grow more freely on milk containing copper salts, probably because they are left a freer field for development. The origin of small traces of copper in the milk supplied by a Cincinnati firm was traced to contamination of the sterilising cloths, pails and other utensils with the boiler compound used to soften the water. Copper salts have an anti-putrescent effect on blood albumen, egg albumen, meat, milk and sewage solutions.

The report of the committee for the study of hydro-aromatic substances (secretary, Prof. A. W. Crossley, F.R.S.) describes the preparation of nitro-derivatives of *o*-xylene and the synthesis of *iso*phorone.

The transformation of aromatic nitroamines committee (secretary, Prof. K. J. P. Orton) summarises the results obtained by the study of the transformation of chloro-aminobenzene into nitroaniline.

The report of the isomorphous benzene sulphonic acid derivatives committee (secretary, Prof. H. E. Armstrong, F.R.S.) contains the crystallographic data of a number of *para*-dihalogen derivatives of benzene; these afford confirmation of Barlow and Pope's conclusion as to the existence of columns of carbon spheres in crystalline benzene derivatives, and support the confirmation previously obtained by Jerusalem by the study of the picrates and styphnates.

The electro-analysis committee (secretary, Dr. F. M. Perkin) reported on experiments upon a new design of potentiometer, on the general simplification of the apparatus, on a method for the electro-deposition of metals by means of graded potential, and in connection with the electro-deposition of mercury upon gold, silver, platinum and mercury kathodes.

A joint meeting with the general physics department of Section A took place on Friday, August 27. A large attendance was attracted, and the communications were discussed by members of both sections. Only the more purely chemical papers are noted in the following. Dr. T. M. Lowry presented the report of the committee on dynamic isomerism in the form of a general discussion on dynamic isomerism in relation to luminous phenomena. Attention was in the first place directed to the decisive evidence adduced that the presence or absence of a band in the absorption spectra of a camphor derivative is in no way dependent on the occurrence or non-occurrence of isomeric change. Certain luminous phenomena, *e.g.* mutarotation and phosphorescence, have been shown to be manifest only in presence of a catalyst, and not when pure materials are used; they are therefore dependent on chemical change. Refraction, dispersion, and optical rotatory power do not appear to be dependent on the presence of foreign substances, and are to be referred to physical characteristics of the molecule. Colour, fluorescence, and triboluminescence are still subjects of controversy. The last two are probably dependent on chemical structure, but it is difficult to resist the conclusion that colour is an essentially physical phenomenon in which chemical change plays no essential part. The conclusion is one which is confirmed by the study of crystallisation in relation to phenomena.

This paper provoked considerable discussion. Sir J. Larmor remarked that phosphorescence is due, not to the formation of ions, but to complex molecules forming and breaking up, and instanced that iodine vapour, which is strongly phosphorescent, shows no conductivity, and therefore contains no ions.

In three further notes Dr. Lowry put on record some useful improvements in the technique of optical investigations. Measurements of rotatory dispersion have been made with light of twenty-six different wave-lengths, and the green mercury line Hg 5461 has been selected as the principal standard in place of the sodium doublet on account of its brilliance and purity.

The optical and magnetic dispersions produced by quartz are identical, but optically active liquids have the optical dispersion usually, though not always, higher than the magnetic dispersion. It is suggested that the magnetic rotatory power of liquids depends upon a spiral packing of the molecules of the same general character as that which produces the optical rotatory power of quartz.

To produce a cadmium spectrum of sufficient intensity for polarimetric work, use is made of the silver cadmium alloys; these have high melting points, and give a steady arc which can be kept true to centre by rotating the electrodes in opposite directions. The silver and cadmium lines are so far separated that no overlapping takes place even when the spectroscope slit is opened to its full width. Mercury and cadmium lines are suggested as standards in refractometry.

Two papers by Dr. C. J. J. Fox were taken as read. The constancy of the hydrogen-gas electrode in sulphuric and hydrochloric acids has been investigated when gold or platinum coated with either platinum or palladium black are employed; in a very few minutes values concordant to less than 0·05 of a millivolt were obtained. Palladium coated with palladium black gave a value 4 to 5 millivolts too high. A new method of preparing trustworthy mercurous sulphate for standard cells is described; this consists in heating commercially pure mercurous sulphate for a day or so at 120°–150° in a sealed tube with a little mercury and dilute sulphuric acid. The sulphate is thus obtained free from nitrate and basic sulphate.

The joint discussion with the botanists and agriculturists on wheat and flour had been carefully organised previous to the meeting, so that the contributions might be made in logical sequence and present as full a picture as possible of the exact position of our present knowledge of wheat and flour from every point of view. The present problems are quite clear; the chemist has to map out the wheat soils and to watch the quality of the product; the botanist has to breed wheats that suit local requirements and command a good price in the market.

The subject was particularly appropriate for discussion at Winnipeg, and the discussion, which throughout was very technical in character, was closely followed by an expert audience. The first paper, by Dr. Stapf, on the history of the wheats, dealt with their classification and characteristics. The great economic importance of the wheats proper lies in the fact that the looseness of the grain in the husk enables threshing to be quickly and cheaply accomplished. Dr. E. J. Russell followed with a paper by A. D. Hall and himself on the factors determining the yield of wheat, based on the experiences at the Rothamsted Station since 1851. The chief elements of nutrition derived from the soil or manure are nitrogen, phosphoric acid, and potash; other elements also play their part, but are supplied in sufficient quantity by all ordinary soils. The yield of grain is proportional to the nitrogen supplied, but two sets of factors may be traced in the results. At first the root system of the plant increases with the supply of nitrogen, and the yield is more than proportional to the supply; subsequently other limiting factors come into play, and the increase is smaller for the third and fourth increments of nitrogen.

Wheat does not require large quantities of phosphoric acid; the effects of this manure are secondary, and dependent upon season. A deficiency of potash is shown by a reduced yield, especially in dry seasons, and by increased tendency to disease, rust, &c.

Wheat is one of the crops best adapted to dry regions. High temperatures are not necessary excepting at the time of maturation. The type of soil in relation to climate is a very important factor. To each type there is a limiting yield, beyond which the crop will not go. This limit is not the same for all varieties of wheat.

Mr. F. T. Shutt, chemist to the Dominion Experimental Station, Ottawa, followed with an account of the influence of environment on the composition of wheat. The factors which might be supposed to influence composition are heredity, environment and soil. Soil, however, has very little effect on the composition, as distinct from the yield, of wheat. The shorter the period which elapses from the formation of the kernel until it is ripe the higher the nitrogen content. High temperatures, long days, and absence of excessive moisture during the ripening process hasten the maturation of the grain and increase the percentage of gluten. These are the conditions which prevail in the Canadian North-west.

Experiments were described in which the same wheat was grown on old land and recently cleared land, the older land being the drier and yielding wheat with a higher percentage of protein. It is suggested that the quality of the wheat as measured by the quantity of gluten it contains is dependent on the amount of soil moisture during development and ripening of the grain. The quality of the gluten, however, is considered to be controlled by heredity.

The subject was next developed from the point of view of the miller, a paper by Mr. A. E. Humphries being read by the recorder of the section. This dealt with the vexed question of quality in wheaten flour. Good quality is the sum of excellence on several points, and is technically denoted by the term "strength." Strength is defined as the capacity for making large, shapely, and therefore well aërated loaves. This is a very complex conception, and it is now admitted that at least five separate considerations are included in the term quality; these are (1) flavour; (2) colour; (3) stability of dough; (4) size and shape of loaf; (5) yield of bread per sack of flour. A pleasant flavour is an essential, but the exact flavour desired is chiefly influenced by fashion. Colour in bread is largely a question of optics, a strong flour making a whiter loaf than a weaker flour. A large loaf indicates a high gas-making capacity and a high diastatic power, but this is not a true index of strength. It is the gas evolved in the later stages of panary fermentation which is of importance, and the gas-retaining power of the dough which is the most important factor in strength. This is apparently a function of the quality of the gluten, and dependent on the proportions of various acids and salts which affect the physical properties of the gluten.

Dr. E. F. Armstrong followed with some notes on the chemical properties of flour and an account of the recent work on strength. Flour is composed of (1) starch; (2) several kinds of proteins; (3) mineral matters present only in small quantity; (4) a little sugar; (5) a little fat; (6) moisture; (7) enzymes. It has been the object of the chemist to seek to correlate the chemical properties with baking qualities. Most attention has always been paid to the gluten of flour; generally the strongest flours have the most gluten, but this test is not absolute. Attention has further been directed to measuring the quality of the gluten either by physical or chemical means, such as the amount of water it will retain or the proportion of gliadin in it. The total nitrogen of a flour is another rough indication of quality; latterly the distribution of nitrogen in its various forms has also been studied. To make a light loaf the flour must be one which will give rise to sufficient gas during fermentation; it must contain enough diastatic enzyme or have its starch in a form which is easily attacked. Whymper has found that the largest starch grains are those first attacked by enzymes, and it appears that different flours contain different proportions of large starch grains. The mineral matters and enzymes of flour are likewise of the very greatest importance in affecting quality.

Mr. W. B. Hardy, who followed, dealt with the influence of the minerals of flour on its quality. Gluten owes its tenacity and elasticity to the presence of salts and acids in certain proportions, pure gluten having no tenacity.

Prof. R. Harcourt, of Guelph, directed attention to the comparative milling and baking qualities of a number of Canadian wheats. Though the Manitoba spring wheats do not contain more gluten than the Alberta winter red wheats, they give a better yield of bread and a larger loaf. Blends of Alberta red with soft Ontario winter wheats give a flour superior to either of the constituent flours baked singly. This confirms the common practice of English millers. The discussion then turned to the breeding of wheats. Dr. C. Saunders gave a most valuable account of wheat-breeding experiments in Canada, and a highly suggestive paper on the influence of good seed on wheat production was read by Prof. C. A. Zavitz. A paper by Prof. L. S. Klink dealt with individuality in plants. A general discussion of great interest followed, and it was subsequently agreed by the general committee that the discussion be printed in full in the report of the meeting.

Tuesday, August 31, was devoted to a joint meeting with the representatives of physiology and agricultural chemistry to consider the subject of "food." The views developed were of the very greatest importance, more especially as indicating the lines on which future work in this field should proceed. After some introductory remarks by the chairman, a paper on "Proteins: the relation between composition and food value," was read by Dr. E. Frankland Armstrong. The quotient of the amount of nitrogen in a food material multiplied by the factor $6\frac{1}{4}$ is commonly spoken of as protein without any reference to its nature, although it has long been realised that proteins of different origin are not the same. The proteins have been proved in the main to be built up of amino-acids, belonging both to the aliphatic and aromatic series, or derived from cycloids containing nitrogen, of oxyamino-acids, and of diamino-acids. In different proteins these structural units are present in varying proportions, and, since the amino-acids are very different from one another in their chemical structure, it must be supposed that they each fulfil somewhat different functions in building up the tissues of the body. It thus becomes important to see that each is supplied in the proper proportions required by the body. Further, the analytical results point to the impossibility of entirely replacing a diet composed of one kind of protein—for example, meat—by another diet composed, let us say, of nuts, since the two proteins, though made up of the same structural units, contain these in entirely different proportions.

It remains to solve such problems as the precise function and significance of each amino-acid in metabolism, how far they may replace one another or be absent altogether without injurious effects; further, to what extent each is concerned in the maintenance of a particular tissue. Probably the presence of most, if not all, of them is necessary in a food if health is to be maintained. Tryptophane, for example, has been shown to be essential by Willcock and Hopkins. The ideal diet should contain as much variety of protein as possible in order to provide sufficient of all the possible units of constructive metabolism.

Prof. Starling, F.R.S., suggested that it was possible to attach too much importance to protein as a mere source of nitrogen. In reality, four-fifths of the protein of food is not connected with the nitrogen question. Proteins may decompose in two ways; in the one nitrogen is immediately eliminated, and a residue produced which contains as much energy as the fats or carbohydrates, and furnishes this energy on oxidation. Only a small amount of the protein is built up into the body. A protein diet is never stored as fat, neither is the above-mentioned carbonaceous residue stored as fat. A protein meal is followed by a large output of carbon dioxide and intake of oxygen, the residue being more easily oxidised than the original protein. The value of proteins as a food is due to this, and it is important that the fate of the residue in the body should be investigated.

Proteins also undergo decomposition in another manner, namely, the carboxyl group is eliminated and amines are formed. These amines have a marked physiological action; for example, those from tyrosine and phenylalanine have an action like that of adrenalin. A big meat-eater usually has a high blood pressure, whilst the constant formation of such amines causes the various disorders of middle age.

Dr. E. J. Russell, of the Rothamsted Experiment Station, next dealt with the problems of the stock feeder, who asks for methods by which he can determine the relative food value of various agricultural products. Experience has shown that animals fed on barley meal or cotton cake singly do not do so well as those fed on a mixed diet of both ingredients. A single food is not enough, but it is not known what the ideal mixture should be. Swedes grown on chalk loam have not the same feeding value as those grown on sand. There is a similar difference in the value of grasses grown under substantially the same conditions. Fibre is of very little value as a food—it acts merely to distend the stomach. The mineral constituents are of great importance, and may account for some of the facts recorded. Pigs fed on maize give a low-grade bacon; a diet of maize and minerals gives a better bacon; and the best article is obtained by feeding with barley meal. The food has an effect on the character of the beef and on the production of milk. Cotton cake, for instance, causes the production of milk, whereas with linseed cake the cows lay on flesh instead of producing milk. Prof. Cushny, F.R.S., alluded to the influence of taste and the importance of the mineral constituents.

Mr. F. T. Shutt described some experiments on pig-feeding. The Canadian pork was originally found to be too soft for the packers owing to the quality of the fat. This was got over by the addition of skim milk, which, together with corn, was found to afford an ideal diet. An increase in the proportion of corn softens the fat; too much actually kills the pigs. The fat of the animal and of the cereal is stated to be the same.

Dr. F. N. Alcock alluded to the changes in the habits of the women of the upper middle classes during the last fifty years. Their diet to-day contains less protein and less malted liquors, and this is probably to be associated with the fact that they no longer have large families or are able to nurse their offspring. Infants commonly get too little protein, which necessitates that they receive only a minimum quantity of some—probably essential—residue.

Prof. J. Wilson indicated in historical sequence the views which had in turn prevailed on the feeding of stock. In early days the cattle practically starved during the winter on a large amount of straw, and had no energy left in the spring. A great improvement was experienced about the middle of the eighteenth century, when turnips were added to the diet, and the introduction of oil cake about 1797 made it possible to fatten during the winter. It is found that a linseed-cake feed gives the results most desired by the butcher, a cotton-cake feed giving a poorer bullock. The oil was long considered to be the valuable constituent; later, most importance was attached to the albumenoids. Maize was introduced in 1875, brewers' grains a few years later, and the carbohydrates are now regarded as a most important constituent.

In the subsequent discussion the minimal protein was defined as that sufficient to supply the units for tissue formation. Dr. E. F. Armstrong alluded to the importance of the mineral constituents in a colloidal state and their analogy to enzymes. Prof. Starling pointed out that the physiologists diet for health, whereas the agriculturists feed for fattening purposes.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE meeting of Section H at Winnipeg, apart from being one of the most enjoyable of recent years, was also fruitful of much good work, and was undoubtedly in every respect a great success. It was hardly to be expected that the audiences would be as large as at an English meeting, but although the numbers attending the section were at first few, they increased daily, and at the end were well up to the average. Last year a great diminution in the number of papers dealing with physical anthropology had to be recorded. Unfortunately, this was still more apparent at Winnipeg, and only one paper on the subject was presented. It is to be hoped that this is only a temporary falling off, and that in future years the papers on physical subjects will be as numerous as in the past.

The address of the president, Prof. J. L. Myres, on "The Influence of Anthropology on the Course of Political Science," need only be mentioned here, as it has already appeared in the pages of NATURE. The last few paragraphs of it, however, in which the president urged the importance and necessity of undertaking an ethnographic survey of Canada, must have particular attention directed to them, as, in a way, they struck the keynote of the meeting.

When the association met at Montreal in 1884 Prof. Tylor presided over the newly formed anthropological section, and the chief result of the meeting was the foundation of an ethnographic survey of Canada, under the auspices of the association, which appointed a committee and gave liberal grants. This committee did much good work and published annual reports, but the lamented death of Dr. George Dawson brought work to a standstill. Since then, with the notable exception of Mr. Hill-Tout's work on the Salish of British Columbia, practically nothing has been done by Canadians towards a systematic study of the natives inhabiting the Dominion. It was felt, therefore, that the time was ripe for endeavouring to organise an ethnographic survey, and a whole day was accordingly set apart for papers and discussion on this important subject.

This discussion was opened by Mr. Sidney Hartland, who gave a *résumé* of the work that had been done in the past from the times of the Jesuit fathers onwards. This retrospect made it apparent how small had been the part taken by Canadians in contributing to our knowledge of the natives of the Dominion, and how little interest had been taken by the Dominion and provincial Governments, which had been content to leave inquiries, which have a bearing, not only on scientific questions, but also on the practical problems of government, to the Government and museums of the United States, and to individual effort.

Mr. Hartland was followed by Dr. Franz Boas, of New York, who, in a paper on the ethnological problems of Canada, urged the immediate importance of undertaking such a survey at once, before it is too late. Primitive life is rapidly disappearing before the economic progress of Canada, and unless the work is undertaken at once the opportunity will be gone for ever, and information which will have a most important bearing upon general anthropological problems will never be obtained. Dr. Boas then directed attention to some of the problems awaiting solution, and pointed out what an important field Canada offered to the investigator.

Dr. G. B. Gordon, of the Philadelphia Museum, explained the work which is being undertaken by the Smithsonian Institution and the various museums in the United States.

But the native question, although the most pressing, is not the only ethnographic problem in Canada which requires study. The problem of the white immigrants is in many respects even more important, and a strong feature was therefore made of this side of the question. Dr. Shrubsall, who opened the discussion on this aspect of the problem, pointed out the great importance of collecting careful statistics so as to be able to ascertain the effect of Canadian environment upon immigrants of European origin. He urged the vital importance of a survey of physical characters, mental conditions, and physique, so as to discover what type was best suited to the Canadian environment, and he also pointed out how necessary it was that the Dominion should take preventative measures now to stop the landing of the physically or mentally unfit, rather than remedial measures later. The task before the Dominion was to prevent these problems, which are now facing the great centres of population, from arising in Canada rather than to let them arise and then to attempt to remedy them.

As a result of this discussion a committee was appointed by the association to consider what steps can be taken to organise an ethnographic survey of Canada, and a memorial has also been drafted urging upon the Government the importance of undertaking the work before it is too late. It is hoped that this memorial will be presented in due course.

As was natural at a meeting in Canada, many papers dealing with American, and particularly Canadian, ethnology and archæology were presented to the section.

To take first of all those dealing with Canadian ethnology. Mr. Hill-Tout, whose reports on the various British Columbian tribes have appeared from time to time in the Journal of the Royal Anthropological Institute, presented a further instalment of his work in a report on the ethnology of the Okanagan of British Columbia. These people are the most easterly division of the Salish of the province, but they are not confined to British Columbia, but extend southwards into the United States, the international boundary dividing them into two fairly equal divisions. The material culture and language of the stock was discussed, and from the linguistic and cultural evidence a most important conclusion was arrived at, namely, that the original home of the stock, before its division into its present sections, was not the rivers and bays of the Pacific coast. The staple food of these people is now, and as long as they lived where they do now must have been, the salmon. If, therefore, they had inhabited their present districts before their language was divided into its present groupings, we would expect to find the same word for salmon among the different stocks; but this is not the case, and, in addition, their myths as to the origin of the salmon differ. It seems clear, therefore, that, before the division, the people cannot have inhabited their present district. Where they came from is another matter, but it is noticeable that the linguistic evidence points to a connection with Oceanic stocks.

An interesting paper on the Blackfoot Medical Priesthood was presented by Dr. John Maclean. The paper dealt with every aspect of the subject, with the initiation ceremonies, dress, and facial decoration, and with the causes of disease, especially the influence exerted on the mind and body of the native by his belief in evil spirits. Native medicines and remedies were also discussed, and the value of the work of the medicine-men among the natives and the influence exercised by them on the native religion.

Mr. William McIntosh presented a paper on the present native population and traces of early civilisation in the Province of New Brunswick. At the present time the native and half-breed population numbers about 1500, and is composed of two tribes, the Micmacs, on the east coast and part of the shores of the Bay of Fundy, and the Malecites, on the St. John River valley, which is approximately the site of their ancient habitations. There are abundant traces of the prehistoric occupation of the district by peoples in the Stone age of culture. Kitchen middens and camp sites are abundant; stone implements, almost invariably of the type common to the Algonquin areas, are numerous, while there is a considerable amount of pottery which in material and shape closely resembles Algonquin wares, but shows interesting varieties of ornamentation.

An interesting series of copper implements from a site in western Ontario was exhibited by Prof. E. Guthrie Perry. The collection consisted of a large number of fish-hooks and of spear- and arrow-heads. All were of cold-hammered copper from the Lake Michigan district.

In a paper on the archæology of Ontario and Manitoba, Prof. H. Montgomery, who has spent many years in excavating mounds and other early sites in America, gave a general account of his work on the antiquities in this part of Canada, and exhibited many of the objects discovered.

Miss A. Breton presented a paper on race types in the ancient sculptures and paintings of Mexico and Central America. There is an enormous mass of material available for study, including terra-cotta or clay statuettes, small jadeite heads and figures, archaic stone statuettes, portrait statues and reliefs, stelæ, MS. frescoes and vases. Among distinctive types are the chiefs on the reliefs at Xochicales, the shaven clay heads at Teotihuacan, the priests, with protruding lower lip, of the Palenque reliefs, the caryatid statues, in feather mantles, at Chichen Itza, and the sixteen warriors, at the same place, of a type similar to some of the modern Indians of the villages near Tlaxcala. Portraits of the Mexican kings are on the border of a picture map, representing the western quarter of the town of Tenochtitlan. Of female types there are the painted clay figures of Jalises with compressed heads. The figures of some of these are short and broad, while others are slender, and it is interesting to note that the type still survives. Finally, on the Guatemalan stelæ two female types are shown, the women-chiefs being obviously of a different caste to the victims prepared for sacrifice.

In another paper Miss Breton described the arms and accoutrements of the ancient warriors at Chichen Itza, where the walls of the Temple of the Tigers are covered with sculptured rows of chiefs, carrying a variety of weapons. Among these are stone implements, harpoons, spears, and the throwing stick. For defensive armour the warriors wear protective sleeves in a series of puffs, breast plates and helmets, and carry round or oblong shields.

Dr. G. B. Gordon gave an account of his recent expedition to Alaska on behalf of the University of Pennsylvania. The tribes investigated were those inhabiting the Koskokwim valley, who preserve to a marked degree their aboriginal characteristics. In the upper valley were found Dené tribes preserving the characteristics of the Dené stock. Seven hundred miles from the mouth of the river Eskimo culture began, and two hundred miles further Eskimo culture had entirely replaced the native customs, even in those communities where there was little or no admixture of Eskimo blood. The tendency of the Dené in this region to adopt Eskimo culture, which has intruded from the Bering Sea district, is most marked, and shows the aggressive nature of the Eskimo civilisation. At the mouth of the river the Eskimo have retained in full vigour their peculiar customs and mode of life, because that part of the coast has not been visited by trading vessels or whalers.

As is usual at meetings of the section, papers dealing with Mediterranean archæology and with the work of the British Schools at Athens and Rome were again a prominent feature.

In a paper on recent Hittite research, Mr. D. G. Hogarth gave a most valuable *résumé* of the present state of our knowledge of this interesting subject, and summarised the results of the explorations which have taken place. At first the general opinion was that the Hittite race and civilisation were Syrian, but gradually opinion has changed, and it is now held that the original home of the Hittites must be looked for in Cappadocia, and that only at a later period were they domiciled south of the Taurus. At Boghaz Koi has been discovered what amounts to the collection of royal archives, among them a duplicate of the treaty between Rameses II and Khetasar, inscribed on the wall of Karnak; this discovery shows that Boghaz Koi was the centre of the Hittite confederacy as early as 1280 B.C., and proves that the Hittite power was centred in north-west Cappadocia long before it is mentioned as being at Carchemish by the Assyrian records.

In their paper on prehistoric antiquities of Malta, Dr. Ashby and Mr. Peet, of the British School at Rome, described the excavations on the Corradino Hill, now being conducted by the Maltese Government with the active cooperation of the British School at Rome. The excavation of the rock-cut hypogeum at Halsaflieni shows that its architectural features imitate in a most surprising way the sanctuaries above ground, and it has, moreover, produced an adequate series of Maltese pottery of the Neolithic period. Excavation has shown that the Megalithic buildings on the Corradino Hill are of irregular plan. They were constructed of rough masonry, with large slabs at the bottom and smaller ones higher up. The walls converge as if to form a roof. The use of standing slabs at the base of the walls, with coursed masonry above, is paralleled by the giants' tombs in Sardinia and the prehistoric huts of Lampedusa.

In the report of the committee appointed to carry out archæological and ethnological researches in Sardinia, Dr. Duncan Mackenzie showed that the tombs of giants were the burial places of the dwellers in the Nuraghi, and that these tombs, with their elongated chamber and crescent-shaped front, were derived from the more ancient dolmen type. In one case the chamber of an original dolmen tomb had been elongated so as to resemble a giant's tomb. In another example the large covering slab was supported by upright slabs at the sides and back, and behind are traces of an apse-like enclosing wall, a characteristic of some of the dolmens of northern Corsica and Ireland, where giants' tombs do not exist. A new type of giant's tomb was also discovered in which the mound was entirely faced with stone, upright slabs being used below and polygonal work above. Another feature, hitherto unique, is the discovery of a hidden entrance into the chamber on one side in addition to the usual small hole in front, through which offerings were probably introduced.

The work of the British School at Athens on the site of the shrine of Artemis Orthia at Sparta was fully described by Mr. R. M. Dawkins, the director of the school. At previous meetings of the association the work of excavation for the past year has been described in detail, but in this paper Mr. Dawkins gave a general *résumé* of the work on this interesting and important site.

Two other important contributions to Mediterranean anthropology were the reports of the committees to conduct researches in Crete and on Neolithic sites in Thessaly. The former committee issued an interim report by Mr. C. H. Hawes, who has been conducting somatological investigations. He reported the discovery of human remains certainly not later than Middle Minoan I. These remains consisted of four skulls, two portions of other crania, and several pelvic and long bones. All were in a wonderful state of preservation, and it is hoped that complete measurements will be published at an early date. Mr. Hawes has also been investigating the craniology of the modern population of the island with the view of comparison with that of the ancient population, and it is expected that most important results will be obtained from this investigation.

The work of excavating Neolithic sites in Thessaly has been continued during the past year, and it is now quite clear that there existed, in this isolated part of Greece, a people who were unaffected, until a comparatively late period, by the bronze culture around them, and who remained in the Stone age almost until the beginning of the age of Iron. It is important, too, to note that an analogous state of culture has been discovered in similar latitudes in southern Italy.

A paper on excavations at the Nubian cemetery at Anibeh was presented by Dr. Randall-MacIver. The cemetery, which dates during the first five centuries A.D., exhibits a culture, apparently of negro origin, but strongly influenced by Egyptian, Greek, and Roman art. A most important feature was the discovery of a form of script which has not up to the present been deciphered.

Other papers which call for passing mention are one by Mr. Sidney Hartland, on a cult of executed criminals in Sicily; another, by Mr. W. H. S. Jones, on a study of malaria in ancient Italy, which will shortly be published in the Liverpool Annals of Archæology and Anthropology; and one by Dr. Shrubsall, on the influence of geographical factors on the distribution of racial types in Africa, in which he showed that the trend of the migrations was from the north southwards, and also directed attention to the importance in the problem of the presence of the tsetse-fly in certain areas, which, by modifying the conditions of animal life in those districts, influenced their occupation by the native population.

Among the reports of the various research committees special attention should be directed to that on stone circles, which reported that excavations had been continued at Avebury, with the result that additional evidence had been collected which tended to confirm the opinion, arrived at in the course of the previous year's excavations, that the monument was of Neolithic date.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Colonel Sir T. H. Holdich, K.C.M.G., will deliver a lecture on Thursday, October 21, on some aspects of political geography. The lecture will be given in the large lecture-room of the Sedgwick Museum of Geology. Lieut. Shackleton will lecture on Thursday, October 28. The lecture will be given in the examination hall.

Dr. Breul, the reader in Germanic, will conduct practical exercises in reading scientific German for students of natural science at the literary lecture-rooms on Tuesdays and Thursdays, beginning on Thursday, October 14.

London.—University College:—A course of lectures in electrochemistry will be begun by Dr. Wilsmore on Monday, October 18. The lectures on vertebrate palæontology, by Prof. J. P. Hill and Dr. Woodland, began on Tuesday last. It is announced that Dr. Woodland will deal with fishes in the first term, and Prof. Hill with Amphibia, Sauropsida, and Mammalia in the second and third terms.

Oxford.—Mr. Walter Brudenell Gill, formerly scholar of Christ Church, has been elected to a fellowship at Merton College to undertake research work in physics, and to act as a demonstrator in one of the laboratories of the University.

Dr. G. B. Longstaff, of New College, has, through the trustees of the endowment fund, presented the sum of 2400*l.* to be invested as an additional endowment for the Hope Department of Zoology. A decree will be introduced in Convocation on October 26 to record the gratitude of the University for the gift, and to sanction regulations for the employment of the fund. The regulations contemplate the endowment of an assistantship to the Hope professor of zoology, but the curators of the Hope collections are empowered to make other arrangements with the sanction of the donor.

Miss Alice Parkin has been appointed organising secretary for the courses in home science and economics at King's College, London, for Women.

A special course of lectures by Mr. A. P. Thurston on aëronautics is announced by the East London College, Mile End Road. The first lecture will be given on Monday, October 18.

A lakh of dollars (8750*l.*) has been collected in the Canton district, and forwarded to the Governor of Hong Kong, as a contribution towards the endowment fund of the Hong Kong University.

In addition to the men of science referred to on p. 419 of Nature (September 30), the Bohemian University of Prague has conferred the honorary degree of Doctor of Philosophy upon the following:—Prof. H. B. Dixon, F.R.S., Prof. J. Burnett, and Prof. W. R. Morfill.

The Ottawa correspondent of the *Times* states that Mr. Andrew Carnegie has given 20,000*l.* to the general funds of the McGill University, Montreal. The offer was made upon the condition that 100,000*l.* should be raised from other sources, and this has been done largely through the generosity of Lord Strathcona.

At the inauguration of Dr. A. L. Lowell as president of Harvard University on October 6, the honorary degree of Doctor of Letters was conferred upon the Right Hon. James Bryce, the British Ambassador to the United States, and the following representatives of British universities:—Prof. W. A. Herdman, F.R.S., Dr. W. N. Shaw, F.R.S., Dr. G. A. Gibson, Prof. J. Biles, and Mr. J. Willis Clark.

The opening meeting of the autumn session of the Eugenics Education Society was held last week in the Caxton Hall, Westminster, when Lieut.-Colonel C. H. Melville delivered a lecture on eugenics and military service, in the course of which he stated that one of the objects of eugenics was to improve the individuals of the present generation. He contended that military service, by strengthening character, was a positive benefit to the individual, who was physically improved by better food and housing, while moral advantages accrued from discipline and association with comrades.

The Board of Education has published (Cd. 4875) the fifteenth volume of reports from the universities and university colleges which participated in the year 1907–8 in the annual grant, now amounting to 100,000*l.*, made by Parliament for "University Colleges in Great Britain," and from the three colleges in Wales which received a grant of 4000*l.* each. For the first time a report is included from the London School of Economics, which was in 1907 awarded a grant of 1150*l.* The individual reports are exhaustive and full of information on every matter of importance in connection with higher education in the districts served by the participating institutions; but the value of the bulky Blue-book to students of educational administration is impaired seriously because nothing is attempted by the Board of Education in the direction of summarising the scattered information, or of tabulating the facts concerning the various colleges, so that it may be possible rapidly to compare, say, the local support for higher education in various parts of the country, the cost of such education per head in different districts, and so on. The attention of the Board may be directed to similar reports issued by the U.S. Bureau at Washington, in which reference and comparison is made easy for the student.

An examination of the calendars of the newer universities shows how completely their governing bodies realise the importance of providing, in addition to the more ordinary courses of academic training in arts, pure science, medicine, and law, lectures and laboratory and workshop practice in the higher branches of technology of special importance in the districts in which their universities are located. The current calendar of the University of Leeds, for instance, shows that its students may attend technological courses, and, if they so elect, graduate in, civil and mechanical engineering, electrical engineering, mining, gas engineering, fuel and metallurgy, applied chemistry—whether having reference to leather or colour manufacture or dyeing—and agriculture. The textile industries, too, are catered for in a very complete manner. Facilities for research work also are provided in each of these departments. Similarly, the new calendar of the University of Sheffield gives full particulars of the faculty of applied science in the University. This department provides lecture and laboratory courses of instruction in the subjects of applied science required in the engineering, metallurgical, and mining industries, and awards degrees in engineering and metallurgy. It is a noteworthy sign of the times, also, that each university has a professor of education, and that modern attempts to place educational methods upon a scientific basis are receiving encouragement.

The report of the principal of the Bradford Technical College for the session 1908–9 shows that the total number of students in attendance during the session was slightly greater than in 1907–8. In the day classes the total reached 221, fifty of these being apprentices. The total number of students in the evening classes was 887; 324 were concerned with the textile industries, 169 with chemistry and dyeing, and 394 with engineering. Of the 171 day students other than apprentices, it is satisfactory to find that more than a hundred had previously attended secondary schools. The standard of the entrance examination, which admits new students to the diploma courses, is being raised gradually, and should soon secure adequate and suitable preliminary training for the students. Tenders for the extension of the college have been accepted by the City Council, and the building is now in course of erection. The scheme provides for an entirely new building for the department of textile industries, which is to be equipped with complete plants for the carding, combing, and weaving of textiles. There is also to be provided a small practical dyeing and finishing plant, capable of dealing with the material produced in the textile department. The committee has further decided to erect a power house equipped with various types of modern power-producing plant arranged for experimental use. These extensions constitute the most important developments of the institution within recent years, and, when completed, will place the college in the front rank as regards the facilities offered to students for experimental work in the textile and engineering industries.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 4.—M. Bouchard in the chair.—A method permitting the measurement of the effective temperatures of the stars. First results: Charles **Nordmann.** A development of the photometric method described by the author in a previous paper. Values are given for fifteen stars, ranging from 2980° C. for the absolute effective temperature of ρ Perseus, 5990° C. for the sun, to $>60,000$ for λ Taurus. It is noted that the numbers found, with slight exceptions, are arranged in the order predicted by Sir Norman Lockyer from considerations based on the appearance of the *enhanced lines* of the spectrum.—The hypergeometric equation: Mme. V. **Myller-Lebedeff.**—The differential equations the general integral of which is uniform and admits mobile essential singularities: J. **Chazy.**—The measurement of high pressures deduced from the variations of resistance of conductors submitted to the pressures to be measured: A. **Lafay.** The change of resistance with pressure has been studied for platinum, mercury, and manganin. The first of these is not practicable for pressure measurements, since the temperature coefficient is more than 1900 times the pressure coefficient, and there are variations with different wires. Mercury gives more satisfactory results, but on account of its low temperature coefficient manganin is better.—The thermal properties of silver nitrate: M. **Guinchant.** Cryoscopic determinations with solutions of the nitrates of lithium, potassium, and thallium in fused silver nitrate gave cryoscopic constants agreeing closely with that deduced from the latent heat of fusion. Determinations were also made with lead nitrate, silver chloride, iodide, fluoride, iodate, and sulphate.—The examination of essence of turpentine: Paul **Nicolardot** and Louis **Clément.** Mixtures of pure essences with known quantities of resin oil, petrol, and white spirit were made, fractionally distilled both under ordinary and reduced pressure, and the physical properties of the fractions measured.—The decomposition of silver tetrachlorplatinate by water, and the preparation of fulminating platinum: Jules **Jacobsen.**—The magnetic disturbance and aurora borealis of September 25, 1909: Alfred **Angot.** This magnetic disturbance is the greatest that has been observed since the commencement of observations at the Parc-Saint-Maur Observatory in 1883.

NEW SOUTH WALES.

Linnean Society, August 25.—Mr. T. Steel, vice-president, in the chair.—Contribution to a knowledge of Australian Hirudinea, part iii.: E. J. **Goddard.** Three species are dealt with:—*Glossiphonia intermedia*, n.sp., from a creek near Fairfield; *G. heteroclita*, a European and North American form, now recorded as Australian also; and the common species, usually known as *Hirudo quinquestriata*, Schmarda, but which should bear the name *Limnobdella australis*, Bosisto, of which no adequate account had been published.—Australian fresh-water Polyzoa, part i.: E. J. **Goddard.** Six named species, representing six genera (including Alcyonella), and several unnamed forms, have been recorded from Australia and New Zealand, of which three species are endemic:—*Victorella pavida*, Sav. Kent; *Lophopus lendenfeldi*, Ridley; *Paludicella ehrenbergii*, van Beneden (New Zealand, *teste* Hamilton); *Plumatella Aplinii*, McGillivray; *P. princeps*, Kraepelin; P. sp., and Alcyonella sp. To these are now added *Fredericella australiensis*, n.sp., which grows luxuriously in the screening tank at Potts' Hill Reservoir, near Rookwood, and also in the 72-inch main from the end of the lower canal to Potts' Hill.—Mollusca from the Hope Islands, North Queensland: C. **Hedley.** In continuation of former investigations as to the coral-reef fauna of Queensland, the author organised another party to examine the reefs several degrees further north. The exact position selected was close to the scene of Captain Cook's misfortunes in the *Endeavour*. A week's work dredging and shore-collecting provided a series of about seven hundred molluscs. Of these, one hundred of the more interesting are discussed in the present communication, about half of which are introduced as new species. The novelties are distributed among the genera Chlamys, Cuna, Rochefortia, Sportella, Phacoides, Gafrarium, Chione, Tellina, Arcopagia, Semele, Theora, Liotia, Cyclostrema, Obtortio, Triphora, Cerithiopsis, Epitonium, Vermicularia, Odostomia, Turbonilla, Glyphostoma, Eulima, Marginella, Mangilia, Nassaria, and Retusa.

THURSDAY, OCTOBER 21, 1909.

THE SPECIES QUESTION RE-OPENED.

The Making of Species. By Douglas Dewar and Frank Finn. Pp. xix+400; 15 illustrations. (London: John Lane, 1909.) Price 7s. 6d.

IF this work fails to bring about that revolution in biological science which its announcement led us to expect, it is not for lack of confidence on the part of the authors or their publisher. We were informed (by advertisement) that with the exception of a certain well-known treatise by de Vries this book was "the most important contribution to biological science which has appeared since Darwin's 'Origin of Species.'" We were further told that "the authors have no difficulty in demolishing some of the theories which are most cherished by biologists of to-day—notably those of mimicry and recognition markings in birds," and that "the facts which they have brought together undermine the whole of the massive superstructure which Neo-Darwinians have erected on the foundation of the theory of natural selection." A few extracts from the preface will suffice to reveal the tone which pervades this latest attack upon the theory of natural selection:—

"We fear that this book will come as a rude shock to many scientific men. . . . We are endeavouring to save biology in England from committing suicide, to save it from the hands of those into which it has fallen. . . . The Wallaceians (*sic*) continue on their course and give to the world a spurious Darwinism . . . we were both of opinion that biology is in an unhealthy condition, especially in England, and that the science sorely needs some fresh impetus."

After such a flourish of trumpets we naturally turn eagerly to the text for the "fresh impetus," but fail to find inspiration. There are many gibes aimed at and epithets attached to "Wallaceians" and "Neo-Darwinians," and there are some very remarkable perversions of the history of organic evolution. The authors set out, in fact, with an attempt to explain the reasons why the "Origin of Species" was accorded a "rapturous welcome . . . by the more progressive biologists," and how

"the man in the street was able to comprehend the theory of natural selection. This was greatly in its favour. Men are usually well disposed towards doctrines which they can readily understand."

Those who are familiar with the history of the publication of Darwin's great work and the difficulty which he experienced in making even the expert naturalists of his time fully grasp the principles of the selection theory will wonder from what source the authors have derived their information. As another example of historical perversion, attention may be directed to the statement (p. 198)

"that all the opposition to the theory of protective colouration comes from those who observe nature first hand, while the warmest supporters of the theory are cabinet naturalists and museum zoologists."

From this the reader will infer that the founders of that theory, Bates and Wallace, Trimen, Belt, Fritz Müller and Weismann, were not, in the judgment of the authors, observers of nature at first hand.

Within the limits of an ordinary review in these columns it is impossible to discuss in any detail the large body of evidence which the authors bring together in order to "demolish" those whom they dub "Neo-Darwinians," "Wallaceians," or even, when their scorn reaches its highest pitch, "Neo-Wallaceians." The general drift of the work is purely destructive, and its main object is apparently to disprove the all-sufficiency of natural selection. There is nothing very novel in this position, and by attributing to the followers of Darwin and Wallace a highly exaggerated and super-exalted doctrine, which no Darwinian has ever upheld, such refutation is naturally a very simple matter. The authors appear to imagine, for example, that somebody holds the belief that the theory of natural selection has been seriously held "to explain all the varied phenomena of nature" (p. 28). Of course, the very obvious and flagrant cases of adaptational colouring coming under the designations "protective resemblance" and "mimicry," which have generally been looked upon as reasonably explicable on Darwinian principles, come in for a large share of attention, and here is the verdict with respect to these theories:—

"We have examined these mighty images of gold, silver, and brass and iron, and found that there is much clay in the feet. We shall devote this chapter to lifting the hem of the garment of sanctity that envelops each of these images, and so expose to view the clay that lies concealed" (p. 172).

It must be left to the reader, whose flesh has been made to creep by this preliminary threat, to find out how far the authors have succeeded in damaging the evidence which has been accumulated by the joint labours of some of the most acute observers of nature ("at first hand"!) since Darwin gave us the key to the explanation of the phenomena in question, half a century ago. Prof. Poulton, as one of the most prominent of recent workers in this field, comes in for much castigation. The methods of demolition adopted by the authors have been made quite familiar by anti-Darwinians ever since the publication of Mivart's "Genesis of Species." Cases of convergent characters which are non-mimetic are marshalled against the selection theory of mimicry, the facts of mimicry are altogether denied or said to be much exaggerated, and cases of obvious adaptation, such as Kallima, are said (virtually) to be too good to be true, or, in other words, that the imitation is elaborated to an unnecessary extent.

It will naturally be asked whether this great array of objections and difficulties is a purely destructive attack, or whether it is a prelude to some great constructive generalisation. The reader who looks for new light will, we fear, be disappointed, judging from the following specimen of an "explanation" of the mimicry of butterflies by diurnal moths:—

"When two species adopt the same method of obtaining food, it not infrequently happens that a professional likeness springs up between them" (p. 250).

S

In so far as there is any positive declaration to be found in the volume the authors may be classified with the "mutationists." They are at great pains, in fact, to define their precise position as members of that school "of which Bateson, de Vries, Kellog, and T. H. Morgan appear to be adherents" (p. 26). They state further that, "like Darwin," they "welcome all factors which appear to be capable of effecting evolution" (p. 27). What these factors are beyond natural selection (to which they assign some value) it is not quite easy to gather from the present work. Isolation, correlation, variation, and heredity have been considered very seriously by all evolutionists from Darwin down to the present time, and it cannot be said that Messrs. Dewar and Finn have shed any new light on these subjects. They tell us (p. 387) that species are made by

"the inherent properties of protoplasm and the laws of variation and heredity. These determine the nature of the organism; natural selection and the like factors merely decide for each particular organism whether it shall survive and give rise to a species."

This will seem to the reader who is not a "mutationist" to be very like pure Darwinism with a dash of "inherent properties of protoplasm" thrown in. The introduction of "biological molecules," which are defined (pp. 157–9) as the units of which the germ cell is composed, may be considered as the substitution of a vague conception for the very definite mechanism which has been introduced into the theories of heredity associated with the names of Darwin, Herbert Spencer, Weismann, Mendel, and others. One example of the use of this conception will suffice to show its vagueness:—

"Thus the phenomena of 'mimicry' and 'reversion' are, we believe, due to the fact that in the fertilised egg of both the pattern and its copy a similar arrangement of biological molecules obtains. If we regard the sexual act as resembling in many respects a chemical synthesis, the phenomenon need not surprise us" (p. 293).

The reasons for associating mimicry with reversion and sexual reproduction are not very obvious, even from the authors' own point of view. Dealing with the first set of phenomena only, if the "explanation" means that in a mimic and its model the similarity of colour and pattern is due to an identity either of physical structure or chemical constitution, or of both, it is untrue in fact. If it means that the resemblance has arisen because the units (*i.e.* "biological molecules") of which the ovum is in each case composed give rise to a similarity of colour and pattern on development, this appears to be a mere paraphrase of the description of the facts and no explanation at all.

It is to be regretted that Messrs. Dewar and Finn have made this aggressive incursion into the domain of biological theory. They are favourably known as popular writers on Indian ornithology and other natural-history subjects. Although in the present volume none of the objections brought against natural selection are new in principle, it must be placed to the credit of the authors that, unlike so many of the earlier critics of Darwin's work, they are able to give a certain number of illustrations derived from personal observation and experience. But the work as a whole will not add to their reputation; with the majority of readers it will probably have the reverse effect. If the general object of the book is simply to emphasise the point that the theory given to science by Darwin and Wallace need not arrest further research in the domain of bionomics, there will be a very general unanimity among workers of all schools as to the soundness of their contention. But if the authors attribute any neglect, real or imaginary, of the study of bionomics to the direct influence of the teachings of Darwin and Wallace and their followers, they are inverting the truth. No greater stimulus was ever given to research in this domain than that given by the theory of natural selection. Any neglect with which English biologists can be charged is due to their ignoring and not to their acceptance of the teachings of the founders of that theory.

R. Meldola.

THE GEOGRAPHICAL DISTRIBUTION OF LEPIDOPTERA.

Die geographische Verbreitung der Schmetterlinge. By Dr. Arnold Pagenstecher. Pp ix+451. (Jena: G. Fischer, 1909.) Price 11 marks.

THE author of this work is one of the older German entomologists, who has been working for many years in the formation of a collection of Lepidoptera, and has published many valuable lists and monographs of the species found in various limited regions. He has now utilised his materials in a work which cannot fail to be interesting, not only to entomologists, but also to all naturalists who direct their attention to the numerous problems connected with the present geographical distribution of animals over the surface of the globe.

Dr. Pagenstecher remarks that the geographical distribution of Lepidoptera, like that of plants, is closely connected with certain physical and organic factors. The most important physical factors are (1) soil; (2) temperature and light; (3) moisture; (4) atmospheric conditions. The first portion of this work is therefore devoted to general observations on the geographical conditions of the continents, and the influence of mountains, desert or fruitful plains, the neighbourhood of rivers and seas, continental and oceanic islands, &c., on distribution. The influence of temperature, moisture, atmosphere, &c., is then briefly described; then vegetation, carnivorous habits, commensalism, &c. This is followed by sections on the distribution of Lepidoptera as affected by altitude, notes on migration, cosmopolitan species, and season-dimorphism and local variation. After this, the organic (physiological) factors of the subject are discussed, with special reference to former geological and climatic conditions, and some reference to fossil Lepidoptera. After some remarks on structure, and on the enemies of Lepidoptera, the section concludes with a summary of the Macro-lepidoptera of Central Europe (1626 species, according to Lampert), and a table of the species of Papilio found in the more important districts of the world.

The second section of the work is devoted to the regions and subregions of the world as defined by Wallace, Sclater, and others, with some reference to the views of other zoologists and botanists on the subject. After this, the various regions and districts of the world are discussed, first with regard to their climatic conditions, and secondly with reference to the species of Lepidoptera known to inhabit them, of which, in many instances, very full lists are given. This portion of the work contains an enormous amount of valuable detail, and much scattered information is brought together which it would be very difficult to utilise in its original form. This portion of the work is the most extensive, but cannot here be discussed in detail.

The concluding section deals with the geographical distribution of Lepidoptera under their families and genera, and this also is very completely set forth. The book is illustrated by two outline maps, one (facing p. 62) indicating the regions and subregions of the world, as mapped out by Wallace and Sclater, and the other (facing p. 217) representing the Malay Archipelago from the Nicobars and Malacca to the Philippines, New Guinea, and North Australia.

Dr. Pagenstecher has not indulged in much theorising, but his book forms a great quarry from which philosophical speculators will be able to extract a vast amount of material. It is not a book that either systematic lepidopterists or philosophical naturalists can afford to ignore, and they will have reason to be very grateful to the author for the conscientious care that he has devoted to this most laborious and useful book.

W. F. K.

AGRICULTURAL FERTILISERS.

Fertilisers and Manures. By A. D. Hall, F.R.S. Pp. xvi+384. (London: John Murray, 1909.) Price 5*s.* net.

MR. HALL has again succeeded in producing a work which will appeal with equal force to the practical and to the scientific agriculturist, and will do much to overcome that innate prejudice of the ordinary practical farmer against science by showing him the enormous influence science has had in determining a rational system of manuring, and in giving him the knowledge of a variety of substances of use to him in his business of food production, as well as in securing for him a safeguard against adulteration by unscrupulous traders. In the history and evolution of the practice of keeping up the crop-producing power of the soil Mr. Hall examines critically the various theories of manuring adduced from time to time, and the experiments upon which they are based, and the study of merely this part of the work will be of supreme importance to the practical man and to the student in showing how experiments may be misconstrued and conclusions of the most erroneous description drawn.

The recommendations as to the manuring of farm crops are tempered with sound advice, and the impossibility of prescribing more than a generally suitable method of manuring without a careful study of soil and climatic conditions extending over some years is well demonstrated. Mr. Hall gives some timely warnings as to deductions from field experiments, of which there has been such a plethora in recent years, with their unscientific methods both of carrying out and of deduction. The importance of taking into account the experimental error, which is estimated at ±10 per cent., and of neglecting results within these limits should be taken to heart by all who carry on these so-called "experiments."

The chapter on farmyard manure is eminently practical and useful, and recent work on such subjects as root excretions, effect of fertilisers on tilth, and on residual values of manures, brings the book well up to date. It is sought to distinguish between manures and fertilisers, the former designating more or less complete plant foods, the latter those materials which supply one element in the plant food, nitrogen, potash, or phosphoric acid. The perversion of the meaning of the word manure from its original significance, hand work, is no less curious than the use of the word tillage to mean artificial manures, which use still persists in the eastern Midlands. The part of the work relating to lime is worthy of serious attention from all agriculturists, as it is probable that the lack of carbonate of lime in a soil is more often than any other cause an explanation of the comparative infertility or absence of satisfactory results from manuring. A chapter on the valuation and purchase of fertilisers puts this important method of calculation simply and accurately, and a concise statement of the Fertilisers and Feeding Stuffs Act will be useful to all users of manures.

Mr. Hall's remarks on the soil-inoculation question supplement and strengthen the advice he gave in his work on the soil, and the experiments on the new nitrogenous fertilisers, cyanamide and nitrate of lime, show the values of these fertilisers in terms of their competitors, nitrate of soda and sulphate of ammonia. The Rothamsted experiments are, of course, freely drawn upon to provide data, and in the hands of the present director of that station these results are being endowed with fresh life and excellently practical applications. The tables of results are concise and well arranged, so that the reader is not faced with an immense array of figures and tables, and bewildered without being enlightened. To sum up, this is a sound and scientific book which should be in the hands of every practical agriculturist as well as in those of the student, the teacher, and the manufacturer.

M. J. R. D.

THE NATURE OF ATTENTION.

Attention. By Prof. W. B. Pillsbury. Pp. x+346. (London: Swan Sonnenschein and Co., Ltd., 1908.) Price 10*s.* 6*d.* net.

IN 1906 Prof. Pillsbury published a book on attention in the "Bibliothèque internationale de Psychologie expérimentale." This work, with substantial additions, now appears in English as the latest volume of Prof. Muirhead's Library of Philosophy. It may be welcomed as a useful member of the series, though it can hardly compare in importance with some of its brilliant predecessors.

Prof. Pillsbury, like his former teacher, Prof. Titchener, in a still more recent book, defines attention as "an increased clearness and prominence of some one idea, sensation, or object." His first thirteen chapters are devoted to the illustration of this description from general psychological processes; to an analysis of the part played by attention in the phenomena of perception and ideation, of memory, action, reason, emotion, and the self; and to a study of the conditions which determine the incidence of attention. With regard to the latter, he contends for a simplification of current classifications. The "forms" of attention generally recognised are distinguished either by the presence of elements (such as strain sensations) which are extraneous to the sensation-process or else by the nature of the objects to which attention is directed. There is really only one kind of attention, though the conditions of its emergence are two-fold. These are: objective conditions which consist in characteristics of the stimulus, such as its intensity, extent and duration; and subjective conditions, such as the momentary mood and past experiences of the individual. Finally, it must be noted that these conditions never or rarely appear in entire separation.

The later chapters are mainly given to theories of attention, grouped as physiological theories, theories that treat attention as a phase of mental activity, and theories that seek in some particular feature or accompaniment of the attention-process the cause of the predominant "clearness" of certain sensations and ideas. As a critic of preceding theories Prof. Pillsbury's best work is his interesting and useful treatment of apperception. His own theory is a physiological one, and assumes "localisation" of the activity of attention in the so-called anterior association centre of Flechsig. By a kind of "drainage," for which there is experimental evidence, the discharge through a given neuronic system may be heightened by the coexistence of less energetic discharges in connected systems, or depressed by a still more energetic discharge in such a system. The association centre provides lines of irradiation along which reinforcement and inhibition may in this way spread from one sensory centre to another. By such a concept Prof. Pillsbury believes that the determination of attention, both by strong stimuli and by past experience, can be explained in accordance with the postulate of psychophysical parallelism, and without the hypothesis of an unverifiable agent "that stands behind consciousness."

The book ends with a chapter on pedagogical applications. The author attacks the doctrine that makes "interest the measure of what shall be taught" to a child. He argues for the use of "social pressure," and the appeal to duty in education. "They are just as important as the conditions which we ordinarily call interest in governing attention, and it is quite as justifiable to make use of them in practice." This warning of a psychologist against making education "soft" is not untimely, although (owing to the lamentable ambiguity of the word "interest") he is condemning a theory of teaching which no responsible pedagogical writer—at least in this country—would dream of defending.

In addition to a good index the book contains a bibliography of the subject for which the student will be grateful.

TABLES FOR MATHEMATICIANS AND PHYSICISTS.

(1) *Five-figure Logarithmic and other Tables.* By Frank Castle. Pp. 58. (London: Macmillan and Co., Ltd., 1909.) Price 1s.

(2) *Taschenbuch für Mathematiker und Physiker.* 1 Jahrgang, 1909. By Felix Auerbach. Pp. xliv+450. (Leipzig: B. G. Teubner, 1909.) Price 6 marks.

(1) MR. CASTLE is well known as the author of a series of elementary text-books on mathematics. He now gives us a new set of five-figure mathematical tables. So many tables of this sort have appeared of late years that innovation in this field is rather difficult. Mr. Castle's tables are very similar in contents to Dale's five-figure tables, with the advanced functions cut out. One happy alteration is that, in the early part of the table of logarithms, mean differences are calculated for every five entries instead of for every ten. This renders possible the use of mean differences in all parts of the table without loss of accuracy. Another good point is a table of degrees and circular functions for equal intervals of radian measure; this should be most valuable for advanced work.

On the other hand, there seems a needless amount of repetition in printing. Thus the table of sines is printed separate from the table of cosines, although the one table is merely the other read backwards. The same holds of tangents and cotangents, secants and cosecants. It may be argued that this makes the tables easier to handle for readers with little theoretical knowledge, but it seems doubtful whether it will not encourage rather than check the common fault of *adding*, instead of *subtracting*, differences for the cosine, cotangent, and cosecant.

A more serious defect is the omission, from the table of cube roots, of the cube roots of numbers from 100 to 1000. This means that the present tables cannot be used to find rapidly the cube root of, say, 0·3.

(2) A pocket-book of reference for mathematicians and physicists will strike most mathematical readers, at all events in this country, as a novelty. Such a pocket-book was recently brought out in Germany by Dr. Felix Auerbach, working in collaboration with Drs. Knopf, Liebmann, and Wölffing. Facing the title-page is a portrait of Lord Kelvin, and the volume opens with a notice of his life and work.

It is intended that this shall be an annual publication. For this reason, Dr. Auerbach tells us in his preface, many matters have been only lightly touched upon, or even omitted altogether, in the hope that further details concerning them may be included in a later issue.

As it is, the initiated reader must be amazed at the amount of useful information which has been compressed into 450 small octavo pages. In every branch and sub-branch of mathematics all the fundamental definitions, theorems, and formulæ have been given, sufficient explanation being added to make the whole intelligible to the average mathematician. A similar plan has been adopted for the physical and astronomical parts, numerous tables of constants being given, as well as descriptions of apparatus. At the end of the book is a useful list of mathematical and physical books and periodicals.

We have noticed a few errata, *e.g.* p. 44, the first theorem of the mean is incorrectly stated, and p. 46, $\int_0^\infty \frac{\sin bx}{x} dx$ is equal to $\pi/2$ only if $b>0$. These, however, are slight blemishes, inevitable in a first issue. In conclusion, we wish the "Taschenbuch" all the success it undoubtedly deserves.

OUR BOOK SHELF.

An Introduction to the Science of Radio-activity. By C. W. Raffety. Pp. xii+208. (London: Longmans, Green and Co., 1909.) Price 4s. 6d. net.

THE aim of this book is to present a concise and popular account of the properties of the radio-active elements and of the theoretical conceptions which are involved in the study of radio-active phenomena. With this object in view, the treatment throughout is purely descriptive, and no attempt is made to develop the mathematical side of the subject. Nevertheless, the author has succeeded in describing and discussing most clearly the various phenomena of radio-activity.

The book is divided into three parts. The first part is descriptive, and, after a general note on the radio-active elements, is devoted to the consideration of the nature of the various radiations emitted by radio-active bodies. The characteristics of the α, β, and γ radiations are carefully explained.

In the second part of the book the author deals with the subject of radio-active transformations, and describes in detail the various disintegration products produced from thorium, uranium, and radium. Chapter iv. in this section contains an account of the theory of atomic structure from the electron point of view. The evidence drawn from various phenomena shows large variations in the number of electrons associated in the atom. The author gives the numbers calculated from experiments on kathode rays. The third part of the book is devoted to kathode, canal, and X-rays, and gives experimental details which should enable an amateur to carry out successfully a number of experiments with a small amount of apparatus. A feature of the book is the appendix, in which the author has collected and tabulated the physical constants of the α, β, and γ rays, the products of decay of the radio-active elements, with their rates of decay, and the absorption coefficients of the radiations emitted by the radio-active bodies.

Altogether the book can be heartily recommended to mathematical, as well as non-mathematical, readers who desire an acquaintance with the subject of radio-activity.

British Mountain Climbs. By George D. Abraham. Pp. xvi+448. (London: Mills and Boon, Ltd., 1909.) Price 7s. 6d. net.

MR. ABRAHAM here provides the lover of British mountaineering with a conveniently small and concise guide to the British rock-climbs. The climbs are grouped around the most convenient centres, and detailed instructions as to how to perform the various expeditions safely are given. The book is provided with eighteen illustrations and twenty-one outline drawings, showing the principal routes. It is written in a bright, interesting style, and is sure to become a favourite among mountaineers who are willing to learn from it the beauties and difficulties of climbing at home.

The Pond and other Stories. By Carl Ewald. Translated from the Danish by Alexander Teixeira de Mattos. Pp. 320. (London: Everett and Co., 1909.) Price 6s. net.

THIS series of eleven stories deals with animal and plant life in a way dear to children. The birds and beasts talk to one another, and incidentally supply the reader with many familiar facts of nature-study. Each story is provided with a good illustration, and the easy colloquial English of the translator will be understood by the young children for whom the book is evidently intended.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Magnetic Storms.

DR. CHREE contends that magnetic observations have now reached a high pitch of perfection, and that their discussion is not lightly to be undertaken by outsiders. That is no doubt so, and there must be many features about magnetic storms which are known only to experts. But when we find experts in doubt on such a fundamental matter as whether the cause of those storms is to be found in the sun or in the earth, it appears to be worth while to emphasise some comparatively simple and fundamental considerations which may possibly have become rather covered up by a mass of information.

The simple points that I venture to emphasise, with all due deference to specialists, are:—

(1) That by reason of the high temperature and convulsions of the sun it is almost bound to emit electric projectiles.

(2) That when the visible sign of a solar eruption is aimed at the earth, magnetic storms are often felt, while they are not so frequently experienced from eruptions the emissions of which may be reasonably supposed likely to miss the earth.

(3) That, taking into account the varying aspect of places on the earth to a solar beam, such a stream of particles is well qualified to produce changes in all the magnetic elements during the course of a day—even though deflection by magnetic lines, and the effect of currents induced in the conducting layer of the upper atmosphere, were ignored. (I do not say that the details of a storm fit so greatly simplified a theory.)

(4) That a great beam of this kind is not likely to be uniform, but may be supposed to contain rays of special intensity, the passage of which will cause well-marked and rapid reversals, such as are observed.

(Of course, I never thought that the recent storm was over in fifteen minutes; it was common knowledge that it lasted for hours. I must have expressed myself badly if I conveyed such an idea.)

(5) That detection, in storm-recurrence, of any periodicity which corresponds at all closely with the period of the sun's relative axial rotation—such as is maintained by Mr. Maunder and apparently *half* admitted by Dr. Schuster—would surely be conclusive as to something solar in origin.

(6) And, especially, that simple calculations from known laboratory data show that the magnitude of the effect observed is not unreasonably great to attribute to local solar radio-active emissions.

Hesitation as to the truth of this last proposition was, I understand, Dr. Chree's basis for his most anxious doubts; and the object of my letter was to try to remove at least this form of doubt from the minds of astronomers and responsible magneticians.

One more quite minor point I may take the opportunity of mentioning, though it is connected rather with a letter of Dr. Chree's in the *Times* than with his letter in NATURE.

(7) Disturbance of terrestrial rainfall—say an increase for a short period due to influx of cosmic nuclei—need not be supposed to modify the usual local *distribution* of rain, but only to increase its amount in the customary localities.

This I only venture to say very tentatively, and with no dogmatism at all. It is clear that the total rainfall all over the earth during a long period cannot exceed what the sun can evaporate in approximately the same period, and therefore depends more on the sun's total activity than on anything else. It is also clear that rain is a local circumstance, and that the conditions which determine whereabouts rain shall fall are mainly local. But I question whether either of these propositions really negatives the idea that cosmic causes may occasionally affect the rainfall during any given month, even in a specified locality.

OLIVER LODGE.

Why has the Moon no Atmosphere?

PROCTOR ("The Moon," p. 334) says:—"It has been held, and not without some degree of evidence in favour of the theory, that in our Moon we have a picture of our Earth, as she will be at some far distant date . . . when her oceans and atmosphere have disappeared through the action of the same circumstances (whatever they may be) which have caused the Moon to be airless and oceanless."

The following considerations suggest what the circumstances referred to may have been, and present what seems a possible cause for the absence of an atmosphere.

(1) Apart from all theory, we know that the sun exerts a repulsive force on matter around him. The phenomena of comets' tails show this as clearly as the streamers from a flagstaff show that a wind is blowing. Kepler first suggested the existence of this force. Sir John Herchel, in his essay on comets, said, more than forty years ago, that "they have furnished us with a proof, amounting to demonstration, of the existence of a repulsive force directed . . . *from* the Sun."

(2) Maxwell in 1873 deduced from his electromagnetic theory the pressure of light, which Arrhenius in 1900 applied to explain the formation of comets' tails. Each particle projected from the comet, under the influence of the sun's heat when nearing the sun, being submitted to two opposing forces, viz. gravitation and the pressure of light, he pointed out that since the pressure varied as the surface, while the weight varied as the volume, *i.e.* one compared with the other, varied as the square of a number compared with its cube, then, when the particles were small enough, the repulsive force of the pressure might be many times as great as the force of attraction, and drive away the particles with great velocity.

As a common example of such action, I may remark that we have the case of a wind blowing on a newly macadamised road or on a single stone on the road. While the stones are unbroken the wind cannot move them, but when they are crumbled to powder it sweeps them away in clouds.

(3) In this way the sun exercises a sort of sifting process in space, sweeping away very small particles and drawing the larger ones towards him.

(4) Assuming that the moon had an atmosphere for many ages, the particles would be acted on by the repulsive force of the sun radiating from its centre, and by gravity directed to the centre of gravity of the moon. During the time that the moon retained its atmosphere it is evident that gravity must have been the preponderating force. The atoms, as Dalton called them, were not small enough to allow the pressure of light to prevail over the weight.

(5) But the atmosphere has disappeared, and we have to account for this fact. Can the particles have been in any way reduced in size?

If we are sure that the chemical atoms, as Dalton called them, despite the protests of such men as Davy, Wollaston and Berzelius, cannot be decomposed or disintegrated, then an hypothesis to the contrary must be rejected.

(6) But the recent discoveries in radio-activity are opposed to this. It has been shown that the radio-active elements are disintegrating slowly and gradually from their own internal energy. The process has been going on for indefinite time, although only lately discovered accidentally because of certain radiations. Have we reason to believe that it is limited to these elements? Prof. Rutherford has pointed out that the existence of rayless changes in these elements "indicates the possibility that undetected changes of a similar character may be taking place in the non-radio-active elements" ("Radio-activity," p. 455, 2nd edition). If we suppose that such changes took place at the outer surface of the moon's atmosphere, resulting in particles sufficiently small, then part after part of the atmosphere may have been stripped away until the present condition has been reached.

(7) The same process may be going on now with the earth's atmosphere, notwithstanding the greater force of gravity.

Briefly, if the atmosphere of the moon was ever driven away—the repulsive force of the sun (pressure of light) is the only driving force we know of—the component particles must have been originally too heavy to be driven off, and were therefore in some way reducible; the transformations in the radio-active elements suggest a possible process.

Thus the present condition of the moon is an argument for the disintegration of some of the non-radio-active elements, and the argument is the stronger in proportion to the difficulty of finding a solution otherwise to this old astronomical problem.

ALEXANDER JOHNSON.

Montreal, Canada, September 30.

A "Canaan Stone."

CAPTAIN B——, of the Brixham (Devon) trawler fleet, recently showed me what he termed a "Canaan stone." He told me that in the hands of his wife's mother it had effected many miraculous cures of diseases of the eye, and that by its use she had been especially successful in curing cataract. The stone was a polished sphere of agate, translucent, and of a faintly greenish-yellow tint, containing several red-brown patches due to the presence of iron. It was about ¾-inch in diameter, and had been drilled through the centre, as though it had at one time formed part of a necklace. The treatment simply consisted in "striking" (*i.e.* gently rubbing) the eye with the stone. No prayers or incantations were used, but it was essential that different parts of the stone should be used in different diseases, and the part used also varied with the colour of the patient's eyes. The stone was rubbed actually on the conjunctiva, not on the lids. The secret of the exact method of treatment died with the old lady, who is reported to have had quite an extensive ophthalmic practice, and I was appealed to in order that I might explain the secret to the present owners of the stone. Beyond the fact that the stone had been bought by its late owner from a man in Cornwall for 40*l.*, no history was available.

The following extract from the Book of Tobit suggested itself to me as a possible explanation of the origin of the belief in the curative value of the stone:—

"When Tobias and Raphael came to the river Tigris, a fish leaped out of the water and would have devoured him, but the young man laid hold of it and drew it to land. The Angel bade Tobias open the fish, and take the heart, and the liver, and the gall, and put them up safely. . . . And the Angel said . . . As for the gall: it is good to anoint a man that a whiteness in his eyes shall be healed. . . . Tobias met his father at the door, and strake of the gall on his father's eyes . . . and Tobit recovered his sight."

It does not require a great stretch of the imagination to see a resemblance between this translucent, greenish-yellow stone, with its red-brown patches, and the distended gall-bladder of a fish, excised with small portions of liver adherent to its surface. The expression "to strike," for to anoint or rub, is still quite common in Devon. In the country districts a usual treatment for sprains or abrasions is to "strike them with fasting spittle," *i.e.* to apply saliva when rising in the morning, before any food has been taken. G. Harold Drew.

Marine Biological Laboratory, Plymouth.

Orthite in North Wales.

In March, 1908, an unfamiliar mineral was discovered by Mr. W. G. Fearnsides in a narrow vein which traverses the intrusive granophyric mass of Tan-y-grisiau, near Ffestiniog, and was submitted to me for identification.

It has proved to be the somewhat rare silicate *orthite*, and its occurrence will be of considerable interest to mineralogists both on account of the amount of material available and for the large size of the crystals, which range up to $1\frac{1}{2}$ inches in greatest dimension.

Hitherto orthite, which contains a number of the rarer elements, such as cerium, lanthanum, didymium, yttrium, &c., has not been found in any quantity in Britain, and then only as microscopic crystals and grains. The crystals from Tan-y-grisiau are well-formed, black to dark grey, submetallic tables with bright faces; they are conspicuously tabular, parallel to the form T{100}, and are modified by narrow prism and dome faces.

It is the "unknown and very interesting mineral" to which the attention of those members of the Geologists' Association who took part in the long excursion to North Wales this year was directed.

The exact locality is the north-west face of a quarry at Cefn-bychan, south of Tan-y-grisiau, Blaenau-Ffestiniog, belonging to the Ffestiniog Granite Quarries Co., Ltd.

The physical properties of the orthite are undergoing investigation, the results of which will be published at a later date. Herbert H. Thomas.

Geological Survey and Museum, Jermyn Street, S.W.

Drought in South-west Ireland.

Whilst all round us have been reports of wintry weather and unceasing rain during the summer months, we in this small south-westerly area of Ireland have been passing through a period of abnormal drought, in fact a record season, accompanied by high temperature throughout.

I have recorded the annual rainfall here (Bandon) for some years, but I have never had anything approaching a similar experience, and the oldest inhabitant here cannot recall so continued an absence of rain as we have felt this season, that too in a country where the rainfall is generally excessive. I am bound to say, however, that the elements are *now* distinctly making up for lost time, as though in revenge for letting us off so easily before.

I give you the rain-gauge readings for the months June, July, August, and September, which speak for themselves, and may perhaps prove of some interest to your readers.

The readings were taken with a 5-inch Negretti and Zambra gauge, and registered daily:—

June.—Total for month, 1·08 inches. Twenty-five days absolute drought. Highest reading=0·47 inch, on June 24.

July.—Total for month, 1·02 inches. Twenty-three days absolute drought. Highest reading=0·34 inch, on July 10.

August.—Total for month, 0·54 inch. Twenty-five days absolute drought. Highest reading=0·32 inch, on August 1.

September.—Total for month, 0·41 inch. Eighteen days absolute drought. Highest reading=0·08 inch, on September 28. Geo. A. Armstrong.

Ardnacarrig, Bandon, Co. Cork, October 13.

The Meteor in Sunshine, October 6.

The great daylight meteor of October 6 was observed by many persons in various parts of the country. The particulars to hand are not, however, very definite, and it is scarcely possible to compute the real path of the object. From a comparison of about fifteen descriptions, there seems little doubt that the meteor moved in a direction from south to north over Reading, Thame, and on to a termination near Market Harborough.

The radiant point was in Leo, and it is hoped that more observations of an exact character will be supplied. The sky was clear over a large extent of England, and hundreds of persons saw the meteor, though only a small proportion of that number have reported their observations.

The great daylight meteor of 1900 January 9 was directed from Aquila, that of 1894 February 8 emanated from Hercules. It is seldom that meteors appearing at such times can be suitably observed, as the sky does not afford any reference objects such as is furnished by the stars at night. W. F. Denning.

An Aurora Display on October 18.

I witnessed last night one of the finest displays of the aurora borealis which it has been my good fortune to see in this country. It happened at about 9 p.m., and I was at the time upon one of the highest summits of the Cotteswold Hills, close upon 1000 feet above the sea-level, so that I had an uninterrupted view of the magnificent spectacle. The first I saw of it was several streamers and an indistinct band low down on the northern horizon, with a detached red, cloud-like portion almost due west. These resolved themselves eventually into two bands, the uppermost stretching right across the sky from north-west to north-east, and during the maximum phase of the phenomenon was a truly grand spectacle, with numerous streamers connecting the two bands. The uppermost band finally faded away, leaving the lowermost one still visible but very indistinct, with two or three faint streamers shooting upwards.

I take this opportunity of inquiring what is the most austral or equatorial limit from whence the aurora borealis is visible, or rather has ever been observed? This subject is of particular interest to me from the circumstance that when I was at Darjeeling some years ago I was informed that the phenomenon had been seen from thence, although this well-known hill station is so far south as 27° north latitude. Although it is not impossible for it to be seen from the altitude of Darjeeling (which is 7500 feet above the sea-level), for far away are seen the tops of the Himalayas, I feel convinced that what has been seen from thence, and mistaken for the aurora, is nothing more than the afterglow or reflection from the snow-fields and glaciers upon exceedingly thin masses of aqueous vapour, or rather spicules of snow, floating upwards to 1000 feet or more above the summits of the highest Himalayan peaks. This latter phenomenon I frequently witnessed after sunset, and it certainly possessed the appearance, upon many occasions, of the aurora, hence the mistake, possibly, of unscientific observers. W. Harcourt-Bath.

October 19.

Jupiter's South Tropical Dark Area.

All the transit estimates, numbering fifty-two, of the south tropical dark area on Jupiter, obtained during the apparition of 1908–9, have been reduced to longitude. The area in 1908 December was found to be more than 50° in length at the south equatorial belt. From this date to the close of the observations in 1909 June its dimensions exhibited a gradual increase, and in the latter month it covered considerably more than 90° of longitude. This longitudinal growth was due chiefly to a marked difference in the observed rate of velocity of the two ends of the area. While the preceding end drifted at a pretty normal rate of 15° per month in excess of the adopted zero meridian of System II., the following end exhibited a monthly drift of only 9°. The following part of the area, therefore, was not keeping pace with the preceding portion, and accordingly the object itself became distended in longitude.

The mean rotation period of each end, as well as the middle, of the area would seem to have been as under:—

Number of observations	Number of rotations	Mean daily drift (°)	Mean rotation period h. m. s.
20	430	−0·4823	9 55 20·8
16	295	−0·3754	9 55 25·3
16	379	−0·2989	9 55 28·3

The above period for the following end is the longest that has been recorded, either for this or any other part of the area, the existence of which became known in 1901 February.

Leeds, October 15. Scriven Bolton.

FURTHER EXPERIMENTS WITH THE GRAMOPHONE.

In NATURE of April 15 I described a number of experiments with the gramophone. Since then I have continued to work on this interesting subject, and have at last succeeded in transcribing the vibrations of tones or chords as these are produced by the gramophone; that is to say, during the time that the sounds are given forth. The method is illustrated in the figure accompanying this paper (Fig. 1), and I also give several illustrations of the tracing so obtained. The sounds of the gramophone are carried by a tin tube from the end of the arm of the instrument to which the horn or trumpet-resonator is attached, to a physiologists; but, taking a hint from the use of elasticity in the construction of the reproducer of the gramophone and improved phonograph, I arranged thin india-rubber bands so as to hold the keeper of the tiny electromagnet about one or two millimetres from the small soft iron cores, and so placed that the keeper was kept in equilibrium between two forces, at the distance I have mentioned. I found that with this arrangement, when the gramophone was played, the electromagnetic recorder gave forth the tune with perfect accuracy, and when one touched the keeper it could be felt thrilling on the finger.

The electromagnetic recorder acted like a little telephone. After many contrivances, I found the best method was to place the recorder on the well-known

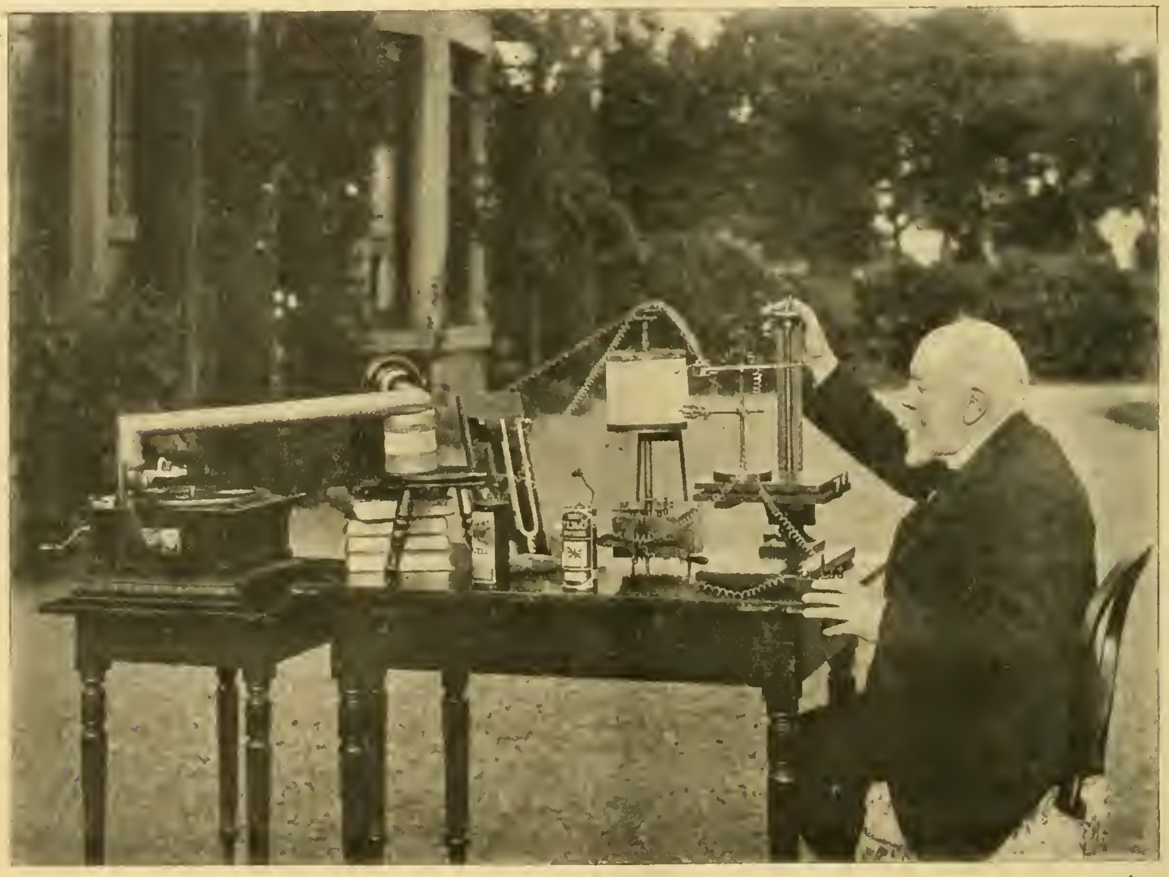

FIG. 1.—Arrangement of apparatus. Gramophone to the left. Observe the tin tube carrying the sound waves to the microphone. The operator is on the right controlling the movable stage. The upper electromagnetic marker adjusted to the cylinder (revolving drum) registers the vibrations of the 1/100th per second tuning fork seen in the middle of the table. The lower electromagnetic marker writes the vibrations of the sound waves as these act on the microphone. While it is registering the lower marker gives forth the sounds played by the gramophone.

sensitive microphone. The microphone used was made by Herr Müller-Uri, of Brunswick, and was intended to be used in the experiment of the singing-arc flame and also for a loud-speaking telephone. In the circuit of the microphone I have five or six dry cells giving a current of about five volts. In the same circuit is the recorder, which is a very small electromagnet having a marker attached to the keeper.

In early experiments I used a large electromagnet acting on a spring that carried a marker, but such an arrangement only recorded notes or chords, as regards intensity, but without showing the constituent vibrations. It was not quick enough. Accordingly I adopted a small electromagnetic arrangement, like a "Deprez-signal," known to Cambridge platform-stand, which can be moved up or down by a finely cut strong screw (see Fig. 1). On the platform I placed a device of my own, by which I could adjust the marker on the smoked paper with great nicety. On the same platform, as shown in the illustration, I placed an electromagnetic recorder controlled by a 100 vib. tuning fork, so as to register on the tracing 1/100ths of a second. The drum used was an old-fashioned Hawksley drum, well known to physiologists, and it rotated at a speed that gave 12 inches per second. The paper was smoked in the usual way over a camphor flame, and, after the tracing was taken, it was fixed by clear shellac varnish. The tracings shown are from slightly enlarged photographs of a portion of each tracing, and the length of each line, from side to side, represents in time 0·3 second. Short descriptions of the tracings are printed below the figures.

The experiment was performed thus:—After carefully adusting the markers on the smoked paper, the cylinder was allowed to rotate until it reached its maximum uniform speed. By closing a key, a time record was taken. Then the gramophone was started; the sound waves acted on the microphone, and the little electromagnetic marker began to sing or play; finally, by having my right hand at the top of the screw, as shown in the figure, I was able slowly to raise the platform, carrying the recorder, so as to describe a long spiral line, about 135 feet in length, from the bottom to the top of the cylinder. On reaching the top, the experiment came to an end. To secure good results, great care had to be taken to secure nicety of adjustment. It must be explained that in the tracings so taken the recorder traverses 12 inches per second. The waves in my tracings are thus compressed laterally. To obtain waves at the speed of the gramophone, I had a wooden cylinder made which was attached to the circular plate of another gramophone, and having a circumference such that the recorder traversed from 21 to 24 inches per second. The two gramophones, one to play, the other to carry the wooden drum, were driven at the same speed. Tracings were thus obtained similar to the indentations or waves on the gramophone record. Trouble arose, however, from the oscillations of the gramophone plate (one of the conditions of the success of the gramophone, in which all the arrangements are more or less mobile), but this difficulty was easily surmounted. Finally, I found that with my arrangement it was not necessary to use the gramophone, as it was easy to record the vibrations of a human voice by causing the singer or speaker to sing or speak direct to the microphone. The arrangement is an excellent phonautograph. About five minutes are occupied in taking a tracing, the average length of which is 135 feet.

An inspection of these tracings shows the wonderful variety of pressures pouring in upon the ear as we listen to music. Three or four or more notes differ-

Fig. 2.—Small portion of tracing of the Westminster chimes. The tracing begins at the left-hand corner at the bottom, runs along the line to the right, then is continued in the next line above, again at the lower left-hand corner, and so on. The length of time represented by the length of one line from left to right is about one-third of a second. The tracings of the 1/100th of a second are seen at the top. The tracing is from the portion of the record giving the strokes of twelve o'clock. Near the top little groups of waves indicate the beats, &c., after the last stroke.

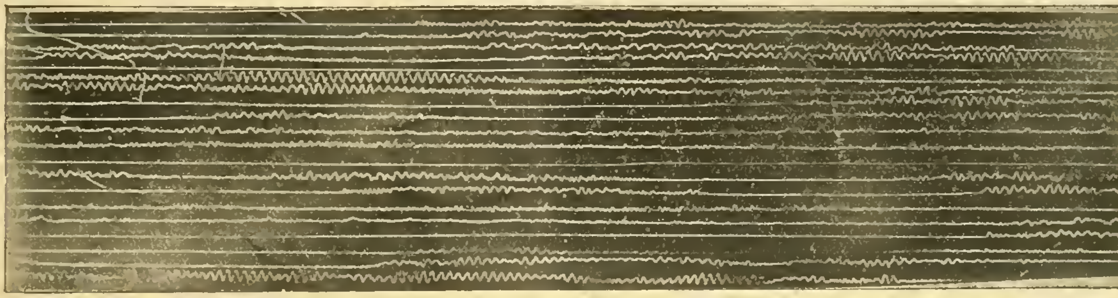

Fig. 3.—Small portion of tracing of a number of male voices singing the "Soldiers' Chorus" from *Faust*. From the La Scala Theatre, Milan. The time relations, &c., are the same as in Fig. 2. Observe the complicated form of the curves.

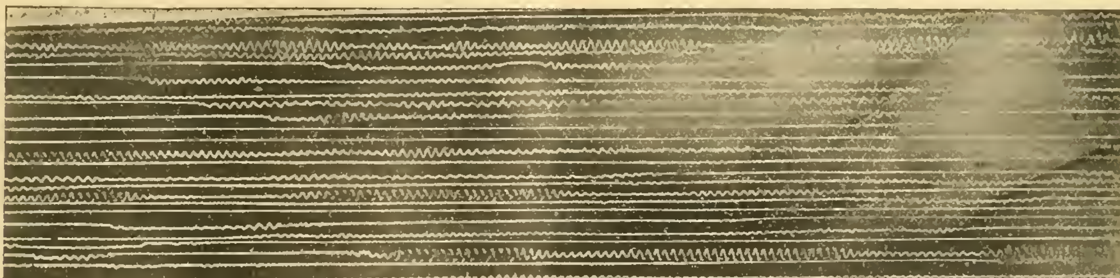

Fig. 4.—Small portion of a tracing giving the vibrations of the voice of Signor Caruso in singing "Spirito Gentile." Time relations, &c., same as in Fig. 2. Observe the crescendo and diminuendo of certain notes, the high pitch of others, and the regularity in form of the waves.

ing in pitch may affect the ear in a second of time. From ten to twenty vibrations, falling on the ear at a certain rate, are sufficient to arouse the sense of pitch of a tone of that frequency. It would seem that with notes of low pitch, within limits, fewer vibrations are required to enable the ear to appreciate pitch, and the opposite holds good with notes of high pitch. This corresponds with the fact that differences of pitch are difficult to detect both in the upper and the lower limits of the scale of audibility, whereas a skilled ear in the middle ranges of the scale can appreciate a difference of one sixty-fourth of a semitone. The tracings also indicate approximately the pitch of any note registered. Suppose three small waves correspond to the wave of the one-hundredth of a second, then the pitch of the note will be about three hundred per second, or (taking the middle *c* at 256) a little below *f*. The highest pitch I have mentioned is g'', or more than 1500 vibs. per second, in the "Bell Song," Lakmé (Delebes), by Madame Tetrazzini. I have also observed that the tracings show intervals in which there is a straight line, with no vibrations. If those intervals are very short, then the interval may not be appreciated by the ear, even with the most careful attention. In all the tracings the wave form is compound, not only owing to the existence of overtones, but also because the voice is usually accompanied by an instrument, the piano, or an orchestra. I took one tracing of voice-tones (a bass voice) with no accompaniment.

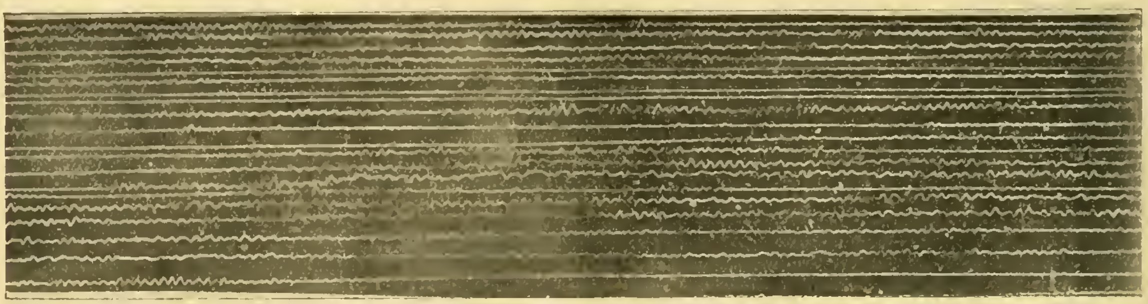

FIG. 5.—Small portion of a tracing from the record of the overture to *Tannhäuser* played by the band of the Coldstream Guards. Time relations, &c., as in Fig. 2. Observe the variations in pitch as indicated by the number of waves in a short period, and the irregularity in form of the waves.

The most complex waves are those produced by the blending of many voices or by an orchestra (see Figs. 3 and 5). Here again there arises a curious consideration. Suppose that in an orchestral piece all the instruments do not *attack* at the same instant, or if one lingers after the rest the fraction of a second, in both cases the wave form and the tracing picture in general will be affected. If the want of coincidence passes beyond a limit, which it is difficult to define, a musical ear finds the result defective, although one can scarcely tell why. Nothing has excited more in my mind a feeling of wonder at the powers of the ear than the inspection of these tracings. Is there a damping mechanism, or is a damping mechanism necessary? May it not be, after all, that our perceptions of musical tones, as in a musical composition, are the result of different *modes* of stimulating the ends of the cochlear nerves? May not innumerable varieties of pressures act on the nerve-endings, possibly as a whole, and send corresponding impulses to the brain? I confess that in the face of these tracings I find it more difficult to realise an analysis in the cochlea; but if not there, where does it take place? That there is an analysis when we make an effort of attention there can be no doubt.[1]

JOHN G. MCKENDRICK.

[1] I have to thank Prof. Noël Paton, of Glasgow, and Prof. MacWilliam, of Aberdeen, for the loan of some portions of the apparatus.

PEAT IN NORTH AMERICA.

FOR many years peat was looked on as a source of fuel in poor countries only, where communications were undeveloped, and where cottagers extracted it by their personal labour for use in their own household fires. To this day, the economist will probably find that this is the best and most practical treatment of a peat-bog. It becomes idle in such cases to speak of relative calorific values, and to point out that, even under present conditions of transport, coal would form a more effective fuel. Where the right of digging peat over a certain area is included in the rent of a small holding, this peat is dug at odd but suitable times, when the crofter or his family might otherwise have remained idle. The cost of labour thus becomes insignificant, especially where creels are used for transport; and even the horse or ass must be fed, whether or no he is engaged in drawing the red cart along the ridges between cutaway boglands, or down the grooved hillside from the high-level deposit on the plateau.

But from time to time capitalists have turned longing eyes towards these stores of carbonaceous matter, and have sought to get rid of the 80 or 90 per cent. of water in the peat, and to produce a fuel economically capable of transport. Others have proposed to produce gas at the bog itself; while others, often with marked success, have manufactured moss-litter for use as an absorbent bedding for city stables and dairy barns.

The various uses of peat have now attracted attention even on the North American continent. Messrs. E. S. Bastin and C. A. Davis have provided an introductory manual on the subject in their description of "The Peat Deposits of Maine" (Bulletin No. 376 of the United States Geological Survey, 1909, pp. 128). They acknowledge that they have been preceded by Mr. Erik Nyström's treatise on "Peat and Lignite: their Manufacture in Europe," issued a year previously by the Canadian Department of Mines. Messrs. Nyström and Anrep have now also published the results of their "Investigation of the Peat Bogs and Peat Industry of Canada, during the Season 1908–9" (Bulletin No. 1, Department of Mines, Canada, 1909, pp. 25).

The deposits in Maine are at present so little utilised that Messrs. Bastin and Davis direct attention to the various ways in which peat has become profitable elsewhere, and, we must admit, to the various ways in which it has been worked without profit to anyone except the makers of machinery. The buildings and heaps of scrap-iron lying derelict beside the bogs of Europe have not yet served to warn those who are fascinated by some fancy process, put before them under seductive influences in the glamour of a well-lit exhibition. The authors of the United States bulletin have no false enthusiasms, and they lay proper stress on the really practical results obtained in the manufacture of peat-coke, power-gas, and moss-litter. They point out the agricultural capabilities of decomposed black peat soils in Maine (p. 57), and the use of dried peat as an auxiliary fertiliser in composts with barnyard manure, and they especially urge the introduction of air-dried peat as an absorbent in stables and as a deodoriser. Descriptions of special bogs follow, accompanied by neat maps in the text. These bogs have been tested with an ordinary ship-auger (p. 60), fixed on 21 feet of ½-inch gas-pipe, and an improved form is described, by which, as in many soil-testers, samples can be still more safely collected at any particular depth. The bogs in Maine appear rarely to be 30 feet deep. As is customary in publications of the United States Geological Survey, sufficient explanations are given of technical terms to enable any intelligent citizen to utilise this handy and scientific treatise.

In the case of the Canadian Survey, general principles have been dealt with in the earlier memoir to which we have referred, and the present bulletin describes in considerable detail certain bogs which possess commercial possibilities, and which lie not far from Ottawa. Lines were run across the bogs, usually 1000 feet apart, and drillings were made in each of these lines at intervals of 500 feet. The samples thus collected were often put together in groups, as representing, when combined, certain areas of the bog; but special local features of interest were noted wherever necessary. An ingenious system of lettering on the maps shows the character of the peat at each point, and its relative suitability for moss-litter or for fuel. The Canadian mode of gathering is by breaking up the surface of the bog so as to promote air-drying, and then stripping off this surface-layer. The bog is thus in most cases worked horizontally, and not vertically, as in Europe. The large scale of the maps inserted in the bulletin, and the completeness of the descriptions, remind one of the fine old bog-survey of Ireland published some eighty years ago, which still remains a standard work of reference. The peat industries of Canada, like those of the United States, are still mostly in an experimental stage, and little more can be said of those organised from time to time in Ireland. Meanwhile, in Europe, at any rate, the humble tiller of the soil, with his old-fashioned hand labour, continues quietly to remove the peat, in which he possesses a clean and economic fuel.

G. A. J. C.

AN ANTHROPOLOGICAL SURVEY OF THE SUDAN.

THAT the study of anthropology is of great scientific and practical importance has been acknowledged of late years by various Governments within the Empire. Our readers will remember that the Indian Government assisted Mr. A. R. Brown in his investigation of the Andamanese, and the Ceylon Government two years ago invited Dr. C. G. Seligmann to study the Veddas. The Anglo-Egyptian Administration, as is well known, fully recognises the far-reaching interest which attaches to the natural and human history of Egypt and the Sudan, and directly and indirectly it has done a great deal to extend our knowledge of the meteorology, geology, geography, zoology, botany, and archæology of these regions. In continuance of that enlightened policy, arrangements have been made to organise an ethnographical survey of the Sudan. Those in authority realise that it is impossible to educate or govern a people without some knowledge of their psychology, and no mere facility with their language will suffice without a knowledge of native customs, ceremonies, ideas, and ideals. Especially is it necessary to record the unwritten laws and usages which regulate private and public life and to appreciate the safeguards for personal and social morality which occur in every community. The native conceptions of the relation of the individual to his fellow and of the authority of the head of the local state are very different from those of Europeans, and it would be disastrous suddenly to break up the structure of native society, to weaken authority, or to promulgate revolutionary ideas. It is also recognised by the Sudan Government that failure in the past has been due to lack of scientific knowledge, and they seek to avoid mistakes in the future by acquiring that knowledge upon which a firm and just administration alone can rest.

In the spring of last year the Sudan Government stated that they were prepared to contribute a sum of money sufficient to enable anthropological investigations to be undertaken in the Sudan for at least two years (a part of this sum is set aside for the publication of the results), and Dr. and Mrs. Seligmann were appointed to conduct these investigations. At that time the Seligmanns were still in Ceylon, and as it would take them several months to work up their field-notes, the Sudan expedition was postponed till this year. The Seligmanns leave England on November 2nd, and will proceed with as little delay as possible to investigate the Dinkas and Shilluks in the Upper Nile Province. Probably they will also study the pagan Nubas of Southern Kordofan, and possibly some other tribes as well.

Those who are conversant with recent anthropological literature are fully aware of the competence of Dr. Seligmann to undertake this work. It is significant of the times that Mrs. Seligmann is officially recognised as a co-investigator with her husband. Judging from what Mrs. Seligmann did in Ceylon, there is no doubt that this enlightened new departure of the Sudan Government will be fully justified. During a part of the time that the Seligmanns are in the field they will be accompanied by Dr. W. H. R. Rivers, who will thus be enabled to compare from personal knowledge the systems of kinship and the sociological conditions of Papuans, Melanesians, Polynesians, and Todas with those of various North Sudanese tribes.

Dr. Seligmann hopes to initiate an anthropometrical survey of the Sudan during the work of the following season.

A. C. HADDON.

NORTH SEA FISHERY INVESTIGATIONS.[1]

THE Blue-book before us, which has recently been issued by the North Sea Fisheries Investigation Committee, completes the second report of the Marine Biological Association on the investigations which they have been conducting in the southern part of the North Sea and in the English Channel, in connection with the international investigations of the fisheries of northern Europe.

A memoir by Mr. J. O. Borley describes the experiments which have been made on board the s.s. *Huxley* in order to determine the probability of survival of trawl-caught fish if they are returned to the sea. From the point of view of the fishery legislator this is a matter of considerable importance, since the probable effect of any law regulating the size at which fish might be placed on the market would depend very largely upon whether or not fish below the legal size, which had been caught in the trawl,

[1] North Sea Fisheries Investigation Committee. Second Report (Southern Area) on Fishery and Hydrographical Investigations in the North Sea and Adjacent Waters, 1904–5. Part ii. Pp. v+345; 8 plates. (London: His Majesty's Stationery Office, 1909.) Price 8s. 9d.

would survive if returned to the sea. The experiments were conducted with both otter- and beam-trawls, and show that fish from long hauls of the trawl are much less likely to survive than those from short hauls, and that the otter-trawl, which is now practically exclusively used by steam trawlers, inflicts much more serious injury on the fish than does the beam-trawl. The effect of exposure of the fish on the deck of the vessel for different periods of time has also been studied.

Dr. W. Wallace writes on the subject of the size and age of plaice at maturity. The method used for determining age has been the examination of the otoliths or ear-stones of the fish, the alternate dark and white rings of which form a record of seasonal growth. The most striking result of Dr. Wallace's work is the determination of the fact that the average size and age of plaice at first maturity varies in different regions. In the central part of the North Sea, around the Dogger Bank, female plaice are, on the average, 16 inches long, and the majority are just six years old when they become mature for the first time. In the southern bight of the North Sea the average size of the females at first maturity is only 13 inches, and the age five years; in the western part of the English Channel the average size is about the same as in the southern North Sea (13 inches), but the average age is four years instead of five, owing to the more rapid growth of the young plaice in the Devon bays. Similar differences are found for the male plaice also, which mature at a smaller size than the females.

The report on records of catches furnished by the captains of Lowestoft sailing-trawlers, which is written by Miss R. M. Lee, shows the value of such records provided by fishermen in supplementing and extending the work done by the scientific steamers. The area worked over by the Lowestoft men corresponds roughly with the southern bight of the North Sea. The analysis of the figures, which Miss Lee has been able to make, indicates that in the northern part of this region plaice occur in maximum quantity by weight during the summer and in minimum quantity during the winter months. In the southern part of the area, on the other hand, the maximum is in winter and the minimum in summer, whilst in the intermediate region there are maxima in spring and autumn. These records, therefore, clearly confirm the southward migration of plaice for the purpose of spawning in winter, which marking experiments in this part of the North Sea had already foreshadowed.

An account of the hydrographical investigations in the English Channel for the years 1904–5 is contributed by Mr. D. J. Matthews, and is illustrated by a series of very valuable plates, which set forth the results in graphic form by means of coloured charts and sections. The importance of these hydrographical investigations in the English Channel in connection with the problems of North Sea fisheries can scarcely be exaggerated, since the Atlantic water which reaches the southern area of the North Sea comes practically exclusively by way of the English Channel. In both the years 1904 and 1905 the salinities in the English Channel reached a maximum in the early months of the year, and fell to a minimum in the summer. The evidence indicates, further, that the movements of the water were more frequent and rapid in 1904 than in 1905. Special attention was given to the conditions prevailing at the mouth of the English Channel, where the two conflicting currents already demonstrated in 1903 were again encountered, a low salinity current flowing southwards from the Irish Channel across the mouth of the English Channel, and a current of high salinity entering the Channel from the south-west.

The volume, as a whole, contains a large mass of data of the greatest importance for the solution of many of the problems dealing with marine life, and more particularly with the natural history of fishes. It must be borne in mind, however, that it is essentially a contribution of data to the much wider and more comprehensive scheme of investigation which is being carried out in connection with the International Council, and not until the whole work which the various countries have done has been brought together and the results duly correlated can the full fruit of these researches be gathered.

DOUBLE-STAR STUDIES.[1]

A COMPLETE record and discussion of the double-star measures made at the Potsdam Observatory by Prof. Lohse, the director, during the period 1899 to 1908 is given in Publication No. 58 of the Observatory. Prof. Lohse employed a refractor made by Schroeder about twenty-five years ago. The objective is eleven inches, and the flint is dark green. It may be described as a good instrument, but not of the highest quality. Nevertheless, we notice that Prof. Lohse was able to secure measures of some difficult pairs, notably δ Equulei, κ Pegasi, and Sirius. The filar micrometer has one fixed and one movable thread. Generally the power employed was 550, but occasionally one of 800 was used. The power ordinarily used with the Greenwich 28-inch refractor is 670, and occasionally 1120. Setting out with a definite programme, he chose a working list of 166 double stars made up of known binaries and others of interest, and during the nine years he was making measures of these systems he collected those made by other observers, and hence was in a position to make a useful discussion of his results.

The present volume is therefore divided into two portions. Part i. contains the measures made at Potsdam, and part ii. their discussion in combination with measures made since the discovery of each pair. Prof. Lohse uses the method of Zwiers to determine his orbits, and discusses altogether thirty. The actual elements arrived at in most cases differ little from previous orbital elements, and do not call for special remark, except, perhaps, in the cases of η Cassiopeiæ and 70 Ophiuchi. The apparent orbit given for η Cassiopeiæ does not seem the most suitable, and brings out a period of 345 years, or 100 years larger than that generally accepted. In the case of 70 Ophiuchi, Prof. Lohse has done a good piece of work in attacking one of the anomalies often found in double-star orbits. It is found that the differences between the computed and observed positions of the companion tend to periodicity. This may be due to some fault in the gravitational theory, to errors due to personality, or to the effect of some disturbing body. The binaries ζ Herculis and 70 Ophiuchi are excellent examples of this, and Prof. Lohse, who favours the personality explanation, has taken great pains to compute the relative areas swept out by the companion to 70 Ophiuchi every six months, and obtains figures in agreement with those deduced by quite independent methods. He is, however, unwilling to admit the reality of the figures, and remarks that by a judicious selection of observations the deviations from the law of equal areas may be reduced. This is the method advocated by Prof. Burnham, but it is not easy to

[1] Publikationen des Astrophysikalischen Observatoriums zu Potsdam, No. 58. Zwanzigsten Bandes, Erstes Stück. Doppelsterne von O. Lohse (Director). Pp. 168. (Potsdam, 1908; in Kommission bei W. Engelmann in Leipzig.)

understand such an attitude in so experienced a computer as Prof. Lohse. However, this only emphasises the thoroughness with which his work has been done. It is a well-planned and complete work, and Prof. Lohse is to be congratulated on making so real a contribution to double-star astronomy.

The following predicted places for 1910·0 for a few of the more interesting binaries may be found useful:—

	°		″
η Cassiopeiæ	241·1	and	6·24
Sirius	89·4	,,	8·87
Castor	220·5	,,	5·44
α Centauri	215·3	,,	19·41

NOTES.

THE third International Congress of Physiotherapy will be held in Paris on March 30 to April 2, 1910. The congress is to be divided into seven sections.

A PRIZE of 160*l.* has been awarded to M. W. Haffkine by the Paris Academy of Medicine for his work on inoculation against cholera.

THE Bradshaw lecture of the Royal College of Physicians of London will be delivered on November 2 by Prof. J. A. Lindsay, who will take as his subject Darwinism and medicine. The FitzPatrick lectures will be delivered by Sir T. Clifford Allbutt, K.C.B., F.R.S., on November 4 and 9. The subject will be Greek medicine in Rome.

THE Société d'Hygiène de l'Enfance of Paris, we learn from the *Lancet*, is offering prizes for essays on the punishments of children. The essays, which must be original, and written in French, German, English, Italian, or Spanish, will be received by the society not later than December 31 next. The papers are to become the property of the society, which reserves the right of selecting from them material for a pamphlet.

ACCORDING to the *Times*, the exhibit of British chemical industries at next year's International Exhibition at Brussels promises to be of great interest and importance. It is stated that the new exhibitions branch of the Board of Trade is already experiencing some difficulty in providing for the requirements of would-be exhibitors, although the area originally allotted to the exhibit has been largely added to.

PRIZES to the value of 1500*l.* are offered by the National Medical Academy of Mexico for work on typhus fever. Of the sum named, 1000*l.* will be awarded to the discoverer of the cause of typhus, or of a curative serum, and 500*l.* to the investigators whose work is judged most useful in helping towards such discovery. The competition is international, but all essays must be written in Spanish. They can be received up to February 28, 1911.

THE annual "Fungus Foray" of the Essex Field Club will be held on Saturday, October 30, at High Beach, Epping Forest, under the direction of Mr. George Massee, of the Kew Museum. Botanists wishing to attend should apply for programmes to Mr. W. Cole, the Essex Museum of Natural History, Romford Road, Stratford, Essex.

THE death is announced of Prof. J. Scott, author of various text-books on farm engineering, and formerly professor of agriculture and rural economy at the Royal Agricultural College, Cirencester.

THE death is reported, in his sixty-third year, of Dr. Irving Stringham, professor of mathematics in the University of California since 1882. He was a graduate of Harvard, and also spent some time in study at European universities. He was the editor of the American edition of C. Smith's "Elementary Algebra," and was the author of a "Uniplanar Algebra."

DR. GEORGE E. POST, whose death was recently reported at the age of seventy, was for many years head of the Medical College established at Beirut, Syria, by the American Presbyterians. He was the author of several medical and scientific text-books in the Arabic language, as well as of a flora of Syria, Palestine, and Egypt in the same tongue. His "Plantæ Postianæ" was written in Latin and French, and published at Geneva. He contributed also to the leading English and American Biblical dictionaries a large number of articles on the flora of Bible lands. In recognition of his work at Beirut Dr. Post received decorations from the Turkish and German Governments.

Science reports the return of the Peabody Museum Expedition, which for the past three years has been exploring the headwaters of the Amazon River in the interior of Peru and Bolivia. The primary object of the expedition was the study of the native tribes of those regions, but, incidentally, collections were made in natural history; meteorological observations were taken, and topographical work was done. A map of the entire region, based on traverses and astronomical observations, was made for the Peruvian Government.

DR. ALLAN KINGHORN has been sent by the Secretary of State for the Colonies to West Africa to investigate sleeping sickness there, with the view of recommending measures for the prevention of the spread of the disease into certain of the British West African colonies. Dr. Kinghorn recently returned from north-east Rhodesia and Central Africa, whence he was sent with Mr. R. E. Montgomery by the Liverpool School of Tropical Medicine to prosecute inquiries into sleeping sickness, and has just completed a report, with Mr. Montgomery, of the Zambezi Sleeping Sickness Expedition.

THE following courses of free public science lectures are announced for delivery in the Manchester Museum:—some forms of vegetation, by Prof. F. E. Weiss, on November 6, 13, and 20; some problems of embryology, by Prof. S. J. Hickson, F.R.S., on January 8, 15, and 22; and the structure of a crystal, by Sir T. H. Holland, K.C.I.E., F.R.S., on February 5, 12, and 19. In addition to the foregoing, Prof. Boyd Dawkins, F.R.S., has begun the delivery of a course of twelve short addresses on geological subjects on Saturday and Sunday afternoons.

WE learn from the *Revue scientifique* that the Institute of France has received a gift of 50,000 francs from M. Patouillard to found two Montyon prizes, one literary and one scientific, of equal value. The latter is to be reserved for some man of science distinguished in electricity chosen by the Paris Academy of Sciences. From the same source we learn that Dr. Von Brunck, formerly director and a member of the committee of management of the "Badische Anilin," has made a gift of 50,000 marks to the Munich Academy on the occasion of the fortieth anniversary of his entry in the industry.

A MEETING was held on October 13 at Christiania to consider plans for the proposed Zeppelin Polar Expedition, at which, the *Times* reports, Prof. Hergesell explained the object of the expedition, which, as at present planned, will last one Arctic summer. It will not be undertaken until the development of the airship has given it an effective scope of 2500 kilometres, or a journey of three or four days without landing. The pioneer expedition may be expected to take place in two or three years' time. Meanwhile, a ship will proceed next summer to Spitsbergen to make preliminary investigations for the purpose of discovering suitable airship anchorages. During 1911 an airship will make long experimental cruises over the sea from a port on the north coast of Germany. In 1912 two airships will proceed to Spitsbergen and establish a central station, equipped with wireless telegraphy, in Cross Bay. The second airship will remain in reserve.

The Royal Scottish Museum has recently acquired by purchase the well-known collection of Scottish Carboniferous fossils formed by Mr. James Neilson, Glasgow. This collection contains more than twenty thousand specimens, among which are many type-specimens of lamellibranchs and brachiopods, which have been figured in the publications of the Palæontographical Society and elsewhere. These are remarkable for their wonderfully perfect state of preservation, many of them showing delicate internal structures, such as the spires of Spirifer. The collection also contains Gyracanthus spines, of remarkable size, and other valuable fish fossils, including the unique *Cladodus neilsoni* (Traquair). Some time must elapse before the specimens can be arranged for exhibition, but, in the meantime, facilities will be given, so far as possible, to experts who wish to study the collections.

A Reuter message from Simla states that the Imperial Malaria Conference, which has finished its sittings, has drawn up a series of conclusions and recommendations under the following heads, among others:—(1) The appointment by the Government of India of a scientific investigation committee, to be linked up with special organisations for dealing with malaria in each province, the investigations to be specially directed to (*a*) the distribution of malaria in India; (*b*) the epidemiology and endemiology of the disease; and (*c*) the actions of quinine and other remedies for malaria. (2) Practical measures, including (*a*) the extirpation of anopheles, regarding which further investigation is recommended in order to discover how this can be done at a reasonable cost; (*b*) minor drainage operations, which are recommended when they are certain to be effective; (*c*) the restriction of wet cultivation near towns when the lands cultivated are known to be a source of anopheles; (*d*) the introduction of fish into tanks and other collections of water; and (*e*) the oiling of small collections of water which cannot be filled up. (3) (*a*) On the suggestion of the president of the conference, Sir Herbert Risley, it is recommended that committees of officials and non-officials, directed by the elected members of the new councils, be formed to spread among the people knowledge regarding malaria and the measures which it is possible to take against it; (*b*) it is also recommended that the subject be taught in the schools. (4) Local Governments should be invited to make an annual assignment of funds for malaria investigation and prevention.

The project of organising and bringing into existence in 1911 a "Scottish Exhibition of National History, Art and Industry" is rapidly taking shape. The object primarily aimed at is to aid, and finally complete, the raising of a fund for the endowment of a chair of Scottish history and literature in Glasgow University; but, according to the *Engineer*, the executive council is considering a scheme of exhibits which takes account of the following:—that there should be a collection of exhibits showing the varied nature of Scotland's industries and of those carried on by Scotsmen in the colonies and abroad, and that in many industries a contrast should be made between the old and the new; that there should be an electricity exhibit, dedicated to the memory of Lord Kelvin; that there should be a shipbuilding and marine engineering exhibit of a historical nature, showing the development of steam navigation in its home on the Clyde; that the river Kelvin should be taken advantage of to represent historic episodes in Scottish life and industry; that the colonies, so largely peopled from Scotland, be invited to tell of the progress of the Scot abroad.

Dr. L. A. Bauer informs us that the magnetic survey vessel, the *Carnegie*, arrived at Falmouth on October 14, twelve days after leaving St. John's, Newfoundland. Magnetic observations were secured every day except one. The *Carnegie* will remain at Falmouth until the end of this month. Having completed the harbour observations and the tests ashore of the instrumental constants, the *Carnegie*, under the command of W. J. Peters, who was in charge of the Pacific Ocean vessel, the *Galilee*, from 1906–8, will go to Madeira, returning to New York, *viâ* Bermuda, about March 1 of next year. The September number of *Terrestrial Magnetism and Atmospheric Electricity* contains an account of the launch of the *Carnegie* at Brooklyn in June last, and her departure on this—her first—cruise to Newfoundland, Hudson Straits, and England. There is a further article, by Mr. J. Craig, jun., on the non-magnetic gas engine with which the vessel had to be provided to enable her to continue her voyages when the wind was not strong enough for sailing. It appears that the cheapest power plant would have been a gasoline engine, but that the cost of maintenance would have been greater than for a gas-producer plant, which was finally selected as best. The material used in construction was mainly manganese bronze, a few of the valves being the only parts of steel or nickel-steel. The engine is of the four-cylinder type, and resembles the regular Craig air-starting engine.

The second Model Engineer Exhibition is now being held at the Royal Horticultural Hall, and will remain open until October 23. The opening ceremony was performed by Sir Hiram Maxim on October 15, and the appropriateness of the selection of this distinguished experimenter in aviation is evident from the very large number of model aëroplanes exhibited. These constitute a special competition class, in which there are more than fifty entries. Many of the designs are original, others are copies of well-known successful types, and we noticed some in which the workmanship was excellent. Considerable variety is shown in the selection of the material for the supporting surfaces; generally fabric is employed, but others having wooden, aluminium, and mica planes are to be seen. There is also a very fine collection of steam and other engines, model yachts, and electro motors. An interesting feature of the exhibition is the completely equipped model engineering workshop in operation. Several firms also show their specialities in machine tools, &c., for model-making. Perhaps the most noteworthy advance in model work recently has been in connection with model motor-boats. At the time of the first exhibition, in 1907, the speed record was 8·76 miles per hour; the present record is above 15 miles per hour, a result which is very creditable to the ability of amateur engineers.

Prof. C. Lombroso, professor of criminal anthropology and psychiatry in the University of Turin, died on October 19 at seventy-three years of age. From an interesting notice of his work and career in the *Times* of

October 20 we derive the following particulars as to his work and career. After graduating at Padua he went for some time to Paris and Vienna to continue his studies. At the very outset of his medical work he was attracted by nervous and mental diseases, and while still a student he published two treatises, one on "Insanity in Antiquity" and the other on "The Insanity of Cardan" (the sixteenth-century mathematician). In the latter essay he first advanced the theory of the relation between genius and crime, which was to form the chief purport of his later work. While serving as a surgeon in the army his attention was attracted at Calabria by the diversity of type exhibited by the soldiery, who were drawn from all parts of Italy. He conducted a series of studies, which he endeavoured to make the basis of an anthropological chart of Italy. He measured and examined no fewer than 4000 individuals, and gained an invaluable experience, which stood him in good stead in his subsequent criminological investigations. The removal of his regiment to Pavia, a university town, gave Lombroso an opportunity of continuing his study of nervous diseases at the district asylum, but his military superiors did not look with favour on these scientific labours; difficulties were placed in his way, and Lombroso finally determined to leave the army. Shortly after, he was appointed professor of psychiatry at the University of Pavia at a small salary. He prepared a short inaugural address entitled "Genius and Insanity," in which all the main ideas of his *magnum opus* were outlined. In 1872 he made a discovery which proved to be of considerable scientific and economic importance. He noted the fact that a large number of the inmates of the asylum were suffering from "pellagra," a curious disease, which first affected the skin and afterwards attacked the brain and nervous system. Lombroso discovered that the disorder was to be traced to a poison contained in diseased maize. Upon his appointment to the chair of psychiatry at Turin Lombroso continued his criminological studies. He was the first to apply the anthropometric method to the study of criminology, and his collection of skulls was unique. He showed that the overwhelming majority of criminals suffered from some form or other of nervous disease. These views are embodied in his great work entitled "L'Uomo Delinquente," published in 1889. Lombroso had a somewhat similar theory for the existence of genius, which he declared was a form of larvate epilepsy; this somewhat fantastic thesis was presented in his "L'Uomo di Genio," which has been translated into several languages.

In Witherby's *British Birds* for October Messrs. W. Davies and F. Coburn record the breeding, during the past season, of the marsh-warbler in Worcestershire. The nest was attached to the stems of cow-parsnip and nettles. Mr. Coburn was of opinion that this was the first record of the breeding of the species, but, as the editor points out, a pair nested in the valley of the Avon in 1892.

The *Selborne Magazine* for October opens with a short biography, accompanied by a portrait, of Sir Joseph Hooker. In connection with the discovery of fossil bones near Crayford, referred to in the report of the Selbornian excursions, the editor will perhaps permit us to point out that no such species as *Canis domesticus* is known to science, and that none of the bear-skulls found in English Pleistocene deposits belongs to the American *Ursus horribilis*.

At the conclusion of a paper on the birds of the mountains of the Malay Peninsula, published in vol. ii., No. 4, of the Journal of the Federated Malay States Museums, Mr. H. C. Robinson expresses the opinion that the fauna is of Indo-Malay origin, and that the species have spread in comparatively recent times north-west from the Sunda islands rather than south-east from Burma. Secondly, that the mountain-fauna is composed of a continental and a Sumatran element, and that the connection with the mountain-fauna of Burma is remote. On the other hand, there appears to be evidence of a recent land-connection with Sumatra, and also that the southern portion of the peninsula has been disconnected from the land to the north.

Considerable interest attaches to the discovery of large quantities of shells of the pearl-mussel (*Unio margaritifer*) in gravel of apparently Pleistocene age in the Thames near Mortlake. Messrs. J. W. Jackson and A. S. Kennard, who record the fact in the October number of the *Journal of Conchology*, state that "at the close of the Pleistocene period the land stood at a much higher level than it does to-day, and the Thames was then a quick-flowing stream in a deep and narrow gorge. . . . The cause of the extinction of the species is explained by the fact that as the land sank the river became more sluggish, and silt and mud commenced to accumulate. Such conditions would prove highly detrimental to its welfare, and the species soon ceased to exist."

Taking as his text the apparent fact that a nematode worm effects an entrance into the swim-bladder of rainbow-trout by burrowing through the intestinal wall, and thereby likewise permits the entrance of bacteria, Dr. A. E. Shipley, in the September issue of the *Journal of Economic Biology*, brings forward additional evidence in support of his view that the appendix vermiformis is a functional, and not a decadent, organ, and that appendicitis is probably due to the presence of entozoa. Messrs. Berry and Lack are cited as evidence in support of the contention that the appendix is a functional lymph-gland, and the author expresses his disbelief in the existence of any functionless organs. The remarkable increase of appendicitis in modern times is attributed by him to the practical cessation of the administration, from time to time, of vermifuges, and certainly no other satisfactory explanation of the phenomenon has been given. If this suggestion be substantiated, it tends to prove that our forefathers were not such fools as we often imagine.

The importance and interest of large and properly classified and arranged collections of photographs—whether these subjects be nature or art—were emphasised by Sir Martin Conway at the Museums' Conference recently held at Maidstone, and his address is published in full in the September number of the *Museums Journal*. Many difficulties must be encountered in forming extensive collections of this nature; but, provided the necessary funds are available, they are not insurmountable, and Sir Martin urges that series of photographs relating to particular subjects ought to be collected by the various museums in the country. If private collectors would also devote themselves to photographs, a system of exchanges could probably be established which would greatly facilitate matters.

The common fresh-water Hydra was one of the first subjects upon which the experimental zoologist exercised his special genius. More than a century and a half ago Trembley demonstrated the remarkable power of regeneration of lost parts which this little animal possesses, and not a few experimenters have followed in his footsteps. Of late years there has been quite an outburst of activity in this direction, and some highly remarkable results have been obtained. The latest contribution is a paper, by Miss

E. N. Browne, in the August number of the *Journal of Experimental Zoology* (vol. vii., No. 1), dealing with the production of new hydranths by the insertion of small grafts from another individual of the same species. This paper is particularly interesting on account of the ingenuity of the methods employed. In order to determine the exact origin of the regenerating material, the author makes use of Whitney's discovery that the green colour can be entirely removed from *Hydra viridis*, without killing the animal, by keeping it for some weeks in a 0·5 per cent. solution of glycerin. The artificial white hydras thus produced form perfect grafts with ordinary green forms, giving rise to parti-coloured colonies in which the boundaries between the tissues of the green and white components remain clearly defined.

Irish Gardening (October) contains various seasonable articles, notably on the cultivation of seakale and the gloxinia. A very charming bell-shaped ericaceous plant, *Zenobia speciosa*, is recommended for the garden by Mr. C. F. Ball; in the variety *pulverulenta* it attains to the dimensions of a good-sized bush. It requires a peaty soil or the nearest equivalent, and is propagated from seed or by layers.

THE *Country Home* (October) appears in an enlarged form from the offices of the *Sphere* and *Tatler*. The botanical and zoological articles are chiefly utilitarian or popular. The intensive cultivation of asparagus is explained by Mr. L. Terasse, and vegetative propagation forms the subject of an article by Mr. W. M. Webb, while Mr. H. B. Buchanan gives advice on the breeding of pigs.

FOLLOWING up a line of work instituted in the United States of America, the examination of parasitic fungi that attack scale insects has been taken up by the Department of Agriculture for the West Indies. Three species of Ascomycetes, *Sphaerostilbe coccophila*, *Ophionectria coccicola*, and *Myriangium Duriaei* are specified in the *Agricultural News* (September 18) as having been taken on scale insects infesting lime or citrus trees in Dominica, St. Lucia, and other islands, and a fourth fungus is noted, but not identified. It is proposed to experiment with cultures of these fungi on nutrient media which could be distributed to cultivators.

THE most striking point in a description of fungus maladies of the sugar-cane, prepared by Dr. N. A. Cobb, and published in Bulletin No. 6 of the division of pathology and physiology in connection with the Hawaiian Sugar-planters' Association, is the attribution of parasitism to the phalloid fungi *Ithyphallus coralloides* and *Clathrus trilobatus*. The mycelium of Ithyphallus was found attached to cane trash and the roots, while the mycelium of Clathrus passed in among the roots of canes where disease was abundant, so that the author classes them with species of Marasmius as sources of root disease. With the view of identifying the mycelium of these Phalloideæ, a special study was made of their sphæro-crystals.

IN connection with a visit of German systematic botanists, Dr. E. Issler prepared an account of vegetation conditions in the Central Vosges Mountains, which is published in Engler's *Botanische Jahrbücher* (vol. xliii., part iii.). The formations distinguished in the montane region are spruce, beech, mixed fir woods, and the vegetation of the forest streams. It is a curious fact that the beech in many places ascends higher than the conifers, the reason being that the upper tree limit, at the low altitude of 4000 feet, is determined by the wind, which the beech is better able to withstand. In the subalpine region different types of flora are provided by the rocks, meadows, and swamp, and in certain parts there are areas of ling and sphagnum moors. Among the rare plants to be found are *Mulgedium alpinum*, *Rhodiola rosca*, *Luzula spadicea*, two species of Isoetes, and *Subularia aquatica*.

THE *Bio-chemical Journal* for September (iv., No. 8) contains a paper, by Dr. Otto Rosenheim, on the nomenclature of lipoid substances. He proposes to classify them in three main groups, the cholesterins, the cerebrogalactosides, and the phosphatides. Prof. Moore and Drs. Wilson and Hutchinson contribute a paper on the biochemistry of hæmolysis.

PROF. HALLIBURTON, in the *Journal of Hygiene* (vol. ix., No. 2, September), directs attention to the fact that large quantities of flour, both in this country and abroad, are artificially bleached. Some experiments he has performed distinctly indicate that both the starch and the gluten are rendered less digestible by the process of bleaching, though whether the change is sufficient to be serious to children or invalids is a question on which there is at present no evidence.

IN the Bulletin of the Johns Hopkins Hospital for September (xx., No. 222), Dr. Charles White discusses in a suggestive manner the municipal management of tuberculosis. He points out that our struggle must be for an immune race, not for the extermination of the last tubercle bacillus. More and more we see the evidence of protection of *small* doses in healthy resistant bodies. In municipalities the aim should be to get rid of sources of large doses of tubercle bacilli, and to establish resistant bodies by healthy lives, mainly in the children.

AN account of the mathematical work of Sully Prudhomme is given by Prof. H. Poincaré in the *Revue générale des Sciences* for August 15. Sully Prudhomme received a scientific education in his youth, but was prevented by ill-health from attending the École polytechnique. That he nevertheless gave a large amount of attention to mathematics is evidenced by the numerous manuscripts left by him, including the rough drafts of a memoir on geometry. It appears, however, that the manuscripts now in existence cannot be regarded as more than rough drafts of ideas which Prudhomme had further developed and considerably modified after writing them. Prof. Poincaré concludes that it would be undesirable to publish them *in extenso*, and he therefore devotes the concluding portion of his paper to a general account of their salient features.

UNDER the title of "The Gambler's Ruin" (*Annals of Mathematics*, x., 4), Prof. J. L. Coolidge discusses certain problems connected with games of chance which have not hitherto received complete treatment. It is pointed out that while the problem of determining the odds that one player may ruin another has been worked out thoroughly for the case where the amount staked at each turn is the same, the case where the stakes are varied, whether they be limited or unlimited, has been less fully discussed. The author considers the "systems" proposed at Monte Carlo and elsewhere, and gives a deductive proof that no such system can have more than an easily calculable chance of success. He concludes with the quotation from Sir Hiram Maxim's book :—"Je me rends parfaitement compte du désagréable effet que produit sur la majorité de l'humanité, tout ce qui se rapporte, même au plus faible degré, a des calculs ou raisonnements mathématiques."

A SYSTEMATIC study of the influence of the surrounding medium on the lines of the spark spectrum has been undertaken by Dr. H. Finger at the suggestion of Prof.

Konen, of Münster, and his principal results are summarised in No. 17 of the *Verhandlungen der deutschen physikalischen Gesellschaft*. A comparison has been made between the spectra of more than twenty metal electrodes in air and in water, the spark being produced by an induction coil of 40 cm., having a capacity of 0·02 microfarad in parallel with its spark gap. The spectra in air and in water were photographed on the same plate, a concave grating of radius 180 cm. being used. The spectra in water show no air lines, but a large proportion of them show a more or less extended continuous spectrum with the lines of water vapour reversed. Some lines are unchanged, while others are broadened on one or on both sides, lines belonging to the same series being modified in the same sense. No trace of the spectra of salts in solution in the water has in any instance been detected.

PART iii., vol. xvi., of the Proceedings of the Cotteswold Naturalists' Field Club maintains the high standard of style and illustration which distinguishes this publication. A large part is concerned with the record of excursions chiefly to places of geological or antiquarian interest, and is illustrated by no fewer than nine plates of photographic reproductions. Of the papers published, the longest is on "The Lower Severn: Valley, River, and Estuary from the Warwickshire to the Bristol Avon," by Mr. T. S. Ellis. The principal aim of the author is to show that the generally accepted views of river development associated with the name of Prof. W. M. Davis are not applicable to the district with which he deals, and by inference to other districts also. His position is indicated by the following sentence:—"As I believe, we cannot have a right conception of the development of rivers unless we keep our minds free from all idea of original lines of streams or of any principal line as the initial condition. In my view, a river system is evolved not *into*, but *from* a network of streams, formed in the drainage area before any definite line of principal stream has been settled." Accounts are given of places and objects of scientific interest visited during excursions, and among these is a record of an excursion to Shepton Mallet and Vallis Vale, which is well known for its romantic scenery and geological unconformities. The report contains the accompanying illustration, reproduced by permission of the council of the Geological Society, of the classic section showing Oolite resting upon Carboniferous Limestone, which was pictured by Sir H. de la Beche. Short papers by Messrs. L. Richardson and C. Upton, and a report by the Rev. H. J. Riddelsdell, on the progress made in connection with the flora of Gloucestershire, complete the issue.

View of Quarry, showing the Inferior Oolite resting unconformably upon the Carboniferous Limestone in Vallis Vale. Photograph by Prof. S. H. Reynolds.

Le Radium for August contains a very useful table of the principal minerals containing uranium and thorium, prepared by M. B. Szilard, of Madame Curie's laboratory. It occupies seven pages of the periodical, and gives the name, the composition, the percentages of uranium and of thorium, the localities in which the mineral is found, and its crystalline form. In addition, a map of the world, in which the localities are shown, is given.

MR. HAROLD MOORE, of Woolwich Arsenal, read a paper on the Brinell method of determining hardness at the International Association for Testing Materials. We note from an abstract in *Engineering* for October 8 that the author's results show that the thickness of the test specimen has no influence on the result provided that the depth of the impression made by the ball does not exceed one-seventh the thickness of the specimen. A safe rule to be adopted is that the distance of the centre of the impression from the edge of the specimen should not be less than 2·5 times the diameter of the impression. For calculating the hardness number, 30° should be chosen as the standard angle of impression, this giving a diameter of impression equal to one-half the diameter of the ball. The hardness number then becomes the mean pressure per unit area when the diameter of the impression is one-half the diameter of the ball. In practice it is convenient to employ a known load, and measure the diameter of the impression obtained. The hardness number is then calculated from the formula

$$H=\frac{16PD^{n-2}}{\pi(2d)^n},$$

where P is the load in kilograms, D is the diameter of the ball, d is the diameter of the impression, and n is a coefficient determined by making two impressions with the same ball and different loads, and applying the formula

$$n=\frac{\log P_1-\log P}{\log d_1-\log d}.$$

A revised impression of Sir Robert S. Ball's little work "Time and Tide" has just been issued by the Society for Promoting Christian Knowledge.

A cheap edition of "Extinct Animals," by Sir E. Ray Lankester, K.C.B., F.R.S., has been published by Messrs. Constable and Co., Ltd. The original edition of the work was reviewed in Nature of November 2, 1905 (vol. lxxiii., No. 1879).

We are in receipt of a new catalogue of books and papers (more than 1400 in number) dealing with ornithology which Messrs. John Wheldon and Co., of Great Queen Street, W.C., have for disposal.

The October classified list of second-hand scientific instruments offered for sale or hire by Mr. Charles Baker, of High Holborn, has reached us. The catalogue, which contains upwards of 1300 items, will be sent free of charge upon request.

MM. A. Hermann et Fils, of Paris, have published a translation into French, by Dr. Paul Lemoine, of Prof. James Geikie's "Structural and Field Geology," which was reviewed in these columns on July 6, 1905 (vol. lxxii., p. 223). M. Michel-Lévy has contributed a preface. The price of the French work is 15 francs.

A new edition (the eighth) of "Quantitative Chemical Analysis," by Clowes and Coleman, has been published by Messrs. J. and A. Churchill at 10*s*. 6*d*. net. The work has been revised and enlarged, but the size of the page having been increased the thickness of the volume remains as before.

Messrs. Constable and Co., Ltd., have sent us a cheap edition of "Time and Clocks," by H. H. Cunynghame, C.B. A review of the first edition appeared in the issue of Nature for January 17, 1907 (vol. lxxv., No. 1942).

OUR ASTRONOMICAL COLUMN.

Mars.—The advisability of watching Mars closely, at this period of favourable opposition, and seasonal changes on the planet itself, is illustrated by a brief message communicated to the *Astronomische Nachrichten* (No. 4362, p. 303, October 9) by M. Jarry Desloges. Whilst the planet was being observed at 9h. 15m. on October 6, a projection was seen on the terminator in the neighbourhood of Electris. This projection lasted for ten minutes only, whilst a similar one observed by Messrs. Lowell and Slipher, on May 25, 1903, endured for only thirty-one minutes; the latter was ascribed to a cloud of dust some 300 miles in length.

In No. 4361 of the same journal M. Jonckheere announces the discovery, on September 28, of a canal which is probably a new one, and extends from Cyclopum Lucus to Hephæstus; the same observer records a further observation of the new land "Stella" on October 7.

A large number of observations of different features are recorded and illustrated by MM. Quénisset and Antoniadi in the October number of the *Bulletin de la Société astronomique de France*. Numerous canals were observed, the Solis Lacus was seen to be divided, and important changes in the colour and visibility of various regions were closely followed. M. Antoniadi is confirmed in his opinion that these changes are caused by the passage of Martian clouds across the various features, and, from the yellowish tinge which colours the indistinct areas, he confirms the opinion expressed by Prof. W. H. Pickering in 1905, that these Martian clouds are probably yellow.

Solar Observations: a Novel Spectroscope.—In order to continue his solar observations, Mr. W. M. Mitchell found it necessary, at the Haverford College Observatory, to devise a large spectroscope which might be used in conjunction with a small equatorial. The telescope at Haverford is of 10 inches aperture and 12 feet 6 inches focal length, and cannot, therefore, carry a large, and consequently heavy, spectroscope of the ordinary type. Acting upon a suggestion from Prof. Hale, he has erected a spectroscope which is mounted upon, and is parallel to, the telescope tube, and finds that the device answers very satisfactorily. The beam from the 10-inch objective is reflected on to the slit of the spectroscope by a 90° prism, and, passing through the slit, is again reflected by a similar prism on to a 3-inch collimating lens of 39 inches focal length. Thence it passes to a grating and back through the 3-inch lens to the eye-piece, the grating and lens being slightly tilted. A negative lens placed between the 10-inch objective and the first reflecting prism gives a larger image, which in Mr. Mitchell's observations was of 3·2 inches diameter. The spectroscope tube is constructed of wood, saturated with hot paraffin before assembling to obviate subsequent warping.

With this instrument Mr. Mitchell gets a resolving power of 70,000 in the third-order spectrum, and was able to observe visually the Zeeman effect in sun-spot lines. An interesting observation on May 11 showed that at one end of a spot "bridge" certain lines were doubled, whilst at the other end, the farthest from the centre of the spot group, the same lines were triple; other lines were double in both regions. A list of lines, recorded as bright in a chromospheric outburst on January 21 7h. to 9h. G.M.T., is also given, and Mr. Mitchell urges the necessity for more laboratory work in connection with chromospheric radiations.

We regret to learn that astronomical observations are to be suspended at the Haverford Observatory, and, consequently, Mr. Mitchell's observations cannot be continued.

The Aurora of September 25.—In No. 4361 of the *Astronomische Nachrichten* (p. 287, October 7) Herr Torvald Köhl records that a fine display of the aurora was observed at Odder, Denmark, on September 21, and adds that a similar display was observed in Stockholm on September 25.

September Meteors.—The appearance of a magnificent fireball on September 27d. 7h. 20m. is recorded by Herr Köhl, who observed it at the Carina Observatory, Odder, in No. 4361 of the *Astronomische Nachrichten*. Herr Köhl finds from his meteor-catalogue that he observed similar apparitions on September 27–28 in ten different years between 1870 and 1909. He also has records of meteors on December 12–13 for eleven years between 1875 and 1908.

Hydrogen Layers in the Solar Atmosphere.—In the *Comptes rendus* for September 20 (No. 12, p. 521) MM. Deslandres and d'Azambuja review the work which has been done in separating the various layers of calcium vapour in the sun's atmosphere, and describe the results of similar researches on the hydrogen and iron vapours recently carried out at Meudon.

The image, obtained by using the centre of the Hα line, differs from the Mount Wilson photographs, and shows the details, exactly, of the K_3 calcium images, the same dark filaments and the same bright areas. The authors suggest that the Mount Wilson images were produced by mixtures of the different parts of the Hα line, and that the sinuosities in the edges of the various sections might produce this effect. In the dispersion used at Meudon 1 mm. = 6 Å.

PERCY SLADEN MEMORIAL EXPEDITION IN SOUTH-WEST AFRICA, 1908–9.[1]

II.

IN the latitude of Loanda (8·9° S.), behind a dry, sparsely populated coastal belt about 150 miles wide, lies a mountainous zone, for the most part densely forest-covered to an elevation of 4000 feet. Within this zone is the historic locality of Golungo Alto, where Welwitsch lived for two years, and in which a large part of his rich collection was obtained. Here he discovered *Gnetum africanum* in 1855.

FIG. 1.—A glade in the Bauhinia forest showing a Baobab just before the beginning of leaf-fall

A few miles to the south-east of Queta, a station on the railway within the forest zone and not far from its eastern edge, is situated the Government experimental plantation (Granja San Luiz), under the energetic direction of Mr. J. Gossweiler, to whom I am indebted for valuable advice and assistance during my residence there from April 1–12. The forests are here very dense and the undergrowth thick and very varied in character. After an unsuccessful search of some days' duration, Gnetum was eventually found on April 7 in a very dense and dark forest on the coffee and rubber estate of Montobello (2600 feet), some thirty miles to the west of Granja San Luiz and ten miles south west from the railway station of Queta. It was very abundant within a strictly limited area and its occurrence is clearly "sporadic," as described by Welwitsch. It may be noted that the native name "N-coco" given by Welwitsch is now applied indifferently to various plants of climbing habit; of Gnetum itself the natives seem to have no special knowledge.

Leaving Loanda on April 16, I arrived on April 21 at Mossamedes, where the third section of the journey commenced. Quite exceptional rains had recently fallen here, as in so many other districts to the south, and the gently rising plains behind the town resembled a waving cornfield rather than a desert. They supported a thick, uniform growth of a tall Aristida (? *A. prodigiosa*, Welw.), among which there flourished a considerable number of small annuals. In sandy places, especially in shallow, dry water-channels, dense crops of the erect plumose awns of Aristida seeds, forced beneath the surface by their hygroscopic movements, were commonly seen. So unusual a supply of food had tempted into the vicinity of the town springbok, gemsbok and other antelopes, while ostriches had reappeared after an absence of many years. Very large Welwitschia plants were found in abundance about eight miles to the south of Mossamedes in the direction of Cape Negro, the locality in which it was discovered by Welwitsch. The plants had coned freely, but almost without exception the cones, severely attacked by a fungus (probably a Cladosporium), were in a state of decomposition—no doubt another consequence of the excessive atmospheric humidity earlier in the season. A large number of young seedlings were found. The Damaraland localities previously referred to, in which no Welwitschia seedlings have been found within recent years, are about forty miles from the sea. But even in these southern latitudes normal seed-reproduction seems to occur on the coast. A recent letter from Dr. Hintrager, Acting Governor of German South-West Africa, contains the interesting statement that "wenige Kilometer nordöstlich von Cape Cross[1] die Welwitschia noch häufig und in fast allen Alterstadien, also auch in jungen Pflanzen vorkommt." It is not improbable that a condition of its seed-germination in nature is a degree of atmospheric humidity which is constantly realised near the sea though now usually absent from desert places inland.

On April 27 I left Mossamedes with the intention of crossing the Huilla plateau and reaching the Cunene River. I was accompanied by Mr. H. G. Mackie, H.B.M. Consul in Angola, to whose kind support the success of this part of the journey was very largely due. The light railway, at present working to the 107th kilometre, leaves Mossamedes in a northerly direction and crosses the broad beds of the periodical rivers Bero and Giroual, in which, near the sea, a few tropical and subtropical crops are cultivated. So far inland as the present railhead, the rainfall is small and inconstant and, in normal seasons, the country is practically waterless. At about 80 km., however, the typical desert vegetation mingles with shrubs and a few dwarf trees, which are found in greater luxuriance on the lower

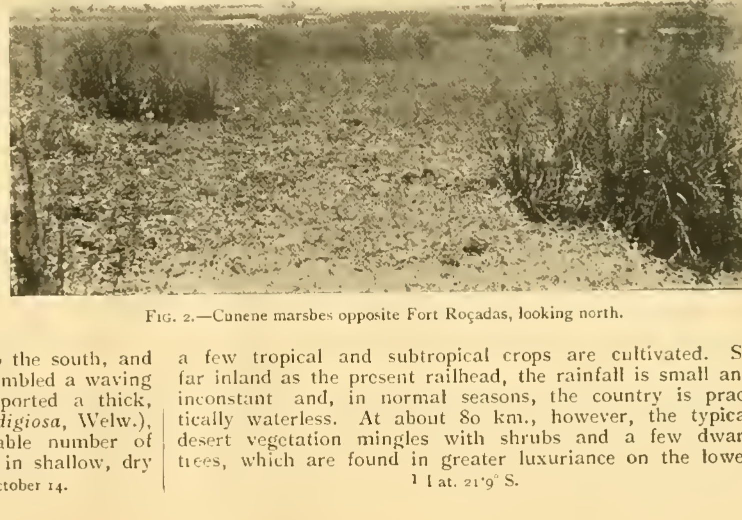

FIG. 2.—Cunene marshes opposite Fort Roçadas, looking north.

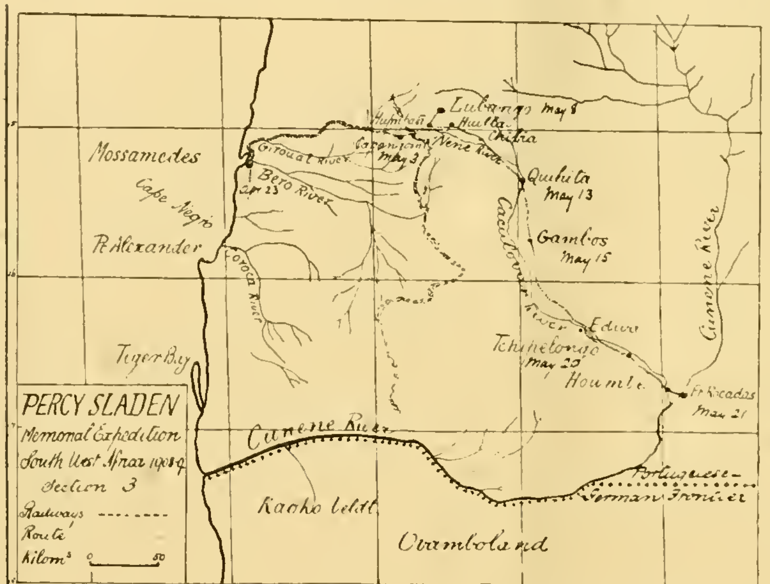
[1] The first article appeared in NATURE of October 14.

[1] Lat. 21·9° S.

slopes of the Chella Range. The railhead is situated in an open forest of stunted trees, among which Acacias, a Bauhinia and the Baobab are prominent, with wide, grass-covered glades. This formation extends to the lower slopes of the Chella Range becoming denser as it ascends until, near the summit, it effects a junction with a Savannah, the characteristic species of which include a number of Proteaceæ and other southern forms. The western face of the Chella Range rises sheer to some 3000 feet from the forest which clothes its base, above which the bedding planes of its grey, lichen-covered sandstone are plainly visible. Except for its great extent, the whole range bears a striking resemblance to Table Mountain as seen from Table Bay. Opposite Capangombe there is a gap, the entrance to a kloof up which winds a steep footpath to the top through an increasingly dense, dripping forest, with a magnificent undergrowth of maiden-hair and other ferns. Near the summit a tall Euphorbia with the habit of *E. grandidens* occurs in great abundance.

Leaving the Boer village of Humpata (6000 feet) on May 10, we approached the Cunene along the now well-known track down the valley of the Caculovar. On descending the eastern slopes, which are less steep than the western, we passed through the same changes of flora, in the reverse order, as those already observed



on the other side. Passing the Huilla Mission—the scene of the botanical labours of Fathers Antunes and Dekindt—we arrived on May 13 at Chibia (4500 feet), where the proteaceous flora thins out and gives place again to the open, dry forest, in which the Bauhinia and Acacias in turn predominate. Henceforward the surface, frequently broken by tumbled heaps of gneiss and ironstone, 50 feet to 500 feet high, slopes gently down to the Cunene. From Gambos (4100 feet) the water-supply, after the end of the rainy season (April), is meagre and its quality bad, and the whole district is fever-stricken. The temperature becomes very high after mid-day, and whirlwinds of great violence spring up very suddenly, and carry columns of dust and other light objects to great heights. Three hours by waggon from Houmbe brought us to the Cunene marshes, which are here confined to the right bank of the river. Owing to the unusually late rains they were still nearly two miles wide, and it was with great difficulty that a crossing to Fort Roçadas on the opposite bank was effected. This stronghold is placed upon the high calcareous cliff forming the left bank of the river. Its neighbourhood, the scene during recent years of many engagements between the Portuguese and the trans-Cunene Ovambo tribes, has become so extremely unhealthy that it will in future be manned entirely by native troops.

The country at its foot is thickly studded with small Baobabs and away to the east the open Acacia and Bauhinia forest again prevails, and undoubtedly merges farther south into the thorn-bush of Ovamboland and the Acacia park-formation which extends far to the south of Okahandya and Windhuk.

I take this opportunity of acknowledging the effective support which has been very kindly given to the objects of the expedition by Their Excellencies Sr. Capt. H. de Paiva Couceiro, Acting Governor-General of Angola; Herr Regierungsrath Dr. Hintrager, Acting Governor of German South-West Africa; and the Hon. W. F. Hely-Hutchinson, G.C.M.G., Governor of Cape Colony.

H. H. W. PEARSON.

MODERN METHODS OF ILLUMINATION.[1]

A GREAT change has come over the methods of lighting within the last few years. We have now at our disposal means of lighting which would have seemed incredible a few years ago. Step by step with these developments has taken place the progress of education and the increase of printed matter, with the result that we use our eyes to-day far more than in the past. Our main object, therefore, should be to consider the subject of illumination from the point of view of the impression received through the eye. After emphasising this aspect of illumination, Mr. Gaster proceeds with a summary of recent developments in electric lighting.

Electric Glow-lamps.

It has long been known that a carbon filament glow-lamp could be made to yield more efficient results by bringing it to a higher temperature, *i.e.* running it at a pressure higher than that ordinarily utilised, but such a gain in efficiency has only been found possible at the expense of life and durability.

Within the last few years we have seen the development of lamps with filaments made of other and more refractory materials, such as the Nernst lamp, and the various metallic filaments, such as osmium, iridium, tantalum and tungsten, &c. The two last-named lamps, of course, now play a great *rôle* in electric lighting.

In addition, attempts have been made to improve carbon filaments in the United States by the graphitising process of Mr. Howell, by the aid of which a consumption of 2·5 watts to 3 watts per candle was attained. Another interesting attempt in this direction is the Hopfelt lamp, in which the carbon filament burns in an atmosphere of mercury vapour, with, it is stated, a consumption near 1·5 watts per candle. The Helion lamp, again, is believed to utilise a filament mainly composed of silicon; it is claimed to run for 1000 hours at 1 watt per candle, and even in the open air, without requiring to be enclosed in an evacuated globe; but it has not yet come upon the market. Perhaps the best known metallic filament lamps in use at the present day are those utilising the metal tantalum and those described by various names, but generally believed to contain as the main constituent the metal tungsten. Tungsten lamps are burned at a consumption approaching 1 watt per candle-power, and are generally stated to have a life, under good conditions, of 1000 burning hours. One great difficulty, however, has been the manufacture of lamps of moderate candle-power for high voltages, and capable of being used in any position; very recently, however, lamps having as low a candle-power as 25 or 30, and for pressures extending to 200 volts to 260

[1] Abstract of a series of four Cantor lectures delivered by Mr. Leon Gaster before the Royal Society of Arts and published in the Journal of the Society for August 6, 13, 20, 27; September 3, 10.

volts, have been produced; one company has even professed to manufacture a 200-volt 16-candle-power 25-watt lamp.

Attention may also be directed to the cooperation between the lamp-makers and the electrical supply companies characteristic of the United States, and to the work of the National Electric Lamp Association in that country. A large number of lamp-makers belong to this association, determine standard prices, and support a laboratory for the purpose of carrying out common tests on lamps for their mutual benefit. In addition, the cooperation between lamp-maker and supply company is naturally very beneficial to both parties in pushing the sale of lamps in desired directions.

Electric Arc-lamps and Vapour-lamps.

The most marked development in arc-lamps of late years has been the introduction of flame carbons, that is, carbons such that the light comes from a bridge of incandescent vapour instead of the tips of the electrodes. By this means consumptions so low as 0·2 watt to 0·3 watt per mean spherical candle-power are said to have been obtained. Flame carbons, however, burn away very quickly, and in order to extend their life lamps in which a succession of carbons is automatically used have therefore been introduced. Another development, the enclosed regenerative lamp, involves methods enabling the access of air to the carbons to be restricted, so that a high efficiency, and yet a fairly long life, is obtained. Mention must also be made of the new Blondel flame carbons, yielding a very white light, which have been stated to yield a polar curve of light-distribution specially well adapted for street lighting, and are burned vertically one above the other.

Another direction of progress has been the improvement of small candle-power enclosed arc-lamps, which formerly served to bridge the gap between high candle-power flame arcs and glow-lamps. By securing more complete exclusion of the air from the globe, the Regina Arc Lamp Company claims to manufacture a lamp consuming only 0·8 watt per candle, and lasting for 250 hours without recarboning. High candle-power metallic filament incandescent lamps, which are manufactured up to 1000 candle-power, now also serve to fill this gap.

The chief drawback of mercury-vapour lamps is, of course, the peculiar colour of their light, there being practically no red rays. It has, therefore, been proposed to mix certain salts with the mercury, to use fluorescent materials, &c., in order to improve the spectrum, but few such devices have come to a practical issue. A recent advance has, however, been achieved by Dr. Küch, of Germany, by the use of a tube composed of special quartz-glass, which can stand a very high temperature. By this means a consumption of only 0·27 watt per mean spherical candle-power is said to have been obtained; an incidental advantage is that the luminescence in the tube seems to be partially replaced by temperature radiation, and therefore the light contains a distinct red element, the spectrum broadening out into a more or less continuous band instead of consisting of isolated lines.

In addition, quartz-glass allows ultra-violet light to pass through with special ease, and the lamp is therefore believed to have special uses for the destruction of bacteria, photographic purposes, &c. For ordinary illuminating purposes a special absorbing glass envelope restricting these rays is used. The Moore tube utilises gases in a rarefied condition and subjected to a high-tension alternating discharge. The essential feature of this arrangement is the use of a valve which automatically keeps the condition of the gas within the tube constant.

Gas Lighting.

Great advances have been made in the efficiency of gas burners since the early flat-flame burners yielding only about 3 candle-power per cubic foot. The most recent figure is furnished by the Keith high-pressure light, for which 60 to 70 candles per cubic foot have been found by some observers.

Improvements have been made in the incandescent mantle both in the direction of the colour of the light and through durability. Even so, manufacturers in England have stated that, as a rule, mantles require renewing every 200 hours.

A new departure was introduced some years ago by the Plaissetty soft mantle, and more recently the Cerofirm Company is stated to have made advances in the same direction. For such mantles it is claimed that their softness renders them convenient for package, and that they naturally burn into the shape of the flame, and are thus used under the most efficient conditions. The introduction of the inverted mantle has, of course, also been a great advance, although only two years ago there were many who doubted its commercial possibilities.

At the same time, steady improvements in the design of inverted burners have proceeded. Many types on the market are specially designed to avoid discoloration of the fitting through heat, to secure all the conditions most favourable to complete combustion. Whittaker and Litle in the United States, and, more recently, Lebeis in Germany, have described thermostatical methods of automatically regulating the access of air to the burner, which frequently requires adjustment, as the burner after lighting gradually becomes heated.

Perhaps the greatest advance has been in the direction of *high-pressure* gas lighting, which serves to promote an intimate mixture of gas and air, favouring complete combustion. To this end gas at high pressure may be used, or air at high pressure led into the burner, or a mixture of gas and air at high pressure. In any case, however, special external arrangements are needed with an existing low-pressure installation. Self-contained, highly efficient lamps, which can be run off the ordinary low-pressure supply, have therefore been designed. For instance, the Lucas lamp employs a small fan driven by an electric motor, which receives current from a thermopile near the mantle. In the Chipperfield lamp, a small hot-air engine placed above the burner automatically pumps air under pressure into the burner.

An important field in gas lighting is the use of automatic ignition devices. These may consist of electric sparking apparatus, of clock-work arranged to turn on and off the gas by means of a bye-pass at specified hours, or automatic devices of the same type manipulated by a rise or fall in pressure. Clock-work systems are very trustworthy, but, of course, do not take account of peculiar atmospheric conditions, such as fog. Apparatus of the last type can be controlled from the station, and lamps can be lighted up or extinguished as the engineer desires.

Mention must also be made of the special Norwich system for interior lighting and of the pneumatic methods; these, too, involve the use of the pilot flame.

The subject of street lighting formed the object of study of a deputation to the Continent recently appointed by the Corporation of London, and was subsequently investigated by the lecturer in a visit to Germany. A novelty of considerable interest, with which experiments are being made at Stuttgart, consists in slinging gas lamps on wires spanning the street, just as is done in the case of electric arc-lamps in Cannon Street at present. Lastly, in this section of the subject, the lecturer refers to the recognition of the importance of the heating power of gas, which is now regarded as more vital than its "illuminating power," according to the prescribed tests with flame-burners, for modern methods of lighting, and discusses the suggestion of a calorific standard in the future.

Gas, Oil, Acetylene, and other Self-contained Methods of Lighting.

The simple method of lighting by petroleum lamps, the author points out, should not be neglected. It is used, for instance, in the Church of St. Sophia of Constantinople, where it is preserved on account of its decorative value and because of religious tradition. In addition, petroleum lamps are still used in the country, and give good results when properly handled; in this connection the researches of Mr. Guiselin, who has demonstrated the advisability of keeping the reservoir in oil lamps well filled, are of interest. For instance, the illuminating power was found to be improved by 20 per cent. when 700 cubic centimetres instead of 500 were retained in the reservoir.

Recently many methods of incandescent oil lighting, that is, the use of vaporised fuel with an incandescent mantle, have been devised. The Kitson system and the Empire light are stated to be very efficient for lighthouse work and for the illumination of large outdoor areas in remote localities. Other types of lamps are the Blanchard, the Petrolite, &c., which are described in detail.

A special account is also given of petrol air-gas lighting, three typical systems, the Machine Gas Syndicate (Cox's system), the Aërogen, and the National Air Gas, being exhibited. This system of lighting has attracted great attention recently for the lighting of private houses in districts where gas or electricity are not available. A mixture of a small percentage of petrol vapour with air is generated outside the building, and passed through pipes to the burner in the usual way.

The method of lighting by alcohol lamps is worth consideration in agricultural districts where petroleum may not be available, but alcohol is readily manufactured. There are also a number of liquid-gas systems in which gas is stored under pressure in liquid form, and has been effectively used for railway-carriage lighting, &c.

Acetylene Lighting.

Mr. Gaster deals briefly with the historical development of acetylene lighting, and describes the modern form of generator and several types of portable acetylene lamps; these are frequently used in mines, for motor-cars, &c.

Acetylene, like petrol-air gas, finds its main application where gas and electricity are not available. A recent development of considerable interest is the method of dissolving acetylene in acetone, which, at a pressure of ten atmospheres, absorbs about 240 times its own volume of acetylene, but liberates it when the pressure is released. Tubes of dissolved acetylene have been widely used for portable lighting, on motor-cars, railway trains, and even in emergencies for interior lighting. Perhaps one of their most successful applications, however, is for the lighting of buoys and beacons in remote localities.

There are several types of ingenious valves which are very effective in saving the consumption of acetylene in the above circumstances. For instance, the Dalen solar valve automatically cuts off the main supply of acetylene in daylight, leaving only the bye-pass burning, and rekindles it at night.

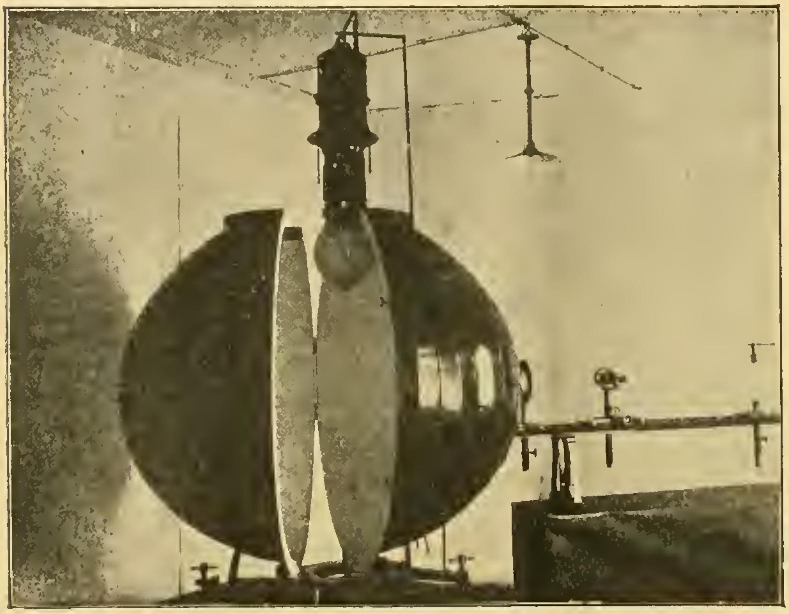
General Problems in Illumination.

In the last of these four lectures Mr. Gaster discusses the question of illumination in general terms. He again directs attention to the increasing brilliancy of modern illumination, and points out that the eye must have developed mainly in compliance with daylight conditions, and therefore we ought not to utilise artificial methods of lighting differing too widely from diffused daylight. The importance of providing for proper access of daylight in the design of buildings, particularly schools, is insisted upon. In this connection, the choice of wall-papers and the scheme of decoration are of considerable importance.

It is pointed out, too, that the intrinsic brilliancy of illumination has gradually increased of recent years. The effect of gazing directly upon such bright sources is very fatiguing and distressing to the eyes, and the author suggests that the time is now ripe for Governmental recommendations on this point.

In order to reduce the intrinsic brilliancy of light sources, suitable shades may be employed, and special reference is made to the Holophane diffusing globes and reflectors, which enable the light to be distributed and concentrated in any desired direction.

Some particulars are given of recent progress in photometry. The line of development of special consequence has been the introduction of so-called illumination photometers, which measure, not the actual intensity of the source, but the actual illumination on the pavements or at the desk at which we read. Sir William Preece so long ago as 1883 emphasised the value of such measurements. Another interesting development is the Globe photometer, an example of which is shown in the accompanying illustration.



The Ulbricht globe photometer, by the aid of which the mean spherical candle-power of a source can be determined by a single measurement.

Perhaps an exceptionally important development during the last year has been the establishment of the international unit of light between England, France, and the United States, and the recognition of a simple relation connecting this unit with the value in use in Germany. The success of co-operation in this direction in this country is felt to be largely due to the fact that representatives of the gas industry and the gas referees were invited to act with those connected with electricity on the commission studying this subject.

Turning next to some practical examples of illumination, the author insists upon the importance of adequate school lighting, quoting many authorities to show that the eyesight of school children deteriorates during school life; he suggests that tests of the children's condition should be accompanied by the preservation of data relating to the methods of illumination employed in such schools, as this is believed to have a very vital influence on the health of the child.

In the same way the lighting of factories, hospitals, libraries, &c., should receive very careful study, for good illumination is as much a necessity as the provision of adequate sanitation and good ventilation; it is hoped that in the future, conditions of illumination, like the matters referred to above, will become the subject of Government inspection and recommendation. In addition, it is pointed out that even from the point of view of expediency employers would do well to pay attention to this matter, as a relatively small expense involved in securing good lighting is more than counterbalanced by the improvement in the quality and output of work. In hospitals it is obvious that the lighting should be exceptionally perfect, since people in an invalid condition are specially liable to feel the effect of bad methods of lighting.

Libraries, again, are frequented by people engaged in strenuous work and taxing their eyes severely; it is therefore suggested that in this case also no pains should be spared to make the methods of lighting convenient to the workers, and that when great expense is incurred in collecting valuable books and housing them in handsome buildings, the provision for the necessary illumination by the aid of which the books alone can be read should not be grudged.

A subject on which cooperation between different authorities is badly needed is street lighting. It is pointed out that there is room for the establishment of some central testing department where thoroughly trustworthy and impartial tests could be carried out and used for the common benefit of those interested. In particular, it is suggested that it cannot be decided by the mere personal impression of a non-technical body of observers whether the lighting of the street is good or bad. This must be determined by the aid of precise scientific tests, carried out by impartial experts, who have made a thorough study of the subject, and can provide records by which experiences can be checked and subsequently repeated.

Other instances of problems in illumination in which there is great field for scientific treatment are shop-window lighting, stage lighting, and light-house illumination; in the two former fields, in particular, there is ample scope for the ingenuity of those who are up-to-date in their knowledge of the different illuminants, and possess, in addition, the requisite taste.

In the next section of this lecture Mr. Gaster deals with the scientific basis of light production, pointing out how the nature of the radiation from an illuminant depends in general upon its temperature, and indicating some of the possible lines of future development. The figures of authorities in this matter differ very greatly, but it is generally considered that the percentage of energy radiated in the form of light is very small indeed. The problem of light production is complicated by the fact that some invisible kinds of radiation seem to exert a prejudicial effect on the eye. The author describes some experiments showing the nature of the ultra-violet rays, which some authorities consider to be injurious.

In conclusion, Mr. Gaster points out that the problem of illumination is a complex subject which deserves special consideration by itself. There is a need for men who are not connected with any particular illuminant and who are able to take a wide view of the different aspects of the matter, so as to deal with modern problems of lighting. In order to focus interest in this subject and to bring into contact the engineers, architects, oculists, and others interested in illumination, a society has been formed this year which will, it is hoped, gradually lead to the solution of the important questions on which further exact data are felt to be desirable; this is termed the Illuminating Engineering Society. The first president of the society is Prof. S. P. Thompson, and the opening session will commence in November.

ANNUAL METEOROLOGICAL REPORTS.

THE Deutsche Seewarte has issued part xvii. of its over-sea meteorological observations for 1907, containing very carefully prepared summaries, and in some cases individual readings, at some thirty stations. The principal localities include Labrador, Morocco, Shantung, German East Africa, and some islands in the Pacific Ocean; there are also some isolated stations, including one recently established at Babylon. Scientific investigators will be grateful to the Seewarte for references which are given in all cases to the periodicals in which previous observations and results have been published.

The annual report of the Philippine Weather Bureau for 1907, part i., contains hourly readings at the Manila Observatory, together with means deduced therefrom. The tables also show the extreme values recorded, and the departures of the monthly and yearly means from the average. The mean temperature of the year, 79·5°, was practically normal; the absolute extremes were 98·1° in April and 59·0° in January. The rainfall, 72·5 inches, was 3·3 inches below the average; of this amount 64 inches fell from June to October inclusive (the period of the south-west monsoon). An appendix shows the greatest daily and hourly rainfall registered at the observatory in past years; the greatest daily falls were 13·3 inches and 12·1 inches, on September 24 and 25, 1867.

The report of the Liverpool Observatory for the year 1908 has been received from Mr. W. E. Plummer. This useful establishment is maintained by the Mersey Docks and Harbour Board in the interest of shipping, and is well provided with meteorological and astronomical instruments. In addition to the continuous use of the transit instrument for the determination of time, observations of selected stars and of comets visible from the observatory formed the chief astronomical work of the year. A Milne seismograph for the registration of tremors in the earth is kept steadily at work; during the Messina earthquake (December 28) the duration of disturbance was 1h. 41m., and the amplitude (half the complete range of maximum motion) was 15 mm. The meteorological results are very complete, *e.g.* the wind observations show the maximum velocity for each day recorded by Dines's apparatus, the extreme pressure on the square foot by Osler's anemometer, the horizontal motion by Robinson's anemometer, and the number of hours that the wind blew from different points of the compass. The mean temperature of the year (49·2°) was practically normal, and the rainfall (28·9 inches) slightly above the average.

The annual report of the United States Weather Bureau for the fiscal year ended June 30, 1908, shows that the research work at Mount Weather Observatory has been carried on without material curtailment, notwithstanding the destruction by fire of the administration building in October, 1907. Investigation of the upper air by means of kites and captive balloons is made daily (except Sundays), and the data are telegraphed to Washington for the use of the forecast division. The work on solar physics includes the measurement of solar radiation and the degree of absorption by the atmosphere. Considerable discrepancies exist in the values of the solar constant, even computed from observations on the same day at Mount Weather and at Washington; in most cases these are traceable to the unsteadiness of the atmosphere. Great activity exists in the divisions dealing with land and ocean meteorology; the number of climatological stations now exceeds 3700, and more than 1600 vessels cooperated with the Bureau during the year. All data referring to the Indian Ocean are lent to the Indian Meteorological Department, where they are copied and returned. In the forecast division isobaric charts are prepared from daily telegraphic reports from selected stations throughout the northern hemisphere, and forecasts for about a week in advance were published during the last three months of the year. The library now consists of about 28,000 books and pamphlets. In addition, meteorological articles contained in periodicals and transactions are catalogued under both author and subject; this bibliography is said to be more frequently consulted than the catalogue of books.

The Survey Department of Egypt has published its meteorological report for 1907, containing hourly readings at Helwan and climatological tables at thirty-five stations of the second and third order; the monthly tables give tri-daily readings in the form adopted by the International Meteorological Committee, and also include the daily amount of evaporation, as that element is of considerable importance in Egypt and the Sudan. Additional tables include hourly observations by Dines's pressure anemometer at Alexandria, rainfall and wind direction for a number of stations, and river-gauge observations. In compliance with a desire expressed by the International Meteorological Committee in 1907, tables of normal values are also given. Rainfall was in excess in Egypt and in North Sudan, but in considerable defect throughout the rest of the Sudan, and, as we have previously stated, the Nile flood was worse than any recorded during the past fifty years.

The meteorological year-book of the Bremen Observatory for 1908 has been received. From small beginnings this institution, under the superintendence of the late Dr. P. Bergholz, has attained a position of considerable importance; the observations, which include hourly readings and means, with monthly and yearly summaries, have been reduced by Prof. Grosse in the same thorough manner as heretofore, with the addition of hourly tabulations of sunshine records and monthly means of earth temperatures. The valuable materials, which now extend over many years, await a general scientific discussion; this desideratum is urgently pointed out by Dr. Grosse, but under present arrangements, while the director has to divide his energies between the observatory and other official duties, this important work has to be postponed.

WORK OF THE PHYSIKALISCH-TECHNISCHE REICHSANSTALT IN 1908.

FROM the annual report of the above institution for last year, recently published, we find that the same steady progress is made in research work of a varied nature; the following notes give some particulars of a few of the more interesting investigations completed or in progress in 1908.

The saturation pressure of water vapour between 50° and 200° was determined as a continuation of the experiments in the previous year, the resultant pressures being tabulated in the report. The limit of accuracy over the whole range depended on the measurement of temperature, and the greater part of the work was devoted to such measurements. In the neighbourhood of 100° the temperature scale could be considered as trustworthy to 0·01°, and at 200° to 0·02°. The platinum thermometers used were compared at 150° and 200° with the nitrogen thermometer, after the constants of the latter had been determined, the comparison being made in an electrically heated oil-bath.

The experiments on the heat of evaporation of water, which were previously made between 30° C. and 100° C., have been continued for temperatures above 100°. Up to the present it had only been possible to obtain the values for the evaporation-heat from Regnault's observations of the total heat by calculating the heat of the water. It therefore appeared desirable to make direct measurements of the evaporation-heat. The experiments were carried out between 100° C. and 180° C. The results show that in the first approximation it is admissible to extrapolate beyond 100° the formula

$$L = 94{\cdot}210(365 - t)^{0{\cdot}34129} \text{ Cal. } 15,$$

which has been drawn up for the evaporation-heat L between 30° C. and 100° C. as limits for t.

The work connected with the silver voltameter was brought to a conclusion, and a paper published dealing with the subject. The object of the measurements was (1) to compare with the aid of the voltameter and a resistance the E.M.F. of the Weston normal cell, which was last determined by means of the silver voltameter in 1898; (2) to determine the accuracy attainable in measurements with the silver voltameter (*a*) under conditions which are as regular as possible, and (*b*) with a variation of the factors in connection therewith. It was found (as at the National Physical Laboratory) that the differences obtained by Richards and by Schuster, attributable on the one hand to the influence of the anode liquid, and on the other to that of the oxygen, could not, within the errors of observation, be confirmed.

Particulars of the changes in shellacked manganin coils due to varying humidity were published in 1908. The changes in question are so slight in the German climate as only to be of importance for resistances equal to or greater than 100 ohms, and even then only for measurements of the highest precision. For resistance standards of 1000 and 10,000 ohms the changes during the summer of 1908 amounted to 5 parts in 100,000 only. By taking the precaution of keeping resistances in a hygrostat of 50 per cent. humidity the constancy of all resistances up to a 100,000-ohm coil was secured. A comparison of the mercury standards with the manganin coils is in hand.

Various institutions (*e.g.* the National Physical Laboratory, Teddington, and the Bureau of Standards, Washington) have issued specifications for the setting up of standard cells, and detailed instructions are given for the preparation of the mercurous sulphate. It is directed that this salt shall not be washed with water, but with dilute sulphuric acid or with a saturated solution of cadmium sulphate. The Reichsanstalt is of opinion that the manner of washing the preparation is without influence on the result. It follows from this that the same E.M.F. results whether the salt be hydrolysed or not.

In connection with the research on anode rays mentioned in the last report, it was found that when in the presence of substances which emit intense anode rays the electro-negative bodies such as iodine, bromine, &c., considerably favour the formation of the rays. It was found that the red and blue fluorescent tints of glass which can be produced by slow kathodic rays can also be caused by sufficiently dense kathodic rays. For the blue fluorescence it was shown that they are connected with the emission of negative electrons. A fixed point for the presence of the positive electrons could not be ascertained.

The experiments commenced in 1907 on the electrolytic properties of silver and copper were concluded, and show that silver in the aqueous solutions of HCl, HBr, and HI, and copper in the aqueous solutions of HF indicate an electrolytic valvular action which does not appear, as in the other metals, to be caused by a gas stratum, but by a solid stratum.

For the determination of the absolute values of standards of self-induction, which are made by comparing with capacities measured absolutely, a standard air condenser was constructed. The new air condenser consists of 107 magnalium discs of 20 cm. diameter, 1 mm. thickness, and 1 mm. apart. It has a capacity of about 0·03 mfd. Amber is used for insulating, the insulation resistance being of the order 10^{15} ohms.

The work done in the magnetic laboratory includes a comparison of the methods of testing magnetic materials and experiments on initial permeability. An exhaustive series of measurements of self-induction was carried out with high-frequency alternating currents, and papers bearing on this subject have been published. A rotating interrupter for absolute capacity measurements by Maxwell's method is described.

A number of tests were made on various forms of flicker photometer which could be used on a straight photometer bench, with the view of determining whether the use of the flicker photometer is to be advocated for tests. It was found, however, that the flicker photometer offered to the skilled operator no advantage over the usual method of measurement as regards rapidity and certainty of adjustment.

Nearly seventy official and private papers of a scientific nature by members of the staff were published during 1908, particulars of these being given in an appendix to the report.

ZOOLOGY AT THE BRITISH ASSOCIATION.

BY arrangement between the organising committees, the presidents of the biological sections gave their addresses at different hours, so as to make it possible for members to attend them all. The address in Section D was delivered by Dr. Shipley on Friday, August 27.

The programme for Thursday, August 26, was opened by Dr. E. Goodrich with a paper on the origin of the vertebrates. The object of this paper was to show that none of the theories of the origin of vertebrates hitherto brought forward, deriving them from some existing class of the invertebrates, was satisfactory, because the theories violated the sound principles of phylogeny based on the combined evidence of comparative anatomy and physiology, embryology and palæontology. This evidence enables us to trace back the Gnathostomes to a primitive shark-like fish, the Gnathostomes and Cyclostomes to a common form of much more uniformly segmented structure, and, finally, the Craniata and Cephalochorda to an ancestor of very simple structure, without dermal skeleton and without pronounced cephalisation, which probably became extinct even before the Silurian age.

Mr. C. L. Boulenger followed with a paper on certain subcutaneous fat-bodies in Bufo. These structures are to be found in a number of different species, and consist of masses of adipose tissue situated at the junction of the hind-limbs with the trunk.

On Friday, August 27, after the presidential address, Prof. H. Jungersen read a paper, illustrated by lantern-slides, on the osteology of the Lophobranchii. The author pointed out that the skeletons of these fishes have hitherto been most unsatisfactorily examined, and the cranial structures, especially the suspensory apparatus, the gill-arches and the scapular arch, have been incorrectly interpreted by all previous authors. In the skull, parietals and opisthotics are wanting, the pterotics are greatly developed, reaching below to the basioccipital, and preventing the exoccipitals from meeting the prootics. These two features, together with the prolongation of the anterior part of the skull (mesethmoid and vomer), the Lophobranchii have in common with the Solenostomidæ, the Fistulariidæ, the Aulostomidæ, and the Centriscidæ, these families forming with the Lophobranchii a natural group, the "Solenichthyes" of Regan.

The scapular arch is cartilaginous to a much greater extent than is the case in other Teleosteans, but a small ossified scapula is to be found as well as a coracoid.

The three anterior vertebræ are immovably joined together, their neural arches being firmly bound by sutures with long dentations; in addition, the two anterior ones are fixed to the expanded clavicle. The vertebræ bearing the interspinous bones for the dorsal fin are provided with secondary transverse processes behind the primary ones, thus enlarging the surface which gives attachment to the powerful muscles of the dorsal fin, the chief agent in swimming.

After a paper by Dr. S. Hadwen on Texas fever in cattle, and its cure by the use of drugs, the day's programme closed with the reports of the special committees on grants.

The meeting on Monday, August 30, was opened by Prof. A. B. Macallum, who read a paper, illustrated by numerous lantern-slides, on palæobiology and the age of the earth.

Prof. C. J. Patten followed with two papers:—(1) on the pre-nuptial plumage in *Calidris arenaria*, illustrated by lantern-views of the sanderling at different periods; (2) on the germinal disc in naturally incubated eggs of *Passer domesticus*. Due reflection of the facts that nests (or, in the case of those birds which make no nest, the soil on which the eggs are deposited) vary to an extraordinary extent in their heat-retaining properties; that the protecting egg-shells vary strikingly, not only in their thickness, but in their porosity and other structural peculiarities; and, lastly, that avian embryos vary to a considerable extent as regards their vitality when heat is withdrawn from the shell, has led the author to think that the method of studying avian embryology by means of the artificial incubator is not always the most trustworthy. He therefore described the changes which he observed during the first six hours in a clutch of naturally incubated eggs of the house-sparrow (*Passer domesticus*).

The next paper, on the *rôle* of visual function in animal and human evolution, was, in the absence of the author, Dr. G. M. Gould, taken as read.

Prof. S. H. Reynolds read a paper on the British Pleistocene Canidæ. Three species are found, the wolf, the fox, and the Arctic fox. There is no evidence of the existence in Britain in Pleistocene times of any animal that could be called a dog. The jaw described as *Lycaon anglicus* is thought by the author to be better regarded as a somewhat abnormal wolf. While, apart from any difference in size, the skull of a fox is readily distinguished from that of a wolf or dog by the depressions in the post-orbital processes of the frontals, it is extremely difficult, if not impossible, to find any valid distinctive character between dogs and wolves. The most useful character, for which we are indebted to Studer, is the orbitofrontal angle. He regards as belonging to wolves skulls in which this angle measures 40°–45°, and as belonging to dogs skulls in which the angle is greater than 45°. The author's measurements, while confirming Studer's contention that the angle in question tends to be decidedly less in the wolf than in the dog, show that the distinction is not absolute, and cannot be relied on in all cases.

The programme for the last day of the meeting, Tuesday, August 31, opened with a paper by Mr. C. F. Rousselet, on the geographical distribution of Rotifera. The author showed that the results of recent investigations point more and more to the fact that the Rotifera enjoy a cosmopolitan distribution, which is not limited to continents, but extends to all places on the surface of the earth where suitable conditions prevail. Wherever search has extended in Europe, America, Africa, India, China, Australia, and even the north and south polar regions, the same genera, and even species, have been met with, and it is not possible to speak of any typical or peculiar rotatorian fauna for any continent, zone, or region.

The very erratic appearance of rare or uncommon species in widely separated places seems to show that distance is no obstacle to their distribution, provided only that they find suitable conditions. To account for such a distribution over the whole of the globe, it has been supposed that most species of Rotifera can be dried up and their bodies carried by the wind, as dust, for long distances, and then come to life again on landing in suitable surroundings. This Mr. Rousselet showed to be a very erroneous generalisation of the fact that a very few species of bdelloid Rotifera, and in particular *Philodina roseola*, are capable of secreting a gelatinous envelope in which they can resist drought for many months, and come to life again on being placed in water. The author's experience has shown him that the vast majority of rotifers die immediately on being dried, and do not revive after complete desiccation; but their eggs, and in particular their resting eggs, can stand a prolonged state of desiccation and also freezing, and can therefore readily be transported by the wind or by aquatic birds and other animals, and will hatch when deposited in suitable pools of water. In his opinion it is by this means that the cosmopolitan distribution of the Rotifera over the world has in the course of time been brought about.

Dr. J. Pearson read a paper on the processes of autotomy in the Crustacea, and Prof. H. Jungersen communicated an account, by Dr. J. Schmidt, of the distribution of the fresh-water eels (Anguilla) throughout the world.

The following papers were, in the absence of the authors, taken as read:—Dr. F. A. Dixey, on the parallelism between the nymphaline genera Adelpha and Chloríppe; and Mr. W. J. Dakin, histology of the eye of Pecten.

In the afternoon Mr. J. Stanley Gardiner delivered a lecture on coral-reefs, illustrated by numerous lantern-views.

Two resolutions were passed by Section D during the meeting at Winnipeg:—

(1) "The zoological section of the British Association wish to record their sense of the danger caused by the approach of the Norwegian rat, which threatens the wheat industry of western Canada, and to urge the Governments concerned to take immediate steps to organise the extermination of this dangerous pest."

(2) "In view of the enormous importance of the fisheries of Canada in connection with her prosperity and her rapidly developing position as the great source of the food supply of the Empire, and appreciating the danger of exhaustion which menaces certain of the fisheries, the members of the zoological section of the British Association for the Advancement of Science, now in meeting in Winnipeg, desire to congratulate both the Dominion and the Provincial Governments upon the work already accomplished in connection with the study of the food-fishes, upon the establishment of a marine biological station on both the Atlantic and Pacific coasts, and upon the cooperation with the Government of the United States in an International Commission from whose labours much may be expected. At the same time, the members of the section are of the opinion that further and more extensive efforts in all these directions are urgently needed if certain of the fisheries, notably that of the Pacific salmon, are to be maintained even at their present condition of productiveness. For the framing of satisfactory and effective regulations for the utilisation and conservation of the food-fishes a complete knowledge of their life-history is absolutely necessary, and the section desires to impress on the Governments concerned the immediate need for an extensive prosecution of investigations along this line, for greater facilities for the scientific study of the fisheries, especially those of the Pacific coasts, and for a continued cooperation of the Dominion Government with the governments of the provinces and also those of the United States in all efforts looking towards the conservation of the fisheries, one of the most valuable natural resources of Canada."

GEOGRAPHY AT THE BRITISH ASSOCIATION.

THIS section was presided over this year by Colonel Sir Duncan A. Johnston, K.C.M.G., C.B., formerly director-general of the Ordnance Survey of the United Kingdom, and, as usual, the opening address dealt with matters of which the president had been made intimately cognisant through his life-work. After briefly referring to the additions made to geographical knowledge during the year by the journeys of Dr. Sven Hedin, Dr. Aurel Stein, and Lieut. Shackleton, Sir Duncan Johnston devoted the bulk of his address to the subject of topographical maps, considering specially the preliminary triangulation for such maps, the methods of detail survey, the scale of the map, the scale of the field survey, the methods of representing details on the map, and the methods of reproduction. The address was printed in NATURE of September 9.

The remainder of the first morning sitting of the section was taken up with the reading of papers by Miss Luella A. Owen, of St. Joseph, Mo., on floods in the great interior valley of North America; by Mr. James White, head of the Geographical Department of the Dominion of Canada, on the nomenclature of the islands and lands of Arctic Canada; and Dr. Robert Bell, formerly head of the Geological Survey of Canada, on the Hudson Bay route in its present aspect. The first of these papers, written by an eye-witness of the flood of 1903, when at the end of May and the beginning of June the valley at Kansas City "was filled from bluff to bluff with the turbulent muddy waters, which on June 2 completely submerged the entrances to the main waiting-room of the Union station," gave in a compact form an account of the conditions which produce floods in the region in question and of the diversified character of their consequences, and then considered the possibility of their future control as a subject of vital interest to the United States, and one involving a careful examination of the methods of control in order to avoid the possibility of bringing about evils more disastrous than the floods themselves. Mr. White's paper necessarily consisted entirely of details, but as these are of no little interest in the history of geography, geographers will be glad to learn that they will be made available in the pages of the *Geographical Journal*. In the third of the morning papers Dr. Bell reiterated the views he has long held and urged as to the practical importance of the Hudson Bay route for the development of the north-west of Canada, emphasising on this occasion the urgency of the problem in view of the rapidity with which that development is taking place and the effect which it may be expected to have in promoting more intimate commercial relations between that region and the mother country.

No separate meetings of Section E were held in the afternoons, but the afternoon of Thursday, August 26, was devoted to a joint meeting of that section with the subsection on agriculture, at which a paper contributed to Section E by Prof. A. P. Brigham, secretary of the American Association of Geographers, on the development of wheat culture in North America, was followed by one contributed to the subsection on agriculture by Prof. Mavor, of Toronto, on the agricultural development of Canada, 1904–9. The first of these papers will be published in full in the annual report of the association, as well as in the *Geographical Journal*. Here, therefore, it will be enough to say that it laid stress on the enormous possibilities still remaining for the expansion of wheat production even in the United States, directing attention, among other things, to the large production of wheat relatively to population in some States not generally thought of as wheat States, such as Maryland, which this year produced eleven bushels of wheat per head. Prof. Mavor's paper was a continuation of his well-known report to the Board of Trade on the same subject, coming down to the year 1904, and, like it, protested against some of the more sanguine estimates of the possibilities of wheat production in Canada, although he admitted that his estimates of 1904 ought to be increased. An animated discussion followed the reading of the two papers. The prevailing note of that discussion was sanguine, both as to the possibility of enormously extending the area under wheat in North America and increasing the production in the area already placed under that crop. Major Craigie, chairman of the subsection on agriculture, directed attention, however, to the dependence of that increase on the distribution of population, and thus implicitly raised the question of the future rate of increase of wheat production in North America, and the possibility of maintaining that increase without a concurrent advance in prices.

The first paper read in Section E on Friday, August 27, was also by Prof. Mavor—a summary sketch of the economic geography of Canada. Mr. J. Stanley Gardiner, F.R.S., then gave a semi-popular account, illustrated by many beautiful lantern-slides, of the Seychelles, a subject on which he sent a report to the association as secretary of the committee for the investigation of the Indian Ocean appointed by the association. Two papers relating to physical geography followed. The first of these, by Prof. W. H. Hobbs, of the University of Michigan, Ann Arbor, developed an interesting theory of the cycle of Alpine glaciation, showing how many of the phenomena of glacial erosion found their explanation in the alternation of the conditions bringing about the advance and retreat of glaciers. This paper will also appear in the pages of the *Geographical Journal*. The other was by Prof. Dodge, of Columbia University, on the formation of arroyos in adobe-filled valleys in the south-western United States. The origin of these arroyos, or wadis, as they would be termed in arid regions frequented by Arabic-speaking peoples, was attributed in this paper to the introduction of sheep, the grazing of the herbage by which in gently sloping valley floors first gave the water an opportunity to become concentrated in streams instead of running off the surface in sheets, a theory which confirms an observation of the Navajos, the native race of the region. The last paper read that morning was by Mr. Lawrence J. Burpee, of the Carnegie Library, Ottawa, on the water route from Lake Superior to the westward. Of the three routes, that of the Kaministikwia, that by Grand Portage, and that by way of Lake Nipigon, the first-mentioned was the first to be discovered, but was neglected and forgotten after the discovery of the Grand Portage route, and remained forgotten until the Canadians ascertained that Grand Portage lay in the territory of the United States. Search for another route led to the re-discovery of that by the Kaministikwia, and rendered the nearly simultaneous discovery of the Nipigon route of no practical importance.

Two hours of the morning of Monday, August 30, were taken up with a discussion on the teaching of geography in secondary schools at a joint meeting of Sections E and L, held at the meeting place and under the chairmanship of the president of the latter section. The discussion was opened by an informatory and helpful paper by Prof. R. E. Dodge, of Columbia University, New York, and followed by one (read in the absence of the writer by the recorder of Section E) by Dr. C. H. Leete, principal of the Sachs School for Girls, New York, who has been engaged in the secondary teaching of geography for upwards of a quarter of a century. Several professors and teachers of geography took part in the discussion that followed, and almost all these coincided with the view expressed by Prof. Dodge, that the teacher of geography should look upon it as his business to let the relation of the earth to man dominate his presentation of the subject. The remainder of the morning was taken up with a lecture by Mr. A. O. Wheeler, president of the Alpine Club of Canada, on some characteristics of the Canadian Rockies, which attracted a larger audience in Section E than was assembled on any other occasion during the meeting.

The meeting on Tuesday, August 31, was opened by a carefully prepared and instructive paper on the influence of mechanical transportation upon the framework of cities, by Mr. George E. Hooker, civic secretary to the City Club of Chicago. It was, unfortunately, read to a very meagre audience, but there is reason to hope that it will appear somewhere in a permanent form. Prof. A. P. Coleman, of Toronto University, followed with a paper on the Yellowhead Pass and Mount Robson, an adjacent peak, the highest in the Canadian Rockies. Prof. J. W. Gregory, of Glasgow, then gave a brief but very illuminating account of the remarkable success which has attended the replacement of kanaka by white labour on the sugar plantations of Queensland. The last two papers read that morning furnished two illustrations of the action of waves and currents in bringing about changes in shore-lines. The first was by Prof. Douglas W. Johnson, of Harvard University, and dealt with the physical history of Nantasket

Beach, a spit running northwards from the east end of the south shore of Boston Harbour. This beach consists of sand, gravel, and cobbles deposited by wave action between several drumlins which formerly existed as islands, and with the aid of a series of lantern-slides the reader of the paper showed how the form of the beach ridges and their relation to abandoned marine cliffs on the drumlins prove the former existence of several drumlin islands now entirely destroyed by the sea. The second of these papers was by Dr. F. P. Gulliver, secretary to the geographical and geological section of the American Association for the Advancement of Science, and dealt with what he called the Wauwinet-Coscata Tombolo, Nantucket, Mass. The term tombolo, the Italian for a "pillow," applied in Italy to the low ridges or necks connecting Mt. Argentario with the mainland, Dr. Gulliver proposes as a general designation for such necks. The paper described and illustrated by lantern-views the opening of the neck referred to by a storm in December, 1896, when a channel navigable by small boats was formed, and the closing of this channel by waves and currents nearly twelve years later—November, 1908.

Some of the most interesting papers read in the section during the meeting were reserved for the last day, Wednesday, September 1, which was so far fortunate that the winding up of several other sections on the previous day allowed of the gathering of a larger audience in this section than was present on most of the other mornings. The first two papers were by Mr. James White, of Ottawa, one of them on the progress of the geographical knowledge of Canada from 1497 to 1909, the other on the economic development of Canada from 1867 to 1909. The subject treated of in the first of these two papers, which will appear in full in the *Geographical Journal*, was illustrated by a number of maps for different dates, for the most part at intervals of fifty years, illustrating for the earlier years the extent of exploration within the territory of the present dominion, and for the later years the extent of territory that remained unexplored. The subject of the second was illustrated mainly by means of statistical diagrams. These were followed by a very interesting paper by Mr. J. B. Tyrrell, formerly of the Geological Survey of Canada, on a remarkable forgotten, or nearly forgotten, geographer, Mr. David Thompson, a native of London but of Welsh parentage, who, in the latter part of the eighteenth and the early part of the nineteenth century, travelled more than fifty thousand miles in the western wilds of Canada, making surveys wherever he went, and producing a map which was for many years the only one available, and was distinguished by such accuracy as to induce the reader of the paper to claim for its compiler the designation of the greatest practical land geographer who had ever lived. This paper also will appear in full in the *Geographical Journal*. Dr. L. A. Bauer, director of the department of terrestrial magnetism at the Carnegie Institution of Washington, then gave a brief general account of the progress of the general magnetic survey of the earth in recent years, a subject dealt with more fully in a paper read by the same author to Section A. It may here be mentioned, however, that the author stated that since April 1, 1904, the declination and dip of the magnetic needle and the intensity of the magnetic current had been determined at some 900 land stations in different parts of the world, and a general magnetic survey of the Pacific Ocean had been made, in the course of which the non-magnetic cruiser *Galilee* had made cruises amounting to about 60,000 nautical miles. The last paper read before the section was by Mr. Allorge, of the Oxford School of Geography, on the eastern (Tunisian) Atlas Mountains, their main structural and morphological features, a paper embodying the results of a journey made by Mr. Allorge and a companion in Tunis last spring.

It may be mentioned, in conclusion, that a somewhat dramatic incident marked the close of the meeting of this section. The last paper had been read, the audience had withdrawn, and the two secretaries, after winding up the work of the meeting, were just about to leave also, when they were summoned to the telephone to be informed of the reported reaching of the North Pole by Dr. Cook.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

THE president's address on "The Physiological Basis of Success," as distinguished from simple survival, has already appeared in NATURE (September 23, p. 384).

The report of the committee on Anæsthetics formed the basis of an interesting discussion. Presented by Dr. Waller, the chairman, the report gave, in the first instance, a summary of the work done during the year by the members of the committee, each of whom added appendices on the particular branch of the subject they had investigated. Appendix i. gave the results in clinical practice of Drs. Hewitt and Blumfeld, who employed a mixture of two parts of chloroform and three parts of ether; this they consider to be safer than chloroform alone when given by the open method.

Appendix ii. described Dr. Waller's chloroform balance, which shows at a glance the percentage of chloroform given to the patient. Appendices iii. and iv. summarise Dr. Waller's results on the comparative anæsthetising power of chloroform, ether, and alcohol, and Appendix vi., by Drs. Waller and Symes, gave a method of intravenous anæsthesia which can be used for the basis of a similar calculation. The very important results are reached that 1 gram of chloroform is equivalent to 8 grams of ether and 32–40 grams of alcohol, according to the method used for the calculation. Further, the effect of mixtures of anæsthetics is that of the sum of the constituents. As the anæsthetic action of ether (and still more of alcohol) is so much less than that of chloroform, a mixture of ether and chloroform will behave in practice like dilute chloroform, so far as the experiments have gone.

In the discussion that followed all the speakers expressed their appreciation of the scientific value of the determinations that had been made. Dr. N. H. Alcock referred to the excellent results that had been obtained by the administration of known percentages of chloroform vapour, and summarised the work that had been done on the individual variations in susceptibility to the drug. He regretted that the case of sudden death under a mixture of chloroform and ether (*Times*, August 5) had supplied such an inauspicious comment on Appendix i. of the report.

Prof. A. R. Cushny considered that the results obtained by Messrs. Buckmaster and Gardiner were of great importance to the general theory of pharmacological action. He considered that as the concentration of chloroform in the blood of patients who had succumbed during anæsthesia had not yet been ascertained, it was possible that the concentration was not unduly high.

Prof. W. T. Porter suggested that the unhappy result in some of these cases could not at present be averted by the most skilful anæsthetists, and that the cause might be sought in the hyper-irritability of the heart and vaso-motor apparatus.

Dr. Webster contributed a paper on the use of atropine and allied drugs in conjunction with anæsthetics, giving the results of numerous experiments. The conclusion reached was not favourable to the use of drugs of this class in conjunction with a general anæsthetic.

Prof. A. B. Macallum read two papers on the inorganic constituents in the blood of fishes, the first dealing with the osmotic pressure and the second with the relations of the inorganic salts to one another. He also read a third paper, on the inorganic composition of the blood in puerperal eclampsia, in which he pointed out the greater preponderance of magnesium, and especially potassium, in comparison with sodium.

A group of papers on the tracts in the spinal cord was furnished by Dr. Page May and Prof. Sutherland Simpson. Dr. Page May, who exhibited microscopical specimens and lantern-slides, gave a further description of a descending tract discovered by him, and which he names the "postero-septal tract." The origin and course, as determined by Wallerian degeneration and by retrograde chromatolysis, is from a joint region of the optic thalamus and corpora quadrigemina along chiefly the mesial fillet into the posterior column of the spinal cord, where it lies symmetrically on either side in close contact with the posterior septum, terminating in the tenth and eleventh thoracic segments. Its function is still undetermined, a series of detailed experiments showing only that it is not concerned with the pyramidal or voluntary motor path, or with any obvious vasomotor process of the spleen, kidney, and other organs, as examined with the plethysmograph.

Dr. Page May also demonstrated, by the method of retrograde chromatolysis, the delimitation of the motor area in the cerebral cortex. The method is free from the fallacies that attend stimulation and ablation, and has enabled the author and Dr. Gordon Holmes to map out the cerebral motor area with great precision. This area in man and the higher mammals is definitely precentral, as Sherrington and Grünbaum have found by other methods.

Dr. Sutherland Simpson and his pupils described the pyramidal tract in the sheep and guinea-pig. The fibres were traced by the degeneration method after removal of the motor cortex of one side, the staining being carried out with Marchi's method. In the sheep it was found that no pyramid fibres could be found in the posterior columns, the proportion of direct fibres was large as compared with the crossed fibres, and the fibres could not be traced at all below the first cervical segment.

Prof. Simpson also communicated a paper by Mr. E. C. Peterson on the ascending tracts in the spinal cord of the cat.

The report of the committee on the ductless glands, drawn up by Prof. Swale Vincent, furnished an interesting group of papers by Mrs. W. H. Thompson (of Winnipeg), Drs. Halpenny and Brandson, and Dr. Young.

Mrs. Thompson (who illustrated her paper with a series of excellent diagrams), as a result of the study of the thyroids and parathyroids throughout a wide range of the animal kingdom, supported the views of Vincent and Jolly, and Forsyth, that these bodies are not separate and independent, but are very intimately related. Although distinct in the lower Vertebrata, and of somewhat different embryological origin, in the Mammalia they form, in fact, one apparatus.

Dr. Halpenny discussed the operation of parathyroidectomy, and also the effect on the parathyroids after excision of the thyroids.

Dr. Young investigated the effect of excluding the blood passing through the adrenals from the circulation; he found no fall of blood pressure even after several hours; there was, however, a distinct rise when the ligature was removed.

In presenting the report of the committee on Arum spadices, Dr. Waller referred to the result obtained by him of the effect of local heat on vegetable and animal tissues. "Thermic shocks," short of actual injury to the tissues, produce no excitation, in contradiction to the usual text-book statement, but give an electrical effect of opposite sign to that given by excitation.

Prof. E. J. McWeeney read a paper on the bacilli connected with food poisoning, for the details of which the report must be consulted.

The joint discussion with Section B, to which Dr. E. Frankland Armstrong, Dr. E. J. Russell, and Prof. J. Wilson communicated papers, proved one of the most successful features of the meeting, and it is to be hoped that the precedent thus set will be followed on future occasions. Dr. E. Frankland Armstrong directed attention to the difference in composition of different proteins, and pointed out that not only should the total nitrogen be taken into account in comparing the different foods, but due regard should also be paid to the composition and nature of the constituent units. Dr. E. J. Russell referred to the very great difference in food value between different samples of hay and roots, which showed but small variation with the usual methods of analysis. Prof. J. Wilson gave a most interesting historical account of the practice of farmers in feeding live-stock, particularly bullocks. He pointed out the great economic importance of the knowledge of the proper amount of the different proportions of the more expensive protein to the less expensive fat and carbohydrate, and showed how the practice of farmers had changed in this matter. Prof. H. E. Armstrong, Prof. Cushny, Dr. Alcock, and Dr. Hardy also joined in the discussion.

On the last day of the meeting Dr. Alcock gave a demonstration of his chloroform apparatus in the theatre of the Winnipeg General Hospital, and subsequently there was a discussion on the structure and function of the nucleus, in which Prof. A. B. Macallum and Dr. W. A. Hardy took part.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—At a meeting of the master and fellows of St. Catharine's College, held on October 19, Prof. R. H. Biffen, of Emmanuel College, was elected to the vacant professorial fellowship. Prof. Biffen, who was a scholar of Emmanuel College, was placed in the first class in part i. of the natural sciences tripos in 1895, and in the first class in part ii. of the same tripos in the following year. Shortly after taking his degree he was elected to the Frank Smart studentship at Gonville and Caius College, and soon afterwards he undertook a research which greatly modified the process of the manufacture of india-rubber. Later, as professor of agricultural botany, he has done much to produce new wheats, some of them rust-resisting, others combining a high yield with the "strength" which bakers desire. This autumn, for the first time, the seeds of these wheats are being distributed to agriculturists. Prof. Biffen is also a well-known authority on fungoid diseases of plants.

Mr. V. H. Mottram, of Trinity College, has been appointed additional demonstrator of physiology until Michaelmas, 1912.

Mr. W. McD. Scott has been elected to a John Lucas Walker studentship, and Dr. C. W. Ponder, of Emmanuel College, has been elected to a second studentship.

The Arnold Gerstenberg studentship has been awarded to Mr. C. D. Broad, scholar of Trinity College.

MANCHESTER.—In response to the appeal made by Prof. Perkin at the opening of the new extension of the chemical laboratories on October 4, the following donations have been received towards the cost of the necessary apparatus, material, and equipment:—Dr. Hugo Müller, 300*l.*; anonymous, 250*l.*; Mr. Vernon K. Armitage, 250*l.*; Mr. M. J. Fernandez Ferreira, 50*l.*; Mr. Noah Kolp, 50*l.* The sum of 1100*l.* is still required.

Dr. C. P. Lopage has been appointed lecturer in observation of children and school hygiene.

OXFORD.—The geographical scholarship for 1909–10 has been awarded to Mr. H. Wallis, scholar of Hertford College.

MR. A. P. I. COTTERELL has been appointed lecturer on sanitary engineering in the faculty of engineering of the University of Bristol. The faculty is provided and maintained in the Merchant Venturers' Technical College.

DR. A. CAMPBELL GEDDES has been appointed successor to the late Prof. A. Fraser in the chair of anatomy at the Royal College of Surgeons in Ireland. Prof. Geddes was formerly assistant to the late Prof. D. J. Cunningham, F.R.S., Edinburgh.

To show his personal interest in the new Hong Kong University, the King has directed that holders of Government scholarships shall be styled "King Edward VII. scholars." Lord Crewe, the Secretary of State for the Colonies, suggests that the scholarships should be confined to Hong Kong Chinese and Chinese born in the Straits Settlements.

THE corporation of Yale University has received from Messrs. W. D. and H. T. Sloane, of New York, a gift of 425,000 dollars for the erection and equipment of a physics laboratory. Among other recent gifts are 25,000 dollars from Mr. A. G. Vanderbilt toward the general endowment, and 15,000 dollars for the school of forestry from Mr. G. H. Myers, a graduate of that school.

THE Joint Matriculation Board of the Universities of Manchester, Liverpool, Leeds, and Sheffield has appointed Mr. J. Murray Crofts, of Emmanuel College, Cambridge, as their organising secretary for the inspection and examination of schools. Mr. Crofts was for two years assistant master at Giggleswick, for two years junior inspector of the Board of Education, secondary branch, and for five years headmaster of the Johannesburg College, Transvaal, a post which he recently resigned.

WE learn from the *Scotsman* that during the recent recess many alterations and additions to the buildings in connection with the physiological department of the University of Edinburgh have been carried out, and that the additional accommodation will be available in the course of the present month. By utilising what was formerly the lecture-room, a new physiological chemical laboratory has been obtained, and the former chemistry room has been re-fitted as a laboratory for special research in chemical physiology. In addition to the foregoing, a new lecture-room has been erected on a piece of vacant ground at the south-west corner of the new buildings of the University. It is a one-storey building, designed to harmonise in appearance with the older adjacent buildings, and accommodates about 350 students.

THE *Electrician* for October 1 reprints in slightly abridged form from the *Electric Journal* an article by Mr. F. W. Taylor, an employer and past president of the American Society of Mechanical Engineers, on the reasons why manufacturers dislike college graduates. The difficulty in America appears to be that the graduate, on first entering works, becomes dissatisfied with the simplicity of the jobs allotted to him, and only after a year or two of shop experience develops character enough to do monotonous, unpleasant, or disagreeable work. Mr. Taylor suggests as remedy a year of hard work in the shops to follow immediately the first year of college life of all students, whether they are intended ultimately for the engineering profession or the Church. He believes they will in this way get a sounder knowledge of man and his duty in this world than can be gained by any other means. The *Electrician*, in a leading article devoted to the question raised by Mr. Taylor, cordially endorses many of the opinions he expresses.

PROF. W. OSLER, F.R.S., formally opened on October 15 three new laboratories for physiology, chemistry, and physics, respectively, at the London Hospital Medical College. The laboratories have been constructed and equipped at a cost of about 8000*l*., and afford accommodation for some 120 students. In declaring the laboratories open, Prof. Osler said that, after all, laboratories are the foundation-stones on which the work of a hospital rests. Medical students cannot spend too long a time in them. Medical students ought to get their laboratory methods so thoroughly ingrained into their constitution that they carry them with them to their dying day. If they are to be good practitioners they have to carry their laboratory work with them into their practice. Prof. Osler said he would like every medical student in one or other of the laboratories to undertake during some portion of his career a small piece of research work. It is difficult, but it altogether depends upon the individual will of the individual man. All can do it if they only make up their minds to it, and in view of their large research endowment fund there is no reason why some of the money should not go to helping the research work of some of the younger men.

THE new University College of South Wales and Monmouthshire at Cardiff was opened on October 14 by Lord Plymouth, president of the college. The King, as Protector of the University of Wales, sent wishes for the success and prosperity of the future work of the college. The Prince of Wales, as Chancellor of the University, sent a letter to Lord Plymouth to be read at the ceremony. In the letter the Prince said:—"The steady growth of the college and the record of work accomplished during the first twenty-five years of its life are evidence that it has adapted itself to the needs of the community. This development is particularly noticeable in the technological and medical schools, and, thanks to the generous support of the coalowners of South Wales to the former and the assistance specially given by the Treasury to the latter, still further vigour and usefulness may be looked for from these departments. To Principal Griffiths and the students past and present I offer my hearty congratulations upon the good results achieved by the college. Meanwhile, we must look ahead and endeavour to be ready to meet all the requirements of scientific and intellectual progress. The imperative necessity for higher education and research is becoming more and more recognised, and I feel sure it is not lost sight of by those who direct the great commercial industries of the district. The University College of South Wales is destined to provide the want, and I confidently believe that the people of South Wales, through whose patriotic generosity so much has already been accomplished, will by their continued sympathy and material support not only extinguish the debt upon the new buildings, but secure the funds necessary for still further developments."

THE trustees of the Oxford University Endowment Fund have completed the first year of their administration of the fund. The total sum received by the trustees was 86,570*l*., the greater part of which was forwarded to them as the result of Lord Curzon's appeal for donations for the further endowment of Oxford University. Among grants made by the trustees the following may be mentioned. A grant of 500*l*. a year has been promised for eight years to the curators of the Bodleian Library. The trustees have also provided the funds required to convert the North Gallery into a new reading-room, and have undertaken to meet the cost of constructing an underground chamber for the storage of books belonging to the Bodleian Library. It is estimated that this chamber will cost 10,000*l*. Five hundred pounds have been offered to meet the cost of equipment for further accommodation if space can be found by the University for the expansion of the school of geography. The trustees have agreed to pay for three years the salary of the newly appointed lecturer in Japanese, so that the school of Japanese—the first to be established in any English university—may be initiated without more than nominal calls upon the funds of the University. A school of engineering has been provided, largely by gifts allocated by donors and passing through the hands of the trustees. From the sum thus provided the trustees have promised a payment of 600*l*. a year for five years as a contribution to the cost of the engineering school, and have paid 300*l*. for equipment. Out of the general income of the trust fund a further sum not exceeding 150*l*. per annum has been promised for three years to furnish accommodation for the professor, for whom at present there is no adequate laboratory available. The sum of 61,553*l*. has been invested. The income will enable the trustees to make annual grants in aid of studies at present endowed inadequately, or in the establishment and initiation of new studies.

SOCIETIES AND ACADEMIES.

MANCHESTER.

Literary and Philosophical Society, October 5.—Mr. Francis Jones, president, in the chair.—A new binary progression of the planetary distances, and on the mutability of the solar system: Dr. H. **Wilde.** In his table of planetary orbits the author has adopted the radius vector of Mercury as the unit to which the other planetary distances should be referred, the terrestrial unit being a survival of the geocentric system of the universe. The change in the unit of distance has revealed a new binary progression of the planetary distances nearer the observations than that of Bode's law.

PARIS.

Academy of Sciences, October 11.—M. Bouchard in the chair.—The total sugar of the plasma and globules of the blood: R. **Lépine** and M. **Boulud**. The sugar estimated in the blood by the ordinary methods is called by the authors the immediate sugar of the blood; after heating with hydrofluoric acid the maximum amount of sugar found is called the total sugar. An investigation is described on the estimation of the immediate and total sugar in the blood from dogs both in a normal healthy condition and after deprivation of food.—Observations on the surface of the planet Mars from June 4 to October, 1909: R. **Jarry-Desloges**. The work was done at two observatories, both at a high altitude, at Revard (1550 metres above the sea) and near Massegros (900 metres). The paper is illustrated by two diagrams.—The effects of mechanical shocks on the residue of condensers: Paul L. **Mercanton**. A glass condenser was charged to about 400 volts, and the effects of mechanical shocks and also vibrations on the amount of the residual discharge studied. The results are summarised in tabular form.—The reduction of weighings to vacuum applied to the determination of atomic weights: Ph. A. **Guye** and N. **Zachariades**. The substances studied in this work, twenty-six in all, were chosen from material actually used in atomic-weight determinations. The reduction to vacuum weights was first applied in the usual way from the known densities of the substances, and the results compared with direct weighings in a vacuum. The differences on 100 grams of material varied between 1 and 32 milligrams, and the conclusion is drawn that it is completely illusory to weigh bodies closer than 1 part in 10,000, or to calculate atomic weights with a greater precision, whenever the weights of powdered substances, determined in air, are reduced to vacuum by calculation.—The probable influence of the motion of the moon on atmospheric radio-activity. Some meteorological consequences: Paul **Besson**. The radio-activity of the principal spring of Uriage-les-Bains has been found to vary with the barometric pressure and also with the movements of the moon. If this latter effect is confirmed, it would result that the moon, by increasing or reducing the number of condensation nuclei, would have an effect on weather.—The asymmetry created by a continuous current in liquid chains, initially symmetrical, formed by aqueous couples of identical viscosity: M. **Chanoz**.—The revision of the density of gaseous hydrochloric acid; the atomic weight of chlorine: Otto **Scheuer**. Twenty-eight determinations, made in seven series, of the density of hydrochloric acid gas give 1·6394 grams as the normal weight of a litre ($t=0°$ C., $H=760$ mm., $h=0$, $\gamma=45°$). This leads to the figure 35·45 as the atomic weight of chlorine.—The spectrographic analysis of blendes: G. **Urbain**. The spectra were taken from the arc, iron being taken as the comparison spectrum. Out of sixty-four blendes, thirty-eight gave clear evidence of the presence of germanium, and amongst these five contained the element in such a proportion that all the germanium lines were observed. Indium was found in forty-one blendes, three being remarkably rich. Nearly all the blendes contained gallium, there being only five in which gallium could not be detected. The other elements noted included iron, copper, silver, tin, antimony, cobalt, bismuth, arsenic, and molybdenum.—Some derivatives of hexahydro-oxybenzoic acid: P. J. **Tarbouriech**. This acid was first obtained by Bucherer from cyclohexanone. This latter substance can now be readily obtained in quantity by the Sabatier and Senderens reaction, and Bucherer's work is repeated and extended.—A new series of leucobases and colouring matters derived from diphenylethene: P. **Lemoult**.—The liquid crystals of the combinations of cholesterol and ergosterol with urea: Paul **Gaubert**.—The Dioscorea cultivated in tropical Africa, and on a case of natural selection relating to a species spontaneous in the virgin forest: Aug. **Chevalier**.—The stratigraphical position of the *Heterodiceras Lucii* layers at Salève: E. **Joukowsky** and J. **Favre**.—The distribution of granites in the French Congo: H. **Arsandaux**.—The earthquake of October 8, 1909: Alfred **Angot**. The earthquake felt in Croatia was registered in the observatories of Parc Saint-Maur and Grenoble.—Some remarks on the great magnetic disturbance of September 25, 1909, and the accompanying solar phenomena: Émile **Marchand**.

THE CLEAVAGE OF THE OVUM.

Lehrbuch der vergleichenden Entwicklungsgeschichte der wirbellosen Thiere. Allgemeiner Theil, Dritte Lieferung. By Prof. E. Korschelt and Prof. K. Heider. Pp. 166. (Jena: Gustav Fischer, 1909.) Price 4.50 marks.

IN the development of the individual organism there are involved growth, cell-division, and differentiation. It is with the second of these that the present instalment of a splendid text-book deals.

Apart from certain alterations of egg-structure which are consequent upon fertilisation, the subdivision of its material is the first sign the fertilised ovum gives of its activity, and this "segmentation" proceeds with great regularity until other events—germ-layer formation—supervene. The problems that at once arise are therefore: (1) What is it which sets a term, not, indeed, to cell-division, for that continues, but to the period of segmentation? (2) To what causes must the definite pattern of division—spiral, radial, or bilateral, and so on—be attributed? and (3) Is there any necessary relation between the manner in which the ovum is thus cut up and the ultimate processes of differentiation?

In this volume—a very admirably written and beautifully illustrated description of the various types of cleavage—these problems are to some extent touched upon, and we are glad to see that the view is taken that it is the attainment of a definite size-relation between nucleus and cytoplasm which defines the end of this, the first phase of development (p. 7), though Boveri's important experiments are not noticed here.

In respect of the other two problems—which, indeed, largely overlap—the position which the authors appear to have adopted—that cleavage is necessarily a process of differentiation, that in some, *e.g.* in the spiral type, it is a "Mosaikarbeit" in Roux's sense, and that the blastomeres in this case are not interchangeable (pp. 15, 115)—is not, we believe, wholly justified by the results of experiment, though in dealing with the amphibian egg they admit (p. 38) that the relation between cell-division and differentiation is "wenig fixirt."

The truth is that Roux's attempt to demonstrate an absolute coincidence of the first furrow and the sagittal plane in the frog's egg, and the consequent formulation of the "Mosaik-theorie," with its imaginary qualitative division of the nucleus, still casts its shadow upon this discussion. That hypothesis, however, so far as the nucleus is concerned, has now been abandoned, while recent work has shown that the factors which determine the pattern of cleavage are distinct from the causes of differentiation, even in those cases in which cell-division does look like a "mosaic." Thus there is in the frog's egg a far closer relation between the plane of symmetry and the sagittal plane than between the latter and the first furrow. The type of segmentation may be altered, by pressure or other means, without prejudice to normal development. In the Ctenophora abstraction of the vegetative egg-substance involves absence of costæ in the embryo, but division is still normal, while the isolated *D. blastomere* of a Dentalium ovum will produce a normal larva, in spite of the fact that its cleavage is partial, because it contains the polar lobe. Moreover, cells occupying identical positions in similar cleavage systems have *not* always the same fate.

The two sets of factors may coincide, but they do not necessarily do so. The causes of cell-division will be found in the relations between nucleus and cytoplasm, surface tensions, and so on, of differentiation in the various substances present in the cytoplasm (and the nucleus), but the way in which this heterogeneous material is cut up in cleavage is a matter of indifference; what is essential is that it should be diminished by division until the necessary ratio between cytoplasm and nucleus has been reached.

A CANADIAN MINING AND METALLURGICAL DIRECTORY.

Report on the Mining and Metallurgical Industries of Canada, 1907–8. Pp. xvi+972. Canada, Dept. of Mines, Mines Branch. (Ottawa: Government Printing Bureau, 1908.) Price 1 dollar.

THE Dominion of Canada, having the area and varied geological and geographical structure of half a continent, has naturally a great diversity in its mineral wealth. The mining fields are widely scattered, and most of them are imperfectly known. Hence, in accordance with a wise provision of the Canadian Mining Act of 1907, a detailed guide to the mining and metallurgical industries of Canada has been prepared by the Department of Mines. The work has been prepared under the superintendence of the director, Dr. Haanel, and edited by Mr. S. Groves. In order to secure the most trustworthy and recent information, a series of special investigators have visited all the mining districts of the Dominion, and numerous short reports on the geology and on mining and metallurgical methods are included from members of the Geological Survey and from mining engineers. The work includes 936 pages of text, and is illustrated by numerous maps and plates, showing the distribution of the mining fields and views of the surface operations at the mines and metallurgical works.

The book is divided into two main sections, the first dealing with the metalliferous ores and fuels, and the second with building materials, cements, clays, ochre, &c. Each part is subdivided geographically; the history of mining in each province is recorded, and there is a brief, often, perhaps, too brief, statement of the structure of the mining field. The bulk of the work consists of an account of the present condition, including capital, staff, area, equipment, and operations, of every important mine and metallurgical establishment in the Dominion. This valuable directory of Canadian mining gives a clear idea of its growing importance and variety.

T

In the far west, both in Yukon and in British Columbia, gold was the first attraction. The history of Yukon mining is summarised since the first report of gold there by Whymper in 1869. There is reference to the Klondyke boom in 1897–8, and the subsequent decline of the field. Lode mining there is still unimportant. Five dredges are at present mining the alluvial deposits, but they cannot work economically in frozen ground, which has to be thawed by the play of steam upon it.

In British Columbia gold mining began with the Fraser river rush of 1858, followed by twenty years of placer mining. Since 1887 lode mining has made steady progress; the gold is generally associated with copper, silver, or silver lead, and these ores have usually to be smelted. The most famous mining centre is Rossland, which includes some large copper deposits in which the unoxidised ore rises to the surface, and, according to Mr. Brock's account, some of these ores have been deposited parallel to the present land surface. The ores at Rossland occur in fissure veins in sheared and shattered belts, and as irregular impregnations of the country rock. The veins, such as that at Le Roi, the chief Rossland mine, are usually well defined. The ores are low-grade and their concentration is difficult, as the chalcopyrite which contains so much of the gold readily flows away in water.

Of the mines worked primarily for copper, the gold being obtained as a by-product, the most important in British Columbia is the Britannia Mine on Howe Sound, which consists of a mineralised belt of country up to 600 feet wide and two miles in length. Most of this rock contains only 0·5 per cent. of copper, and the ore of commercial value, containing an average of $1\frac{3}{4}$ per cent. of copper, occurs in large patches scattered through the mineralised belt.

The iron ores of British Columbia have hitherto been little used, but the Puget Sound Mine on Texada Island, a contact deposit between granite and limestone, and replacing both rocks along their junction, has been smelted with bog iron ores in San Francisco. The Glen Iron Mine, situated on the Canadian Pacific Railway, is worked to supply flux to the British Columbian smelters.

The most sensational story in recent Canadian mining history is that of cobalt, which was discovered by accident in 1903, and is famous for its narrow, rich veins of silver. They are found traversing ancient quartzites and conglomerates that have been intruded by diabase.

The Sudbury field is of great commercial, historical, and theoretical interest; it gives Canada the control of the world's nickel market, and has been the subject of a long controversy as to the origin of its ores. They are claimed by some authorities such as Prof. Coleman to be due to direct segregation from a molten rock, a norite gabbro; whereas other authors, relying on the microscopic structure and sequence of the minerals, claim that the ores were deposited long after the consolidation of the adjacent igneous rocks.

The volume contains a short account of Dr. Haanel's fruitful experiments at Sault Sainte Marie on the electric smelting of iron, and its maps give impressive evidence of the vast extent of the coalfields of western Canada, as well as of the widespread and varied mineral wealth of the Dominion.

A MONUMENT TO LATIMER CLARK.

Catalogue of the Wheeler Gift of Books, Pamphlets, and Periodicals in the Library of the American Institute of Electrical Engineers. Edited by W. D. Weaver. With Introduction, Descriptive and Critical Notes by Dr. Potomian. Vol. i., pp. viii + 504; vol. ii., pp. 475. (New York: American Institute of Electrical Engineers, 1909.)

ALL who knew Mr. Latimer Clark will feel the most lively satisfaction that his cherished and invaluable library of books ancient and modern relating to electricity should have found the resting-place and custodian which kind fate and American generosity have provided. The position is best expressed by the following three quotations from the book under review:—

"It was Mr. Clark's wish that this valuable collection of his should eventually be transferred to the United States, inasmuch as London was already in permanent possession of the Library of Sir Francis Ronalds. Failing an American purchaser, it was to go to Japan, 'a rising country which would greatly value such a unique collection.' Thus wrote Mr. Clark to Mr. P. Fleury Mottelay, of New York, on February 21, 1898, eight months before his death."

"My object in securing the collection was to present the books to our Institute and make it the custodian of the most complete electrical library in the world, as well as to stimulate such interest that the Institute may in time own a permanent home in New York."

"This work is due to the generosity of Mr. Andrew Carnegie, who donated a fund to house, catalogue, and complete the celebrated Latimer Clark collection of books, pamphlets, and periodicals presented to the library of the American Institute of Electrical Engineers by Dr. Schuyler Skaats Wheeler."

Given an unrivalled collection and a free hand, it is not every librarian or every professor of physics who could, in preparing what is called a catalogue, have produced what is in reality also a delightful book, which will afford the book-lover some of the inspiration and charm which the library itself alone can provide in full. The books are numbered in chronological order, the earliest being Vincentius (1190–1264). The system is to give a copy of the material on the title-page, with some account of the nature of the contents of the book. Where this is of exceptional importance, a facsimile of the frontispiece, title-page, or of some page or pages from the text, and of some illustrations is given also. On turning over the pages, the reader not altogether devoid of historical interest cannot fail to be attracted by these glimpses of the work of long ago, and to be driven to seek in the library itself the continuation of accounts of investigations to which the end of a page sets a disappointing limit. Among the facsimiles is the historic letter, a typical example of the official *non possumus* attitude not even unknown at the present day, dated August 5, 1816, from the secretary of the Admiralty to Mr. (afterwards Sir) Francis Ronalds, F.R.S., relative to the electric telegraph.

"Mr. Barrow presents his compliments to Mr. Ronalds, and acquaints him with reference to his note of the 3rd inst. that telegraphs of any kind are now wholly unnecessary; and that no other than the one now in use will be adopted."

This was a semaphore!

The two volumes contain 5966 entries, and they are completed by a name-index.

The American Institute of Electrical Engineers is to be congratulated upon its possession of so valuable a library, the contents of which have been brought home to them in so pleasing and sympathetic a manner.

C. V. Boys.

COMPARATIVE ANATOMY OF ANIMALS.

An Introduction to the Study of the Comparative Anatomy of Animals. By Prof. Gilbert C. Bourne. Vol. i. Second edition, revised. Pp. xvi+299. (London: George Bell and Sons, 1909.) Price 6*s*.

PROF. BOURNE says rightly that there is a considerable difference of opinion as to the limits of elementary teaching in comparative anatomy, which he defines as "the science which treats of the architecture of animals." The second edition of his well-known and interesting text-book will be welcomed by all serious students of animal biology, for it is with animal biology rather than pure anatomy that it deals. This is necessarily the case, for anatomy and physiology must ever go hand in hand.

The position of biology in the University curriculum is at the present time a very critical one, especially in the case of medical students, for whom this work is expressly intended. The enormous increase in our knowledge of the detailed structure of all the commoner forms of animal life which has taken place during the last few years makes it more and more difficult to select the materials for a first year's course. The introduction of too large a number of types necessitates superficial treatment, while, on the other hand, the too detailed study of only a few types leaves the student without time to follow even the main steps in the evolution of the animal kingdom. He cannot see the wood for the trees. The chief value of the study of comparative anatomy and physiology for the medical student lies in the fact that they help him in the end to understand the structure and functions of the human body, but there is very much in the minute structure of the lower animals which is not necessary for this purpose, and we fear that the insistence upon what many regard as superfluous detail has done much in late years to discourage the study of zoology, not only amongst medical students, but also amongst others who doubt their ability to digest and assimilate (especially for examination purposes) the immense mass of intellectual food set before them. Fortunately so much detail, however interesting in itself, is not really necessary for the comprehension of the great principles of the subject.

Prof. Bourne's view is, as he tells us in his preface, that the more elementary the teaching the fuller it should be, and this view finds full expression in the volume before us, which, we venture to think, is likely to appeal to the advanced perhaps even more than to the elementary student. Protozoa are fashionable at the present day, but it is, perhaps, a pity that Prof. Bourne did not follow what he tells us was his original intention, and omit some of the types with which he deals so fully. Actinosphærium, at any rate, has very slight claims to inclusion in an elementary text-book. On the other hand, a cordial welcome may be extended to Copromonas, a very valuable new type, of which an admirable account is given, based upon the work of Mr. Dobell.

A few inaccuracies in phraseology might with advantage be attended to in future editions, *e.g.* "smell and taste are localised patches of end organs" (p. 9), but these are minor blemishes which detract but little from the thoroughness with which the author has carried out his extremely useful work.

MODERN MIRACLES.

The Faith and Works of Christian Science. By the writer of "Confessio Medici." Pp. xi+242. (London: Macmillan and Co., Ltd., 1909.) Price 3*s*. 6*d*. net.

THE cult, if it may be so termed, of Christian science has taken considerable hold on a section of the community here and elsewhere, and we welcome this book by the author of "Confessio Medici" exposing its fallacies, inconsistencies, and dangers. No one, perhaps, could do this in a more genial manner, but the whole forms a scathing indictment indeed.

In the introductory pages the author tries with more or less success to put into plain words the contrast between philosophy and Christian science. He then arranges in the form of articles some of the tenets of Christian science taken from Mrs. Eddy's writings, discusses life and Christian science, the reality of disease and the reality of pain, and gives a brief survey of Mrs. Eddy's remarkable career. Next, and most important, the record of the testimonies of healing by Christian science is critically examined. Two hundred recent cases (April–August, 1908) are analysed; the author has taken the trouble to write to many of the patients for additional information, and a more inadequate and unconvincing series could hardly be imagined. This one is healed of "kidney and liver trouble," that one of "stomach trouble," a third of "fever," a fourth of "colds and eruptive fever," and so on. The details are of the scantiest, and, in most instances, the diagnosis is the patient's own. The author concludes from these evidences

"that Christian science accepts all testimonials, even the most fantastic and illiterate. That she embellishes what she publishes. That she evades investigation. That her claim to cure organic disease breaks down under the most elementary rules of criticism. That she does cure 'functional' diseases. That she has never cured, nor ever will, any disease, except those which have been cured, a hundred thousand times, by 'mental therapeutics.'"

Two further lines of criticism are pursued by the author. First, he pictures a large hospital given over to the care of Christian "scientists," with its cases of appendix abscess rupturing into the peritoneum, strangulated hernia going on to gangrene, advanced heart disease getting out of bed and taking violent exercise, and spinal disease hanging on gymnastic bars! Secondly, he has obtained information from various medical practitioners of cases of organic disease going from bad to worse under the "treatment" of Christian "scientists."

The author is no dogmatist; he freely admits the influence of mind over body, that Christian science may cure hysteria and the liquor habit, that as regards the revival of "spiritual healing" it is for the patient and the family to have what ordinance or ritual they wish to have. No doctor would find fault with that sort of work provided it is kept in its proper place. This aspect of mind renders the book all the more convincing, and we feel sure that it may fill a useful place in refuting the pretensions of Christian "scientists." R. T. H.

SEMITIC MAGIC.

Semitic Magic, its Origins and Development. By R. Campbell Thompson. Pp. lxviii+286. (London: Luzac and Co., 1908.) Price 10s. 6d. net.

MESSRS. LUZAC have produced a useful as well as well-looking volume as the third contribution to their "Oriental Religious Series" in Mr. R. Campbell Thompson's "Semitic Magic." Mr. Thompson's book is an attempt to bring our knowledge of Arab, Hebrew, and Babylonian (Assyrian) magic into line with the scientific treatment of the demonology and witchcraft of other peoples which the labours of many devoted workers have given us during the past half-century.

It is not too much to say that the field of Semitic magic has hitherto been somewhat unduly neglected by writers on the subject. Probably shyness of dealing with a subject which must owe so much to a correct interpretation of the cuneiform texts has had much to do with this fact. A knowledge of the necromantic ideas of the Jews and the Arabs, especially of those of the former people, we have always possessed in abundance, but Semitic magic without Babylonian and Assyrian magic would indeed be Hamlet without the Prince of Denmark, and up to the present time general anthropologists have rightly been diffident of their power to collate adequately material of which they have no first-hand knowledge with the results of their study of the necromancy of the Jews and Arabs. It was first necessary that a cuneiform scholar should be found with an active interest in the general subject, and a competent knowledge of the other anthropological material, not only from the rest of the Semitic nations, but from the whole of the primitive world.

Mr. Thompson, who is an Assyriologist with a general knowledge of anthropology and a special interest in the subject of magic, has essayed to fill the gap; and we think that as a first essay he has done so very successfully. His book is not an exhaustive treatise; it can be regarded simply as an introduction to the subject, based from the Semitic side ultimately on Robertson Smith's epoch-making book, "The Religion of the Semites," and from the general side largely on the work of Frazer. But at the same time, Mr. Thompson is an original thinker who does not hesitate to criticise the work of his models when he thinks they are wrong, and to draw new conclusions from the large amount of new material which he now places in our hands, derived from his own Assyriological knowledge. Later on Mr. Thompson may perhaps produce a larger work on the subject, to which his present volume will serve as a preface. As it stands, his book is an authoritative contribution to anthropology, which will be found of very great use by all students of the beliefs of primitive mankind.

Mr. Thompson lays great stress upon the subject of tabu, of the existence of which he finds constant evidence among the Semites, while demoniac possession, sympathetic magic, and the specially Semitic ideas of the Atonement, Sacrifice, and the Redemption of the Firstborn, all have chapters specially devoted to them. The long quotations which he gives from the cuneiform texts are of great interest, and enable us to form an adequate idea of the great part which magic played in the daily life of the oldest civilised peoples of the ancient world.

OUR BOOK SHELF.

British Rainfall, 1908. On the Distribution of Rain in Space and Time over the British Isles during the Year 1908 as recorded by more than 4500 Observers in Great Britain and Ireland, and discussed with Articles upon Various Branches of Rainfall Work. By Dr. Hugh Robert Mill. Pp. 100+304; with maps and illustrations. (London: Edward Stanford, 1909.) Price 10s.

The author has stated elsewhere that the perfect rainfall map is a thing of the future, many preliminary studies being necessary before it can be drawn. The irregularity of rainfall and its dependence upon orographical features require a very large number of stations, and observations made during the same period for at least thirty or thirty-five years for determining its average annual distribution and variation. By the energy of the late Mr. G. J. Symons, the founder of the British Rainfall Organisation, and his successors, the British Isles can boast of a system of rainfall observations quite unique and unrivalled by that of any other country; the data published yearly in "British Rainfall" supply invaluable materials for general discussions, and, in fact, have been frequently utilised by various authorities. Part i. of the present volume, the forty-eighth of the series, contains articles by Dr. Mill on new recording rain-gauges, by Mr. A. Lockwood on rainfall observations in Snowdonia, and others; also records of evaporation and percolation, duration of rainfall at various stations, and other matter. Part ii. includes, *inter alia*, observers' weather notes for days, months, and the year, heavy rains for short periods and for days, monthly and seasonal rainfall, and a general table of the annual rainfall at all stations. There is also a coloured frontispiece map showing the relation of the rainfall of 1908 to the average of 1870–99. The rainfall of Scotland and Ireland, generally, was practically normal, that of England and Wales rather more than one-tenth less than the average. Only a small part of England and Wales, but a large part of Scotland and Ireland, had more than the average; parts of the south of Ireland, south-west and east of England and east of Scotland were very dry. The greatest annual amount recorded was 237·3 inches, at Llyn Llydaw (Snowdon); the least, 15·6 inches, at Bourne (Lincolnshire). Among the changes introduced in this volume may be mentioned (1) that, in discussing monthly rainfall, maps of the actual fall are given side by side with those showing the percentage difference from the normal; (2) much fuller treatment of the sections relating to heavy falls on rainfall days and in short periods. Although efforts have been made to economise space, and no part is a repetition of any previous issue, the present volume is larger than any of its predecessors, and, we think, compares favourably with them.

La Mesure rapide des Bases géodésiques. By J. René Benoit and Ch. Ed. Guillaume. Quatrième édition. Pp. 228. (Paris: Gauthier-Villars, 1908.)

The invention of invar, the nickel-steel alloy with a small or zero coefficient of expansion, in 1897 imported new conditions into determinations of length. The great value of this invention for the measurement on the ground of the base-lines of a survey was at once apparent, and during the next year the new method was tried by the joint Russo-Swedish expedition in Spitsbergen. The results obtained equalled the most sanguine expectations. Not only was a high limit of precision attained, but the rapidity of the work, as compared with the old methods, was enormously enhanced. It was obvious that the geodesist had in his hands a new tool which greatly accelerated the most laborious portion of his operations, and at the same time gave him a degree of accuracy at least equal to that hitherto achieved with far more cumbrous apparatus.

These results came into prominent notice at the International Geodetic Conference held at Paris in 1900, and a further and more minute investigation of the whole problem was undertaken by the Comité international des Poids et Mesures.

At the meeting in 1905 a report was furnished by the present authors, to be expanded into a more complete form for presentation to the Geodetic Conference of 1906. The large demand for copies of this report, and the fact that the new method has now been adopted by almost all surveys having any pretensions to execute work of the first order, have induced the authors to put the record of their investigations into a permanent and convenient shape. Of the present little volume we can only say that it is one that must be in the hands of every geodesist. It contains, in a succinct form, the general theory of measurements by wires hung freely between supports, a short discussion of the physical properties of invar, an account of the testing and standardisation of the wires and of their possible distortions under different conditions of tension, temperature, repeated windings and unwindings, and, in general, their stability under the practical conditions of their employment in the field. This is followed by a description of the auxiliary apparatus used for base measurement, all of a very simple character, and a full account of the routine of the field work and of the calculations for the reduction of the measures to the horizontal, including the necessary tables.

A summary of the actual results attained in practice shows that a rate of measurement of about 5 kilometres per day can be kept up with a limiting error of between $\frac{1}{500000}$ and $\frac{1}{1000000}$. With special precautions a still higher degree of apparent accuracy can be reached, but such appearance is largely delusive, and in geodetic work would soon disappear in the angular measures.

We congratulate the authors, not only on their most valuable investigations, but also upon the excellent form in which their conclusions are presented.

E. H. H.

Bibliotheca Geographica. Jahresbibliographie der gesamten geographischen Literatur. Herausgegeben von der Gesellschaft für Erdkunde zu Berlin. Bearbeitet von O. Baschin. Band xiv. Jahrgang, 1905. Pp. xvi+545. (Berlin: W. H. Kühl, 1909.)

This is one of those publications (and there are not a few) for which British geographers may well be grateful to German. We do not produce many works of this kind—works which can hardly bring profit sufficient to reward the labour of their compilation. The "Bibliotheca Geographica" is a wonderfully full bibliography of geographical books and papers published, in all parts of the world, during the year 1905—it is not to be wondered that the volume bears a date of issue four years later, when the magnitude of the task of tracing such a vast number of publications is considered. General treatises on the various scientific branches of geography are given first; after these there follows what occupies the bulk of the volume—a bibliography according to topographical divisions. Each topographical division is minutely subdivided according to special subjects, an arrangement which partially disarms the criticism that the entry of a publication under its own title or the name of its author seems somewhat arbitrary.

It is doubtful, however, whether any large bibliography would entirely escape this criticism. Some difficulty, again, is evidently felt with regard to the entry of individual papers out of collected volumes. Thus, when the report of a research committee of the British Association is entered only under the name of the secretary of the committee, it may be doubted whether this method gives the reader the best chance of finding the reference. On the other hand, cross-references are provided from one subject subdivision to others of a kindred nature, and at the end there is an authors' index, so that one cannot but recognise that the system of the whole work is well-nigh perfect. Moreover, the entries, so far as can be judged, appear to be admirably accurate.

The Invicta Number Scheme. By J. W. Ladner. (London: George Philip and Son, Ltd., n.d.) Handbook, price 8*d.* net; Number Board, price, with plain edges, 6*s.* 6*d.* per dozen; with edges, cloth-mounted, 8*s.* 6*d.* per dozen.

This device is a method found useful by a practical schoolmaster of experience in teaching the fundamental principles of arithmetic by constant reference to the decimal system of notation. The plan utilises not only the ears, but the hands and eyes of the children. Though many original teachers will have developed equally good expedients for rendering their lessons in arithmetic practical, interesting, and intelligible, the scheme may be recommended to the attention of teachers who have not as yet adopted concrete aids in their instruction. It is now very generally agreed that children learn best by doing, and Mr. Ladner's method of teaching will certainly assist the children to arrive at the rules they have to learn from the results of their own experiments.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Magnetic Storms.

In his article upon the recent magnetic storm (Nature, September 30) Dr. Chree writes:—"Another difficulty in regarding the phenomena of magnetic storms as entirely and directly due to the action of electrical currents associated with aurora is that it is a frequent occurrence—as on the present occasion—for the horizontal force to be considerably depressed below the normal value when the storm has apparently ceased and for some considerable time thereafter. It is possible, of course, that the external currents have partly demagnetised the earth, or at least modified its distribution of magnetism, and that there are recuperative tendencies tending to cause reversion of what is for the time being a more stable distribution, but if this be the true explanation the demagnetising action and the recuperative tendencies are presumably in action during the course of the storm, and profoundly modify the magnetic phenomena."

I wish to add to Dr. Chree's words the remark that this phenomenon of decrease in horizontal intensity is nothing but part of the phenomena I described a long time ago,[1] and about which I exchanged opinions with Dr. Chree in *Terrestrial Magnetism*.

Later on I found occasion in several publications again to deal with those phenomena of "Post-turbation"; also recently, at the meeting of the Helvetic Association of Natural Science at Lausanne.

In a short statement I directed attention to the fact that the results of my investigations on magnetic perturbation are in accordance with the splendid results and theories of Birkeland and Størmer.

My results were shortly as follows:—

A force of disturbance is always present; it strongly increases when a storm appears, decreasing afterwards. The horizontal component of this force is chiefly directed to the magnetic south, *i.e.* along the meridian of the regular magnetism of the globe, thus lying in the plane through the magnetic axis and the station.

The vertical component, on the contrary, mostly has the same direction as that of permanent magnetism, *i.e.* downward in the northern hemisphere. Its character and sign are much less constant than those of the horizontal component.

The regular post-turbation is most frequent at lower latitudes.

An extensive study of all the storms recorded at Batavia has taught me that the post-turbation often emerges in a negative sense (northerly), but shortly after turns and reaches its maximum positive value. Afterwards it decreases at a slower rate, and this decrease continues until a new storm (it may be a very small one) appears. I found that successive quiet days show that same decrease. This is the same that Dr. Chree also detected, and called non-cyclic variation.

At Lausanne I pointed to the fact that this kind of disturbance corresponds to Birkeland's class of positive equatorial disturbances. He also found negative disturbances, but from my statistics it is evident that they are much less frequent than the positive.

As to the cause of these positive equatorial disturbances, Birkeland, according to his experiments with his terella and the theoretical calculations of Størmer, accepts currents of electrons flying around the magnetic equator of the earth. As for the negative ones, he accepts electrons which move also in that plane, but through a loop in their orbit, thus having a contrary direction.

If we accept the cause of the post-turbation to be the presence of an electric current, this current must be extra-terrestrial, because the vertical component generally increases when the horizontal one decreases.

The less regular character of the vertical component may be explained by the currents of induction raised inside the globe. Accordingly, an effect of demagnetisation of the earth seems to be improbable.

From the inspection of thousands of magnetic curves recorded at Utrecht, Batavia, and other non-Arctic stations, I received the impression that the increase and decrease of the post-turbation are fairly regular, the rapid oscillations being superposed on this variation.

No doubt these rapid oscillations are caused by currents of electrons nearly approaching the earth, and this will happen more frequently in the polar regions than in the equatorial ones. Thus the action of the ring current will show itself more distinctly at stations at lower latitudes, the ring being nearer to them than to stations at higher latitudes, and it will be less disturbed by other currents coming very near to the earth.

Dr. Chree concludes his article with wise words, saying:—"To many minds subscription to some theory may be a necessity for intellectual comfort, but in the case of magnetic storms reservation of judgment appears at present the more scientific attitude."

I fully agree with him in this respect, but I think he, who himself has contributed so much to the science of terrestrial magnetism, will agree with the call for more activity. The work of Birkeland and Størmer is splendid indeed, but it is only in the power of international cooperation, such as in the year 1882–3, to unravel all the problems of magnetic disturbance.

We should repeat that work, considering that at present we are able to do so much better and more completely than our predecessors were in those days.

Concentration of our efforts on special problems, I think, would be more effective than the unsystematic accumulation of material nowadays.

The crowding of permanent magnetic observatories in Europe may be favourable to the solution of minor problems; it is a hindrance to that of the fundamental ones, because it absorbs too great a part of the powers at our disposal.

W. van Bemmelen.

Homogeneous Corpuscular Radiation.

When a metal plate is subjected to a beam of Röntgen rays, a corpuscular radiation is in general emitted, in addition to the secondary radiation of the Röntgen type.

This corpuscular radiation has been investigated by various experimenters. They have shown that the intensity and the absorbability of this radiation vary when different metals are used, and that they are also dependent upon the degree of "hardness" of the exciting radiation. In particular, Cooksey has recently shown that the corpuscular radiation excited by a "hard" primary beam is homogeneous, while that excited by a "soft" primary is heterogeneous.

But the primary beams used in these investigations were necessarily heterogeneous, and it is therefore impossible to decide with certainty which components were chiefly concerned in producing the phenomena under investigation.

It has been shown in various papers by Prof. Barkla and myself that a series of secondary Röntgen radiations can be obtained from the group of metals the atomic weights of which lie between those of chromium and silver, each radiation being homogeneous and having a perfectly definite coefficient of absorption by a given metal, *e.g.* aluminium. The absorption coefficients of the beams from the different members of the series vary greatly in value; thus for the secondary radiation from iron the absorption coefficient by aluminium is 240, while for that from silver it is only 6·7.

I wish to place on record a summary of the results of some investigations I have made upon the corpuscular radiations excited in various metals when these homogeneous secondary beams are employed as primaries instead of the heterogeneous primary beams used by previous investigators.

(1) It had been shown by Prof. Barkla and myself that the penetrating power of the incident primary radiation must exceed that of the homogeneous secondary Röntgen radiation characteristic of a metal before the latter is excited. Using homogeneous beams, I have shown that when the primary beam is only just more penetrating than the secondary Röntgen radiation characteristic of the metal, the intensity of both the secondary Röntgen radiation and

the corpuscular radiation is small. For a slightly more penetrating primary beam a rapid increase in the intensity of both the secondary Röntgen radiation and the corpuscular radiation takes place. This seems to suggest that the production of corpuscular radiation is in some way intimately associated with the emission of the Röntgen type of radiation.

(2) I had recently shown that when homogeneous radiation falls upon a thin layer of a substance which may act as a secondary radiator, a portion is transmitted unchanged, and that the fraction of the remaining energy which is transformed into secondary Röntgen radiation *decreases* as the primary beam becomes more penetrating. In the present experiments it is found that the corresponding fraction of the remaining energy which is transformed into corpuscular radiation *increases* as the primary beam becomes more penetrating.

(3) The corpuscular radiation emitted by these metals when subjected to homogeneous beams is itself surprisingly homogeneous, whether the exciting beams are "soft" or very "hard."

(4) The absorption coefficients of the corpuscular radiation from a given metal excited by homogeneous secondary Röntgen radiation vary with the nature of the exciting radiation. These absorption coefficients are a decreasing linear function of the atomic weight of the secondary radiator.

I hope to publish further details of these experiments shortly. CHARLES A. SADLER.

Drought in South-west Ireland.

THE deficiency of rainfall in the south of Ireland, to which Mr. Armstrong refers in NATURE of October 21 (p. 487), has been apparent in the annual total rainfall for the last three years, the deficiency also affecting the south-west of England. At the same time, there has been a marked excess of rainfall in the north of Ireland, deficiency and excess being taken as synonymous with quantities below and above the average of many years. It is frequently found that parts of the country, often quite narrow strips, show a marked deficiency of rainfall for several successive years, and afterwards revert to an average condition or show an excess. The most probable explanation seems to me to be a change, perhaps a slight one, in the prevailing tracks of the centres of barometric minima, but I have not found data in a form suitable for testing the truth of the suggestion.

The extreme dryness of August was experienced over a large area of the south of Ireland, less than half an inch of rain having fallen over about 2800 square miles. In September less than half an inch fell over not more than 500 square miles.

I may perhaps be excused for pointing out that while Mr. Armstrong uses "absolute drought" to describe a period of twenty-four hours without rain, it has been usual for many years to reserve the words "absolute drought" for a period of more than fourteen *consecutive* days without recorded rainfall. HUGH ROBERT MILL.

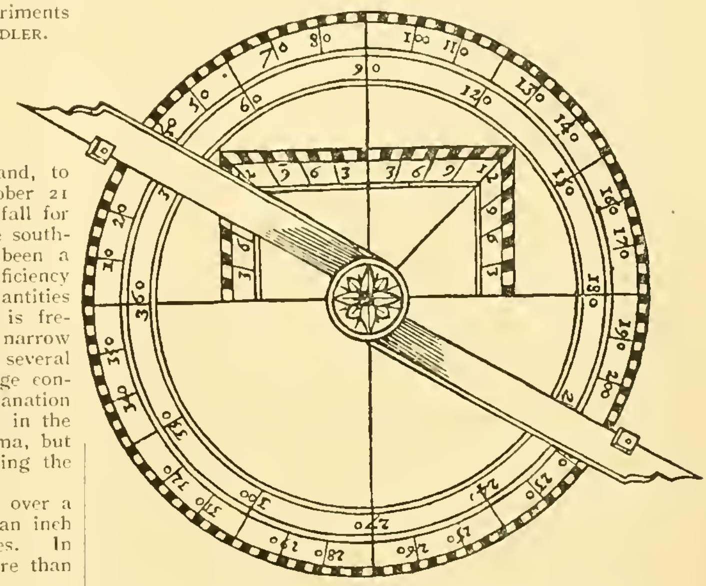
Derivation of the Word "Theodolite."

ALTHOUGH the etymology of the word theodolite has been discussed from time to time,[1] no satisfactory solution has hitherto been established. It was first used in England, and the earliest reference to it is contained in a book by Leonard Digges (completed and published by his son, Thomas) called "Geometrical practical treatize, named Pantometria, diuided into three bookes, longimetria, planimetria, and stereometria, &c.," first published in 1571, with a second edition in 1591, wherein the "composition of the instrument called Theodelitus" is represented as a "circle diuided in 360 grades or degrees, or a semi-circle parted in 180 portions"; or again, "the composition also of the Square and Planisphere or Circle named Theodelitus for measuring lengthes, breadths, and distances." It had a "*double scale*," an "index," "the sightes," and the circle was 2 feet in diameter, and "fastened in the top of some staffe." He does not state how the name was derived, and spells it "theodelitus" and "theodolitus" alternately. William Bourne ("Treasure for Travailers," 1578) named the same instrument "horizontall or flatte sphere," and not theodelitus; but when he speaks of the alidade he calls it only once *alideday*, but otherwise always *athelida*. After this de Morgan, who first discussed the derivation in the *Philosophical Magazine*, concluded that the "theodelited circle" of Digges, who, however, does not use that adjective, and "athelidated circle" of Bourne, were various corruptions of the Arabic word *al-idhâda* (a sort of rule), from which the word *alidade*, which carries the sights or telescope of a theodolite, is derived.

It has been suggested by various writers that theodolite is derived from the Greek roots θέα (sight), ὁδός (the way), and λίθος (a stone), for the latter root λιτός (smooth) being



Reproduction of Digges' illustration of his "Theodelitus." From the *Zeitschrift für Vermessungswesen.*

substituted by others; also from θεάω (I see) and δολιχός (long). Another suggested derivation is the English article "*the*" combined with the Arabic "*alidhada*."

In searching for a more satisfactory solution, the idea occurred to the writer that the word would naturally be compounded to represent the principal parts of the instrument, and when reading Prof. E. Hammer's latest and most interesting discussion in the *Zeitschrift für Vermessungswesen*, vol. xxxvii. (1908), pp. 81–91 and 113–25, he was impressed by one of the illustrations reproduced of Digges' "theodolitus" and description of it, with special mention of the words "sightes," "index," and "double scale." He would submit, therefore, that the true etymology is from the Greek words θέα = a sight; ὀδελός = any pointed instrument; ἴτυς = a circle or a felloe of a wheel. These Greek words appear to be those which would actually denote the three essential parts of the instrument, viz. the *sight*, the *index arm*, or alidade (Digges uses the word index, never alidade), which is represented as a pointed instrument, and the limb of graduated *circle*. The spaces on the circle appear like the

A Supposed New Mineral.

A SPECIMEN of a mineral, forming portion of a mass stated to have been found in the basalt of Co. Antrim, was recently sent for identification to the office of the Geological Survey of Ireland by Mr. S. B. Wilkinson, the senior geologist, to whom it was handed by the finder. As it presents some peculiar features, and appears to be new to science, we take this opportunity of recording its occurrence. The complete examination of the mineral will necessarily occupy some time.

The mineral strongly resembles cobaltite in appearance. Its lustre is metallic, hardness about six. It breaks with a surface which under the microscope shows a finely conchoidal structure. When etched with an acid a crystalline structure becomes apparent; it is fusible with difficulty, but in the oxyhydrogen flame it melts without apparent alteration. Heated in a closed tube it does not yield any sublimate.

When the mineral is powdered, or even its surface scratched, it emits an odour like that of acetylene prepared from commercial calcium carbide. Hydrofluoric acid dissolves the mineral, the other acids have little effect upon it, while it is readily decomposed by fusion with the alkaline hydroxides.

A preliminary chemical analysis shows that the mineral is essentially a compound of iron, silicon, and carbon.

The Pitcairn Islanders.

WHEN reading Mr. M. J. Nicoll's "Three Voyages of a Naturalist" a short time ago, I came across the following passage on p. 211 in the chapter on Pitcairn Island:—

"The older people, as well as the younger children of Pitcairn, have fair complexions, but the people of from thirty to fifty years of age are quite as dark as the average Polynesian. It appears from this that the Pitcairners resemble their ancestors, the 'Bounty' mutineers, every alternate generation."

It may be remembered that in 1790 nine mutineers, six native men, and twelve native women sailed from Tahiti to Pitcairn; the native women killed the native men, and by 1800 only one British sailor was left, from whom the present inhabitants are descended.

Just before the above extract Mr. Nicoll tells us that "Lord Crawford paid a visit to the two oldest inhabitants . . . both of whom are grandchildren of the original mutineers." So we see that the grandchildren and the great-great-grandchildren were fair, resembling the British men, while the great-grandchildren were dark, resembling the native women. That is to say, that F_2 and F_4 generations resembled the ♂ P_1, while F_3 generation resembled the ♀ P_1.

These facts struck me as being particularly interesting, as experiments of this nature in human heredity are difficult to obtain. Perhaps some "Mendelist" may be able to use or explain them.

The Auroral Display of October 18.

I WAS very much interested in Mr. Harcourt-Bath's letter describing an auroral display which he saw from the Cotteswold Hills.

From West Kirby Hill, on the Wirral, I noticed a luminous band low down on the horizon, with upward streamers and "a detached, red, cloud-like portion" rather north of west.

What struck my attention, however, was that behind this red patch there were dark clouds, at no great altitude, faintly illuminated on the underside by the aurora.

As the red colour outlasted the streamers by several minutes, I was brought to the conclusion that it was independent of the auroral display.

However, in view of Mr. Harcourt-Bath's letter, I am led to ask you if observers have ever thought that an aurora could be comparatively close to the earth, and not of necessity in the "highly rarefied layers of the air"?

ERNEST J. BATY.

"Nunclose," West Kirby, Cheshire.

IT may interest Mr. Harcourt-Bath to know that the auroral display of October 18 was strikingly visible at Dudley. At 9.15 p.m. there were six or more broad beams of white light of unequal lengths and widths. These sprang normally from a broad circular arc resembling a "Milky Way" in luminosity and a broad rainbow in shape and size.

The central vertical beam was the brightest, widest, and longest, extending vertically about 45°, but not terminating definitely; it was about 10° W. of N.

The broad arched base appeared to cross through Ursa Major, the vertex being about 20° above the horizon, and was not uniformly bright. About 9.30 p.m. the left-hand (W. of N.) half of the base became a soft violet light; the right-hand portion remained white, but grew fainter.

The Occurrence in India of the Pappataci Fly (*Phlebotomus papatasii*).

THE *rôle* nowadays assigned to *Phlebotomus papatasii* in the transmission of a certain type of fever (see "Das Pappatacifieber," 1909, by Drs. Doerr, Franz and Taussig) makes the geographical distribution of this little fly a matter of practical importance. It is therefore interesting to note that this species is common in certain parts of northern India. Some time ago Mr. F. M. Howlett, second imperial entomologist, sent me specimens from Rawalpindi, in the Punjab, and Pusa, in Bihar, which I identified as belonging to a species allied to *P. papatasii*. Through the kindness of Dr. J. H. Ashworth I have now been able to compare some of these specimens with European examples of *P. papatasii* in the zoological laboratory of the University of Edinburgh. I can find no difference except that the Indian specimens are perhaps slightly smaller than the European ones. The former agree as regards venation, genitalia, &c., with Grassi's beautiful figures (" Ricerche sui Flebotomi," 1907).

In addition to *P. papatasii*, six Indian species of Phlebotomus are now represented in the collection of the Indian Museum. They will be fully described shortly.

N. ANNANDALE.

The Mansfield Automatic Water-finder.

WITH reference to Mr. A. A. Campbell Swinton's letter in regard to Mansfield's water-finder, which appears in NATURE of October 14, it may be of interest to state that I made inquiries from Messrs. Mansfield and Co. in May, 1908, asking for the names of the "leading scientists and engineers" who, as they stated, "vouched for the successful application of the invention"; they did not send me any names, but allowed a friend of mine in Liverpool to call to see the documents. One was from an architect in Liverpool, another from a firm of well-borers, and there were some foreign ones, but none were produced that were signed by persons whom I should describe as "leading scientists and engineers."

I may add that I expressed my willingness to test their instrument, but one was not placed at my disposal.

J. WERTHEIMER.

Merchant Venturers' Technical College, Bristol, October 20.

TO DETERMINE THE REFRACTIVITY OF GASES AVAILABLE ONLY IN MINUTE QUANTITIES.

ON a former occasion [1] I described a refractometer capable of dealing with rather small quantities (12 c.c.) of gas. The optical tubes, one of which would contain the material under investigation and the other air, were of brass, 20 cm. in length and 6 mm. in bore, and were traversed by two pencils of light from the same origin, subsequently brought to interference in the observing telescope. For this purpose the object-glass of the telescope was provided with two parallel slits opposite the axes of the tubes. The image of the original slit, formed in the focal plane, was examined through a high-power cylindrical lens, constituting the eye-piece of the telescope, and exhibited the familiar pattern of interference bands the position of which shifts with changes in the densities of the gases occupying the tubes. With this apparatus, and using pressures not exceeding one atmosphere, it was possible to compare refractivities $(\mu - 1)$ with a relative accuracy of about one-thousandth part.

In recent conversation my son, the Hon. R. J. Strutt, raised the question as to the minimum quantity of gas upon which a determination of refractivity could be made, having in mind such rare gases as the radium emanation. Towards answering it I have made a few experiments dealing merely with the optical side of the question.

A reduction of volume in the gas tube implies a reduction of length below the 20 cm. of the apparatus just referred to, and this carries with it a loss of accuracy. A reduction to 2 cm. should leave possible an accuracy of at least 1 per cent., and this was the length chosen. As the inquiry was limited to the optical conditions, it was unnecessary to close the ends, and thus the tubes reduced themselves to two parallel tunnels through a block of paraffin 2 cm. thick. They were prepared by casting wax (from a candle) round two similar sewing needles of suitable diameter previously secured in a parallel position. The rest of the apparatus was merely an ordinary spectroscope arrangement (without prism). Sunlight admitted through a slit, and rendered parallel by the collimating lens, traversed the double tunnel, and was received by the observing telescope focussed, as usual, upon the slit. It is necessary, of course, that the length of the slit be perpendicular to the plane containing the axes of the tunnels.

The appearance of the bands as seen with a given telescope depends upon the size of the apertures and upon their distance apart. The width of the bands is inversely as the distance between the centres of the apertures (tunnels), and the horizontal diameter of the luminous field upon which the bands are seen is inversely as the diameter of the apertures themselves. Since a large number of bands is not required, small and rather close apertures are indicated. The only question is as to the amount of light. If we suppose the apertures and their distance apart to be proportional, we may inquire as to the effect of linear scale L. Here a good deal may depend upon the relative values of length of slit, focal length of collimator, length as well as diameter of tunnels. In my apparatus the slit was short, and the height, as well as the width of the field of view, was determined mainly by diffraction. If we suppose the slit very short, the calculation is simplified, though this cannot be the most favourable arrangement. With a given width of slit the whole light in the field of view is then proportional to L^2. Since the angular area of the field practically varies as L^{-2}, it would seem that the brightness varies as L^4. This would impose an early limit upon the reduction of L; but there are other factors to be regarded. In order to secure an angular field of given size, we must use an eye-piece the magnifying power of which is proportional to L. This consideration changes L^4 back to L^2. Nor is this all. With a given eye-piece the admissible width of primary slit varies inversely as L, and thus, finally, the brightness of a field of given angular width, and containing a given number of bands, varies as L simply.

In the earlier experiments the tunnels were of $\frac{3}{4}$ mm. bore, and were too widely separated. In order to see the bands well, a very powerful eye-piece was needed. An attempt to gain light by substituting a cylindrical lens (very successful in the former apparatus, where the beams are limited by *slits*) for the spherical lenses of the eye-piece showed little advantage. Subsequently smaller tunnels were prepared $\frac{1}{2}$ mm. in bore, and so close that the distance of the nearest parts was rather less than the diameter of either. These gave splendid bands with the ordinary eye-piece of the spectroscope, and I estimated that there should be no difficulty in setting a web correctly to one-twentieth of a band.

The capacity of one of these passages is about 4 cubic millimetres, and I have no doubt a further reduction might be effected, so far as the optics is concerned; but the further such reduction is carried the greater, probably, would become the difficulties of manipulation. The mere closing of the ends of such small tubes with plates of glass would not be an easy matter. In order to prevent encroachment upon the course of the light, it might be necessary to enlarge the ends so as to allow a little more room for overflow of cement. For the present I content myself with showing that it is possible to obtain well-formed black bands on a sufficient angular scale with light which has traversed tubes 2 cm. long and $\frac{1}{2}$ mm. in bore. RAYLEIGH.

[1] Proc. Roy. Soc., vol. lxiv., p. 95, 1898; Scientific Papers, iv., p. 364.

GAY-LUSSAC'S LAW—ITS CENTENARY.

GAY-LUSSAC'S law regarding the composition of gases by volume was made known about a hundred years ago. The paper in which he elaborated it, having been read to the Société philomatique on December 31, 1808, was published in the Mémoires de la Société d'Arceuil in the following year. Since then the law has come to have a history of its own. Chemists were at a loss and made many efforts to get it and the atomic theory to suit one another, and the place of the law in science, though not now likely to change, was for long unsettled and dubious.

Ostwald puts the law in the following way:—"If several gases appear or disappear in a chemical change, they do so always in simple ratios by volume." For example, one volume of hydrogen and one of chlorine yield two volumes of hydrochloric acid, and, again, one volume of oxygen and two volumes of hydrogen give two of steam.

The composition of nitrous and nitric oxides and numerous other gases was discovered for the first time by Gay-Lussac. But no one who has paid much attention to the history of science can be surprised that observations had been made earlier in the same field. William Higgins knew that hydrogen and oxygen combine, yielding water, in the proportion 2 : 1, and this was probably only a version of Cavendish's result. He knew also Austin's experiment proving that sulphuretted hydrogen contains its own volume of hydrogen, and he had himself observed that sulphur dioxide contains its own volume of oxyyen. It must be admitted that Higgins, who stated these facts and reasoned very justly upon them in his "Comparative View of the Phlogistic and Anti-phlogistic Hypotheses" (1789), did not give any sign, by collating them, that he felt himself on the threshold of a great discovery. Again, Gay-Lussac and Humboldt, taking up the study, for purposes of eudiometry, of the combination of hydrogen and oxygen, found the ratio between these gases to be 2 : 1 as nearly as they could measure. This was in 1804. The observation arrested Gay-Lussac's attention. Curious to find if other suchlike cases exist, he began work which resulted in the discovery of his law, one of the most important in science.

Gay-Lussac, like Newton, did not form hypotheses. The memoir in which he set forth his work is remarkably free from speculative matter. His conviction was that "in natural science, and above all in chemistry, generalisation should come after and not before a minute knowledge of each fact." And assuredly the history of Gay-Lussac's law in science does show that a "law of nature" may prove a dangerous weapon to the man who puts it to theoretical and practical uses, before its range and bearings in nature have been accurately fixed.

The law when published aroused the widest interest. The world of science was just then pondering the atomic theory in the form impressed on it by Dalton, and it was obvious that theory and law must stand in the most intimate relation to one another. Strangely enough, the law was objected to by Dalton of all people, and by him alone. In the second part of his "New System of Chemical Philosophy," published in 1810, he made strictures on it, and concluded :—"The truth is, I believe, that gases do not unite in equal or exact measures in any one instance; when they appear to do so, it is owing to the inaccuracy of our experiments. In no case, perhaps, is there a nearer approach to mathematical exactness, than in that of one measure of oxygen to two of hydrogen; but here the most exact experiments I have ever made gave 1·97 hydrogen to 1 oxygen." Berzelius wrote to Dalton protesting in the most courteous way against the part of the atomic theory "which obliges you to declare as inaccurate the experiments of Gay-Lussac, on the volumes in which gases combine. I should have thought rather that these experiments were the finest proof of the probability of the theory; and I confess to you, that I will not so readily think Gay-Lussac at fault, especially where the point is one of good or of bad measurement." Nothing, however, could ever remove the distrust Dalton felt in the law.

The chemists who accepted both Dalton's theory and Gay-Lussac's law had themselves to solve the problem of defining the relation between the two. No more than Dalton would Gay-Lussac do anything to help them. Even so late as the year 1814, in his memoir on iodine, and in the one on prussic acid of the following year, he ignores the atomic theory. He uses the word "molecule" for the sake of convenience, and that is all. Yet there must be a connection between the specific gravities, that is, the weights of equal volumes, of different gases and their atomic weights. This connection is the primary subject of a paper by Prout, published in 1815. Here he advanced his famous hypothesis that the atomic weights of the elements are multiples of the atomic weight of hydrogen, but there is good reason to think that the hypothesis was conceived after the data had been rounded off.

Berzelius had already, in 1813, if not earlier, given his solution of the problem. This was his "volume-theory," that equal volumes of different gases contain the same number of atoms. This hypothesis affords a basis of a purely physical kind for the determination of atomic weights, for it means that the atomic weights of different gases stand in the same ratio to one another as the weights of equal volumes of the gases.

The "volume-theory," plausible as it seems, involved its author in difficulties one after another, which finally became overwhelming. One arises as soon as the theory is formulated. Each atom of hydrogen, on combining with chlorine, could, as Berzelius and Dalton understood the atom, yield only one compound atom of hydrochloric acid. But the volume of the hydrogen is half that of the hydrochloric acid which it produces, so that the atom of the element occupies only half the volume of the compound atom. Hence the theory must either be limited to elements, or given up altogether. Years before Dalton had to face the same difficulty in the case of nitric oxide. What he did at first was to abandon outright the hypothesis that atoms of different gases have the same volume, and then to object even to Gay-Lussac's law. Dalton was "for thorough." What Berzelius did was to make the "volume-theory" apply only to the elements.

In course of time another difficulty appeared. The atoms of many important elements seemed to enter into combination only by pairs. This strange result arose in the following way. Berzelius began in the year 1826 to ascribe the general formula RO to all strong bases. Now, by the chemical equation for the formation of a chloride from a base—$RO + H_2Cl_2 = RCl_2 + H_2O$—it is plain that the amount of acid needed to form a chloride with one molecule of a base contains two atoms of hydrogen and two of chlorine. That is, as Berzelius saw, the hydrogen enters into chemical combination in pairs, and so does the chlorine atom.

This, be it noted, involves a conception of the element which is precisely the reverse of the modern one. Hydrogen is now supposed to consist of physical atoms, each of which can be halved when it enters into chemical combination. The physical atom of hydrogen is composed of two chemical ones. Berzelius had formed the conception of a chemical atom composed of two physical ones. It applied to quite a large number of elements in addition to hydrogen, namely, to chlorine, fluorine, bromine, iodine, nitrogen, phosphorus, antimony, and arsenic.

The very natural comment on this was made by Gmelin, that the "existence of the physical atom was improbable and its adoption superfluous and troublesome." One could arrive at Gmelin's system of chemical formulæ by suppressing every pair of physical atoms in Berzelius's formulæ, and putting in a chemical atom instead. Thus H_2O became HO. Nobody could help seeing that Berzelius's system simply led the way to Gmelin's. This was a great blow to the "volume-theory," for Gmelin's system differs from Berzelius's only by leaving out the "volume-theory" and all its consequences.

The above as an objection to the theory was perceived and felt to be overwhelming only in course of time. As already explained, from the first the theory could include in its scope only the elements. But before long Berzelius had to limit the theory still further. So long as it is applied to elements the molecules of which are of the same degree of complexity, hydrogen and oxygen, for instance, the physical method of finding atomic weights is in agreement with the chemical. The ratio H_2/O_2, which the former method gives, is the same as the ratio H/O given by the latter. But this is a matter of accident. About the year 1826 Dumas succeeded in finding the vapour-density of elements such as mercury and phosphorus, and was therefore enabled to calculate their respective atomic weights by the physical method. For mercury the ratios are Hg/O_2 (physical) and Hg/O (chemical), and for phosphorus P_4/O_2 (physical) and P/O (chemical).

These discrepancies forced Berzelius to limit the "volume-theory" to gaseous elements, and to such as are easily converted into gas. Finally, when discrepancies, no less serious, arose in the case of sulphur and of arsenic, he decided to abandon the theory. This was in 1833, after he had held to it for twenty years.

The only sound application of the law to theoretical chemistry was made by Avogadro in 1811. In considering his teaching, it is best to set aside the word atom and its associations, at least in the first place, and to use the word "molecule" instead. Avogadro's hypothesis is that equal volumes of different gases contain the same number of molecules. In that case the weights of equal volumes of gases are proportional to their molecular weights.

The hypothesis has a special and important consequence regarding the constitution of the molecule. For instance, each molecule of hydrogen, with the necessary chlorine, yields two molecules of hydrochloric acid. But each molecule of the acid contains hydrogen, and therefore the hydrogen molecule has certainly been halved. This conception of the molecule of an element as a thing which may consist of parts is an inevitable consequence of Avogadro's hypothesis, and it was boldly accepted by him. The mere possibility of such a thing was scouted by Thomson, and Berzelius, and Graham as utterly subversive of the atomic theory. Yet it forced itself forward again and again upon Ampère, Dumas, Prout, Waterston, Krönig, Gerhardt, Laurent, Clausius. Finally, in 1860, Cannizzaro was able to convert chemists to Avogadro's hypothesis and all its consequences. Since then the hypothesis, based as it is upon Gay-Lussac's law, has been the fundamental doctrine of chemistry.

One thing about the definition of the law is worth noting. Nothing is said in it, but much is implied, regarding the conditions under which the gases are measured. The teacher would do well to direct attention to this. There is the obvious assumption that the different gases concerned in a particular experiment are measured under the same temperature and pressure. But the definition implies another assumption, namely, that different gases behave in the same way under the same conditions. Otherwise the combining ratio, say, of hydrogen and chlorine, could not remain constant over a range of temperature and pressure.

Of course, we know that the combining ratio of two gases does not remain strictly constant when the conditions alter. The fact that a gas such as carbon dioxide deviates considerably from Boyle's law and Charles's law leads to the expectation that Gay-Lussac's law is itself only an imperfect description of the facts. The expectation is verified, for even the combining ratio of hydrogen and oxygen is not strictly 2 : 1, but has been ascertained to be 2·00285 (Scott), 2·0037 (Leduc), and 2·0027 (Morley). This is an important consideration, for molecular and atomic weight data obtained on the assumption that Gay-Lussac's law is strictly accurate must be defective. The physical method cannot lead to the same result as the chemical until a correction is introduced, and then the discrepancy is found to disappear. One systematic way of making this correction has been devised and used by M. Daniel Berthelot, and another by M. Guye.

Berzelius was led into a grave numerical error by his unqualified acceptance of Gay-Lussac's law. In the year 1819, in conjunction with Dulong, he determined the atomic weight of carbon by the physical method. The process adopted was to weigh a certain bulk of carbon dioxide and subtract the weight of the same bulk of oxygen. The difference is the weight of the carbon, on the incorrect assumption that carbon dioxide contains exactly its own bulk of oxygen. The atomic weight was found to be 76·44 (O = 100) or 12·23 (O = 16). This datum, which as a matter of fact is much too high, was long used in chemistry. Berzelius should not have fallen into this error, for he had received a warning two years before against the danger of the physical method. He had determined the atomic weight of sulphur by an experiment, similar to the carbon dioxide one, with sulphur dioxide, and he set aside the result, which was 103·35 (O = 100), because it differed so much from the figure, 100·7, which he had obtained by a chemical method.

Dumas and Stas found it necessary, in the year 1839, to embark on a re-investigation of the atomic weight of carbon. Dumas had been analysing the hydrocarbon naphthalene, and had obtained the anomalous result, again and again, that the percentages of carbon and hydrogen added up to much more than 100. As a result, the atomic weight of carbon was found to be 75·00, instead of 76·44, as Berzelius had said.

This was a severe blow to Berzelius. He had endured many reverses. One cherished conviction of his had gone after another. Chlorine and nitrogen had proved to be elements and not compounds of oxygen, the "volume-theory" had become untenable, his electrochemical theory was undermined, and his system of chemistry was threatened by Gmelin. Berzelius was yet the great master of atomic-weight determination. Even that satisfaction was now denied him; none of his atomic weights was to be above suspicion any longer, all because he had made an unjustified use of Gay-Lussac's law, twenty years before. There is a strange irony in the difficulties in which Berzelius involved himself time and again by his use of this law, in view of the protest he had made against Dalton's refusal to accept it.

A. N. MELDRUM.

ANEMOGRAPHIC OBSERVATIONS IN INDIA.[1]

MOST of these memoirs are by the late Sir John Eliot, whose loss, while he was still capable of much useful work, all meteorologists deplore. They deal with the changes in wind direction and force at the stations, showing both the diurnal and the seasonal variations, and form a store-house of information for anyone who wishes to study the Indian monsoons.

Saugor Island is situated in the north-west of the Bay of Bengal on the coast, about sixty-five miles in a direct line from Calcutta, and ninety if the bends of the river are followed. The land around it is perfectly flat, and only a few feet above the sea, so that the exposure is an excellent one.

The land at Alipore is also flat, but there are many trees in the district the tops of which are level with or above the anemometer. As might be expected, the winds are far stronger at the coast station.

Saugor Island lies in the track of the circular storms (cyclones) of the Bay of Bengal, and it is of interest to compare the maximum hourly velocity in these

[1] A Discussion of the Anemographic Observations recorded at Saugor Island from March, 1880, to February, 1904. Also at Alipore, Calcutta, from March, 1877, to February, 1904. Vol. xviii., part ii. Also at Pachmark from September, 1883, to April, 1887. Also at Nagpur from January, 1882, to December, 1902. Vol. xix., part i. At Roorkee from September, 1879, to August, 1904. At Lahore from January, 1889, to May, 1905. At Mussoorie from May to October, 1877 to 1888. (London: Harrison and Sons.)

storms with that which occurs in other places. Unfortunately, the factor that has been used is not given, but it is probably the old erroneous factor 3. It is in few years that this velocity exceeds 50 miles per hour—37 on the present scale of the Meteorological Office—and there are few stations on the British coast at which this is not often exceeded. One instance of 90 (66 corrected) is given.

It does not seem unlikely that the violence of the tropical hurricanes is somewhat overestimated owing to the contrast with the usual calm of the tropics, and also, perhaps, because the proximity of violent winds from different directions produces a very irregular and dangerous sea.

The memoirs also contain curves showing the direction and magnitude of the daily variation. The results for St. Helena have lately been treated in a similar manner with very interesting results. The daily oscillation of the barometer, more particularly the second term in the harmonic series with the twelve-hour period, must be associated with the transfer of a considerable mass of air from place to place, and it is of interest to try and trace this transfer in the anemometric records from various parts of the globe. These variations, as they are shown at the mouth of the Ganges and in Northern India, are very fully discussed. The conditions are naturally very different at the different stations, both in space and with the changing seasons, and the causes that produce local winds are so complex that it is almost hopeless to try and correlate cause and effect. At all the stations the change from hour to hour seems to be large by day and small by night, from which one may perhaps conclude that local heating by the sun plays an important part in the phenomena.

Although the observations at Mussoorie were only taken during the summer, they are of especial interest, since the station stands on the summit of one of the outer ridges of the Himalayas at an elevation of some 6500 feet above the sea. The hourly and monthly values, as at the other inland stations, are very complex; but there is, as might be expected, a distinct tendency for the air to run up the slope of the mountains during the day and down during the night. Naturally, also, the winds are stronger than at the stations in the plains.

ROCK PAINTINGS OF THE LOWER EBRO.

A VERY interesting article on this subject by MM. l'Abbé Breuil and Juan Cabré appeared in the January–February number of *l'Anthropologie*. The first part of the paper deals with the painted rocks on the Calapatà at Cretas (Teruel) first observed by M. Cabré in 1903, although it was not until 1906 that he communicated his discovery, having then realised its significance in relation to Quaternary art. The pictures, which are painted under a shallow shelter, represent animals in various attitudes, and show considerable vigour of execution. Close by, flint flakes are to be found which exhibit no Neolithic characters, but rather Magdalenian. The paintings comprise three deer, a bull, and a small subject difficult to determine. All are done in dark red, and are outlined by a very lightly engraved line; certain details, such as eyes and nostrils, are added in the same way, as they would not otherwise appear in a monochrome without shading. The first deer, measuring 30 cm. by 25 cm., is represented in a graceful attitude in the act of rising to its feet; the second (33 cm. by 27 cm.) is walking rapidly towards the first, the movement being admirably depicted. It is interesting to note that in all the stags drawn in profile the antlers are conventional, as if seen partly from the front, partly from the side. This curious disposition of the branching is met with, not only at Cretas, but also at Cogul (Lerida), and in France in the reindeer drawings of the Portel grotto. This points to a closer connection in late Quaternary times of the tribes of Aragon and Catalonia with those of the Ariège than with any others.

The second part of the article describes a series of rock paintings at Cogul, in Lerida (Catalonia), which was brought to the public notice in 1907. The surface painted measures about 2 m. across, and lies beneath a ledge of rock. Altogether there are five distinct pictures. Two are hunting scenes, of which the figures are drawn schematically. M. C. Rocafort regards this as a hieroglyphic inscription, possibly of the Iberian period, but the authors consider that it cannot be thus separated as regards date from the accompanying paintings. The third picture (measuring 75 cm. across) represents a stag surrounded by hinds. The animals of this group are less realistic than those of Cretas, but none the less the execution is delicate, and the attitudes graceful and lifelike.

The right-hand lower scene apparently represents nine women dancing round a man, four being to the right of the man, and five to the left. The man is much smaller than the women, and has no clothing beyond an ornament at the knees; the women are all wearing petticoats reaching to the knees, while the upper part of the body is bare. The figures are painted in black, red, or black and red; the man is dark brown rather than black. The outlines of the four right-hand figures are emphasised by engraving. The whole group measures 68 cm. across.

The dress of the women presents a superficial analogy with the Cretan series, but the lifelike character of the Minoan figures and many details are in strong contrast with the stiffness of the Cogul "ladies." Much more definite evidence would be necessary in order to establish any connection between the two series.

The style of the animal frescoes at Cogul, as of those of the Calapatà (Cretas), is that of our Quaternary drawings, not of later art. This indication is corroborated by the presence, not far from the painted rock at Cogul, of small Magdalenian stations with numerous flint flakes (in some cases retouched) of the type usual in France. Thus it is certain that in the immediate neighbourhood of the painted rocks there existed stations of the late Palæolithic age, contemporary with our civilisation of the Reindeer age; it is also highly probable that the whole of these open-air frescoes are to be attributed to the peoples living there; those of single animals afford further beautiful specimens of Quaternary art in animal-drawing. The hunting pictures at Cogul introduce a historic scenic episode as yet unknown in mural art. The dancing scene described raises a small corner of the veil drawn over the social life of those remote ages, and the style of dress tells us something of the use to which the Magdalenian seamstresses put those fine eye-needles which the caves of the Cantabrian Mountains, the Pyrenees, and Dordogne have so long yielded to the astonished eyes of investigators.

PROF. HUGH BLACKBURN.

THE unexpected decease of Prof. Hugh Blackburn, who occupied the chair of mathematics in the University of Glasgow from 1849 to 1879, was announced by Principal Sir Donald MacAlister to the great audience of students and friends assembled to hear the inaugural address of Prof. Gibson. The news came as a great shock to such former students as were present, among them his then retiring successor, Prof. Jack, and Prof. Gibson himself, and Prof. Blackburn's old student, colleague and life-long friend, Prof. Ferguson. It was well known that Prof. Blackburn's health had broken down seriously in the spring, and that there had been no sensible improvement, but the actual news was unexpected.

Prof. Blackburn's family have been connected with Glasgow for at least three centuries. An ancestor of his, Peter Blackburn, was one of the "regents" of the slowly growing University, from 1574. He was appointed when the Town Council handed over to the University grants made to themselves of lands and buildings by Queen Mary in 1567. From that time until Peter Blackburn was appointed a regent in 1874 the University had been all but moribund. Blackburn was brought from St. Andrews, where he had graduated, and he acted as regent shortly before the arrival of the great reformer Andrew Melville. During Melville's epoch-making six years as principal, and for two years after it, Mr. Blackburn acted as third or principal "regent." The regents used each to take the students committed to them through all their subjects, and for their whole university course. Melville revolutionised this system, setting each regent to teach some special branch of the graduation course to all the students. Mr. Blackburn was, in fact, "professor" of physics and astronomy in the modern sense until he left for Aberdeen, two years after Melville had left for St. Andrews.

It is curious to find the name Peter surviving after three centuries in the family of which Prof. Blackburn was a member. His eldest brother was Peter Blackburn, long M.P. for Stirlingshire and chairman of the Edinburgh and Glasgow Railway before it was merged into the North British. His second brother, Colin Blackburn, afterwards the famous Lord Blackburn of the High Court of Appeal, was eighth wrangler in 1835, and Hugh Blackburn, the youngest brother, was fifth wrangler in 1845. It was a memorable year at Cambridge. William Thomson, afterwards Lord Kelvin, then a boy of eight, came across from Belfast to Glasgow, where, in 1832, his father had been appointed professor of mathematics. At the age of twenty-one he was second wrangler and first Smith's prizeman, and founder and editor of the famous *Cambridge and Dublin Mathematical Journal*. To its first volume Prof. Blackburn contributed a paper on the variation of elements in the planetary system. Nothing quite like that first volume had previously appeared in the British mathematical world. Side by side with Prof. Blackburn's paper were one by Cayley (senior wrangler in 1842); a note on induced magnetism on a plate, by William Thomson; a paper by Sir William Rowan Hamilton, Irish Astronomer Royal; and another on quadrature of surfaces of the second order, by Mr. John H. Jellett, fellow and tutor, and afterwards provost, of Trinity College, Dublin. In the same volume there were papers by Leslie Ellis, senior wrangler in 1840; by Boole, afterwards the famous professor at Cork; by Augustus de Morgan, London; by Stokes, senior wrangler in 1841; by D. F. Gregory, fifth wrangler in 1837; by Townsend, of Dublin, and Liouville, of Paris, with four other papers by the young editor himself. In that splendid galaxy of men of mathematical genius Prof. Blackburn took a distinguished place, and he had deeply impressed his friends, and Thomson, no doubt, in particular, by inventing and exhibiting in his rooms his well-known pendulum with double suspension. A little later the two young Scotchmen, Thomson and Blackburn, went to Paris together on a mathematical and physical pilgrimage, and all their lives they remained attached and devoted friends. In 1871 they published together the full text of Newton's "Principia." Later, Prof. Blackburn published a revised and extended edition of Sir George Airy's treatise on trigonometry from the "Encyclopædia Metropolitana," which appeared in a separate cabinet form in 1855.

William Thomson entered in 1846 on his splendid tenure of the chair in natural philosophy in Glasgow, which he filled for fifty-three years. Two years later his father, the professor of mathematics there, died unexpectedly, and it was probably largely due to Thomson's entire conviction of the exceptional mathematical ability of his friend that Prof. Blackburn was appointed in 1849 to succeed Prof. James Thomson.

His students always felt for him the greatest affection and respect. Every teacher's qualities are appraised by the world very much as Mr. Lowe used to judge primary teachers under the famous revised code—by results. Prof. Blackburn had many distinguished pupils who took high places in the mathematical world. I may name Dr. Thomas Muir, who was an admirable assistant to the professor, and who has never, in spite of his engrossing duties as director of education in Cape Colony, intermitted his work on determinants. There was Sir Charles Abercrombie Smith, formerly Auditor-General in Cape Colony and now Vice-Chancellor of the Cape University; Mr. Dickson and Mr. Dodds, formerly tutors of Peterhouse; Prof. Pinkerton, of Cardiff, and Mr. Nixon, of Belfast. But Prof. Blackburn was much more than a mere mathematician. His University speedily discovered his administrative and financial strength, and made him successively convener of its library and its finance committees. Mr. Blackburn was, perhaps, more trusted and more responsible than any of his colleagues in the removal of the old college from the site it had occupied for four centuries, after it had become unsuitable and perhaps insanitary, to the present splendid buildings. Among his colleagues his authority was always great, and he owed this to the strength and simplicity of his character, and to the clearness of his practical and judicial mind. Students and colleagues alike, who knew him better than others could, honoured him and believed in him. Of a sensitive and artistic nature, he did not, however, care, after thirty years, to continue services which increasing deafness made irksome and difficult.

For years, Prof. Blackburn, in declining strength and health, never left the estate, beyond the Mull of Ardnamurchan, where he had found a home in 1879, and where he died.

W. J.

NOTES.

SIR RAY LANKESTER writes to inform us that he has heard from the representatives of the late Prof. Anton Dohrn to the effect that the Zoological Station at Naples remains the property of the heirs of its founder. Neither the German Government nor any German society have acquired any rights in its future disposition. Dr. Reinhardt Dohrn, who has for two years been the acting director of the Zoological Station of Naples, is now director, and has inherited from his father (by agreement with his brothers) the actual property and the leases granted by the Naples municipality as to the site. We wish Dr. Reinhardt Dohrn success and happiness in carrying on the work of his eminent father.

THE Meteorological Office has received reports of observations of an aurora on the nights of October 17, 18, and 19, at several places in England, Scotland, and Ireland. An aurora is also reported in the French *Bulletin International* as having occurred at Haparanda on the night of October 18, and vessels engaged in the Transatlantic trade report an unusually brilliant display of aurora on the same night—October 18–19—over practically the whole route between Europe and the United States of America. In connection with these reports, it is of interest to note that considerable magnetic disturbance was recorded at Kew on October 18–19, though nothing at all approaching that recorded on the late occasion. The whole afternoon of October 18 was slightly disturbed magnetically, but there was a marked sudden development about 8.30 p.m., and a considerable disturbance prevailed thereafter until 6 a.m. on October 19. During this time there was a range of $37\frac{1}{2}'$ in the declination, of 130γ in the horizontal force, and of 170γ in the vertical force. The most noteworthy features were that the declination needle remained to the east of its normal position continuously from 8.30 p.m. on October 18 until 3.30 a.m. on October 19, while the vertical force was depressed below its normal value from the commencement of the storm until 7 a.m. next morning. There was further disturbance, but of a minor character, later on October 19.

MR. W. E. COOKE, Government astronomer, Western Australia, informs us that the most magnificent aurora visible in Australia for half a century occurred on September 25. From reports in the *West Australian*, it appears that the aurora was observed throughout Australia, as well as at Cocos Island, Batavia, Singapore, Rodriquez, Durban, and elsewhere. Magnetic disturbances appear to have been recorded generally, interfering considerably with the telegraph and cable services. The electrical engineer in the Western Australia railway department (Mr. Dowson) informed Mr. Cooke that for the space of half an hour on the evening of Saturday, September 25, the lines between Perth and Kalgoorlie (350 miles), and between Perth and Albany, worked well with all the batteries cut out. The current was at least double that which is usually employed, and the needle of the ammeter went hard over at 35 milliamperes. The pressure must have been at least 150 volts. As the auroral light waxed and waned the current followed suit. By a curious coincidence, the last great display in Australia occurred almost exactly fifty years ago.

THE Bakerian lecture for the session 1908–9 will be delivered at the Royal Society on Thursday, November 18, by Sir J. Larmor, Sec.R.S., on "The Statistical and Thermodynamical Relations of Radiant Energy."

THE annual Huxley memorial lecture will be delivered by Prof. Gustaf Retzius on Friday, November 5, at the Royal Anthropological Institute. The subject will be "The North-European Race."

RECENT American obituary includes the name of Dr. Hermann Endemann, a German by birth, who was for several years one of the editors of the publications of the American Chemical Society, and frequently appeared as an expert chemist in the courts and before legislative committees at Washington and Albany.

MR. HORACE G. KNOWLES, recently U.S. Minister at Bucharest, has been so impressed by the value of the sturgeon fisheries of the Danube that he is making an attempt to re-introduce the sturgeon into the rivers of the Atlantic coast, where for many years it has been almost unknown. He has obtained the consent of the Rumanian Government to the shipment to America of a car-load of the fry of the Black Sea sturgeon, said to be the best in the world. His efforts are warmly approved by the U.S. Fish Commissioner, who believes the experiment will be successful.

THE Secretary of State for the Colonies has appointed an advisory committee on medical and sanitary questions connected with the British Colonies and Protectorates in Tropical Africa. The members of the committee are:—Mr. H. J. Read, C.M.G. (chairman); Sir Patrick Manson, K.C.M.G., F.R.S.; Sir Rubert Boyce, F.R.S.; Mr. C. Strachey; Mr. W. T. Prout, C.M.G.; Dr. T. Thomson, C.M.G.; Prof. W. J. Simpson, C.M.G.; and Dr. J. K. Fowler. Mr. A. Fiddian, of the Colonial Office, will act as secretary to the committee.

AT the general meeting of the Royal Society of Edinburgh, held on October 25, the following office bearers and members of council were elected:—*President*, Sir William Turner, K.C.B., F.R.S.; *vice-presidents*, Dr. R. H. Traquair, F.R.S., Prof. Crum Brown, F.R.S., Prof. J. C. Ewart, F.R.S., Dr. J. Horne, F.R.S., Dr. J. Burgess, Prof. T. Hudson Beare; *general secretary*, Prof. G. Chrystal; *secretaries to ordinary meetings*, Dr. C. G. Knott, Dr. R. Kidston, F.R.S.; *treasurer*, J. Currie; *curator of library and museum*, Dr. J. S. Black; *councillors*, Prof. F. W. Dyson, F.R.S., Prof. D'Arcy W. Thompson, C.B., Dr. O. Charnock Bradley, C. Tweedie, Prof. J. W. Gregory, F.R.S., Dr. A. P. Laurie, Prof. Wm. Peddie, Prof. H. M. Macdonald, F.R.S., Prof. D. Noël Paton, Dr. W. S. Bruce, Prof. F. A. Baily, J. G. Bartholomew.

THE council of the Institution of Civil Engineers has made the following awards for the year 1908–9:—Telford gold medals, Prof. B. Hopkinson and G. R. G. Conway; Watt gold medals, D. A. Matheson and W. C. Popplewell; George Stephenson gold medals, E. H. Tabor and A. J. Knowles; the "Indian" premium and a Telford premium, T. R. Nolan; Telford premiums, S. J. Reed, C. T. Purdy, L. A. B. Wade, G. Hobbs, W. Cleaver, J. D. W. Ball, Prof. A. H. Gibson, and R. D. Gwyther; the "James Forrest" medal and a Miller prize, J. A. Wotherspoon; the Miller scholarship, J. A. Orrell; the "James Prescott Joule" medal and Miller prizes, W. E. Fisher and E. B. Wood; Miller Prizes, W. E. R. Gurney, E. G. L. Lovegrove, J. Purser, G. C. Minnitt, S. F. Deacon, C. H. Bradley, and A. E. Marshall.

NEWS of large disturbances of seismographs by distant earthquake shocks was recorded in the *Daily Mail* of Friday, October 22, by Prof. Milne (Shide, Isle of Wight), Prof. Belar (Laibach, Austria), and Prof. Michie Smith (Kodaikanal, southern India). The earthquake occurred at 11.47 p.m. Greenwich time, and the duration of the motion was more than three hours. Prof. Milne's records indicated that "its origin was about 80° distant, which is about the distance of Japan, San Francisco, and Mexico. The probability is that it occurred in the east." Prof. Belar reported that "the place of origin was distant about 3750 miles to the east." On the following day telegraphic messages from Calcutta and Simla announced that there had been a great earthquake in Baluchistan. Belput, about two hundred miles from Quetta, is said to have suffered severely from the earthquake.

ON Thursday last, October 21, the King performed the ceremony of opening the new Royal Edward Tuberculosis Institute at Montreal by means of an electric current sent from West Dean Park, Chichester. A special telegraph line was laid from West Dean Park to Chichester, and from there the General Post Office lines were used to the Royal Exchange office of the Commercial Cable Company. The line used by the Commercial Cable Company was their shortest route *via* Waterville (Ireland) to Canso (Nova Scotia), from where it was transmitted by land lines to

Montreal. The arrangements made by the cable company were such that by means of relays and repeaters at the intermediate points the signal sent by the King travelled the whole distance without manual help. The current transmitted from West Dean Park released a current at Montreal which opened the doors of the new institute, hoisted a Union Jack, and turned on the electric light. This is, we think, the first time that a ceremony of this kind has been performed at such a distance, namely, 3000 miles, without any outside assistance, and shows the great advance that has been made in telegraphic transmission of late years. Within one minute of the key being pressed at West Dean Park a return signal was received from Montreal intimating that the ceremony had been performed satisfactorily, and a message of congratulation was sent by the King to the manager of the Commercial Cable Company within four minutes of the first signal. All these facts prove that modern telegraphic instruments are becoming more and more efficient, and the latest accomplishment will doubtless advance the closer relationship between the Mother Country and the colonies.

The United States Government, says *Science*, is now carrying on work at regular forest experiment stations similar to the agricultural experiment stations in the different States. The first forest experiment station created was the Coconino Experiment Station at Flagstaff, Arizona, established in 1908. Investigations covering many phases of forestry in the south-west have already been undertaken at this station. The second forest experiment station has been established this year on Pike's Peak, Colorado. The need for such stations becomes apparent when the long time necessary for handling forest experiments is considered; in forestry, because of the long time required for trees to develop, scores of years are often required to complete a single experiment. All experimental work is conducted under the direction of men who have had training in technical and practical forestry. The greatest technical problem which now confronts the forester in handling the great pine forests of Arizona and New Mexico is that of establishing a new stand of trees to replace the old timber which is cut off. This was the first problem undertaken by the Coconino Experiment Station. Much information regarding the factors influencing natural reproduction has been secured already, but many years of systematic study will be required to solve the problem. The feasibility of artificial regeneration by planting and sowing is also being tested. The plans for the near future provide for a detailed study of the problems concerning the natural and artificial regeneration of other commercial trees, such as Douglas fir, Engelmann spruce, and the junipers.

We learn from the *Pioneer Mail* that a committee has been appointed for establishing a Pasteur institute in Burma, and is actively engaged in forwarding the scheme. Recently the Secretary of State intimated, in view of the straitened condition of the provincial finances of Burma and of the fact that there was no guarantee that the initial capital outlay on the institute would be met from private subscriptions, sufficient cause to resort to public money had hardly been made out, and consequently regretted his inability to sanction the project as outlined in the first instance. A subcommittee, appointed to formulate a working scheme for the building and equipment of the institute, has reported, and is of opinion that it is possible to provide for bare requirements for one-half of the available capital. The institute, it is hoped, will in course of time find itself in proximity to a general bacteriological institute, and it is considered desirable that the buildings of the institute shall be permanent and substantial, so that they will be a creditable feature of the entire group of buildings to be constructed ultimately for scientific research. The subcommittee recommends, also, that the institute should be under the direction of an officer specially selected in the United Kingdom for his success in bacteriological research. Such an officer, it is suggested, should be appointed on a special agreement, and should not expect transfer, war service, pension, private practice, or any other of the special privileges open to members of the Indian Medical Service.

The third part of vol. vi. of the Annals of the South African Museum is devoted to the continuation of Messrs. Gilchrist's and Wardlaw's description of a collection of fishes from the coast of Natal, among which several are new.

In a paper on the remains of Carboniferous air-breathing vertebrates in the U.S. National Museum, published in No. 1696 of the Proceedings of that institution, Mr. R. S. Moody directs special attention to the reptile *Isodectes punctulatus*, on account of its bearing on the origin of the reptilian class. The type and only known specimen, which lacks the skull and nearly the whole of the fore-limbs, and measures less than 6 inches, is re-described in detail. It displays indications of affinity with the Microsauria, but its ordinal position among reptiles cannot be determined. Several new amphibians are described in the paper.

To the October number of the *Popular Science Monthly* Prof. W. A. Locy contributes a thoughtful article on the service of zoology to intellectual progress. The study of this science has been a great factor in the cultivation of straight thinking; "its influence has been great in clearing the atmosphere of thought, in dispelling clouds, and in freeing the mind from the bonds of inherited prejudice and traditional superstition." Another result was the conception of the constancy of nature, and, in particular, the idea that all animal life is the result of one continuous and orderly progress. As regards the practical applications of zoology—often in connection with botany—these have been exemplified during the last decade by the wonderful discoveries as to the modes in which diseases are introduced into the human systems by the intervention of insect and other animal carriers, while scarcely less important are the benefits which a knowledge of heredity has conferred upon breeders. Finally, there is the crowning service which zoology has conferred upon mankind in enabling us to realise the existence of evolution, which is so comprehensive in its extent that it enters into all realms of thought, and largely aids in teaching man to comprehend himself, and in some dim degree to understand his own future destiny.

In a pamphlet entitled "Breeding Horses for Use, or Equine Eugenics," published by Messrs. Swan Sonnenschein and Co., Ltd., Mr. Francis Ram seems well pleased to play the part of Cassandra, for he tells us that, six-and-twenty years ago, he issued under the same title an unanswerable pamphlet, and that if the advice contained therein had been followed a sum of at least 100,000,000*l.* would have been saved to the nation, while the breed of horses would have been vastly improved. The main feature of the scheme seems to be the substitution of stallions for geldings in cavalry and omnibus horses, and the selection from among these, after severe tests of stamina and endurance, of a small percentage for breeding purposes. Perhaps the author might have had a better chance of getting his scheme more carefully considered had he not run a tilt at judges at horse-shows and other experts, whom he pronounces utterly unfit for their duties. He also seems to possess better vision than most persons, as he asserts that he can see the true position of the limbs of a galloping horse without the aid of photography, while he also accuses Sir Ray Lankester of being in error regarding the position of the legs and feet in a running dog.

In a paper published in the "Annals and Magazine of Natural History" for 1903, Mr. J. L. Bonhote strongly urged the inadvisability of regarding the numerous island forms of chevrotains as distinct species, and pointed out that there are really only four types entitled to specific rank. This view is entirely ignored by Mr. G. S. Miller in a paper on the mouse-deer (chevrotains) of the Rhio-Linga Archipelago, published as No. 1695 of the Proceedings of the U.S. National Museum, in which a large number of island forms related to the napu are treated as distinct species. Apart from this, Mr. Miller draws some interesting conclusions regarding the development of melanism and other colour-phases in this group. "The only conclusion that seems justified," he writes, "is that the *Tragulus napu* group consists of a series of local species whose colour-pattern, probably for some physiological reason, is varying along two main lines of divergence, both of which are independent of external conditions as ordinarily understood. Each series is equally incapable of explanation by the hypotheses of Lamarck, Darwin, or De Vries. On the larger land-masses such changes as may be taking place are uniform over wide areas and relatively slow, while in the regions which, by submergence, have become divided into small land-areas separated by water the changes are irregular and rapid, though progressing on different islands at a very unequal rate."

Messrs. Williams and Norgate have forwarded to us the third and fourth parts of the thirty-ninth volume of Gegenbaur's *Morphologisches Jahrbuch*, containing papers on the development of the vertebral column in Echidna and in man, by G. P. Frets; the prothorax of birds and mammals, by T. Funccius; the saccus endolymphaticus, by Giuseppe Sterzi; the segmental theory of the vertebrate head, by B. Hatschek; the swim-bladder of Malacopterygii, by L. F. de Beaufort; and the brain-pattern of the anterior cranial fossa, by E. Landau.

We have received from the publishers an essay, by Prof. O. Grosser, on the methods of fœtal nourishment amongst mammals (including man), forming part iii. of the collection of anatomical and physiological lectures and essays edited by Profs. Gaupp and Nagel (*Sammlung anatomischer und physiologischer Vorträge und Aufsätze*, Heft iii.; Jena: Gustav Fischer, 1909, price 60 pf.).

The investigations of the *Challenger* and other deep-sea exploring expeditions have long since made us familiar with the fact that many deep-sea fishes possess luminous organs of various kinds, but one would hardly expect to find such organs in species which live habitually in shallow water. It appears, however, from the observations of Dr. Otto Steche, published in a recent number of the *Zeitschrift für wissenschaftliche Zoologie* (Band 93, Heft iii.), that we must modify our ideas on this subject. *Anomalops katoptron* and *Photoblepheron palpebratus* are two fishes which inhabit the shallow waters of a coral reef in the Malay Archipelago. In each case the luminous organ is a large oval body lying beneath the eye. The author was able to keep the fish in captivity, and gives some interesting particulars of the behaviour of the organ in the living animal, as well as a detailed account of its microscopical structure. It appears that the fishes are well known to the native Malays, who actually make use of the luminous organs for catching other fish, cutting them out and attaching them to the hook above the proper bait, under which conditions they will remain luminous for some hours, a fact which throws an interesting sidelight on the function of such organs. The fishes themselves are, as one would suppose, predaceous, feeding on all the small inhabitants of the coral reef, especially crustacea.

A note on tamarisk manna is contributed by Mr. D. Hooper to the Journal and Proceedings, Asiatic Society of Bengal (vol. v., No. 2). The substance is obtained from the halophytic shrub *Tamarix gallica* and from *Tamarix articulata*, while the species *Pallasii* yields an inferior sweet gum. It has not been ascertained whether the manna is produced by insect agency or is a natural secretion of the plant. The ordinary method of extraction consists in pounding the branches or leaves; the saccharine ingredient of the manna was found to be cane-sugar. A curious occurrence of manna was observed on certain land in Seistan which was subject to inundation; the manna shed by the tamarisk bushes had apparently dissolved in the water and dried out in lumps as the water evaporated.

On the subject of nomenclature in connection with plant formations, an article by Dr. R. Gradmann, published in Engler's *Botanische Jahrbücher* (vol. xliii., part iii.), deserves careful attention. It is pointed out that three methods of classification have been advanced, the physiognomic, adopted by Grisebach, the pioneer in this branch of botany; the ecological, exemplified by Warming's "Plant Formations"; and the purely floristic. As regards the last-named, it is observed that while the designation of formations according to dominant and subdominant or typical plants has its practical uses, the only comprehensive system is furnished by a complete list of all the plants for each individual formation. Three points arise out of this paper:—first, the basis for a system of classification; secondly, a convenient designation for each formation; and, thirdly, the means of differentiation between similar formations.

The *National Geographic Magazine* (p. 822) contains an interesting paper, by Mr. G. R. Putnam, of the United States Coast and Geodetic Survey, on modern nautical charts. The article contains a popular account of the methods of hydrographical surveying and chart construction, and charts of different periods are compared.

The first number of a new volume of the *Abhandlungen* of the Vienna Geographical Society is devoted to a memoir, by Dr. H. Leiter, on the question of changes of climate in northern Africa during historic times. An exhaustive examination from different points of view shows that there is no evidence that any progressive change of climate has taken place.

We have received Publications Nos. 3 and 4 of the Finland Commission for Hydrographic and Biological Investigations in the Gulf of Finland. In the first of these Dr. Johan Gehrke discusses at length the variations in the mean values of temperature and salinity in the waters of the gulf, from observations made at three stations during the years 1902–7. The second memoir consists of a table giving hourly values of water-level at Hangö from 1897 to 1903.

Captain P. K. Kozloff contributes an account of the Mongolia-Sze-Chuan expedition, carried out under his charge on behalf of the Imperial Russian Geographical

Society during 1908, to the October number of the *Geographical Journal*. The work of the expedition was to explore certain unvisited parts of Mongolia, to examine Lake Koko-nor, and to investigate the region of the upper course of the Hwang-ho. Amongst the most important results already obtained from the first part of the journey is the identification of the dead city, Khara-khoto, with Hsi-hsia, the capital of a Tangut kingdom which flourished from the eleventh to the fourteenth century.

An important list of the strong earthquakes felt in the Philippine Islands during the last half-century has recently been issued by the Rev. Miguel Saderro Masô, assistant director of the Weather Bureau. The earthquakes, fifty-five in number, vary in intensity between the degrees 7 and 10 of the Rossi-Forel scale of seismic intensity, five of them attaining the highest degree. The year of maximum activity, when eight strong earthquakes were felt, was 1897, which was also that of the great Assam earthquake; and, during the decade 1890–1900, sixteen strong shocks occurred in the Philippines, while in the same interval no fewer than nine were felt in Japan. The most unstable district in the archipelago is Mindanao, and especially the eastern part of the island, which lies in the neighbourhood of the great geosynclinal of the Pacific Ocean.

An analysis of the underground temperature at Osaka, western Japan, by Mr. T. Okada and Mr. T. Takeda, is contained in the Bulletin of the Central Meteorological Observatory of Japan, No. 2, 1909. The tables show the hourly mean temperature at depths varying from 0·0–0·6 metre for the years 1901–6, and the monthly mean temperature between 0·0 and 5·0 metres for the years 1895–1904. Below the surface the soil consisted of granite sand. At the depth of 60 cm. the diurnal variation is almost insignificant; the minimum occurs between 2h. and 3h. p.m., and the maximum between midnight and 3h. a.m. The mean annual temperature increases up to a depth of 300 cm. and then decreases; at the depth of 500 cm. the minimum occurs in May and the maximum in November. The total annual heat exchange is computed to be about one-thousandth part of the total quantity of solar radiation received by the surface of the soil.

Storms of wind and rain have occurred very generally over the British Islands during the past week, and the weather throughout the period was under the influence of cyclonic disturbances, which arrived with considerable frequency from off the Atlantic. On Saturday, October 23, a south-westerly gale blew in most parts of the country, and at Scilly the wind during the evening blew in squalls with a velocity of ninety miles per hour from the westward. In London the aggregate rainfall to the morning of October 27 is 2·65 inches, whilst the average for the whole month is 2·73 inches, and as yet rain has fallen on twenty days this month.

A preliminary note, by Mr. J. R. Sutton, on the results of observations made during three years upon the diurnal variation of level at Kimberley, is published in the Transactions of the Royal Society of South Africa for July last. It appears from the tables that the movements on the seismograph are very great; the maximum westerly elongation of the pendulum occurs at $5\frac{1}{2}$h. a.m., the maximum easterly about $4\frac{1}{4}$h. p.m., the median positions a little before 11h. a.m. and $9\frac{1}{2}$h. p.m., the mean daily range for the period being 5·5 mm. Not much connection with the weather can be traced; cloud and variations of barometric pressure are thought to be the most potent disturbers in a small way of the regular diurnal march of the pendulum. There was a strong tendency for the pendulum to deviate more and more to the west of its mean position during winter, and to the east during summer.

The *Philippine Journal of Science* for June (iv., No. 3) contains several papers of importance on protozoology and parasitology, and a study of the diet and nutrition of the Filipino people by Mr. Hans Aron.

We have received the first part of a volume of memoirs of the Oswaldo Cruz Bacteriological Institute, Rio de Janeiro ("Memorias do Instituto Oswaldo Cruz," Tomo i., Faciculo 1, 1909). The text is in Portuguese, but in parallel column a translation in German, French, or English is given of each article. It contains three excellent coloured plates and other illustrations. Among the contents are a description of a new species of Tabanus, and a contribution on native Tabanidæ, by Dr. Adolpho Lutz and Dr. Arthur Neiva; observations on Brazilian Anophelinæ, by Dr. Neiva; descriptions of two new species of Plasmodia, by Drs. Aragão and Neiva; a study of a new species of Amœba, by Dr. Aragão; studies on tuberculosis, by Dr. Fontes; concentration of diphtheria anti-toxin, by Messrs. Giemsa and Godoy; and the preparation of anti-plague serum, by Dr. Vasconcellos.

A novel type of gas-driven water pump, designed by Mr. H. A. Humphrey, seems likely to find numerous applications owing to its simplicity and high economy. The pump consists of a vertical U tube, having legs of unequal length. The longer leg enters at the bottom of the delivery tank, and the shorter leg is partly immersed in the tank from which the water to be pumped is drawn. The water enters the shorter leg through a number of admission valves, and the upper portion of this leg forms the combustion chamber, and is fitted with admission, exhaust, and scavenging valves, and also an electric ignition device. The gaseous pressure acts direct on the surface of the water in the shorter leg. By taking advantage of the oscillations set up in the water contained in the U tube, and the consequent alterations in gaseous pressure in the combustion chamber, Mr. Humphrey has succeeded in producing a four-stroke cycle, having a long expansion stroke, a long return exhaust stroke, a short suction stroke, and a short compression stroke, at the end of which the charge is ignited. Prof. Unwin has tested this pump, and finds the equivalent coal consumption to be only 1·06 lb. per pump-horse-power hour, a result doubtless owing to the utilisation of the "toe" of the diagram, which is generally wasted in an ordinary gas-engine cylinder.

In continuation of a previous paper, Prof. James Barnes, of Bryn Mawr College, publishes a note on the new lines in the calcium spectrum in No. 1, vol. xxx., of the *Astrophysical Journal*. The spectra measured were produced by an arc between poles of metallic calcium, enclosed in an exhausted chamber. The first table gives the wave-lengths of two series of triplets previously measured by Kayser and Runge, and three series given by Saunders. The frequencies can be represented by a formula of the Rydberg type, the following giving the first line of each triplet:— $\frac{\lambda}{1}=28911-\frac{109675}{(m+0{\cdot}927)^2}$; for λ 4586·10, the first line of the least refrangible series, $m=3$. There are no lines near λ 6208, which is the approximate wave-length for $m=2$; it therefore appears that the series is a subordinate one, as suggested by Ritz. Prof. Barnes also gives the wave-lengths of the two groups at λ 6382 and λ 6389, observed by Fowler in sun-spots and obtained by Olmsted in the calcium arc in hydrogen, but doubts whether they are due to a compound of these two elements. Between these two groups other bands were observed, and the wave-lengths are given. It is interesting to note that when the arc-gap was lengthened the line at λ 4227 reversed at the positive pole only, while H and K were much stronger near the negative pole than the positive.

The concluding part of the first volume of the Memoirs of the College of Science and Engineering, Kyoto Imperial University, contains a second paper by Mr. Y. Osaka on the mutarotation of glucose. It is shown that the velocity of the change of rotatory power which takes place in freshly prepared solutions of this sugar increases between 15° and 25° in the ratio 1/2·7. Sodium chloride has no catalytic action at dilutions below N/15, but at N/10 and N/5 a distinct retardation could be detected, as already noted by Levy and by Trey; in presence of hydrogen chloride, however, it was found to stimulate the catalytic action of the acid. In accordance with the author's theoretical conceptions, the addition of a trace of a weak acid (N/300 succinic or acetic acid) was found to produce a slight retardation, although larger quantities of the acid accelerated the change. The same issue contains a paper by Kuhara and Komatsu on a series of isomeric phenyl-phthalimides. Two compounds previously described could not be prepared again, but, in addition to the ordinary stable, colourless phthalimide, the authors obtained a colourless isomeride melting at 83–84°, which readily passed over into the stable form, and a yellow compound melting at 125–126°, which could not be transformed. The isomerism of the derivatives of phthalic acid is undoubtedly one of the most important of the cases awaiting investigation, and further work in this direction is much to be desired.

The October issue of *Pearson's Magazine* contains a further instalment of Lieut. Shackleton's narrative entitled "Nearest the South Pole." In the same number is also to be found an illustrated article dealing with oak galls.

MM. A. Hermann et Fils, of Paris, have published a second French edition of the third part of Mr. W. Rouse Ball's "Mathematical Recreations and Essays." The volume includes the chapters on astrology, hyper-space, and time and its measurement, together with additions by MM. Margossian, Reinhart, FitzPatrick, and Aubry. The translation is from the fourth English edition, and its price is 5 francs.

In the Proceedings of the American Academy of Arts and Sciences (xliv., 25) Messrs. Gilbert W. Lewis and Richard C. Tolman discuss the principle of relativity, and the system of non-Newtonian mechanics required to maintain such fundamental conservation laws as that of energy and to reconcile them with the experimental results of Michelson and Morley and of Bucherer.

A series of volumes on the history of science has been arranged by the Rationalist Press Association, and will be published by Messrs. Watts and Co. The first two volumes are "The History of Astronomy," by Prof. George Forbes, and "The History of Chemistry" (vol. i., from earliest times to 1850 a.d.), by Sir T. E. Thorpe. Among the authors who will contribute to the series are Dr. J. Scott Keltie (geography), Mr. Horace B. Woodward (geology), Prof. L. C. Miall (biology), and Dr. A. C. Haddon (anthropology).

The Railway Department of the Cape Government has issued a second edition of its official guide-book under the title "Cape Colony To-day." The book runs to 280 pages, is profusely illustrated, and provides an admirable account of the distinguishing characteristics of the districts described. For the convenience of tourists who wish to explore Cape Colony thoroughly nine tours have been mapped out, and particulars are given of the chief towns and other interesting places *en route*. The principal industries dealt with are fruit and grain growing and ostrich farming in the western province; sheep, goat, and ostrich farming and fruit growing in the midland districts; and the cultivation of maize. Every sort of information likely to be of service to the traveller is to be found in the book.

A copy of the report for 1908–9 of the council of the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne has been received. The society is to be congratulated upon receiving, by the will of the late Mr. George E. Crawhall, a legacy of 6000*l.* to be invested for the benefit of its funds. The legacy was most opportune in view of the many financial needs of the society, and it is to be hoped that the council's appeal for donations to enable the cost of maintenance of the Hancock Museum at Newcastle-upon-Tyne and of printing the society's Transactions to be met will be responded to generously. The curator's report on the museum shows that a complete overhauling and re-installation of the fishes in the zoology department has been effected, and that numerous valuable specimens have been presented to different sections of the museum.

A sixth edition of Mr. Herbert M. Wilson's "Irrigation Engineering" has been published by Messrs. Chapman and Hall, Ltd., in this country, and by Messrs. John Wiley and Sons in America. The fourth edition of the work was reviewed at length in these columns on January 28, 1904 (vol. lxix., p. 291), and it will suffice to mention some of the distinguishing characteristics of the present edition. The book has been re-written almost entirely, and brings up to date the remarkable progress made in construction by the Reclamation Service of the United States. Much old matter has been eliminated, and a large amount of new text and eighty new illustrations, representative of more modern designs for irrigation works, have been introduced.

We have received the third part of the first volume of the Journal of the Municipal School of Technology, Manchester. An explanatory note points out that the journal was established to record the original scientific work done in the school by members of the teaching staff or by students. Such work has accumulated so rapidly, however, that it has been decided to print in abstract only, or in some cases the titles only, of all the work published previous to 1908 which has not appeared in the journal already. The papers for 1908 are to be printed in full. The present issue contains the paper by Mr. J. Prescott on the figure of the earth which appeared in the *Philosophical Magazine* of October, 1907, and abstracts of papers from the mechanical engineering, the physics, the electrical engineering, and the chemistry departments. It is noteworthy that the excellently produced periodical was printed in the photography and printing crafts department of the school.

OUR ASTRONOMICAL COLUMN.

Halley's Comet.—In a communication to No. 4263 of the *Astronomische Nachrichten* (p. 319, October 13), Prof. Millosevich states that the photographic observations of Halley's comet made on September 14 show that the elements already published need very small corrections, and that, according to his calculations, perihelion passage should occur at 1910 April 19·2d. (Berlin M.T.) ±0·5d.

Father Searle, director of the Brooklands Catholic University Observatory (U.S.A.), finds, from the Mount

Hamilton observations of September 12, 13, and 14, that perihelion should occur at 1910 April 18·63 G.M.T., and that the nearest approach to the earth should take place on 1910 May 19 at a distance of about 0·14, *i.e.* about 13,000,000 miles. Further, he points out that on May 18·14d. (G.M.T.) the earth and comet will be in heliocentric conjunction in longitude, the longitude being 236° 48′; the heliocentric latitude of the comet will then be −7′, so that, according to the present elements, no actual transit of the comet over the sun's disc will occur, but a slight change in the elements might produce one. "At any rate," he says, "it seems highly probable that we shall on May 18 be inside the tail."

In a communication to the *Times* (October 25), Prof. Newall announces that he observed the comet, visually, with the 25-inch refractor, power 214, on October 21. The magnitude was about 14·0 or 14·5, and the faint nebulous patch had neither stellar nucleus nor definite borders; the diameter was estimated as 10 or 12 seconds of arc.

At the previous apparations, in 1759 and 1835, the comet was first seen 77 and 102 days, respectively, before perihelion; Prof. Newall's observation was made about 180 days before the calculated perihelion passage of 1910, but he points out that this does not necessarily mean that the comet is so much brighter at the present apparition, for he would probably not have detected it had he not known its exact position as indicated by the previous photographic observations.

QUANTITATIVE MEASURES OF THE OXYGEN BANDS IN THE SPECTRUM OF MARS.—In Bulletin No. 41 of the Lowell Observatory Prof. Very describes the methods by which he measured the relative strength of the B, oxygen, band in the spectrum of Mars, and discusses the results in their relation to the presence of, and quantity of, oxygen in the planet's atmosphere.

As Prof. Very points out, the B band is normally so intense, by the absorption in the earth's atmosphere, that only by a method capable of the minutest accuracy could it be expected that any slight extra intensification, due to the Martian atmosphere, would become measurable. He claims that, over a long series of measures, his improved spectral-band comparator is capable of measuring this added intensification. Briefly, although a visual examination shows no increase of intensity of B in passing from the spectrum of the moon to that of Mars, the comparator measures are surprisingly concordant in showing a positive value, in favour of Mars, several times greater than the probable error; B, in the spectrum of the planet, is 15 per cent. stronger than in the lunar spectrum, and the probable error is 1·8 per cent. There is, as would be expected, a considerable variation among the individual measures, but no contradictory results.

STARS HAVING PECULIAR SPECTRA: NEW VARIABLE STARS.—Harvard College Observatory Circular, No. 143, contains a list of seven stars exhibiting peculiar spectra, and twenty-eight stars shown to be variable. For each star the position, for 1900·0, is given, and the class of spectrum indicated, whilst a series of notes summarises the observations. Some of the variables show a long range of magnitude, in one case amounting to 5·0.

Circular No. 151 is a similar publication announcing the discovery of twenty new variable stars in the Harvard map No. 49. It also describes a star in Taurus, at

R.A. = 5h. 43m. 12s., dec. = +19° 2·0′,

which varies more than five magnitudes, and exhibits a light-curve of the rare R Coronæ Borealis type. Long periods of normal brightness are followed by sudden diminutions over a wide range, the normal brightness being 10·2 and the minimum fainter than 15·5.

THE NATAL GOVERNMENT OBSERVATORY.—Mr. Nevill's report for the year 1908 deals chiefly with the meteorological observations, which, with the time service, form the chief work of the observatory, but it is noted that the large equatorial telescope was overhauled and repaired, and some observations were made with it by Mr. Hodgson. Among these was a new series of lunar photographs, for the determination of the real libration, and some sketches of the surface configurations of Mars, Jupiter, and Saturn.

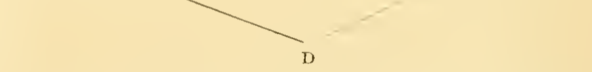
FIRST MAGNETIC RESULTS OBTAINED ON THE "CARNEGIE" IN THE NORTH ATLANTIC.

THE non-magnetic yacht the *Carnegie*, engaged in a magnetic survey of the oceans under the direction of the Department of Research in Terrestrial Magnetism of the Carnegie Institution of Washington, left Brooklyn, New York, on her first cruise, August 21, and proceeded direct to Gardiner's Bay, Long Island. Here several complete swings of the vessel were made with both helms in order to test the instruments, train the observers, and, above all, to determine whether actual non-magnetic conditions had been secured at the various positions of the instruments. These tests resulted most satisfactorily, not only proving the absence of deviations in the three magnetic elements (declination, dip, and intensity), within the errors of observation, at all observation positions, but also showing that with the instruments installed and the methods of observation employed a high degree of accuracy can be obtained.

Summary of Swings at Gardiner's Bay, Long Island, New York, August 31 to September 2, 1909.

Ship's head	West declination		Dip	Horizontal intensity in C.G.S. units	
	M.C.	Deflector	North	L.C.D.C.	Deflector
	Position A	Position C	Position B	Position B	Position C
N.	11°·41	11°·41	72°·02	0·1823	0·1830
N.E.	11·39	11·52	72·12	0·1823	0·1824
E.	11·45	11·48	72·11	0·1823	0·1830
S.E.	11·39	11·29	72·11	0·1826	0·1824
S.	11·34	11·41	72·09	0·1825	0·1831
S.W.	11·33	11·28	72·04	0·1824	0·1827
W.	11·32	11·40	72·08	0·1822	0·1823
N.W.	11·46	11·42	72·18	0·1823	0·1822
Mean ...	11·39	11·40	72·09	0·1824	0·1826

Only one who has had experience both in the observations and reductions of magnetic elements determined at sea can appreciate the full significance of these results and can realise the advance made.



The above diagram will assist in the interpretation of the figures given in the above table, and at the same time make clear the general arrangements of the various instruments and the methods used. Consider the plane ABCD to be a vertical section through the four instrument positions and the fore and aft line of the vessel. Position A is on the bridge above the deck or chart-house, B is in the forward observatory, C in the after observatory, and D at the middle point of the chart-house, vertically below A. The sides of the parallelogram are about $13\frac{1}{2}$ feet.

At A is mounted the standard compass, one of a new type invented and constructed by the Department of Terrestrial Magnetism, and called the "marine collimating compass"; it will be found described in the March (1909) issue of the journal *Terrestrial Magnetism*. The basis of the instrument is a Ritchie 8-inch liquid compass with the card, however, removed, and an optical collimating system with scale introduced, enabling the observer to note the arc of motion of the magnet system *while sighting on the sun or star*, hence knowing precisely to what part of the arc the stellar azimuth applies. In all forms of compass azimuth circles hitherto used, the magnetic azimuth of the celestial body must be taken from whatever point the card in its oscillations to and fro has momentarily reached. In brief, practically the same method of observations can now be used at sea as on land, where the magnetometer circle would be set to some convenient point on the magnet scale and then scale readings taken of the positions of the magnet during the interval of observations. The angle is next determined between the circle setting and some mark, or the true meridian, and the declination is finally deduced. Similarly with the marine collimator compass. The angle (say, middle of scale) between the magnet and some celestial body, as the sun, is read with a pocket sextant to the nearest minute of arc at a given time, and then scale readings of magnet and of watch are taken. With the aid of the time readings, the motion of the sun during the interval of observation is taken into account, and the true azimuths determined, whereas the scale readings give the varying positions of the magnet system.

With this instrument, therefore, one is almost entirely independent of the yawing and rolling of the ship, making it possible still to get satisfactory results when with all other azimuth circle devices hitherto used at sea observations would be wholly impossible, or at least very uncertain.

In five to ten minutes a value of the magnetic declination is now obtained possessing an accuracy attainable with previous instruments only by most careful observation and by laborious repetitions extending over a half-hour or more to eliminate the motion of the card. Thus not only has the accuracy of declinations at sea been increased, but, what is equally important, the time has been reduced and the possibility of getting useful results in all kinds of seas greatly extended.

Furthermore, sufficient attention has not always been paid in previous ocean magnetic work to a proper control of constants. Thus, *e.g.*, with the compass azimuth circles, as usually constructed, there are movable parts subject to wear, such as the axes of mirrors or of prisms and of the azimuth circle on the bowl. The wearing of these parts may easily bring about the same effect as though the compass were not mounted in the fore and aft line, *i.e.* introduce a quantity A not due necessarily to the ship's magnetism, but to instrumental error, which is likely to vary with extent of use of azimuth device. To control such errors, all instruments were invariably dismounted in the case of the vessel (the *Galilee*) employed in the Pacific Ocean work, whenever a port was reached, and corresponding observations made between land and ship instruments. With the present instrument, there being no such wearing parts, there will not be the source of error described.

It may also be pointed out that the *effect of drag of magnet* system moving in the liquid during changes of the ship's head is overcome in the present instrument, as well as in the one mounted at C, for the method of observation involves turning the compass bowl *opposite* to the ship's motion.

At B is the gimbal stand for mounting an L.C. dip circle, as modified for the *Galilee* work, with which the dip is determined absolutely (*i.e.* in all positions of circle and needle, inclusive of reversal of polarity by an electric coil) with two regular dip needles and again by the method of deflections, and total intensity is obtained using two deflecting distances.

At C is a Ritchie liquid compass provided with an improved azimuth circle and a deflecting attachment, both designed and made by the Department of Terrestrial Magnetism. With this instrument declinations are obtained, and also the horizontal intensity of the earth's magnetic force, by the method of deflections independently with two deflecting magnets, the magnetic moments of which are controlled from time to time by shore observations whenever the vessel is in port, and using two deflecting distances. In these deflection observations the yawing of the ship, or the changes in the lubber-line from which the deflection angles are counted, is controlled by the recorder stationed at D, who reads the ship's head by a spare Thomson dry compass. The same kind of deflecting device by which the deflecting magnet is brought at right angles to the axis of the deflected card, thus admitting of the simple sine-computation formula, is likewise attached to the marine collimating compass at A. In the latter case the angle between deflected magnetic system and the sun (or true meridian) is read with a pocket sextant, thus making one entirely independent of the yawing of the ship.

The declinations obtained at C are intended chiefly as some control against any gross blunders which may be made at A; for a fairly smooth sea they compare favourably with those got at A, but in rough seas the great superiority of the A results is very evident.

In brief, then, the scheme of observations, whenever fully carried out, will yield the following determinations in about one hour's time by independent observers, with different instruments, and at different positions on the vessel:—

At A.—Declinations (also horizontal intensity when a celestial body is long enough visible to permit of full sets of deflection observations).

At B.—Two values of dip by the regular absolute method, and two values of total intensity and of dip, using two deflecting distances.

The horizontal intensity is determined by computation from the dip and the total intensity.

At C.—Two values of horizontal intensity independently with two magnets, and using each time two deflecting distances; also, whenever possible, magnetic declinations. D, as above described, is simply accessory to C, and does not furnish any direct result.

It is thus seen that an effective control is obtained for each magnetic element, and it is for this purpose a great gain indeed that it is now possible to compare *at once* the values of horizontal intensity, for example, got at B and C without first waiting until the deviations are well determined, as has hitherto been the case in all previous vessels engaged in magnetic work—even on the *Galilee*, which, before the *Carnegie*, had the smallest deviations of any ship.

Besides the great improvement resulting from having a non-magnetic vessel, and from the perfection of the instruments themselves, the conditions and opportunities for observing have also been materially bettered on the *Carnegie*. Thus the instruments at B and C are under shelter, being mounted in observatories with revolving domes and movable slides, permitting of both magnetic and astronomical observations, with full protection to the observer and instrument from wind and weather.

Outstanding Difficulties.—These are chiefly due to meteorological conditions and the state of the sea. Thus in the absence of sun or star no magnetic declinations can be obtained, though dip and intensities may be got even in a pouring rain, because of the introduction of the sheltering observatories. It is hoped that some instrument based on the gyroscope compass may be soon perfected having the desired accuracy, with the aid of which the direction of the magnetic needle may be referred to an invariable plane to be controlled whenever a celestial body becomes visible.

Were one to wait for a calm or a fairly smooth sea it would occur quite frequently that no magnetic results would be forthcoming. In fact, on the entire recent October passage of the *Carnegie* from St. John's, Newfoundland, to Falmouth, England, there was not a single day which would fall in the usual category of favourable days of observation, but, instead, on nearly every day there was a gale, the sea was rough, the vessel yawed through an angle of 10° or more, and rolled through an arc of 20° to 30° and more, and yet observations were secured on every day except one. That utilisable magnetic results have still resulted under such very adverse conditions is due to the perfection of the instruments, the cutting down of time required for observations to get a desired degree of accuracy, thus reducing to a minimum the condition of steadiness of ship, and, of course, to the skill of the observers. Still further improvements are being striven for with regard to independence of steadiness of ship.

It is thus seen that while the endeavour is steadfastly held in mind to measure the magnetic elements at sea with every possible precision, the improvements made, and yet to be made, are along the line of reduction in time required to achieve the desired result—in other words, towards simplicity. With proper instrumental means and methods it need not require any more time to make accurate observations than to get indifferent results with instruments not adapted to the conditions to be met.

As a proof of this is given below the table of results of the work on board the *Carnegie* from September 1 to October 18, or in about six weeks' time. After the tests in Gardiner's Bay referred to above, the vessel proceeded, under the command of Wm. J. Peters, to New London, Connecticut, to have some slight alterations made. She left this port on September 11 bound for St. John's, arriving there September 25. Here the director rejoined her, having left the vessel in Long Island Sound to attend the meeting of the British Association at Winnipeg, Canada.

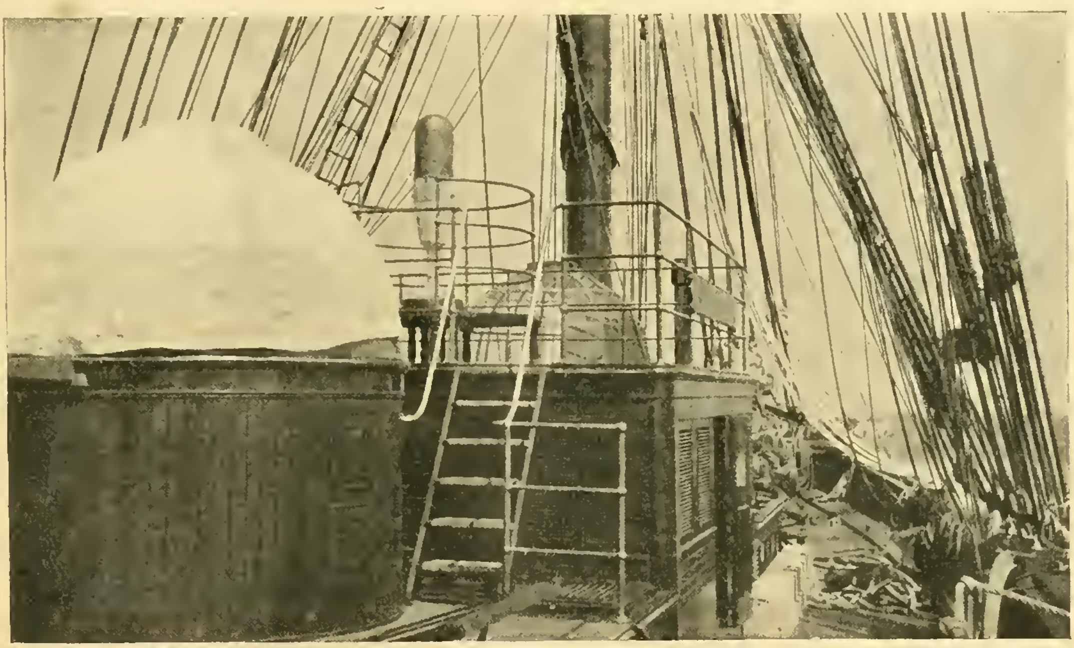
After the necessary shore observations, the *Carnegie* set sail from St. John's on October 2 direct for Falmouth, England, arriving there on October 14, having had favourable winds. Owing to the lateness of the season the Hudson Bay cruise for this year had to be abandoned. After the completion of the harbour and shore observations at Falmouth, the *Carnegie*, continuing under the command of Mr. Peters, will proceed to Madeira, and will return early next year to New York *via* Bermuda, the director returning to Washington.

Personnel.—Besides the director of the department and the commander of the vessel, the scientific and navigation staff is composed as follows:—C. E. Littlefield, sailing master; J. P. Ault, E. Kidson, R. R. Tafel, observers; Dr. C. C. Craft, surgeon and observer; and D. F. Smith, chief engineer. The ship's *personnel* includes, furthermore, two watch officers, two cooks, eight seamen, and one mechanic.

Auxiliary Propulsion.—Of considerable interest in marine circles, aside from the magnetic work on board this vessel, are the experiments being made in the perfecting of a producer-gas engine for marine propulsion. Such a plant—and an almost entirely non-magnetic one—is aboard the *Carnegie*, of 150 horse-power, sufficient to drive her at six knots' speed in calm weather. This engine has already proved a useful adjunct to the vessel's equipment, facilitating the entering and leaving of ports, and such tests as were made at Gardiner's Bay requiring swinging of the vessel. The installation is in the charge of the chief engineer, Mr. D. F. Smith, who has had both theoretical and practical experience with gas engines. Mr. Carl Smith, an acknowledged gas-engine expert of the technological branch of the United States Geological Survey, is consulting expert in connection with this work. Should this type of engine be made a practical success for marine purposes, even though it be but for auxiliary uses, it will be a valuable achievement, being the most economical form of motor now employed.

The Magnetic Results.—In submitting now the magnetic results obtained to date, it should be stated that the computation and revision of results goes on apace on board with the observational work, not only that possible errors may quickly be detected, but also that the results may be made known promptly. It is the intention, hereafter, to publish the results at intervals of about three months.

Accuracy of Magnetic Results.—In general, the declinations given may be taken as correct within 0·1°, and only in but a few instances, when the conditions of sea were unusually bad, will the error be 0·2°; under favourable conditions the observation error in declination with the marine collimating compass for the mean result will be about $\pm 0·05°$ (see the Gardiner's Bay results). About the same statement as made for the declination applies to the dip. The horizontal intensities, as at present given, may be assumed correct within 1 unit in the third decimal for the severe conditions encountered on the greater part of the cruise thus far; for fairly good conditions of the sea the error need not be more than 5 in the fourth decimal, and may be made less, as shown by the Gardiner's Bay work.



Deck view of the *Carnegie*, showing the chart house with Marine Collimator (A in diagram) in the middle and the two observatories. The forward one is uncovered, and inside it position B of the diagram, where the L.C. Dip Circle is mounted; inside the after observatory (the covered one) is mounted the Deflector and Compass (Position C).

In making these preliminary statements, it should be remarked that every possible source of error is considered—in other words, *absolute* accuracy, not relative accuracy, is meant. For example, when it is declared that, given fairly good conditions, it is possible to get the dip on board the Carnegie within 0·05°, *i.e.* within three minutes *absolutely*, this means more than may at first appear. Thus dip circles—especially ship dip circles—have instrumental corrections exceeding frequently the relative error of observation. Accordingly, the dip circle on the *Carnegie* has been compared, not only with various observatory dip circles, but also with an earth inductor at Washington, for the range of dip from $+88°$ to $-60°$. Further control will be had at the various ports of call during the progress of the work. This serves as an illustration of the care required and being taken, not only with this form of magnetic instrument, but with every instrument used aboard.

We have preferred to underestimate our absolute accuracy rather than to overestimate it. In any case, it may be said that the magnetic elements are now being obtained on the *Carnegie* with sufficient accuracy, not only for practical demands, but also for purely scientific ones.

Were we able to choose the time to observe and wait for fairly smooth sea, the magnetic elements could be determined at sea with an accuracy practically the same as in the determinations for land magnetic surveys.

Diurnal Variation Corrections.—No corrections for diurnal variation need, in general, be applied. The attempt is being made to get the magnetic elements at such times of the day when these corrections are small or are of the order of the error of observations. Thus, for example, the most favourable condition for the declination work is when the sun is low, *i.e.* early in the morning or late in the afternoon, and at these times the diurnal variation corrections are small and frequently of opposite sign. Should there be evidence of magnetic disturbance during the observations, or as may appear later from observatory records, the observations, if necessary, will be rejected.[1]

Geographic Positions.—Equal care is bestowed upon the determination of the geographic positions of the points where the magnetic observations are made. The astronomical observations and computations are made in duplicate, and at times in triplicate, by the observers, and thus the positions are effectively checked. Six well-tested chronometers are carried aboard. With the methods followed, it would appear that the errors in the final positions assigned will, in general, be less than three minutes of arc in latitude and in longitude.

Magnetic Results obtained on the "Carnegie," September 1 to October 18, 1909, in the North Atlantic Ocean.

No. 1 in Gardiner's Bay; No. 14 at St. John's, Newfoundland; No. 32 in Falmouth Bay.

[1] *Magnetic Storms and Northern Lights.*—It so happened on board the *Carnegie* that no magnetic observations were in progress during the severe portions of the magnetic storms of September 25 and October 18–19. No Greenwich time signals could be obtained at St. John's from Heart's Content on the morning of September 25 on account of heavy earth currents. Northern lights were seen between 8 and 10.30, local apparent time, of the evening of September 21 in latitude 43° N. and longitude 60½° W. of Greenwich. A glow of white light with occasional streamers extended upward about 10° above the horizon from a low bank of cumulo-stratus clouds. The display was in the magnetic north. The evenings of September 22, 23, 24, and 25 were cloudy or foggy.

Corrections of the Present Magnetic Charts.—The table requires no explanation other than is already given in the headings, with the exception of the last three columns, which exhibit the quantities to be added to or subtracted from the declinations scaled from the lines of equal magnetic declination ("variation of the compass"), first, as given by the British Admiralty chart, 1907; next, by the United States Hydrographic Office for 1910; and, lastly, by the Deutsche Seewarte for 1905.[1] In all cases the values scaled from the charts have been referred to the present time with the aid of the secular variation corrections as given on the respective charts. It will be seen that, in the case of each chart, the corrections are usually less than 1°, and, considering the miscellaneous data at the disposal of the makers of the charts and the uncertainty of the secular variation reductions, the general correctness of the charts is most gratifying.

However, one fact, revealed by the prevalence in sign of the quantities appears to be of sufficient practical importance to require attention. The data given in the table apply pretty closely to the tracks followed by the Transatlantic steamers between New York and England.

Along the portion from New York to a point somewhat beyond Sable Island the corrections for each chart are positive, amounting in the maximum to 1½°; they then change sign, with eastwardly progression, reaching a negative value of nearly 1°. In other words, for the track pursued by the Atlantic liners from England to a point off Sable Island, the present magnetic charts, in general, show too large westerly declination, whereas on the remainder of the route to New York the charts give too small westerly declination.

It can readily be seen what the effect of these systematic errors of the charts would be on the course of a vessel sailing from England to New York if, during the entire passage, no sun or stars were visible, as sometimes occurs, so that the course of the vessel would have to be shaped entirely by the compass and the log. At the end of the 2000 miles of the great circle route the vessel, off Sable Island, would be about thirty miles too far *north* of her regular track, and if the set of the current were in the same direction the vessel would easily be exposed to shipwreck. From Sable Island to New York the effect of the chart errors, being reversed in sign to what they were before, would be in the opposite direction, *i.e.* the vessel would be put out of her true course in a southerly direction.

For a vessel going eastward the effects are just reversed; hence on the course from New York to Sable Island the tendency of the chart error would be to set the vessel to the northward, hence again towards the source of danger; thereafter the vessel would be set to the southward of her outlined course. So that, if proper allowance were not made, a captain would have his vessel turned off towards Sable Island or Cape Race, whether he came from the east or from the west.

It appears to be known to some captains, at least, that there is some such systematic change which, judging from conversations had with them by one of the present writers (Bauer), during various Atlantic voyages, is ascribed by them to a systematic change in their ship deviations. Two captains have told him, independently of each other, that after their compasses had been carefully adjusted they have noticed by repeated observation a systematic change in the deviations, which *reversed* in sign when Sable Island was passed. The effects would be opposite for the eastward and the westward cruises. The deviations referred to by these captains are the differences between chart values and those observed with their adjusted standard compasses; hence they are not pure deviations, but are the sums of ship deviation and chart error. The work of the *Carnegie* has now proved that the cause of the systematic change and reversal of ship deviations encountered by these painstaking captains was due, in part at least, to systematic errors in the variation charts.

The corrections for the chart of the lines of equal magnetic dip (British Admiralty Chart of 1907 and the Deutsche Seewarte of 1905) are generally less than ½′, being sometimes plus and sometimes negative.

The lines of equal horizontal magnetic intensity as laid

[1] The latest chart of the Deutsche Seewarte is not at present to hand.

down on the British Admiralty Chart for 1907 are in error by amounts reaching 16 units in the third decimal C.G.S., and those of the Deutsche Seewarte for 1902 (the most recent chart not being available to us just now) require corrections running up to 12 units in the third decimal on the values obtained by the *Carnegie*. A part of this error is, of course, due to secular variation, but the major portion appears to be due to defective data. For both charts there are five negative corrections, amounting in the maximum to 4 units in the third decimal, four zero values and thirteen positive ones for the "B.A." chart, and two zero and fifteen positive corrections for the "Seewarte" chart. On the average for the Atlantic, from Long Island to Falmouth, the chart values are too low by about 1/45th part of the value of the force, even at times amounting to 10 per cent. to 20 per cent. In the Pacific Ocean the intensity charts gave, in general, too high values by about 1/25th part.

Since the above was written the *Carnegie* has been swung in Falmouth Bay, observations of the three magnetic elements (declination, dip, and horizontal intensity) being made on eight equidistant headings. The mean results of the entire swing are in excellent agreement with what would be deduced from Rücker and Thorpe's magnetic charts of the British Isles applying secular variation corrections as deduced from the records of the Falmouth Magnetic Observatory. The declinations and dips agree within two or three minutes, and the horizontal intensity within 1/2000th part. This again proves that there are no deviation corrections of whatever nature to be applied to the *Carnegie* results; also that the instrumental constants have been well determined. We have here also a satisfactory proof that if the distribution of magnetism is uniform, as appears to be the case here, the sea values, upon careful measurement, will be found in agreement with the shore values.

THE ANALYSIS OF SOUNDS USED IN SPEECH.

THE characteristics of the simpler sounds which form the elements of speech have been studied by many physicists. At first, attempts were made to reproduce the vowel sounds synthetically; Helmholtz achieved noticeable successes in this endeavour, but by themselves synthetical methods can never be quite satisfactory, since it is necessary to prove that the ear does not possess properties similar to those possessed by the eye; it is well known that two mixtures of light may produce identical effects on the eye, although the component waves may be quite different in the two cases.

Many attempts have been made to analyse complex sounds, but the results obtained up to the present have not been quite conclusive. Dr. Erskine-Murray used a thin membrane stretched slackly over the small end of a conical tube; a light mirror was adjusted so that it was rocked to and fro by the motion of the membrane, and a beam of light was reflected from this on to a revolving mirror and thence on to a screen. Such an arrangement is very sensitive for sounds of low pitch, but it is mechanically unsuitable for analysing sounds of high frequency. Hermann, McKendrick, and Bevier have attacked the same problems by analysing phonograph records, and have obtained much useful information; but there is small reason to suppose that a phonograph record, however good it may be, affords an exact equivalent to human speech.

For some time past Mr. G. Bowron, of 57 Edgware Road, has devoted attention to the construction of an oscillograph which projects on a screen a curve representing the sounds produced by a gramophone; a brief notice of this oscillograph was given in NATURE of May 21, 1908 (vol. lxxviii., p. 69). The curves obtained are very instructive, and they appear to possess as much detail as those obtained by the elaborate method of Prof. McKendrick; but the problem of the analysis of the sounds used in speech can scarcely be solved in this way.

The best curves representing vowel sounds have been obtained by Mr. Duddell; some of these are published in the Journal of the Institution of Electrical Engineers (vol. xxxix., No. 186, 1907, pp. 545–6). They were obtained by speaking into a "solid-back" telephone transmitter, and transmitting the periodic current obtained thereby through the high-frequency electrical oscillograph invented by Mr. Duddell. The regularity of these curves is very striking; a perfectly definite curve corresponds to each vowel sound, and with some practice it would be possible to decipher a telephone message by inspecting the curve which corresponds to the telephone current. It may be mentioned, in passing, that the analysis of the sounds which constitute speech is now acquiring commercial importance in connection with the problem of telephone transmission.

Mr. Bowron has constructed an acoustic oscillograph intended to show the vibrations comprised in ordinary speech; but although this gives some interesting information, the curves obtained are not nearly so good as those obtained by Mr. Duddell. The arrangement used is somewhat like that due to Dr. Erskine-Murray, but the slack membrane is replaced by a ferrotype telephone diaphragm. In practice it is found that Mr. Bowron's oscillograph does not give good curves for sounds of low pitch; this is due to the fairly high frequency of the natural vibrations of the diaphragm. It has been pointed out by Mr. A. Campbell (Jour. Inst. Elec. Engineers, vol. xxxix., No. 186, p. 533) that even a microphone transmitter has certain definite free periods, and that sounds of the corresponding pitches are greatly reinforced. Mr. Campbell's experiments in proof of this are worthy of mention here. A solid-back microphone is put in circuit with a battery of 6 volts or 8 volts and the primary circuit of a fair-sized spark coil. The secondary of this coil is connected to a reflecting electrostatic voltmeter reading up to 10 volts. The deflections of the voltmeter afford a sensitive indication of sounds received by the microphone. If the nearly pure note of a stopped organ-pipe be sounded, a deflection of the voltmeter is produced, and if the pitch of the note be gradually raised the spot of light rushes off the scale when the note attains certain definite frequencies. This arrangement might be used with advantage in cases where measurements of the intensities of sounds are required.

There can be little doubt that much remains to be done in connection with the analysis of the sounds used in speech. Thus the curve obtained by Mr. Duddell for the *oo* sound in "coo" scarcely differs from a sine-wave curve; a slight alteration of the mouth introduced the octave of the fundamental vibration. According to the accepted theory of vowel sounds, each vowel is distinguished by the reinforcement of those partials which lie near to certain definite pitches. The question could be answered definitely if we possessed a diaphragn which would vibrate indifferently for all pitches; and since the drum of the ear does this, it may be hoped that we may be able to realise the conditions necessary to the solution of the problem.

EDWIN EDSER.

HEAT TRANSMISSION.

A PAPER on heat transmission was read by Prof. W. E. Dalby before the Institution of Mechanical Engineers on Friday, October 15. The object of the research was to place before the members a general view of the work which has been done relating to the transmission of heat across boiler-heating surfaces, and in carrying this out more than 500 papers have been read and abstracts of the more important prepared.

In a furnace heat is transmitted by three methods simultaneously, viz. radiation, convection, and conduction. It is extremely difficult to analyse the results of experiments, so that the heat transmitted by each of these methods may be stated separately. Formulæ of simple type have been devised to express the results of definite sets of experiments; the application of such formulæ should be strictly limited to cases in which similar conditions prevail and fall within the range of the original experiments.

In discussing radiation, the author gives Stefan's law expressed in British thermal units radiated per square foot per hour as $16\times10^{-10}(T_1^4-T_2^4)$, where T_1 and T_2 are the temperatures of the incandescent gases and of the boundary respectively in degrees Fahrenheit absolute. This formula may be applied in order to find a theoretical upper limit to the quantity of heat radiated to the fire-box boundary on the assumption that the flame is actually composed of solid masses of incandescent carbon, and so follows Stefan's law. Thus, with flame and boundary temperatures respectively of 3000° and 800° F. absolute, the heat radiation is 129,600 British thermal units per square foot per hour. With temperatures respectively of 4000° and 800° the radiation amounts to 410,000 British thermal units, showing the rapidity of increase of radiation as the flame temperature rises. Stefan's law does not apply to cases where the gases are not incandescent.

In transmission by conduction and convection the heat-flow path from the interior of the mass of gas in the fire-box to a point in the interior of the mass of water is made up of the following parts:—the gaseous part from the starting point to the gas film clinging to the plate; the gas film itself; the surface of contact between the plate and the gas; the metallic plate; the surface of contact between the plate and the water; the water film; the water from the film to the point in the mass of water. To these must be added, for dirty plates, a layer of sooty deposit on the gas side and a layer of scale on the water side, on which there may also be a deposit of oily matter. There is evidence that 98 per cent. of the total "temperature" head is required in order to force the heat from the gas into the plate, the remaining 2 per cent. alone being required to transfer the heat from the plate to the water in the boiler. The presence of oily matter may raise the temperature difference between the hot side of the plate and the water from 68° F. to 550° F., depending on the nature and thickness of the greasy deposit. The thickness of the film of gas clinging to the plate is probably of the order of 1/40-inch, and accounts for the greater part of the resistance offered to heat transmission by the total path of flow. The water film clinging to the plate also contributes to the resistance, as convection currents cannot exist in it, and heat must be transferred across it by the conductivity of the water forming the film, which is known to be exceedingly small.

If these films be completely or partially destroyed, the head required to effect the heat transmission from the gas to the water across the plate will be considerably reduced. One of the most potent factors in disturbing the gas film is the velocity possessed by the moving gases. Most of the work in connection with heat transmission since the time of Rankine shows attempts to introduce a velocity factor variable into the expressions. Again, owing to the temperature gradient from the centre of the flue gases to the boundary, the efficiency must increase with a decrease in the size of the flue within limits. Hence the hydraulic mean depth of the flue must form a factor. The importance of good water circulation lies in the fact that forcing water across the heating surface with a high velocity has the effect of breaking up the water film.

Notwithstanding the large number of researches bearing on the subject of heat transmission, there is a general absence of complete data regarding the actual phenomena occurring in a steam boiler when working under ordinary conditions of practice. For instance, no data exist which gives the temperature gradients at different parts of a boiler flue with accuracy. Researches have had little effect in modifying the general design of steam boilers, although the costly nature of these may be understood from a set recently made by the United States Geological Survey, costing 100,000 dollars. The author suggests that the institution might undertake a research in which steam boilers of different types under practical conditions may have all the elements of their working measured, together with temperature measurements for the purpose of establishing the temperature gradients at different parts of the heating surface. Such a research would be costly, but would be well worthy of the institution.

The paper contains elaborate indexes giving reference to all known work bearing on the subject; these will be extremely valuable to all interested in heat transmission.

THE ANTIQUITY OF MAN IN SOUTH AMERICA.

THE views held by Dr. Florentino Ameghino as to the antiquity of man in South America are based on the occurrence of split bones, and bones showing signs of having been cut, side by side with certain scoriaceous products, the "tierras cocidas" of Argentina. We are not as yet in possession of figures of the bones, and it may be presumed that they are regarded as of less importance than the baked and reddened earths. A lively controversy has arisen round the latter, and the question appears to be one that must be decided by the geologist rather than by the anthropologist.

Several series of deposits of Cainozoic age are recognised along the curving coast-line south of the mouth of the Rio de la Plata, past Mar del Plata, and away towards Bahia Blanca. The orientation of one of Dr. Ameghino's maps is unsatisfactory; but much topographical and descriptive matter will be found in his paper on "Las formaciones sedimentarias de la región litoral de Mar del Plata y Chapalmalán" (*Anales del Museo nacional de Buenos Aires*, tomo xvii., p. 343; published November 28, 1908). This, so far as the baked earths are concerned, is overshadowed by a memoir by Señor Outes, Dr. Ducloux, and Dr. H. Bücking, of Strassburg, issued on September 15 of the same year ("Estudio de las supuestas escorias y tierras cocidas de la serie pampeana de la República Argentina," *Revista del Museo de la Plata*, tomo xv., p. 138).

The two authors who have called in Dr. Bücking to their assistance review the question historically. The Araucanian formation, with the Monte Hermoso beds, which Florentino Ameghino prefers to regard as Miocene, is very generally placed by other authors in the Pliocene; but this does not affect the arguments of Outes and Ducloux. They point out that in 1865 Heusser and Claraz, in a paper published in French at Zürich, recognised cellular, and apparently volcanic, material in the lower part of the Pampas beds near Mar del Plata. More than twenty years later, in 1887, Florentino Ameghino gathered similar "escorias" at Monte Hermoso, 60 km. north-east of Bahia Blanca, and in 1889 described others from the neighbourhood of La Plata. These places are, of course, all remote from any volcanic vents that have so far been discovered.

Meanwhile, from 1874 onwards, the more obscure materials known as "tierras cocidas" were collected by Señores Juan, Carlos, and Florentino Ameghino from various places in the province of Buenos Aires, and the last-named writer claimed them as traces of ancient hearths, and as indicating man's antiquity in South America. The field was widened by other observers, and the typical specimens, with new ones personally collected, have now been investigated by Outes and Ducloux.

These authors make no claim to originality in rejecting the opinion of Florentino Ameghino. They quote the views of Steinmann in 1906 (p. 160 of their memoir) as to the andesitic nature of the scoriæ and baked earths, and they go back (p. 191) to Charles Darwin, who recorded, in 1851, the occurrence of pebbles of pumice on the surface of the raised terrace at Monte Hermoso. Darwin attributed these pebbles to the transporting action of ancient rivers, and pointed out how the rivers Negro and Chupat bring down volcanic pumice and scoriæ at the present day. Outes shows that such materials need not have been carried directly from the Andes, but may have been washed out of the detrital volcanic beds of the Araucanian formation, which is much older than the Pampas beds, and possibly than those of Monte Hermoso. The inclusion of vegetable remains in the scoriæ is held not to militate against their volcanic origin. Doering has urged the importance of laterisation in determining the characters of the red beds in the Lower Pampas series, and Outes (p. 194) quotes his views with approval as explaining many of the "baked earths." The elaborate chemical work of Ducloux (pp. 162–184) goes to show that the loess of the Pampas beds and the included scoriæ and "baked earths" have a similar chemical composition, and masses like volcanic scoriæ have been made artificially by heating the loess at 1300° C. to 1350° C. The loess appears to contain abundant minerals that characterise volcanic lavas. The analyses given show a silica percentage of about 66 for the debatable scoriæ and "baked earths," and of only some 57 for the specimens of loess; but the latter loses some 13 per cent. of water, against 4 or 5 per cent. from the former materials. Ducloux opposes the suggestion of Ameghino that alkalies from the associated vegetation, burnt up with the loess, have entered into the composition of the scoriaceous matter.

H. Bücking's petrographic contribution (p. 185) should certainly have been illustrated. The writer, after microscopic examination, has no hesitation in classing the scoriæ as ordinary andesites. He traces volcanic lapilli in a "baked earth" from "Chapadmalal," and describes features in this material and in others sent to him which suggest a laterisation of volcanic dust.

Dr. Ameghino's paper, published in November, 1908, is largely stratigraphical. The beds of Monte Hermoso (p. 344) are here held to be much older than the Pampas formation, on account of their absolutely distinct fauna. If, then, man "or his precursor" is responsible for the "baked earths" found among them, the human race in South America may be traced back further than even Ameghino had previously supposed. We gather that this paper was well advanced before the issue of that by Outes and Ducloux, for Ameghino has since found it necessary to emphasise still further his views on the "baked earths" in a specially written memoir, in both French and Spanish, entitled "Productos piricos de origen antrópico en las formaciones neogenas de la República Argentina" (*Anales del Museo nac. de Buenos Aires*, tomo xix., p. 1; published February 17). He points out that the analyses of Ducloux merely show that the alleged volcanic cinders might have been formed from the fusion of the earth in which they lie, which is precisely the point that Ameghino wishes to establish. But it is not clear that the fused products (p. 17), prepared by Ameghino himself at 950° to 1000° C., have been submitted to microscopic examination, or that they exhibit the felspars and other associated minerals found by Bücking in the scoriæ.

Ameghino (p. 19) states that certain burrows formed as nests by the bee *Ancyloscelis analis* occur in the "baked earth," which must therefore have been burnt after the formation of the nests. Presumably this bee must also be transferred to the Miocene period if this argument is to be sustained. The paper concludes with a statement of how Outes and Ducloux failed to bring forward at Santiago, in Chile, a promised refutation of Ameghino's reiterated views. We may be happy, perhaps, if they consider that enough has now been said. While Florentino Ameghino does not seem to appreciate sufficiently the changes induced in rocks by laterisation, his critics have certainly not utilised to the full the resources of modern petrology. Probably some independent worker will ultimately arrive upon the scene, and we venture to think that he will confirm the views of Steinmann, Outes, and Ducloux. The widely distributed materials which have aroused so much discussion are hardly likely to add to our knowledge of the antiquity of man in South America.

G. A. J. C.

AGRICULTURE AT THE BRITISH ASSOCIATION.

IN view of the outstanding importance of agriculture in Manitoba, it was decided to concentrate attention on a few of the fundamental problems of the North-west and to discuss them as fully as possible both in the subsection itself and in joint meetings with other sections. Such joint discussions are particularly valuable, because the problems in agricultural science are highly complex, and have generally to be dealt with by men working away from large university centres and only occasionally coming into contact with pure men of science. Only those who have had to work under such conditions know what it means to attempt research work in small laboratories in the country without the stimulus of the research atmosphere, often, indeed, with the drag of a considerable amount of routine work and little opportunity of discussing the problem with the chemist or botanist who could throw much light upon it. Under present conditions almost the only opportunity the agriculturist has of meeting his fellow-workers in the region of pure science is at the British Association meeting. For this reason agriculturists are awaiting with no small interest the outcome of the proposal made last year, and carried forward another stage this year, that agricultural science shall form a definite and permanent part of the British Association programme.

In his presidential address Major Craigie dealt with the future wheat supply of the world, and showed that there was no reason for the gloomy apprehensions that have at times been raised, and particularly by Sir W. Crookes at Bristol in 1898, as to whether or not population would outstrip wheat production. The address is printed *in extenso* in NATURE (September 30).

Dr. W. Saunders gave an account of the experimental farm system in Canada. The central farm is at Ottawa, where the scientific staff reside. There are eight subsidiary stations situated at various points between the Atlantic and Pacific coasts, viz. at Prince Edward Island, Nova Scotia, Branden (Man.), Indian Head and Rosthern (Sask.), Lacombe and Lethbridge (Alta.), Agassiz (B.C.). At each of these a scheme of experiments drawn up at Ottawa is carried out under the supervision of an experienced superintendent; different varieties of crops suited to the district and different methods of management are all investigated, and the results published as widely as possible. Any abnormalities or matters of general interest that may require further elucidation are examined in greater detail at Ottawa.

The possibility of extending the food production of Canada was discussed at a joint meeting with the Economics Section, papers by Prof. Brigham, secretary of the Association of American Geographers, and Prof. Mavor, of the Toronto University, forming the text. The possible wheat area of the three provinces Manitoba, Alberta, and Saskatchewan has been put at $17\frac{1}{2}$ million acres, and the possible output at $317\frac{1}{2}$ million bushels, which estimates are not at all accepted by the optimistic westerners. Prof. Mavor, however, points out that wheat cultivation cannot continue to be the mainstay of husbandry, but that mixed farming must become more common. Already, indeed, the wheat area is going down in Ontario, and in certain other districts it is not increasing so rapidly as the area under oats. Dry farming, which alone could be practised over large areas, is as yet on its trial. The difficulty of forming satisfactory estimates is complicated by the fact that two sets of mutually inconsistent statistics are officially issued, one compiled by the Dominion Statistical Department, the other by the provincial authorities.

A joint meeting with the botanical and chemical sections was held for the discussion of wheat problems. An important contribution to the history of the various wheats was made by Dr. Stapf, whose paper was read in his absence by Colonel Prain. Hitherto this question has been very obscure, and has formed the subject of much speculation. Dr. Stapf has succeeded in applying more precise methods, and in replacing the vague ideas hitherto held by definitely ascertained facts. The factors determining the yield of wheat formed the subject of a paper by Messrs. A. D. Hall and E. J. Russell. Wheat is very dependent on a supply of nitrogenous food-stuff; indeed, for small increments of nitrogen a more than proportional crop return is obtained. At a later stage the returns diminish, and after a time cease to yield any profit. Phosphates are of less direct importance, but have considerable indirect effect; in particular, they often enable the crop to be harvested at a somewhat earlier date, and thus they tend to extend further northwards the region of profitable production. It was also shown that wheat is capable of withstanding drought conditions, and is therefore a crop adapted to dry regions. Mr. F. T. Shutt discussed the influence of environment on the composition of the grain. Whilst not prepared to maintain that the percentage of nitrogen, phosphoric acid, or potash in the soil would appreciably affect the percentage of these substances in the grain, he nevertheless showed that the composition of the grain was influenced by its surroundings. Soil moisture affects the quantity of nitrogen present; on adjacent pieces of ground with varying amounts of organic matter, and therefore of moisture, the nitrogen was found to decrease with increasing water content. Thus a strong wheat containing 12·5 per cent. of nitrogen yielded on newly broken prairie land a grain containing only 9·9 per cent. of nitrogen, but on adjacent older and drier land the grain contained 12·4 per cent. of nitrogen. Mr. Shutt's view is that the character of the gluten is a matter of heredity, whilst its amount depends on environment.

Two papers then followed on the strength of wheat, one, by Mr. A. E. Humphries, in which strength was described from the miller's point of view, and one by Dr. E. F. Armstrong, in which the present position of the chemistry of wheat strength was set out. Good quality is the sum of excellence in several directions. The capacity for making large, shapely, and therefore well-aërated loaves; the facility with which large masses of dough can be handled in the bakehouse; the percentage of water required to make a dough of standard consistency, are all taken into account by the miller in valuing his flour. This paper of Mr. Humphries is of great value to the chemist in that it sets forth with clearness the problem that has to be solved; correlations are now wanted between the chemical composition of the flour and these various characters. Dr. Armstrong, in a critical review which was much appreciated, showed what had been done up to the present in tracing such connections, and set forth the methods by which it is possible in particular cases to judge the value of flour. No one chemical characteristic is sufficient; account must be taken of various factors, such as the percentage of nitrogen, the size of the starch grains, and others. Prof. Harcourt then described experiments he had conducted on the baking qualities of certain flours from the western provinces. When Alberta red flour was mixed with soft Ontario winter wheat, a distinctly better result was obtained than when either flour was baked alone. The value of these flours for blending purposes was thus demonstrated. Mr. W. B. Hardy then described the experiments he had made with Prof. Wood to emphasise the importance of mineral constituents of the flour on the plasticity of the gluten.

Dr. C. Saunders approached the subject from quite a different point of view, and described his experiments in breeding wheats. It is fortunately recognised in Canada that wheat may have to be bred to suit local requirements, and indeed has to be bred if the area of the crop is to be pushed northwards. Early ripening is essential in districts where the harvest may be spoiled by frost, and early ripening varieties are being produced by Dr. Saunders at Ottawa. A note on selection was then read by Prof. L. S. Klinck, of the Macdonald College. Finally, Prof. Zavitz discussed the influence of good seed as a factor in wheat production, and described also the work done at Guelph on selection and breeding. Altogether, the wheat papers formed a valuable summary of our knowledge of the various phases of the wheat problem, and general satisfaction was felt at the decision to print them *in extenso* and to issue them in the form of a pamphlet.

Another session was devoted to the discussion of forestry problems. Prof. Somerville opened by a paper on the outlook for timber supplies, pointing out that the consumption of timber is rising faster than the supply, the growing scarcity of timber being clearly reflected in its rising prices. During the past twenty-two years, nine out of thirty-two varieties examined had risen more than 100 per cent. in price, and only two had risen less than 25 per cent. It is to the interest of every country to take energetic steps to prevent waste of timber and to plant up such lands as are not otherwise wanted. The Canadian chief forester, Mr. R. H. Campbell, followed with a paper from which it appeared that perhaps Canada is not yet fully alive to the importance of the problem. The area of forest land is probably not more than 500–600 million acres, only half of which appears to be of actual value. Suggestions were made for conserving the supply, and various administrative, educational, and legislative reforms were urged. The entomological problem was next discussed by Messrs. Lockhead and Swaine, of the Macdonald Agricultural College, who showed that much remains to be done by way of survey to ascertain the damage caused by forest insects.

A morning was devoted to live-stock problems. Mr. P. A. Mørkeberg, the Danish State expert on the breeding of dairy cattle, described the remarkable cooperative system obtaining in Denmark and its effect in increasing both the output and also the value of the output from the farms. Mr. Mørkeberg came over as the foreign representative of the subsection, and his paper was of great value by reason of its suggestiveness to the Canadian authorities who were present, and who are faced by a not dissimilar problem. Mr. Rutherford, the veterinary inspector at Ottawa, sketched out the general character of the western cattle trade, and Prof. Somerville described his experiments at Cockle Park, in which a clay pasture has been improved by basic slag. Prof. Wilson, of Dublin, gave the results of his investigations into the history of the Aberdeen-Angus breed of cattle. The idea underlying the method is that an invading race would bring their cattle with them; thus the original cattle were black; the Romans brought white cattle; the Anglo-Saxons brought red; the Norsemen brought a hornless race; while a large flecked race was imported from Holland in the seventeenth and eighteenth centuries. Prof. Wilson examines the history of each district, and shows how the local cattle have been derived.

The last meeting of the session was devoted to soil problems. Mr. F. T. Shutt described the prairie soils as characterised by a high percentage of organic matter, intimately mingled with clay and sand. The percentage of organic matter is of the greatest importance in determining their fertility, because it so often happens that water is the factor limiting their productiveness. It is hoped that this paper, which summarises a considerable amount of work on the subject, may soon be available for the agricultural chemist. Prof. Alway followed by studies on semi-arid and arid soils, where the problem is quite different in type from that on humid soils. It was found, for instance, that a crop of clover did not increase the succeeding wheat crop, because the clover had taken too much water from the soil. A mere determination of soil moisture is not sufficient to give useful data; the hygroscopic coefficient is wanted before the result can be interpreted. Prof. King, of Wisconsin, sent an admirable summary of his work on soil moisture, which will be much appreciated by English students. The phenomena connected with the water relationships of soils were dealt with in some detail, and a very useful warning was given with regard to "dry farming." By applying certain methods of cultivation that produce a firm subsoil and a loose surface soil it is possible to economise the water supply, and therefore to raise crops in arid or semi-arid regions normally almost desert land; but Prof. King points out that the rainfall goes more or less in cycles, and that the favourable results so often quoted have in some cases, at least, been obtained in seasons when there was quite a considerable amount of rain. Whilst fully admitting the close relationship between cultivation and soil moisture, of which, indeed, his own work forms the best illustration we have, he laid stress on the fact that the large-scale methods are in no sense fully developed.

The last paper, by Messrs. A. D. Hall and E. J. Russell, dealt with the general problem of the conservation of soil fertility, especially with regard to the nitrogen of the soil. At least five factors affect the amount of nitrogen present. Two tend to increase it, viz. (*a*) bacteria fixing atmospheric nitrogen, and (*b*) the combined nitrogen brought down by the rain; and three to decrease it, viz. (*c*) drainage water, (*d*) bacterial action in decomposing organic matter, with liberation of free nitrogen, and (*e*) the growth of plants with its concomitant assimilation of nitrogen compounds. Three sets of cases were discussed. It was shown that the nitrogen content of land under arable cultivation declines when the produce is entirely removed and no organic matter is added as manure. When land rich in organic compounds is subjected to arable cultivation the destructive agents become very active, and the land loses nitrogen rapidly. On the other hand, when land is carrying natural vegetation which is not removed, there is a gain of nitrogen.

BOTANY AT THE BRITISH ASSOCIATION.

So far as Section K is concerned, the Winnipeg meeting must be pronounced to have been a distinct success. Though less than a dozen British botanists and only one Canadian were present, the numbers attending the section were about up to the average. This was largely due to the presence of a number of American botanists, many of whom communicated papers and in other ways contributed to the success of the meeting.

The opening address of the president, Lieut.-Colonel Prain, was delivered on Thursday, August 26. It dealt chiefly with the position of modern systematic botany, and its relations to palæobotany, phytogeography, and other branches of botanical study. The address was published in full in Nature of September 30.

The papers read during the meeting may be roughly classified according to subjects.

Cytological and Fungal Papers.

Prof. J. B. Overton (of Wisconsin) contributed a paper on the organisation and reconstruction of the nuclei in the root-tips of *Podophyllum peltatum.* After summarising the work of Grégoire and others, the author described his own observations, which, in his opinion, strongly support the view of the individuality of the chromosomes. During the passage of the chromosomes from the equatorial plate to the poles, they exhibit progressive vacuolisation. Dr. Overton believes that each individual chromosome increases in size, and ultimately forms an independent elementary reticulum. Thus the reticulum of the resting nucleus is composed of a number of these smaller reticula. Conversely, during the earlier prophases of division, the chromosomes become more condensed and distinct, and, joining end to end, give rise to the well-known spireme.

Mr. Harold Wager communicated a paper by Miss A. Peniston and himself on the nucleus of the yeast plant. The authors contend that the so-called vacuole of the yeast cell is in reality part of the nuclear apparatus. This vacuole is surrounded by a peripheral chromatin network, which in its turn is connected with a stainable nucleolus. The paper was illustrated by a number of convincing drawings.

Miss H. C. I. Fraser discussed the nuclear phenomena of Ascomycetes in relation to heredity. Fertilisation in the Ascomycetes may be either normal or degenerate. The latter, which consists of the fusion in pairs of either ascogonial or even vegetative nuclei, is found in cases where one or both sexual organs are absent. Fertilisation of either type is followed by a second nuclear fusion in the ascus. The sexual fusion is compensated by a true meiotic reduction, while the fusion in the ascus is followed by a simpler brachymeiotic division. It thus appears possible to differentiate between sexual and asexual fusion by a study of the subsequent reduction phenomena.

Prof. A. H. R. Buller (of Winnipeg) gave an account of the production and dispersion of spores in the Hymenomycetes. A number of experiments were made on the rate of spore discharge, the path of the falling spores, &c. During the paper Prof. Buller gave a pretty demonstration of the discharge of spores from the fruit-body of a species of Polyporus. By suspending the fungus in a closed glass chamber, through which a concentrated beam of light was passed, the clouds of falling spores were rendered clearly visible. A full account of this work is contained in the book on fungal researches just published by the author.

Another paper by Prof. Buller, in collaboration with Mr. C. W. Lowe, dealt with the number of bacteria in the air of Winnipeg. Observations were made on the University campus every week for a year. Both the volumetric and the plate methods were employed. During the winter half of the year the average number of micro-organisms in ten litres of air was 0.9, while in the corresponding summer half the average number rose to 10·33.

Papers on Pteridophyta.

Prof. D. H. Campbell (Leland Stanford University) read a paper on the prothallium and embryo sporophyte of Danæa, a fine series of which (belonging to several species) had been procured in Jamaica. Of the points described by the author, two may be mentioned. First, as compared with other Marattiaceæ, the ventral canal cell of the archegonium is very imperfectly developed. Secondly, no trace of a root can be found until the embryo has reached a considerable size. The first root then arises endogenously.

Prof. D. T. Gwynne-Vaughan communicated a paper by Dr. Kidston and himself on the ancestry of the Osmundaceæ. Lalesskya and Thamnopteris are two genera of primitive Osmundaceæ from the Permian deposits of Russia. The stem in these forms contains a protostele with a solid mass of xylem. The latter, however, is not homogeneous, as it consists of a central mass of short tracheids surrounded by a peripheral zone of normal scalariform tracheids. This central mass of short tracheids is held by the authors to be homologous with the parenchymatous pith of the modern Osmundaceæ. They also believe that the Osmundaceæ and Zygopterideæ have been derived from a common ancestor.

A paper was also presented by Mr. W. T. Gordon on the structure of a new Zygopteris. This species (*Z. Pettycurensis*) exhibits a protostele, a type of vascular system which had hitherto not been found in the group. This form thus occupies the same position in the Zygopterideæ as *Thamnopteris schlechtendahlii* does in the Osmundaceæ.

Ecological Papers.

Friday morning was largely devoted to the consideration of papers on ecology. The first was by Prof. H. C. Cowles, of Chicago, on the fundamental causes of succession among plant-associations. In dealing with the fact of succession, Prof. Cowles stated that plant-associations only exhibit this phenomenon when changes occur in the external conditions; but complete stability of conditions is rarely met with, so succession constitutes the normal course of events. The earlier stages may be termed the proximate, and the later ones the ultimate stages. Except in those cases where the proximate and ultimate formations are the same, as, for instance, in deserts, it is only in the ultimate stages that a plant-association becomes relatively stable. The author then discussed a number of the causes of succession. Apart from such obvious ones as topographic and climatic changes, the most important are those which are more or less associated with the plants themselves. Of these, Dr. Cowles laid especial stress on two factors: the accumulation of humus, which involves changes in the temperature, and the moisture and air content of the soil; and the increase of shade, due to the increasing luxuriance of the vegetation. The ultimate formation of any upland will be composed of plants that can germinate in the densest shade that exists there. Other factors discussed were the invasion of an area by alien species, and the influence of man. The latter makes itself felt chiefly by reason of man's destructive activity. Speaking broadly, the effect of interference by man is to keep plant-associations more xerophytic than they would otherwise be.

Prof. F. Ramaley (Colorado) discussed the Rocky Mountain flora in relation to climate. He stated that the flora of the Rockies is remarkably uniform from Canada to Colorado; but any given species must be looked for at higher and higher altitudes as one travels southwards from Canada. The author is of opinion that the chief factor which determines this altitudinal distribution is temperature. This he regards as more important in this instance than either topography, soil, or rainfall.

Prof. B. E. Livingston (Baltimore) then gave an account of the porous cup atmometer as an instrument for ecological research. The author first emphasised the importance of evaporation determinations in ecological investigations, and then described the form of instrument he has himself used. Finally, he gave some useful hints with respect to precautions to be observed when using this instrument.

Prof. R. H. Yapp gave the result of some observations and experiments on the ecology of *Spiraea Ulmaria.* This plant exhibits curious seasonal changes in respect to the formation of glabrous and hairy leaves. It was shown that the production of these two types of leaves in nature varies with the annual march of evaporation and light intensity.

Papers of Economic Interest.

On Monday, August 30, there was a joint discussion on "wheat" by the chemical, botanical, and agricultural sections. Most of the papers read at this discussion have already been noticed in NATURE (see the article on "Chemistry at the British Association," October 14, p. 475, and that on "Agriculture at the British Association" in the present number). The only one that need be further dealt with here is an important botanical contribution by Dr. O. Stapf (communicated by Lieut.-Colonel Prain), on the history of the wheats.

The wheats are generally divided into (*a*) the wheats proper, with tough spindles to the spikes, loose grains, and thick pericarps (N.B.—the first two of these characters are of economic importance, as they greatly facilitate threshing); (*b*) the spelt wheats, with brittle spindles, grains tightly enclosed in the husks, and thin pericarps. The former comprise the soft, hard, and English wheats, together with the dwarf and Polish wheats. The latter include the spelt wheats proper, the emmer and the einkorn wheats, and also the wild *Triticum aegilopioides* and *T. dicoccoides*.

After careful investigation, and in the light of recent discoveries, Dr. Stapf concludes that all the varieties of modern wheat may be traced to some four distinct primitive wild types:—(1) the einkorn to *Triticum aegilopioides*, with its original home in Asia Minor and the Balkans; (2) the emmer and the hard wheats, as also the English and Polish, to *Triticum dicoccoides*, recently re-discovered by Mr. Aaronsohn in northern Palestine; (3) the spelt proper to *Triticum cylindricum*, in an area extending from Rumania to southern Russia; (4) the common or soft, and probably also the dwarf, wheats, to a still unknown species, which probably occurred either in Syria or Mesopotamia.

Dr. Stapf concluded his paper with an appeal for the systematic collection of all the wheats at present cultivated in the Old World, which must, he said, still include many of the more primitive races; also for a further exploration of the Orient, which might well result in the discovery of new wild forms.

Other papers of agricultural interest were read by Prof. H. Bolley (North Dakota), on the destruction of weeds in field crops by means of chemical sprays; and by Prof. Pammel (Iowa), on the delayed germination of seeds. The latter author experimented with the seeds of a number of species of weeds. He found that if the seeds were kept during the winter in paper packages, the percentage germination was lower, and the dormant period longer, than if the seeds were placed in sand and exposed to the climatic conditions of an ordinary winter.

On Thursday afternoon Mr. J. Parkin gave an interesting account of the industry of rubber cultivation. He referred to the various rubber-yielding trees, and more particularly to *Hevea brasiliensis*, the Para rubber tree. After describing the introduction of the latter into the eastern tropics, Mr. Parkin dealt with the methods employed in tapping the rubber trees. He fully discussed the relation between the yield of rubber and the phenomenon known as "wound response," and also the nature of latex coagulation. The paper was fully illustrated with specimens of the plants, commercial rubber, the instruments used, &c. Mr. Parkin also demonstrated the actual coagulation of rubber latex.

Other Papers.

In contrast to the Dublin meeting, there was a noticeable dearth of physiological papers. One, however, was contributed by Prof. R. Willstätter, on the chemistry of chlorophyll. One of the points emphasised by this author was the essential difference between chlorophyll and hæmoglobin in respect to the metals bound up in their respective molecules. Iron occurs in that of hæmoglobin, while in the case of chlorophyll the iron is replaced by magnesium. The action of acids and alkalis on chlorophyll was also discussed.

Mr. J. Parkin put forward some rather novel views as to the evolution of the inflorescence. He is of opinion that racemose inflorescences have been in all cases derived from cymose. According to his view, solitary terminal flowers were primitive; these were succeeded by simple dichasia, and these by compound dichasia. From the latter, racemose inflorescences may have been derived by an increase in the number of lateral flowers, with suppression of tertiary branching, and, finally, of the original terminal flower itself.

Miss E. J. Welsford described the life-history of *Trichodiscus elegans*, an alga belonging to the Chætophoraceæ. It was found in this species that various forms of reproduction may occur under identical external conditions. These results are somewhat at variance with the well-known experiments of Klebs.

Dr. R. R. Gates (Chicago) discussed the effects of tropical conditions on the development of certain English Œnotheras. Two species were grown from seed in a tropical greenhouse. The resulting plants were usually found to continue indefinitely in the rosette stage. Even when ordinary stems were produced they exhibited marked fasciation.

The Semi-popular Lecture.

This was given on the Friday afternoon by Mr. Harold Wager. He chose for his subject the perception of light in plants. The lecturer dealt with the problem as it affects both the lower, free-swimming organisms, such as Euglena, Chlamydomonas, &c., and also the various orthotropic and diatropic organs of the higher plants. With respect to the latter, Mr. Wager criticised Haberlandt's view of the ocellar function of the epidermal cells of leaves. While agreeing that the optical behaviour of those cells may in general be as Haberlandt suggests, the lecturer inclined to the view that the chlorophyll grains, rather than the cytoplasmic lining of the epidermal cells, constitute the actual percipient organs. The lecture, which was thoroughly appreciated, was well illustrated by a number of beautiful photographs.

Several botanical excursions were arranged during the meeting by the local secretary, Prof. Buller. One of these was to Hedingly, where a fine bit of uncultivated prairie was examined. Another was to Winnipeg Beach, on the shores of Lake Winnipeg. On a third occasion Elm Park, on the Red River, was visited. Some of the members of Section K also took part in the western excursion, and so had a further opportunity of witnessing some of the remarkable types of vegetation to be found in travelling from east to west across the North American continent.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—It is proposed that, in accordance with the recommendation contained in a report of the council of the Senate on the endowment of a professorship of German, the generous offer of Messrs. J. Henry Schröder and Company of the sum of 20,000*l.* for the endowment in the University of a professorship of German, to be known as the Schröder professorship of German, be gratefully accepted, and that the thanks of the University be conveyed to the donors.

The superintendent of the museum of zoology has appointed Mr. C. L. Boulenger to the office of assistant to the superintendent of the museum of zoology for one year from October 1, 1909. Mr. H. H. Thomas has been appointed curator of the botanical museum for a period of three years from Michaelmas, 1909, and Mr. Gordon Merriman has been appointed to the studentship in medical entomology lately held by Mr. F. P. Jepson.

The Vice-Chancellor, Mr. R. F. Scott, Mr. Fitzpatrick, Prof. Kenny, Dr. Anderson, Prof. Sorley, Sir J. J. Thomson, Mr. R. T. Wright, Mr. C. E. Grant, and Mr. H. McL. Innes have been nominated a syndicate to consider the question of providing pensions for professors and others in the service of the University.

LONDON.—At the meeting of the Senate held on October 20, the degree of D.Sc. was granted to Mr. L. L. Fermor, an external student, for a thesis entitled "The Manganese Ore Deposits of India," and other contributions; and to Mr. S. Russ, an internal student, of University College, for a thesis on "The Active Deposits of Radio-active Substances."

Many old students of the Royal College of Science and Royal School of Mines having expressed the opinion that there should be a reunion in the Midlands, in addition to the annual dinner of the Old Students' Association in London, arrangements have been made for a dinner at the Imperial Hotel, Birmingham, on Saturday, November 6. Tickets or particulars can be obtained from Mr. Philip C. Coultas, Municipal Technical School, Birmingham.

The commissioners under the Irish Universities Act, 1908, have appointed the following professors, among others, in University College, Dublin:—mathematics, H. C. M'Weeney; chemistry, Dr. Hugh Ryan; experimental physics, Dr. J. A. M'Clelland; mathematical physics, Dr. Arthur W. Conway; zoology, Dr. George Sigerson; anatomy, Dr. E. P. M'Loughlin; surgery, J. S. M'Ardle; geology, H. J. Seymour; physiology and histology, Dr. B. J. Collingwood; pathology and bacteriology, Dr. E. J. M'Weeney; medicine, Sir Christopher Nixon; civil engineering, P. F. Purcell.

The following candidates were successful in this year's competition for the Whitworth scholarships and exhibitions:—*Scholarships* (tenable for three years), 125*l.* a year each. A. W. Judge, Plymouth; J. Airey, Shipley; H. S. Rowell, Newcastle-on-Tyne; H. Mawson, Leeds. *Exhibitions* (tenable for one year), 50*l.* each. F. Duncanson, Sunderland; A. Ryan, Oldham; A. H. Campbell, Portsmouth; J. J. Clark, Liverpool; W. H. Shinkfield, Portsmouth; A. W. Stevenson, Melrose; G. W. E. Hayward, Southsea; J. Morgan, Sheerness; A. F. Grieveson, Chatham; A. E. Gladwyn, Plumstead; W. H. T. Harvey, Swindon; T. H. Webster, Newcastle-on-Tyne; W. J. Davis, Plymouth; O. R. Randall, Birmingham; G. F. Haddock, Sunderland; F. H. Reid, Plymouth; G. B. Kellagher, Gillingham (Kent); T. Norcross, Hollinwood, Oldham; L. P. Parker, Leytonstone; A. Morris, Portsmouth; J. Smith, Crewe; W. Shaw, Woolwich; H. E. Pinch, Sheerness; D. H. Emby, Plumstead; W. Fox, Plumstead; R. H. May, Leytonstone; E. D. Brodie, Swindon; H. J. Goudie, Leith; H. Collins, Gillingham (Kent); C. Williams, Plumstead.

On October 20 the University of Birmingham held the first special degree congregation since its inauguration. In commemoration of the Royal opening of the University in July last, a number of distinguished persons received honorary degrees. Among the representatives of pure and applied science upon whom was conferred the honorary degree of Doctor of Laws were Mr. W. N. Atkinson, H.M. Inspector of Mines for South Wales; Mr. H. T. Butlin, president of the College of Surgeons of England; Sir William Crookes, F.R.S.; Mr. Maurice Fitzmaurice, C.M.G., engineer-in-chief to the London County Council; Sir Archibald Geikie, K.C.B., president of the Royal Society; Dr. John S. Haldane, F.R.S., reader in physiology to the University of Oxford; Sir Alexander Kennedy, F.R.S.; Sir Joseph Larmor, Sec.R.S., Lucasian professor of mathematics in the University of Cambridge; Sir Richard D. Powell, K.C.V.O., president of the Royal College of Physicians; Sir William Ramsay, K.C.B., F.R.S.; Lord Rayleigh, O.M., F.R.S.; Prof. E. Rutherford, F.R.S., professor of physics in the University of Manchester; Prof. S. P. Thompson, F.R.S.; Prof. W. A. Tilden, F.R.S.; Sir Joseph Thomson, F.R.S.; Mr. C. S. Tomes, F.R.S., past-president of the Odontological Society of Great Britain; and Dr. B. C. A. Windle, F.R.S., president of University College, Cork.

The issue of *Science* for October 15 announces the following gifts to higher education in the United States. Yale University has received from Mr. W. D. Sloane and Mr. H. T. Sloane the sum of 95,000*l.* to build, equip, and endow a physical laboratory. This laboratory, it is understood, will replace the present Sloane Physical Laboratory. Yale University has also received 5000*l.* from Mr. A. G. Vanderbilt for general endowment, and 3000*l.* from Mr. G. H. Meyers for the endowment of the Forest School. Columbia University has received gifts amounting to about 47,200*l.*, of which 22,500*l.* is from Mr. W. H. Charpentier, to be added to the J. S. Charpentier fund, and 20,000*l.* is given anonymously. The Pratt Institute of Brooklyn has received the sum of 350,000*l.* from Mr. Charles M. Pratt, son of the founder and now its president, and from his five brothers and his sister, Mrs. E. B. Dane. Dr. D. K. Pearsons has offered to give 20,000*l.* to Berea College, provided that the sum of 80,000*l.* is otherwise subscribed, and Mr. N. B. Duke has made a further gift of 10,000*l.* to Trinity College at Durham, N.C.

The first part of "Statistics of Public Education in England and Wales," 1907–8, has been published (Cd. 4885) by the Board of Education, and deals wholly with educational statistics. We notice that during the year thirty-five technical institutions were recognised by the Board, these being defined as institutions giving an organised course of instruction in day classes, including advanced instruction in science, or in science and in art, and provided with a staff and equipment adequate for the purpose. Provision must be made in such institutions for at least a two years' systematic course in science, or in science and art, either alone or in conjunction with subjects of general commercial, manual, or technological instruction. With a few exceptions, no student may be admitted to the course unless he has passed through a three years' course in a recognised secondary school, or is more than sixteen years of age and is qualified from his general education to profit by a course of advanced instruction. There were in these thirty-five institutions 644 teachers, while 2768 students attended at some time during the year, though 1630 only attended a full course of instruction. It is noteworthy that twenty-one of the teachers were women, and 198 of the students were girls or women. Of the 2570 boys and men in attendance, 7 were fourteen years of age; 492 were fifteen and under seventeen years of age; 465, seventeen and under eighteen years of age; 439, eighteen and under nineteen; 343, nineteen and under twenty; 232 were twenty and under twenty-one; and 592 were twenty-one years of age or more. It must be remembered that, in addition to these students, there were many others attending day technical classes. The Board recognised day technical classes in ninety-six institutions during the year, and upwards of 9000 students attended these classes at some time or other during the year.

SOCIETIES AND ACADEMIES.

London.

Institution of Mining and Metallurgy, October 21.—Mr. Edgar Taylor, president, in the chair.—The influence of the railroads of the United States and Canada on the mineral industry: Dr. J. **Douglas**. After a brief historical summary of the development of the railroad systems of the North American continent, the author gave statistics of the mileage and traffic of the various railroads, showing the proportion of mineral traffic conveyed and its nature. He also showed the part taken by improved railroad communication in developing the mineral resources of the continent, and sought to prove that as the vast regions so far untouched by railroads, especially in Canada, are opened up, it is reasonable to conclude that greater stores of mineral wealth will be discovered and developed.—The development of heavy gravitation stamps: W. A. **Caldecott**. The author opened his subject with the statement that the history of ore crushing by means of gravitation stamps shows a progressive increase in their weight and in corresponding efficiency, and by means of figures he proceeded to prove how closely the factors of weight and efficiency are related. The first stamp-mill erected in the United States, in 1835, was equipped with 50 lb. stamps, this weight being increased to 380 lb. ten years later. Nowadays, on the Rand and elsewhere, stamps are in operation weighing as much as 1750 lb. In the meantime, however, the introduction of secondary grinding by means of tube mills, &c., has modified the original requirements of a stamp-battery, and tended to render the heavier stamps more efficient for their present purpose than were the older and lighter stamps under then existing conditions. The author concludes that the future limit of weight is difficult to foretell, and may be determined by mechanical considerations rather than by any decrease of relative efficiency as a device for pulverising ore. The data given as the result of exhaustive experiments with different weights and duties of stamps add considerably to the practical value of the paper.

Manchester.

Institute of Metals, October 14.—Sir William White, K.C.B., F.R.S., president, in the chair.—The constitution and properties of the ternary alloys aluminium-copper-tin: J. H. **Andrew** and C. A. **Edwards.** The authors recorded an interesting series of conclusions of both a practical and theoretical character, based on a prolonged research which had necessitated the preparation and testing of many hundreds of alloys.—The surface appearance of solders: C. O. **Bannister** and H. J. **Tabor.** Results were given of experiments carried out with a view to obtain exact information as to the effect of small quantities of impurities on the surface appearance of solders, the impurities added to ordinary tinman's solder (50 per cent. tin and 50 per cent. lead) being antimony, copper, silver, and zinc.—Some causes of the corrosion of copper and brass: E. L. **Rhead.** The author dealt particularly with the corrosion of condenser tubes. Samples of hard copper and brass were submitted to corrosion in various saline solutions, some of which were saturated with CO_2. Strips of hard brass were softened at one end and bent into U-shape. It was found that there was a much greater tendency for the hard material to corrode, the corrosion occurring in lines parallel to the direction of rolling. The surface of the hard metal was made very rough and irregular, whilst that of the soft metal remained quite smooth, when both were immersed in saline solutions.

October 15.—Sir William White, K.C.B., F.R.S., president, in the chair.—The copper-zinc alloys: a study of volume changes during solidification: Prof. T. **Turner** and M. T. **Murray.** The authors held that their experiments were likely to have an important theoretical as well as practical bearing, and it was believed that expansometer tests would be largely used in future as an aid to the determination of the constitution of alloys.—The elastic breakdown of non-ferrous metals: Prof. C. A. **Smith.** The author gave the result of researches conducted by means of his instrument, the sphingometer, which showed that, so far as the elastic properties of the material were concerned, mild steel was very much more trustworthy than any non-ferrous metal. The sphingometer was described, and shown to be capable of measuring extensions of length of the astonishingly small amount of a quarter of a millionth part of an inch.—Notes of the production of pure spelter: J. S. **Primrose.** A review of the commercial position of zinc and the existing methods of refining the metal, the author also discussing the theory of the new process of fume filtration purification during distillation.—The technical assay of zinc: H. W. **Greenwood** and Dr. E. J. **Erislee.** The paper described work undertaken with a view to determine the relative value and accuracy of the various analytical methods for the determination of zinc, and also the gathering together of the more important references to the analytical chemistry of zinc in both British and foreign literature. The authors reviewed briefly the more important processes, volumetric, gravimetric, and electrolytic, for the estimation of zinc.

DIARY OF SOCIETIES.

THURSDAY, October 28.

Society of Dyers and Colourists, at 8.—Some Unsolved Dyeing Problems: Dr. E. Feilmann.

FRIDAY, October 29.

Institution of Mechanical Engineers, at 8.—Prof. W. E. Dalby's Report on Heat Transmission (*Resumed Discussion*).

MONDAY, November 1.

Society of Chemical Industry, at 8.—Technical Gas Calorimetry: J. H. Coste.—On Naphthalene Picrate and the Quantitative Determination of Naphthalene: W. P. Jorissen and J. Rutten.—Some Notes upon the Manufacture of Large Blocks of Artificial Stone from Sand and Lime: J. C. Stead.

Aristotelian Society, at 8.—Presidential Address: Sensations and Images: Dr. S. Alexander.

TUESDAY, November 2.

Institution of Civil Engineers, at 8.—Address by the President, J. C. Inglis.

WEDNESDAY, November 3.

Society of Public Analysts, at 8.—Note on the Detection and Estimation of Small Quantities of Antimony: Dr. P. Schidrowitz and H. A. Goldsbrough.—The Phosphates in Certain Vinegars, and in the Materials used in their Manufacture: T. Fairley.—On the Determination of Essential Oils in Spices and Aromatic Drugs: R. A. Cripps and J. A. Brown.—Note on Holde's Test, and the Detection of Paraffin Wax in Lard and other Fats: H. Dunlop.

Geological Society, at 8.—(1) Certain Jurassic (Lias Oolite) Strata of South Dorset, and their Correlation; (2) Certain Jurassic (Inferior Oolite) Species of Ammonites and Brachiopoda: S. S. Buckman.—(1) The Cretaceous and Eocene Strata of Egypt; (2) The Granite Ridges of Kharga Oasis: Intrusive or Tectonic? Dr. W. F. Hume.

Entomological Society, at 8.

THURSDAY, November 4.

Royal Society, at 4.30.—*Probable Papers*: (1) The Development of *Trypanosoma Gambiense* in *Glossina palpalis*; (2) A Note on the Occurrence of a Trypanosome in the African Elephant: Colonel Sir David Bruce, C.B., F.R.S., Captains A. E. Hamerton and H. R. Bateman, R.A.M.C., and Captain F. P. Mackie, I.M.S.—On the Perception of the Direction of Sound: The Lord Rayleigh, O.M., F.R.S.—The Diffraction of Electric Waves: Prof. H. M. Macdonald, F.R.S.—On the Mechanism of the Absorption Spectra of Solutions: Robert Houstoun.—(1) Note on the Spontaneous Luminosity of a Uranium Mineral. (2) The Accumulation of Helium in Geological Time: Hon R. J. Strutt, F.R.S.—On the Physical Properties of Gold Leaf at High Temperatures: J. C. Chapman and H. L. Porter.—The Dimensions and Function of the Martian Canals: Dr. H. C. Pocklington, F.R.S.

Linnean Society, at 8.—Some Account of the Field-botany of Namaqualand, Damaraland, and South Angola: Prof. H. H. W. Pearson.

Röntgen Society, at 8.15.—Presidential Address: C. E. S. Phillips.

FRIDAY, November 5.

Royal Anthropological Institute, at 8.30.—Huxley Memorial Lecture. The North European Race: Prof. G. Retzius.
