pots or pans on a shelf in the propagating house near the light to induce growth, which will commence in about three weeks. When they have made four or five little leaves they may be potted off into single pots. Plants from roots grow very rapidly and strongly.

H. H.

M. WEBER'S MODIFICATION OF THE OSSENKOP METHOD OF STRIKING CUTTINGS.

IN a recent number of the "Revue Horticole," M. J. B. Weber, the head gardener to the city of Dijon, gives an interesting account of his modification of a new method of striking cuttings invented by M. Ossenkop, an Austrian horticulturist. The truth of the principle upon which M. Ossenkop's mode of working is founded has, according to M. Weber, been thoroughly recognised by all of our most eminent horticulturists for many years past. The leading idea of M. Ossenkop's system is, that the cuttings should be so planted that the lower portion should be in a hotter medium than the upper, so as to hasten the development of the rootlets before the buds begin to make their appearance; for when the contrary takes place they do not strike properly, at least in the majority of cases. This doubtless arises from the buds sucking up the whole of the nutritive substances contained in the cutting before the new roots have had time to form. M. Ossenkop's system can only be applied to woody cuttings which have been purposely deprived of their leaves, for it would require a too troublesome and complicated series of appliances in the case of cuttings upon which several of the leaves had been allowed to remain. This method, it must be borne in mind, is not new; for M. Weber has practised it for many years with *Vine* cuttings, and has succeeded so well with it that he has recommended its adoption in his lectures. As soon as the subjects begin to shed their leaves he cuts the necessary number of slips, and prepares them for striking by inserting them in the ground in a well-sheltered position, in a soil that is light rather than compact, the lower end of the cutting being upwards and slightly inclined, the whole being covered over with a layer of soil to a depth of from 4 in. to 6 in. When the cold weather approaches the layer of soil is doubled, or even trebled, and covered over with stable litter to prevent the frost from reaching the cuttings. When the spring begins to set in, the litter is removed and the layer of soil is reduced to its former thickness—i.e., from 4 in. to 6 in.—for it is essential that the heat of the sun's rays

should penetrate the soil and reach the upper ends of the cuttings, so as to set the sap in motion in those parts of the slip which are to emit rootlets, while the part turned downwards, which is to produce buds, remains in an almost complete state of rest until the arrival of the period for planting. The most suitable time for this operation may be easily known by the swelling of the heel of the cutting, and the appearance of a number of fine rootlets. M. Weber generally plants his *Vine* cuttings about the end of the third week in May. This year, however, they were planted five days later. When he wrote, on June 20, many of the rootlets were nearly $\frac{1}{2}$ in. in length, and out of 3000 cuttings of nearly 1000 varieties of *Vine* the whole had thrown out shoots 3 in. or 4 in. in length. As for the many fanciful applications of the principle proposed by M. Ossenkop, they are too difficult of application, and necessitate too great an expenditure of time, in striking cuttings of plants that can be more readily multiplied by much more simple means. For instance, the use of a kind of box with a double bottom, the lower part of which is intended to receive the shoots, or even the buds in a reversed position, and consequently the herbaceous portions which are provided with leaves; while the upper part, which is much shallower, is to receive the soil which is to cover the lower part of the cutting, and in some cases to act as a support for glazed lights, which are intended still more to concentrate the heat of the sun on the layers of soil covering the root end of the slip. The same may be said of the means which M. Ossenkop uses to favour the development of roots in plants which are to be repotted or transplanted. Instead of having to construct enormous wooden frames provided with false bottoms pierced with holes to receive the heads of the cuttings, and to support the layer of soil above them, the preparation and application of a simple layer of soil is much easier, much cheaper, and much more likely to be successful. M. Ossenkop's descriptions, be it said, are often confusing, and not of a nature to insure the proper comprehension of his mode of working, which at one time made such a noise in the horticultural world, but which by this time is almost forgotten, except perhaps by the inventor himself.

C. W. QUIN.

Propagating Kniphofias.—Those who possess and wish to increase their stock of these need not fear to behold those of the caulescent section, as I have repeatedly practised that operation with success; in fact, it is the only way I find to propagate *K. caulescens*, as it so seldom develops offshoots unless so treated, when it will throw up a large number, which, if allowed to remain until a root or two are produced, may be taken off and kept in a close frame for a time and potted in a sandy compost. *K. sarmatosa* is the easiest to increase, as it throws out underground shoots, which may be taken off at any time. *K. Quartiniana* develops small shoots at almost right angles with the base of the stem, and I find, if these be taken off and treated as cuttings, they strike freely. The caulescent group is, of course, best propagated by means of division or seeds.—W.

The California Fan Palm (*Pritchardia filifera*) is a native of California, and is found along the Colorado River, and in some places in the desert in San Diego county. A plant only three years old, grown by Mr. Rock, the well-known nurseryman of San Jose, the seed of which was sown on the 15th of February, 1876, stands now 4 ft. 6 in. high. The objection to Palms has always been their slow growth, taking a long time to make a showy plant. About twenty years ago a quantity of seed of this Palm was brought to San Jose, and M. Prevost, the pioneer nurseryman, cultivated them and raised about fifty plants. These were distributed over the State, notably some of them in front of the cottages at Calistoga, most of them having grown into specimens of 20 ft. and 30 ft. in height. M. S. Latham, of this city, bought two in San Jose, which stood, at the time of purchase, about 25 ft. in height, for the handsome sum of 1000 dollars. These he moved to Menlo Park, a distance of 18 miles. Many doubted their ever growing, but they have done well. They stand now nearly 40 ft. in height, and are almost 3 ft. in diameter, crowded with a beautiful head of fan leaves. They stand in front of a magnificent residence on an open lawn, and present a most attractive aspect. Mr. Grant I. Taggart, of Oakland, informs us that two of these Palms are growing at Shasta on the premises of Mr. Hopping, county judge of Shasta county. They were planted some twenty years ago, and have immense trunks. This must be about as far north as Palms were ever cultivated in the open air. At Shasta the ground is often covered with 2 ft. of snow. The California Fan Palm is the most distinct of the Palms, having an abundance of fine threads hanging down from the leaves. It will be very valuable as an ornamental plant in all sub-tropical climates, being the fastest grower and hardiest of all Palms. Not until the last four years has its native place been known, but upon the completion of the Southern Pacific Railroad they were found along its line, and whole carloads of large plants have been brought to San Francisco and sold. Several large specimens of these graceful Palms are now adorning the residences and lots of our railway magnates on Nob Hill. They may be now had almost at any nursery at a reasonable figure.—"California Horticulturist."

GARDENING FOR THE WEEK.

Flower Garden.

Roses in Unsuitable Soils.—Roses, more than most deciduous plants, are affected by the nature of the soil in which they grow, and to those—and there are many who think more of Roses than all other flowers put together—it is a matter of extreme disappointment, after having procured a collection, to find that they gradually dwindle away. Light, sandy soils do not grow Roses, especially when grafted or budded on the Brier, in anything like the way in which they grow in strong, heavy loam, and on such it is simply a waste of time and expense to attempt their cultivation on the Brier unless means be taken to add to the natural soil in sufficient quantities that in which it is deficient. As the best time for planting Roses—that is, as early in the autumn as the fall of their leaves will permit—is coming on, a few words upon what may be done to render such soils as I have mentioned suitable for them may not be out of place. First, I may observe, that in this, as in other gardening operations, it is much better to do all that is attempted thoroughly than to hazard the result by half measures; consequently, it will in all cases be better to limit the extent of ground that is to be prepared than to extend the space further than the available material will render suitable. Where good heavy loam, almost approaching a clayey nature, that is, containing little or no sand, can be had in quantities so as to lay it on the light soil to the extent of 1 ft. in thickness, this will be the best addition, digging it in with about an equal depth of the land to which it is being added; it may then be left to lay for about a couple of months, say to the end of October, when put on 6 in. of good rotten manure, digging the whole over again so as not only to incorporate the manure with the soil, but, so far as possible, to mix the heavy soil with the light.

Marl or Clay for Roses in Light Soil.—Where good strong loam is not available to use in the way described, marl—if it can be had, and, in the event of this failing, clay—will answer, but it will not do to incorporate marl, much less clay, in a crude state, that is, when fresh dug, with even the lightest natural soil, as it would lay much in the same state in which it was dug, and so quite unfit for the roots of the Roses to enter. To avoid this it must be laid on the surface, evenly spread out—say 9 in. or 10 in. in thickness—exposed to the sun and drying winds for a few weeks, turning it over once or twice, so as to get it dry through, after which, as soon as moistened by the rain, it will fall to pieces almost like slaked lime, when it must be forked in to a similar depth advised for the loam; and, as in the case of the latter, it will be well to again fork the whole over, putting in at the time a full dressing of manure. In light peaty soils the same additions as above advised will be found equally beneficial in their effects.

The Most Suitable Time for the Above Operations.—Where ground has to be prepared in the way here described, there is no season in the year equal to the present, for the obvious reason that the weather we may expect for some weeks yet will be of a character calculated to effect the necessary drying of the marl or clay, which, in itself, is easier procured than later on, and is in a much drier state, consequently better calculated to effect the desired object. Where the natural soil, even if it is of a nature suited to Roses, is too thin, or resting upon a rocky or gravelly formation, an addition, such as the above, will be found the best means of proceeding to grow Roses satisfactorily; likewise where the land has got exhausted through long being under a crop of some sort, for it must be borne in mind that the soil, even for Roses, unless where of the most suitable description, in time gets tired of manure alone. I have said nothing about drainage, for, in such places as indicated, it will be found that the natural soil is already too dry, except where peat is the staple element, when it often happens that there is, especially during the winter, too much water in it. Where this exists drains in sufficient number must be put in before preparing the ground.

Roses for such Soils.—The further the soil is from being adapted to the exact requirements of Roses, the more necessary I have found it to grow them on their own roots, and to confine the varieties to those that are vigorous growers. Weak-constituted sorts are useless for these places; however fine the individual flowers they produce may be, they will be no compensation for a weak habit. Where not to be grown on their own roots, the Manetti stock will be more suitable generally for over-light soil than the Brier, which, although delighting in a naturally dry situation, as note its preference for a dry hedge back, where no stagnant moisture can lodge, yet the Brier, to grow Roses well, should have a naturally heavy loam.—T. BAINES.

Flower Beds and Borders.—Attend to mowing, sweeping, and removing dead flowers and leaves from beds and borders; by this means they will be rendered attractive and enjoyable for at least a month or more to come. The mixed or herbaceous border should now have careful attention, as Phloxes, Pentstemons, and many other late autumnal flowers will now be in full beauty, and should not be in any degree marred or disfigured by being associated with the decaying flowers and foliage of other occupants of the border, nor should such plants be by any means cut down prematurely, or in an unripened condition; but, at the same time, all dead and decaying matter may be removed with advantage to them as well as to the general appearance of the garden. As regards annual plants, they should be at once removed as soon as their beauty is over, unless in cases where seed may be required, and this should be carefully picked as it becomes ripe. A border of herbaceous and Alpine plants and bulbs, whether situated upon the margins or belts of flowering and evergreen shrubs or otherwise, should be so arranged as to have the

flowers peculiar to the different seasons so distributed throughout the entire length and breadth of the border that no portion of it will, at any season of the year, be entirely destitute of flowering plants; and care should also be taken to properly graduate the various species as regards their height, so that dwarf-growing plants may not find themselves partially hid or overshadowed by taller growing sorts. Beds or clumps of double-flowered Zinnias are now in fine condition and are most valuable as autumnal-flowering plants, and possess the power of resisting drought to a very considerable extent, especially if a deep, rich, and well-manured soil has been selected for them, and such encouragement they well deserve. They should be sown under glass, about the end of March or early in April, and should be planted out about the end of May. They may be planted tolerably close together, say about 6 in. or 8 in. apart, and all inferior sorts should be extracted from the bed or clump as soon as they show flower; the space they occupied will soon be taken possession of by the remaining plants. Go carefully over the beds now and select a few of the very finest and most distinct blooms as seed-bearers, and mark them by securing to them pieces of coloured worsted or other material, and pick them as soon as they are ripe. By this means, the strain will be continually improved, while the reverse will be the case if the seeds are gathered indiscriminately. Let Chrysanthemums, German and other Asters, as well as all other late-flowering plants, be carefully staked to prevent them being blown down or injured by high winds. Order, or get in readiness, the various bulbs which will soon be required for furnishing the flower beds for spring. The cuttings of such plants as the Verbena, Petunia, Coleus, and Alternanthera, which may have been struck in close frames or pits, now will, in most instances, be well rooted, and the store pots or pans containing them should be placed on cinder ashes in the open air, fully exposed to the sun for some time, or as long as it can be done with safety; this will have the effect of rendering them robust and hardy, and it is of the greatest importance to have them in this condition before the approach of winter. Care must be taken not to expose them too long.

Indoor Plant Department.

Late-sown Primulas intended for flowering in spring should now be shifted into their blooming pots, which should be 6-in. ones; pots of this size, with the aid of manure water, will be found large enough for fast-growing, soft-wooded plants. Primulas like a compost consisting of good fresh loam with one-sixth leaf-mould and a little sand. An idea is prevalent that they are liable to damp off if the collar of the plant in potting be not kept well up above the soil. Why such an impression should exist it is difficult to surmise, unless it arises from the fact that Primulas are, more than most plants, subject to damp off at the stem, especially during winter, if kept in too low a temperature with correspondingly too much water; I say correspondingly, for if Primulas be grown through the winter in a night temperature of 50° or 55°, they will bear almost as much water as Cinerarias, without suffering in the least from damp, showing clearly that it is the low temperature which they dislike; but when kept warm in this way they must be close to the light, or the growth will be drawn up weakly. Press the soil firmly in the pots, letting it come well up to the base of the under leaves, so as to keep the plants secure in their places without rocking about, as they do when not potted low enough. Let both these and the earlier-sown plants intended to flower through the last months of the year and early portion of the next be for some weeks yet in cold frames exposed to plenty of air, elevated close up to the glass, with the lights off in fine weather, particularly at night, as exposure to the dew is of considerable service to them. A piece of very thin, open netting stretched over the frames during the daytime, when the sun is on them, will be much better than exposing them to its full influence.

Cinerarias.—Attend well to those that were sown earliest, as their pots will now be getting filled with roots, in which case any deficiency in the way of water will so far injure them as to cause the loss of their lower leaves, and when that happens, however well flowered they may be, they lose half their beauty. Let the plants be looked over every ten days in order to see that aphides do not get a lodgment on them, or a like loss of leaf will be the result. If the plants be fumigated to destroy aphides it should be done lightly, or the foliage will be liable to get injured. The safest course is to watch closely, and immediately a plant is affected with either aphides or thrips to dip it in Tobacco water, a supply of which ready for use should always be at hand in every garden, large or small, especially during spring and summer, when these insects come to life so quickly.

Late-struck Double Petunias will, if they have been well attended to, have been found very useful for either greenhouse or room decoration. Cuttings of these should now be put in for flowering next spring and summer, after which the old plants, when done blooming, may be thrown away, as young ones are in all respects better, and occupy less room.

Nierembergias are now much neglected. Although small-growing, free-flowering subjects, they are well worth cultivation. They are very suitable to edge vases for summer decoration, where their drooping habit and profusion of flowers are seen to advantage. They are particularly adapted for use in window boxes or for room plants. Cuttings should at once be got in, selecting the softest shoots that have not a disposition to bloom. Put in the points of these 1 in. apart in 5-in. pots in sandy peat surfaced with $\frac{1}{2}$ in. of sand; water them immediately and cover with a bell-glass, putting them in a little warmth. When they are struck they should be placed singly in small pots for the winter and kept near the

glass. If they can be accommodated with a temperature of 45° in the night it will keep them growing.

Ferns.—Reduce the atmospheric moisture of the Fern house, and also the roof-shading, but this only in a comparative degree; Ferns having no wood to mature and solidify like flowering plants, neither require, nor will they bear this additional sunlight, and drier root treatment being carried so far as in the case of flowering plants, without suffering seriously. What they do require at this season is simply to carry this treatment so far as to check the disposition to make growth and rest the plants, so as to get them in that condition that they will move with vigour when the season of active growth comes round. In places where Ferns are grown, if the plants stand on any loose material that will hold moisture, such as ashes or sand and fine gravel mixed, kinds like *Pteris serrulata*, and the varieties of *Adiantum*, such as *A. cuneatum*, *formosum*, and *pubescens*, will drop their spores and vegetate in quantity without the trouble of a special preparation in sowing them. The young plants that thus come up in spring will now be large enough for putting singly in small pots; for these do not use them too large, but in all cases let them be proportionate in size to the plants. Peat is the most suitable soil in which to grow them when it can be had good, but, where not easily procurable, these and other Ferns will grow in ordinary loam, always taking the precaution of keeping it porous by a liberal admixture of crocks broken to the size of Horse Beans; or coal cinders will do equally well broken small, to which some sand has been added; the proportion of this latter, for these, as for all other plants, cannot be exactly determined, being dependent upon the quantity of sand the soil naturally contains. I am led to make these remarks by so often seeing cultivators fall into the opposite extremes of mixing too little or too much sand with their potting material, the result of which is either the whole mass in the pots gets sour and unsuitable for healthy development of the roots in the former case, or not affording sufficient sustenance through being too open and poor. Ferns, unlike many plants, should, as soon as potted, be immediately watered, for, if ever the soil be allowed to get so dry after potting, as is needful for subjects that do not require so much water, they will flag, and whenever this occurs to a Fern, especially when its roots have been disturbed, as in the case of potting, it receives serious injury, and generally loses many of the fronds. The cultivation of Ferns is often associated with the idea of a dark, heavily-shaded situation. This produces a disposition of the fronds to damp off in the winter, especially if the growth has been made in too close and warm an atmosphere. Ferns so treated generally make very large, deep green fronds, but not enduring; the varieties above named, which are so useful for general purposes, can scarcely be grown with too much light, provided they are shaded slightly from the direct rays of the sun when it is powerful. Older plants of Ferns, such as the above, grown for cutting, should be kept in comparatively small pots; by this means any disposition to luxuriant growth is checked, and they will stand in water for several days.

Window Plants.—Remove plants that have done blooming, and always endeavour to have good healthy foliage if flowers are scarce. The Ivy-leaved Pelargoniums are the best of all window plants; display them to advantage, and pick off seeds and decaying leaves from Tropæolums. Balsams and Asters are now very pretty in windows, as are also some plants of Tagetes and African Marigolds. Give plenty of water to plants of Creeping Jenny, and permit the shoots of the Virginian Creeper to droop in graceful festoons. Introduce a few Cockscombs, yellow Calceolarias, Grasses, and any other miscellaneous plants obtainable. Indeed, a very pretty ornamentation in the window is the Japanese Maize grown in pots. *Mecombryanthemums*, too, are very useful for a dry position, and *Gazania splendens* for a sunny one. The various small-leaved Ivies, too, should not be forgotten; they are useful for suspended baskets, screens, or for spreading over balconies, and they grow and thrive under even adverse circumstances. Ferns and Selaginellas are also, as everybody knows, excellent for windows, especially those facing the north or east; and for windows facing the brightest sunshine, *Acacia lophantha* and other kinds of *Acacia*, some sorts of *Asparagus*, *Convolvulus mauritaicus*, Grasses, and other plants of that sort are suitable.

Indoor Fruit Department.

Vines.—Examine the inside borders of late Vineries, and see that the soil is not too dry before the Grapes become nearly ripe. Where such is the case, lose no time in giving sufficient water to mature the crop, and also to keep the soil moist enough to prevent the fruit from shrivelling during winter. Every favourable opportunity must be taken advantage of to push on very late Grapes this month, for the decrease in the amount of sun-heat, which will be felt in subsequent ones, will be unfavourable to their development. Late Grapes are better flavoured when thoroughly ripe by the end of September than later, and they are not so liable to damp throughout the winter when in this state as when only partially ripe. Gros Colman is, in many instances, a bad kind to colour; but it often keeps well, and is quite eatable when tinted with green. No anxiety need be felt about the colouring of the Black Alicante; it will do so under all circumstances. The surface of the border under Grapes ripe for autumn use should now be kept very dry, to prevent damping amongst the fruit; and do not rake or stir the loose surface soil, or a great deal of dust will rise to rest on and disfigure the berries. Keep the ventilators of all Vineries in which the fruit is all out wide open night and day, so that the wood may become ripe as soon as possible. Do not give young Vines planted this season so much water as they required in the earlier stages of their growth.

Pines.—Plants of all kinds, excepting early Queens, now require more fire-heat than they have had for some months, especially at night. On dull days the fire should be kept going quietly throughout, and water must be given in moderation after this period. Newly-rooted suckers do not generally require much water until spring, and they are more likely to become unhealthy when kept very moist than when they are somewhat dry. Discontinue all syringing overhead, excepting after an exceedingly bright day.

Kitchen Garden.

Late Crops.—Unless where a deficiency of winter vegetables has been put in, and there are good strong plants at hand of Kale or Cole-worts, it is not advisable to plant more of the ground that becomes vacant after this, as the time intervening before the growing season is over is not sufficient to admit of these late-planted crops attaining a useful size, and they seriously interfere with the preparation of the ground for another year without making any adequate return. Let all haulm of Peas, French and Broad Beans, or Lettuces that have run to seed, or anything of a similar description, as soon as they have ceased to bear or to be of further use on the ground, be at once removed. It is a mistake to allow anything of this kind to remain; for, so long as any growth continues, it is so much extracted from the soil to no purpose. They should, therefore, be conveyed to the refuse heap as soon as possible. Let all ground be well hoed as often as weeds make their appearance. These will not cease to spring for some time yet, growing, as they do, with a lower temperature than most cultivated crops. Where salads are in constant demand, especially in the spring, it is well now to sow a little Corn Salad and American Cress. These hardy plants will stand any amount of frost and prove useful in the spring. Sow the seeds in rows 1 ft. apart; this will give room to use the hoe in keeping the ground clean. Thin Turnips as they get large enough; if allowed to remain too long they become drawn, which much interferes with their after growth.

Mushrooms.—Those who have not a regular house for Mushrooms are frequently deterred from attempting their cultivation. In the successful growing of these vegetables much depends upon the atmosphere that surrounds the beds, and it often happens that the most highly-finished Mushroom houses are anything but the best to grow them in. For market purposes, all through the autumn, very large quantities are grown on ridges in the open air, covered with litter in some cases, aided by wooden shutters; but this method requires a good deal of attention and some experience. A few words respecting the conditions essential to the growth of Mushrooms may not be out of place for those who have not had much practice with them. They require a moist, genial atmosphere to grow in; in other words, the air immediately enveloping the beds must be soft and sufficiently warm, subject to no cold draughts or considerable fluctuations in temperature, such as the external air is liable to. From this it will be seen that, to give a reasonable chance of success, a place must be at hand where these conditions, if not existing, can be provided. A close shed—if somewhat low all the better—or any building not too large, that can be spared for the purpose, may be used. Beds of very small superficial area are not likely to bear so well as those that are larger, for the reason that the body of manure in the place is not sufficient to produce the requisite state of the atmosphere. The manure should be procured from stables where the horses are well fed with plenty of corn, and where there is no deodorising chemical powder or liquid used, as these are fatal to the Mushrooms. Let the manure be fresh, not such as has been wet and fermented, and do not use the long littery portion. At the same time, it is not necessary to be particular in having nothing but the manure, as is frequently urged, for a little short straw amongst it will do no harm. As soon as procured, it should either be placed in a covered shed where it will not get wet, or at once put where it is to be made use of. In either case, let it be in a moderate-sized heap, and turn it over several times to prevent its getting too hot; this will work off any superabundant moisture, to assist which it should have plenty of air. In the course of a fortnight or so it will be in a condition for making up into a bed. This should be about 18 in. in thickness, the area of which will be regulated by the size of the building or the quantity of the manure used. As the work proceeds beat it quite solid with the fork and finish off by making the surface hard and smooth with the back of the spade. In a week's time ascertain the heat of the bed by plunging a thermometer in it, and, as soon as it denotes a little under 80° in temperature, put in the spawn. This should be broken into pieces about the size of pigeons' eggs, and should be thrust just below the surface at intervals of 8 in. or 10 in. Try the heat of the bed again in a few days, and, if the warmth is decreasing, put on the soil. Any ordinary loam will do; this must have been turned over several times to get it to the requisite condition. It should not be so wet as to adhere too closely together when pressed by the hand; put it on about 6 in. in thickness, breaking it moderately fine previously, and beating it down with the back of the spade so as to make it smooth. A couple of inches of loose hay should be spread over the surface; in some Mushroom houses it is an assistance, in others it is not needed; but when the houses are small, and there is no fire-heat used, it is generally required. If all goes well, in a few weeks the spawn will begin to run, which will be seen in the shape of white mould on the surface; after this the buttons will soon commence to make their appearance. There is no precise time that can be stated for a Mushroom bed coming into bearing after it is spawned; those that are the longest before they begin to yield are often the most fruitful after they have commenced. As the weather becomes cooler it will be a material assistance to get in a body of new manure, which can be laid 18 in. or so in depth on the path and occasionally turned over; this will raise the temperature of the place and produce an atmosphere conducive to

the growth of Mushrooms. The manure, when fit, can then be made up into another bed to come into bearing after the first is prepared and treated similarly. In growing Mushrooms it is necessary to take the precaution to always have on hand, where it will not get too wet, enough loam for soiling the beds. When the manure is good in quality, many successful growers mix fully a third of loam with it in the beds. Sometimes a bed will get too dry before it has finished bearing, or even before it begins to bear; the latter not so often. In applying water to these, as in its use with many plants, it is a difficult matter to convey in writing a positive knowledge of when it is required. In the cultivation of Mushrooms, if too much be used it will destroy the spawn; if too little, it will not grow. Much may be learnt that will assist in the culture of Mushrooms by observing the combination of conditions that exist in the ground and in the atmosphere in seasons when they are the most plentiful out-of-doors. The most experienced grower will sometimes fail with them. I have known the first attempt to be most successful; where the reverse is experienced, I would say try again. It is only the loss of a little labour, for the manure so prepared is none the worse for ordinary purposes afterwards. In the growth of this esteemed vegetable it is of great importance to be able to command an equable temperature, and a genial condition of the atmosphere in the place in which they are grown. The best house I have ever seen for producing unfailing crops was nothing more than a long, straw-thatched, span-roof, resting on the ground with no side walls but brick gables, with a door at one end, and a flow and return hot-water pipe covered with grating running under the path which was down the centre. The beds, about 6 ft. wide each, were on either side. Mushrooms can be grown in a place of this description when the weather is too warm for them to do well in the houses generally met with.

Extracts from my Diary.

September 9—Sowing Red and White Turnip Radishes. Shifting a few Cinerarias and Primulas into pots for blooming early. Putting in cuttings of double Petunias, Lohelias, and Nierembergias. Cutting and bottling a few bunches of Black Hamburg Grapes left from the second early house, and removing the lights off the same in order to get the wood well ripened. Cutting off all heads of Globe Artichokes that are overgrown. Removing all young shoots from Tomatoes in order to expose the unripened fruit to the sun and gathering those that are ripe; also removing laterals from Vines and cutting out bad berries from the bunches. Making new gravel walks.

Sept. 10—Potting Pelargoniums which have been struck in the open ground. Clearing off Strawberry runners from permanent plants, applying a good coating of rotten manure between the rows and forking it in. Dutch hoeing amongst Broccoli and all other growing crops to kill weeds before wet weather sets in. Planting all spare ground with Cabbage plants to come into use in winter. Gathering Louise Bonne of Jersey, Jersey Gratiol, and a few Marie Louise Pears for dessert.

Sept. 11—Potting a collection of Campanulas. Covering up dwarf Beans with spare lights to protect them from early frosts and heavy rains. Roughly digging and heavily manuring a piece of ground lately cleared of Peas for next year's Onions. Earthing up Celery and Cardoons. Pruning and painting the early Black Hamburg Vines and washing the woodwork and glass. Emptying old Mushroom bed and turning manure for another one. Pinching off all runners from Strawberry plants in pots. Weeding and hoeing amongst Asparagus beds.

Sept. 12—Pricking out Black-seeded Brown Cos and Stanstead Park Lettuces. Thinning out Spinach and afterwards hoeing between the rows. Cutting Grass edgings and turning gravel walks to give them a fresh appearance for the winter. Cutting off Strawberry runners and weeding and hoeing between the plants. Earthing up Celery whilst the soil is dry and friable. Spawning and soiling Mushroom bed. Watering Pines all through; also Lettuce and Cauliflower plants.

Sept. 13—Potting off cuttings of Celery and Alternantheras. Putting in cuttings of Heliotropes and Pelargoniums. Digging ground for August-sown Cabbages. Clearing off Peas and cleaning the ground for other crops. Thinning Turnips. Cleaning, weeding, and rolling gravel walks. Stopping all laterals on Vines. Placing stakes to Pines which are in fruit. Tying out Chrysanthemums. Gathering Yellow Ingestre, Cox's Orange Pippin, and Emperor Alexander Apples; also a few more Marie Louise Pears and Tomatoes. Watering indoor Peach borders.

Sept. 14—Sowing Chervil. Thinning out Mignonette in pots; also Lettuce and Endive in seed beds. Dutch hoeing between all Cauliflowers, Cabbages, and newly-planted Lettuce and Endive. Looking over all Cucumbers and Melons and stopping their shoots where required. Renovating manure linings round frames. Filling up Grape bottles and cutting out all bad berries from the bunches. Fruit in use for dessert: Pines, Grapes, Melons, Peaches, Figs, Nectarines, Pears, Apples, and Plums.—W. G. P., Dorset.

Hyde Park.—The gentleman who wrote so enthusiastically a few days ago in praise of the "carpet gardening" in Hyde Park, and its "marvellous regularity," no doubt represents the taste of some portion of the public; but there are certainly others who, like myself, look upon these marvellously regular beds as anything but the perfection of horticultural art, and would rather see part, at least, of the great pains and cost which they absorb given to the trees and greenward, which have for a long time been so grossly neglected.—WILLIAM ALLINGHAM. [The above is in the "Times" in reply to an amusing note that appeared therein signed "Edward Sullivan."]

GARDEN BOTANY.

(Continued from p. 207.)

PISTILS WITH AN INFERIOR OVARY.—Inferior ovaries usually contain several or many ovules whether one-celled or more than one-celled. The large Natural Order of Compositæ is an exception, the ovary being always inferior and uniovulate. As already explained, the ovary becomes inferior in consequence

Fig. 523.—Pistil of *Samolus Valerandi*, having an inferior ovary.

Fig. 529.—Pistil of *Samolus*, with the top part removed, showing the single cell of the ovary.

either of the calyx tube adhering to it, or the floral axis itself growing up around and to it. Sometimes it is difficult to determine which is the case in a fully developed flower; but this is of little practical importance, because in descriptive botany the distinction is not made. Figs. 528 to 534 illustrate this group. In fig. 530 (*Samolus Valerandi*) the ovary is one-celled,

Fig. 530.—Longitudinal section of the pistil of *Samolus*, showing the free central placenta studded with ovules.

Fig. 531.—Pistil of *Mesembryanthemum cordifolium*, with an inferior four-celled ovary.

with free central placenta; in fig. 534 (*Chrysosplenium*) it is also one-celled, but the ovules are affixed to two parietal placentas; whilst in the four-celled ovary of *Mesembryanthemum* (fig. 532) the ovules have an axile placentation.

The Ovule.

Having already pretty fully described the principal modifications of the seed, it is unnecessary to enter so much into

Fig. 532.—Cross section of the ovary of *Mesembryanthemum*, showing the four cells and numerous ovules.

Fig. 533.—Pistil of *Chrysosplenium* with a half-inferior ovary.

detail here as would otherwise have been the case. Nevertheless, as the development and structure of the ovule cannot be seen and followed without the aid of a microscope, it is all the more desirable to describe and illustrate the leading types of the ovule. At the outset the learner should be careful not to confound embryo with ovule.

ORIGIN OF OVULES.—Ovules appear on the placenta as minute nipple-like projections of homogeneous cellular tissue, which

in course of development differentiates into what is termed a nucleus and integuments, or coats, and a stalk. The nucleus develops as a cellular body in which a relatively large cell is formed; this is the embryo sac. Usually two coats of tissue grow around the nucleus from the base upwards, finally entirely enclosing it, with the exception of a narrow aperture. The inner integument or coat is completed first, though named the

Fig. 534.—Cross section of the one-celled ovary of *Chryso-splenium*, showing the two parietal placentas.

Fig. 535.—Ovule of Rhubarb, torn open to show the two coats or integuments and the nucleus. Enlarged.

secundine, from its position in the perfect ovule, the outer being called the primine. Fig. 535 represents a perfect ovule, very much enlarged and torn, open to show the coats and nucleus. That point of the ovule where an organic connection exists between the nucleus and its coat or coats is the chalaza, in the axis or centre of which is a cord of a different kind of tissue—a vascular bundle, which runs through the stalk of the ovule into the placenta. The stalk receives the distinctive name of funicle, and the orifice leading through the coats to the nucleus is the micropyle or foramen. In consequence of

Fig. 536.—Orthotropous ovule of Rhubarb. Fig. 537.—Anotropous ovule of *Helleborus foetidus*. Fig. 538.—Campylotropous ovule of *Phaseolus vulgaris*.

differences in growth, the relative positions of funicle and micropyle vary very much, and ovules are divided into three classes according to their shape, viz., orthotropous, anotropous, and campylotropous.

ORTHOTROPOUS OVULES.—In this the growth of the nucleus is quite straight, so that the micropyle is at the end of the ovule,

Fig. 539.—Longitudinal section of an orthotropous ovule (represented diagrammatically); *t*, outer integument (secundine); *l*, inner integument (primine); *n*, nucleus; *m*, micropyle; *c*, chalaza; *f*, funicle; *s*, embryo sac.

Fig. 540.—Longitudinal section of an anotropous ovule (represented diagrammatically); *f*, funicle; *r*, raphe; *t*, inner integument; *l*, outer integument; *n*, nucleus; *m*, micropyle; *c*, chalaza; *s*, embryo sac.

opposite to the funicle (see figs. 536 and 539). This kind of ovule is characteristic of the Rhubarb, Dock, Knotweed, Stinging Nettle, many Conifers, &c.

ANATROPOUS OVULES.—When the organic base (chalaza) is at the end of the ovule opposite to that from which the funicle is given off and the micropyle is near the funicle, the ovule is

anotropous (fig. 537). That part of the funicle which adheres to the ovule, running from the chalaza down one side, is termed the raphe (figs. 540 *r* and 546 *r*). Fig. 540 is placed with its

Fig. 541. Fig. 542. Fig. 543. Fig. 544. Anotropous ovule of *Calandina* (*Chelidonium majus*), in different stages of development—*n*, nucleus; *ch*, chalaza; *s*, secundine; *p*, primine; *r*, raphe; *f*, funicle.

organic base downwards; figs. 541 to 544 show different stages in the development of an anotropous ovule. In fig. 541 we have a naked nucleus in an erect position, and in tracing its development onwards to fig. 544 we see that it becomes inverted by the growth of a raphe, or adherent portion of the funicle. This kind of ovule is common to a very large proportion of plants.

CAMPYLOTROPOUS OVULES.—In this modification of the ovule the nucleus and its coats are curved in growth, so as to bring

Fig. 545.—Vertical section of fig. 544. Fig. 546.—Longitudinal section of a campylotropous ovule (represented diagrammatically); the letters have the same significations as in the preceding figures.

the chalaza and micropyle near together (figs. 538 and 546); see also the various stages of development (figs. 547 to 550). Campylotropous ovules characterise the Mallow and Pink families. Besides the foregoing principal forms of the ovule, there are all sorts of intermediate ones, some of which have received special names, but they may well be dispensed with.

FERTILISATION OF OVULES.—This is one of the most interesting processes in plant life, on account of the varied and beautiful contrivances and provisions for effecting it; but it is only within the last twenty years that much attention has been paid to the subject, and we may add that Mr. Darwin was one

Fig. 551.—Vertical section of fig. 550.

Fig. 552.—Mature pollen grain of *Eriogonum*, emitting a tube. Much enlarged.

of the first and most successful students of this branch of knowledge, besides being instrumental in attracting other persons into the same field of inquiry. Almost every species of plant has its peculiar mode of fertilisation, in so far as the

conveyance of the pollen from the anther to the stigma is concerned, and whole books have been written on the subject without exhausting it. In this place we can only explain the general plan, and refer the reader to special works for descriptions of the means by which it is accomplished. From preceding paragraphs the reader will have learned that stamens, the organs in which the pollen or male element is generated, are not always borne in the same flower as the pistil, or even on the same plant. Furthermore, when there are stamens in the same flower as the pistil it does not follow that the ovules will be fertilised by pollen from the stamens of the same flower. Indeed, this is rather the exception than the rule, since the pollen is not always mature at the time the ovules are in a state to receive it. When the ovules are ready for impregnation the stigmatic surface of the style becomes more or less viscid, so that the pollen grains coming in contact with it adhere. Sometimes the pollen escapes before the stigma exudes the viscous fluid, when the flower is termed protandrous; sometimes not until after it is dried up, when the flower is protogynous. Insects and wind are the chief agents in conveying pollen to the stigmas, and in many instances flowers are absolutely dependent upon one or the other for

Fig. 553.—Portion of a stigma penetrated by tubes from the pollen-grains. Very much enlarged.

pollination; not sometimes upon one, and sometimes upon the other. Plants in which fertilisation is aided by the wind are anemophilous, and entomophilous when insects are the agents. Those of the former category often produce pollen in profusion, like the Pines and Firs, whilst the pollen grains of some of those belonging to the latter cohere in masses, as in Orchids, Stephanotis, Hoyas, &c. In many instances the reason why exotic plants rarely produce seed is, that the particular insect that performs the office for it in its native home does not exist in this country, and the gardener omits to fill its place. The pollen of some flowers is dispersed by a sudden jerking movement of the stamens, as in *Kalmia*; or the style moves towards the stamens, as in *Mimulus*. The viscous fluid on the mature stigma not only secures the pollen grains that fall upon it, but it is also conducive to a kind of growth they exhibit. Like seeds, pollen grains, of some plants at least, will retain their vital power, if kept dry, for a considerable period after having attained maturity. Some kinds of pollen, too, are much more easily excited into activity than others, and perform their function more rapidly. What happens when the pollen comes into contact with the stigma is this, each grain puts forth one or more slender tubes (fig. 552), which enter the stigma and

penetrate through the conducting tissue of the style into the ovary (fig. 553). Here they quickly find the orifice in the ovules, and a single tube entering at length reaches the large cell (embryo sac). Within the embryo sac two, or occasionally more, vesicles (embryonic vesicles) are formed, and these become impregnated on contact with the pollen-tube. As soon as this act is consummated, one, or rarely more, of the embryonic vesicles rapidly develops into an embryo by becoming

Fig. 554.—Fertilised embryonic vesicle of an Arabis—*p*, extremity of pollen tube; *s*, wall of the embryo sac, inside of which are formed the cellular layers of the endosperm or albumen; *e*; *e*, embryonic vesicle fertilized and developed into a pro-embryo; *b*, embryo.

clothed with a wall of cellulose (the basis of the vegetable fabric) and internal growth by cell division. Fig. 554 illustrates this. In the course of its development the embryo, as more fully explained in a previous paragraph, either fills the whole cavity, or it is embedded in more or less albumen, and the coats of the ovule form the testa of the seed.

RELATION OF THE DIRECTION OF THE EMBRYO TO THE FORM OF THE OVULES.—Since the radicle of the embryo, with very few known exceptions, points in the direction of the micropyle (through which it emerges in germination), it follows that there must be an intimate relation between the position of the radicle and the form of the ovule or seed. This is more easily seen in ripe seeds, especially after they have been soaked for a time. The sections of seeds (figs. 555 to 558) represent some of the variations. In the orthotropous ovule the embryo is always straight, the radicle pointing to the micropyle and the cotyledons to the funicle.

NAKED OVULES.—From all that has preceded, it would seem that ovules are invariably formed within a closed ovary, but it is not so. There is one important, though small, class of plants in which the ovules are borne on open scales or carpellary leaves, though the seeds are usually protected by the scales eventually growing into dense cones. Cycads and Conifers constitute this class.

INSERTION OR ATTACHMENT OF OVULES.—As may have been suspected from our remarks on the ovary and placenta, the ovules spring from a definite part of the ovary. This character is very constant and particularly useful in classification where there is only one ovule in the ovary or in each cell of the ovary. Thus in all the *Compositae* the solitary ovule is erect, whereas in the three or four most closely allied orders it

Fig. 555.—Vertical section of a seed of the Wall-flower, the embryo filling the whole cavity.

Fig. 556.—Vertical section of a seed of *Lychnis*, embryo surrounding the albumen.

Fig. 557.—Vertical section of a seed of Thorn Apple, the curved embryo embedded in the albumen.

Fig. 558.—Vertical section of a seed of the Marvel of Peru.

is pendulous. In the genus *Heracleum* (fig. 559) and all the large order of *Umbelliferae*, to which it belongs, there is one pendulous ovule in each of the two cells of the ovary. In the ovary of the Grape Vine (fig. 560) there are two erect ovules in each cell. Ovules are collateral when they are placed side by side, as in the Grape Vine (fig. 561), and superposed when one is seated above the other, as in fig. 562. When one end of an ovule is attached to the side of the ovary and the other end directed upwards it is said to be ascending. Generally

the funicle is short, though sometimes very long, as in the common Ash and in many of the Anacardiaceæ.

NUMBER OF OVULES IN AN OVARY.—The ovaries of a very large proportion of plants contain only one ovule, whilst in many instances there are several, or they are numerous. Some few plants produce an exceedingly large number of ovules in each ovary, though it frequently happens that only a small number of them are fertilised and develop into seeds. Perhaps the Opium Poppy is the most prolific of plants in seed bearing. It has been calculated that one capsule contains 32,000 seeds. Another very free-seeding plant is the Foxglove. We have just counted the seeds in one capsule, amounting to upwards of 1200; and the plant from which it was taken bore more

Fig. 559.—Section of an ovary of *Horacleum barbatum*; ovules pendulous.

Fig. 560.—Section of an ovary of Grape Vine; ovules erect.

than 500 capsules, giving a total of 600,000 seeds—a prodigious number indeed!

SINGULAR MODE OF FERTILISATION OF VALLISNERIA SPIRALIS.—We will conclude this section with a description of the mode of fertilisation of this favourite drawing-room aquatic. On account of the elegance of its Grass-like foliage and its easy management in a small aquarium, this plant is now familiar to

Fig. 561.—A pistil of the Grape Vine, torn at the back of one of the cells of the ovary, showing the collateral ovules.

Fig. 562.—Pistil of *Chailetia pedunculata*, torn at the back of one of the cells of the ovary, revealing the superposed ovules.

most people, though it may be that few have witnessed the processes of fertilisation. It is dioecious—that is, the male and female flowers are produced on different plants, so it is necessary to secure both sexes. In a wild state it grows in marsh ditches (in Central Europe), in water 2 ft. or 3 ft. deep. The male flowers are very small and sessile, on a short spike close to the root of the plant. When they are fully developed, they become detached, and from their buoyancy rise to the surface of the water, where they expand, permitting the pollen to escape. The female flowers are rather large, and borne on very long peduncles, which are, however, coiled up at the bottom of the water until the period for fertilisation arrives, when they uncoil sufficiently for the flowers to rise amongst the floating males on the surface of the water. After fertilisation has taken place the peduncles coil up again, carrying the flowers to the bottom of the water, where the seeds can ripen undisturbed.

W. B. HENSLEY.

DEPREDACTIONS OF WASPS, MICE, &c., AMONGST RIPE FRUIT.

IN some situations insects, birds, and small animals do a good deal of mischief amongst ripe fruits. Birds, of course, may be kept off by nets, and a covering of hexagon netting will keep off wasps, but the netting is expensive if a large extent of wall has to be covered. Somehow, too, I always think that fruit covered up during the finishing stage of ripening is not so good in flavour or colour as when fully exposed. Where close netting cannot be had for covering choice wall fruits, such as Peaches and Nectarines, to preserve them from wasps at this season, it is a good plan to hang up bottles half filled with some sweet liquid, such as honey and beer. These should be hung up the moment the first wasp makes its appearance, for, if delayed, the wasps will attack the fruit, and the probabilities are that they will continue to feast upon it, whilst, if the decoy bottles had been at hand, they would have been tempted to enter, and so have found death in the bottle. Where mice are numerous they are often exceedingly troublesome in Vineries in which ripe Grapes are hanging. They run up the Vines and nibble the berries mostly at the top of the bunches, and soon do a large amount of mischief. The remarks just made in reference to wasps are applicable in even a greater degree to mice, for, if they once begin upon the Grapes, traps and poison will have to be baited with something tempting before they will look at them; if, however, a trap or two be kept constantly set about the houses and sheds, when a hungry mouse comes in he enters the trap and is caught before a lodgment of any number can be effected. I have at various times had a good deal of trouble with mice, and I find there is no better plan than keeping two or three traps set in different places about the premises. There is an advantage, too, in having traps of different kinds, for mice have their peculiarities. I have often found, when they have fought shy of the old brick traps, that by substituting Pfallenger's patent or one of the ordinary forms of spring wire traps with a change of bait, that they might be captured. As regards the destruction of wasps, if they are at all troublesome the nest should be hunted up and destroyed. The old-fashioned plan—and it is still as good as any—was to mix some common gunpowder with about a fourth of its bulk of sulphur; moisten it with water so as to form a thick, paste-like putty; form it into small rolls or squibs about 3 in. long by ½ in. in diameter. These, when wrapped in paper, ignited at one end, and dropped into the hole leading to the nest, give off such a thick suffocating smother, as to render the wasps insensible, when the nests should be dug up and the whole destroyed. A little practice will enable any one to destroy wasps effectually in this way, and it is just the kind of work in which boys delight, and for which a little extra pay might be given. Another plan that might be tried in some cases is to pour gas tar down the hole. This blocks up the entrance, and the fumes from the tar smother them. It sometimes, however, fails through the nest being at some distance from the entrance and the wasps opening another outlet.

E. HOBDAV.

The Thrush a Snail Destroyer.—The thrush is no favourite of cultivators, owing to its being fond of hush fruit. Judging from what I have observed of the doings of this bird, however, I am of opinion that the harm which it inflicts upon us is more than counter-balanced by the amount of snails and slugs which it destroys. I do not believe that there is any wild bird so voracious in this respect as the thrush. This season a family of these birds found their way into a small plantation of Raspberries, and I noticed at times a sharp knocking like that of hitting one stone upon another. This I eventually found to arise from one of the birds making use of a large stone upon which to break the shells, and a hetacomb of these lying around plainly indicated the havoc which had been made amongst them. Previous to this discovery, I had observed an unusual number of empty shells scattered about. The parent birds had, doubtless, fed their young upon their contents. I am convinced that were it possible to tame and keep a pair of thrushes in a garden, we should be but little troubled with snails and slugs. To many who may have been annoyed by the depredations of this bird, it may be some consolation to know that during the greater part of the year it lives mainly upon that which is one of the greatest scourges of both the professional and amateur cultivator.—J. CORNHILL.

A Burdock Exterminator.—For years we have been troubled with Burdocks, and, notwithstanding repeated mowing during the summer, they would form seed in the autumn. After many experiments, a certain and speedy remedy for the pests has been discovered in kerosene oil. If a small quantity be poured into the hearts of the plants, directly after cutting, they will disappear entirely, roots and stalks, leaving no trace of their former existence save a small hole in the earth where they stood. This may be styled a crude idea, but refined or crude oil will accomplish the purpose.—"Moore's Rural."

FORFICULA AURICULARIA.

(THE EARWIG.)

THIS insect belongs to the Natural Order Euplexoptera (from the Greek *euplexo*, to fold well or carefully, and *pteron*, a wing). This Order is so named on account of the beautiful manner in which the wings of its representatives are folded when not in use. The earwig is generally distributed throughout this country, and at times may be found in very great abundance and almost everywhere. It is about $\frac{3}{4}$ in. long and of a dark brown colour. The head is furnished with a pair of long antennæ, each consisting of fourteen joints; the upper pair of wings is leathery, and serve as wing-cases for the lower pair; they are very short, and only cover about a quarter of the length of the body. The lower wings, when expanded, are very large, and it is astonishing how they can be covered by such small wing-cases; they are, however, folded in a very curious manner. On the front margin of the wing, about one-third of its length from the base, there is a somewhat horny patch, from which radiate a number of veins covered with a very delicate membrane. When the wing is folded these veins close like a fan, and then are folded back on themselves from a point half-way in their length, so that their tips are towards the centre from which they radiate; from this, as a hinge, the wing is again folded back, and by this means all but the extreme tip, where the hardened point is, can be covered by the wing-cases. The insect is obliged to bring its body to its assistance in the somewhat complicated operations of unfolding and folding its wings. The body of the male has nine joints, but that of the female has only seven; in both sexes the last joint is furnished with a formidable-looking pair

The Earwig (*Forficula auricularia*).

of pincers; those of the male, however, are toothed and are longer and more curved than those of the female.

The earwig, as regards its transformations or changes, is very unlike the insects which have formed the subjects of the previous papers, for it never becomes a grub or caterpillar or chrysalis. All true insects undergo the following metamorphoses, and change from the egg to the larva (or grub or caterpillar), from the larva to the pupa (or chrysalis or nymph), and from the pupa to the imago (or perfect insect). The earwig is no exception to this rule; but the larvæ, when hatched from the egg, very much resemble their parents, but they are of a lighter colour, have not any wings or wing-cases, their pincers are weak and almost straight, and their antennæ have only eight or nine joints. They shed their skins from time to time, increasing in size at each moulting. When they reach the pupa state they are still more like their parents, as they are provided with rudimentary wings and wing-cases.

The female lays her eggs, which are small, oval, and of a pale yellow colour, in the spring and early summer, under fallen leaves, stones, the bark of trees, or other sheltered places, in clusters of fifteen or twenty, and sits and broods over them as a bird would. In about a month the young are hatched, and there seems little doubt but that the mother continues to care for them, as they have been found seeking protection under her. Earwigs are a great source of trouble and annoyance to gardeners; they feed on the flowers and young shoots of many plants, particularly on those of Dahlias and Carnations, which they much injure. They are very fond of Apricots, Peaches, Grapes, Pears, and Apples, which they spoil by making large holes in them; they sometimes creep into Cauliflowers and render them dirty and unfit for use. Their presence in gardens is not an unmitigated evil, as they do not confine themselves entirely to vegetable food, but destroy large numbers of thrips, aphides, and some kinds of wild bees. They are very voracious,

but feed only at night, creeping into some sheltered place during the day. Their natural enemies are small birds, toads, and some beetles, particularly the Fetid Rove-beetle, or Devil's Coach-horse. One of the ichneumonidæ is parasitic on them. The best means of destroying earwigs is to place near plants and to hang on fruit trees which have been attacked by them pieces of Reeds or the stems of Sunflowers, or any hollow stems, into which the earwigs are sure to creep, and from which they may easily be shaken and killed; the stem of the Sunflower is particularly useful, as the insects are attracted by the sweet pith.

The popular notion that earwigs creep into persons' ears at night-time is, I believe, entirely without foundation. Even if they did, it would be impossible that they could, as some persons assert, creep into the brain, as there is no passage from the ear into the head. S. G. S.

PROVINCIAL HORTICULTURAL EXHIBITIONS.

ST. NEORS, HUNTS, is neither a very large nor a very populous town, but its inhabitants work well together, and in the matter of organising horticultural shows might teach a valuable lesson to places of much greater pretensions; this is the reason why I have ventured to refer to the matter here. The schedule appeals to the help and sympathy of all classes, and, as a consequence, brings together a large amount of produce, much of which is really excellent in quality and very creditable to the exhibitors. The main object of the promoters is, of course, to inculcate a spirit of generous emulation among the neighbouring inhabitants, but they do not confine themselves to this alone, as there are open classes admitting all competitors on payment of a small entrance fee. It is true the prizes offered are small, but there are a good many of them, and I have no doubt that the society hopes to be in a position to increase their value, and so draw exhibits from a greater distance to show their own people what others are doing. There are special classes for amateurs, farmers, market gardeners, ladies, cottagers, schoolgirls, and schoolboys, and the exhibits in the latter classes were exceedingly interesting, and the thoughts which such a competition inspires in the youthful mind are, I think, calculated to do much good and to lay a foundation for better things hereafter. I am not going to trespass so far as to ask space for the insertion of any lengthy reference to the prize winners in any of the classes, as that is a matter of merely local interest; but some of the vegetables, especially in the cottagers' and market gardeners' classes, were very good—particularly the Potatoes and Onions, and amongst the cut flowers the Dahlias of one or two exhibitors would have taken prizes at any of the leading exhibitions. The collections of stove and greenhouse plants and Ferns were very creditable, and a plant of *Stephanotis floribunda*, exhibited on the occasion, was, I think, the best and clearest specimen of the kind I have seen in or out of London. The competition of model gardens by schoolboys was very extensive; and, although most of the designs were familiar to frequenters of exhibitions where such displays are encouraged, there were not wanting evidences that one or two of the juvenile artists were breaking away from the square, formal patterns, and had designed their gardens with a freer and bolder hand. Most of the bouquets of wild flowers by schoolgirls were much too crowded. They will, no doubt, learn in time that fewer flowers and more foliage will place them higher in the prize list. E. HOBDAK.

Warm Exposures for Fruits, Flowers, and Vegetables.

—From observations made in different parts of the country, I have come to the conclusion that the south, south-west, and west are the only exposures in a garden worth utilising for the culture of early crops of fruits, flowers, or vegetables. A south-east wall gets the full force of the sun when it shines from early morning till about 11 a.m., but it never experiences the intensity of the sun's rays like a west wall, which is always much the warmer of the two; and, besides, the crops on an east border are more liable to suffer from frost, because the sun shines upon the frozen plants before they are thawed; this they are sure to be on a west border before the sun reaches them. For producing early crops of such fruits as Apricots, Peaches, and Cherries—the latter of which do uncommonly well on a warm wall—there is hardly any position so favourable as the angle of a dwelling house facing the south-west. The heat radiated from both walls after twelve o'clock on a sunny day is often more than tropical, and greater than the temperature of an ordinary south wall. We have seen the thermometer record about 140° in the angle of a castle wall in the north. When early Roses are wanted, no better situation can be had for them. A good climber, like Gloire de Dijon, Maréchal Niel, or,

indeed, any of the dwarf kinds that naturally flower early, produce flowers three weeks or a month earlier in such corners than elsewhere. It is the shelter from cold winds more than the protection from frosts which hurries vegetation.—J. S.

DRESSING AND EXHIBITING FLORIST FLOWERS.

THIS whole subject deserves thorough ventilation, and it should be discussed on general grounds, and without relation to individual opinions or classes of plants. Similar principles and practices, indeed, obtain in regard to most florist flowers. It has generally been held legitimate to remove any excess of parts, to regulate any misplacements, and to reveal any inherent beauty that might be accidentally hidden. The doing of so much can hardly be considered an undue interference with Nature, nor inconsistent with the principles of art, which strives to present its best to the beholder. No doubt flower dressings are often carried far beyond their legitimate limits. Faults and failings are hidden, deficiencies supplemented, and bad or indifferent flowers made to appear good by skillful manipulation. Such arts are mere flower millinery, not floriculture, though skill in the latter is not held to be complete by many unless a knowledge of the former be added to it. Now the dressing of flowers is one of those arts that possess a peculiar fascination to experts. Few who are adepts at it can help being tempted at times to carry it to excess. So powerful is this temptation, that it would probably be well for floriculture could the art of dressing be wholly abolished, and I have therefore the strongest sympathy with THE GARDEN in its efforts to put down dressing. The idea, too, of showing Picotees, Carnations, Roses, &c., in vases or groups artistically or picturesquely arranged is a charming one, and seems simple and easy at first sight; but it is really less so than it seems. The great primary object of the present flower shows is to reward the best flowers, Roses, Picotees, Auriculas, Tulips, or what not, and the present uniform, inartistic, and ugly, if you please, mode of showing the flowers enables the best to win. All the conditions of showing being alike, the sole attention of the judges is concentrated upon the differences of merit between the flowers only. The best flowers are consequently far more likely to win than if the attention of the judges were turned aside into artistic or inartistic settings up or groupings. Every one has his own special standard of art or taste, and the worst flowers might often be the most artistically arranged, and would win in consequence. Such results would prove a sore discouragement to horticulture, and yet there is no doubt the present system of showing is most unsightly. The remedy is not its abolition, but the addition of other modes of showing. Retain the present mode of rewarding the best flowers without alteration; but, by all means, add prizes at all shows for the best baskets, vases, groups of Roses, Carnations, Pinks, &c., artistically arranged. It should also be a condition that each flower should appear with its own foliage or that of its family. It would be necessary to allow so much latitude, as, of course, it would often be impossible to cut sufficient foliage of choice varieties to make the flowers effective; but foreign foliage ought to be a disqualification. It is false alike to Nature and all art deserving the name. The rage for green colours has permitted its use by the highest authorities; but to place false foliage around flowers is to disparage as well as disown their own, and virtually to try to improve Nature in her very highest illustrations of art—that of blending and balancing flowers and foliage in one complete whole of matchless grace and beauty. The freer use of foliage would also dispense with white paper collars and circles, which only give a garish glare to the flowers. By combining more artistic modes of showing these flowers with the present methods of rewarding their individual merits, an additional interest would at once be given to flower shows, and no doubt the flowers themselves would be more highly appreciated and generally grown. Possibly, too, the way might be prepared for testing the merits of individual flowers on more artistic principles; much more of the plants would also be seen. A single flower laid flat on a circle of white paper gives no more idea of the grace and beauty of the Picotee than a single Wheat grain does of the stately grace and glory of the Wheat plant. The same holds good of Roses, Tulips, Narcissi, Gladioli, and other flowers. Note the difference, for example, between a bed or border of the latter, now in all their matchless beauty, and a stand of the same on the exhibition table, mostly far too scant of foliage. The difference is all against the artificial stand. But supposing a stand of single blooms of Gladioli plastered down on paper cards; even the most devoted advocates of dressing would be shocked. Why? Why, indeed? Hollyhocks are often shown in single flowers, not spikes; why not Gladioli? And if not Gladioli, why Picotees? And if Gladioli can be judged in spikes, why not Roses, Carnations, and Picotees in bunches or bouquets?

D. T. FISK.

ANSWERS TO CORRESPONDENTS.

Arbutus Andrachne.—We are forming a garden in the north of Yorkshire, and would much like to know if you think *Arbutus Andrachne* would do well in this part of England. The soil is good, but the subsoil is strong clay. The *Arbutus* could be well protected from all strong winds.—ANA GODMAR. [*Arbutus Andrachne* will do well under such conditions, even in Yorkshire, provided it be fully exposed to the sun in order to ensure the ripening of the young growths by autumn.—Geo. SYMS.]

Diseased Vine Leaf (B. Duffill).—The leaf which you have sent is badly attacked with thrips; a small greenish-white species seems to have done the injury.—W. W. S.

Melon Seeds Germinating Inside the Fruit.—This is not a very rare occurrence; it happens at times in the case of even the best flavoured and finest fruit. We have had at least fifty fine Melons this season which have developed this tendency, and no fault or flaw whatever could be detected in them. At present I can give no explanation as to the cause. I have never had so many examples of it as this season.—D. T. FISK.

Names of Plants.—Young Student.—1, *Eupatorium cannabinum*; 2, *Kauntia arvensis*; 3, *Solidago Virga-aurea*; 4, *Calamintha officinalis*. *T.*—The specimen sent is a small variety of the true Mushroom. *D. E. & Co.*—Maltese Centaury (*Centaurea melitensis*). *M. E., Ipswich.*—1, probably *Dracena Youngi*, but the varieties of *Dracena* are now so numerous that it is impossible to say from a single and imperfect leaf; 2, *Croton interruptum*; 3, *Dracena rubra*; 4, *Gymnogramma Wettenthaliana*. They will all succeed in a greenhouse during summer, but in winter they will probably become unhealthy, unless a little fire-heat can be given them. *Dr. H.*—*Typha latifolia* (the great Bulrush or Reed-mace). *A. H.*—1, *Chrysanthemum foniculaceum grandiflorum*; 2, *C. foniculaceum*; 3, *C. frutescens*; known commonly as Paris Daisies. *A.*—1, *Castilleja*.—1, *Rhamnus latifolia*; 2, some *Rhododendron*, apparently closely allied to *R. jasminiflorum*. *L. C. J.*—*Eupatorium aceratioides*. *L.*—The Oak is *Quercus sessiliflora*, or a slight variety of it. *E. T.*—1, the Macartney Itose (*Rosa bracteata*); 2, *Viburnum lantana*; 3, *Hibiscus syriacus*; 4, *Spiraea callosa*. *A. K.*—*Ipomopsis elegans*; 2, some *Pentstemon*. *Mrs. A. B.*—*Meconopsis semplicifolia*, leaves pale green, lighter on the under side than on the upper. *C. J.*—1, *Hibiscus syriacus*, fl. pl.; 2, *Hypericum calycinum*; 3, some *Escalonia*, probably *E. macrantha*; 4, Common *Arbutus*; 5, probably *Rhamnus Alaternus*. *J. C. & Son.*—An *Astrantia*, and probably *A. major*.

Correspondents sending fruit to be named should send at least three of each kind. The variation of fruits, even on the same tree, is so considerable, that this would very much facilitate ascertaining the correct name. This applies to a Pear sent by "T. B." which it is impossible to name from the single fruit sent.

Mushroom-eating Beetles.—I have a Mushroom bed being completely destroyed by hundreds of beetles. They come out from the bed about eleven o'clock, and disappear soon after three p.m., having, during that time made a good meal of the little Mushrooms. The same beetles, I am told, attack Rose trees, and as we have over 200 standards in the garden, I am particularly anxious to get rid of them.—FERNHURST. [The beetles sent are two common species generally found in or under the manure of horses and cows. The black one is *Aphodius haemorrhoidalis*, the black and red one *Aphodius fimentarius*. They have probably been introduced in the manure of which the Mushroom beds are formed while in the grub state, and then a good opportunity occurs of destroying them.—W. W. S.]

Potato Fungi.—I have sent a few Potatoes covered with a cobweb-like substance which rots the Potato. The variety is Scotch Regent. Can you inform me what the substance in question is, and what I can do to prevent its occurrence? I have about an acre of Potatoes, the middle of which only is affected; the rest are good and sound. The ground last year was cropped with Lucerne, and it has not been under Potatoes before for more than twelve years. I thought of dressing the part affected with lime. Do you think that would stop the disease?—J. D. [The cobweb-like substance is the mycelium of the fungus known as *Rhizoctonia crocorum*, frequently found on the bulbs and corms of the Crocus, Gladioli, Narcissus, &c. Sometimes it attacks Asparagus, Potatoes, and other plants, but we have never before seen such an abundant crop on Potatoes as in the material sent to us by you. Lime is frequently fatal to fungus growths.—W. G. S.]

Making an Asparagus Bed.—"H." (p. 210) had better bastard trench the ground intended for his Asparagus bed, removing the "rub" from the lower spit if the spade comes in contact with it; this will give a depth of 24 in. of soil which will be sufficient if well enriched with good stable manure, decayed turf, and a liberal sprinkling of crushed bones in each trench. Our method of bastard trenching, which we prefer to bringing the poor subsoil to the surface, is, to commence with a trench 2 ft. wide, taken out to a depth of 12 in., and wheeled to the end of the ground to fill in the last trench, the manure being first placed on the ground in heaps at convenient distances apart. In the bottom of the first trench the workmen put in a good coat of manure and dig it well down, sprinkling more manure on the fresh-turned soil before the top spit from the second trench is put on it. After removing the top spit from the second trench, the loose soil left by the spade comes to the surface of the first trench; this method brings the middle soil to the surface, the surface soil to the middle, and the subsoil remains at the bottom, having been well broken up and enriched with manure. Towards the end of March or beginning of April the ground will have subsided and

be ready for planting. The Asparagus may be planted in shallow trenches if intended to be grown on the French system, or on the surface if it be grown in the usual way, simply spreading out the roots, and covering them with 5 in. of light, rich soil; place each plant 2½ ft. apart in the row, the rows being 4 ft. asunder; good strong two-year-old plants may be planted as soon as they have started into growth 2 in. or 3 in. long, planting those which have the strongest shoots and discarding those with weak ones. At the commencement of the third year after planting (provided the plants have grown well) some Asparagus may be cut, but the cutting must not be severe, and ought to cease early if a strong and permanent bed be desired. A full supply should not be cut until it is four years planted. We use one-year-old plants, and wait until the commencement of the fourth season before cutting. A good dressing of manure in the autumn applied to the crowns of the plants, with a sprinkling of salt in the latter part of March, and the same of nitrate of soda a month later, which may be repeated again in May, gives the best results.—W. ALLAN, *Guntton Park, Norwich*.

Nymphæa odorata minor.—Will this grow in a large china basin? Does it require to have the water changed? and what kind of soil must I put in for the roots?—ADA GODMAN. [This may be grown in any vessel, if it be of sufficient depth and width to allow room for the full development of the leaves. The soil, which should be laid at the bottom from 4 in. to 6 in. in depth, should consist of one part fibry loam, half part well decomposed leaf-mould, and half part river sand and gravel. The vessel should be quite filled, and should be made to overflow daily by watering with a fine-rosed watering-pot, as this removes all floating Confervæ, &c. A layer of fine gravel, spar, or similar material should be laid on the surface of the soil, in order to keep it from mixing with the water.—W. G.]

Failure in Parsley.—"A. Z." (p. 210) need not be surprised at his Parsley failing after growing it continuously on one piece of ground for ten years; there is no crop grown that will not deteriorate and finally die off altogether if fresh soil be not given to it. If "A. Z." will sow a row as an edging every year in March, selecting a fresh position each time, he will get abundance of Parsley from spaces that could scarcely be utilised by any other crop. One of the greatest drawbacks connected with small gardens is the lack of attention to the most ordinary precautions as regards rotation of crops; because Parsley, Horseradish, Artichokes, and similar crops will exist in a kind of semi-wild condition, good culture in their case is almost entirely ignored. Try fresh ground, give the plants ample space, and the result will be satisfactory.—J. G.

"A. Z." (p. 210) should sow his Parsley on a fresh spot; the land (to use a common expression) is Parsley-sick; he might sow at once. The roots are probably attacked by insects, but they are a consequence of, rather than the cause of, weakness. If Parsley must be grown for a series of years on the same spot, it should be treated as a perennial, and have all flower-stems pinched off the moment they appear. I have, as an experiment, kept Parsley in good producing condition for five years by carefully selecting and weeding out weakly plants, allowing plenty of room, and by a liberal use of soot mixed with fresh soil as a top-dressing. An amateur friend has some Parsley roots in his garden that he says are twenty years old.—E. HOBDAK.

"A. Z.'s" border is Parsley-sick. Fancy repeating Parsley for ten years on a bed alongside a water channel, probably at times flooded with hot sewage! The wonder is not that very little Parsley has lately been gathered from that bed, but that any ever consented to grow there. Parsley should never be repeated on the same ground, to say nothing of ten repetitions. Few crops pay better for a bit of fresh ground annually than Parsley. The ground should be rich, deep, and dry, as well as fresh; ashes and soot are the best manures. These make matters disagreeable for the worms where they abound. But "A. Z." must change the place of his Parsley bed at once.—D. T. FISH.

Wintering Half-hardy Bedding Plants.—"V." (p. 210) will find that most kinds of half-hardy bedding plants are readily struck from cuttings inserted about this time (September), but they succeed much better if struck earlier, say in the first week in August. All sections of the Pelargonium family, including the variegated and tricolor kinds, will root readily in pots or boxes filled with light, sandy soil and placed in the open air, or they may be inserted in the open border, and taken up and potted about the beginning of October. In the absence of a greenhouse or glass structure, they may be wintered in a light room as near the windows as possible, setting them back during severe frosty weather, and giving very little water during the dull days of winter. Frost should, of course, be excluded by fire-heat or otherwise, although 3 or 4° will not injure them. Verbenas, Calceolarias, &c., may be

inserted in the form of cuttings, in a mixture of sand and finely-sifted leaf-mould, using well-drained pots some 6 in. in diameter, and these should be placed in a frame, which should be kept quite close until the cuttings are fairly rooted, when air may be freely admitted whenever the weather is fine. Such plants may generally be wintered in an ordinary garden frame, but care must be taken to cover the frame with mats or litter during severe frosty weather, when water should be given very sparingly, and only when the soil is found to be dry. Those not in possession of glass structures should trust more to annual plants for furnishing their flower beds than they usually do. Annuals may generally be sown where they are intended to flower about the end of April or early in May, or, what is better, they may be sown in pans, pots, or boxes about the beginning of April, and placed in a frame on a slight bottom-heat, pricking the young plants out when large enough into other pots or pans, and gradually inuring them to the open air, finally planting them in their beds soon after the middle of May. Many annuals make excellent bedding plants. Nothing can surpass in beauty some of the varieties of Phlox Drummondii, Dianthus Heddeewigi, and its varieties, some of the dwarf Marigolds, Asters, Stocks, &c., all of which will remain in great beauty throughout the greater part of the season.—P. G.

Phloxes Abroad and at Home.—In answer to "A. V." (p. 210), I can only attribute the superiority of the Phlox in France to the influence which a more genial climate and somewhat higher temperature exercises upon its growth. There is there a comparative absence of those periods of wet weather, accompanied by chilly nights, which we in England experience during most summers. The same causes which promote healthy growth will also induce perfection in the way of colour. I have seldom, for instance, seen the dwarf Phlox in this country with colours so brilliant and well defined as at Erfurt, where many acres of them are grown for seed.—J. CORNHILL.

I believe the climate on the Continent in many places to be less favourable to Phloxes than that at home, for this reason, Phloxes receiving ordinary attention, i.e., planted in mixed borders or beds, may always be noticed to be stronger in growth and finer in flower in cold, wet, and upland situations than in lowland and drier districts in the south. It is probably the deep, rich, and moist soil that makes the difference in the appearance of Phloxes abroad. The ground is made artificially very rich, receives plenty of water, and is often mulched. The brightest collection of Phloxes I have ever seen was that of the late M. Lierval, whose garden near Paris was destroyed during the Franco-Prussian war. The ground in which these Phloxes grew was prepared something like that for Celery, with plenty of well-rotted manure, and it was always moist and well mulched.—K.

Early Peaches.—I would recommend "A Subscriber" (p. 210) to grow Hale's Early Peach, an American variety, and Early Louise for his earliest sorts. Early Beatrice under glass is worthless for anything but its earliness, being undersized and watery in flavour. No better variety can be grown under glass than the Early Grosse Mignonne, for it is a sure bearer, of good size and flavour, and it may be ripened early in August without much forcing. Two new varieties of early American Peaches are highly recommended there; they are said to be as early as Beatrice, and better flavoured, and, if so, they must be worthy of a trial in our climate. Early York is an excellent Peach, and Dr. Hogg, for a mid-season Peach, is likewise to be recommended. The Alexandra Noblesse is like the old Noblesse in colour and flavour, but, unlike it, it is not subject to mildew.—W. TILLERY.

Among other questions asked by "A Subscriber" (p. 210) I find one in reference to the quality of the Alexandra Noblesse Peach. It is superior to the Noblesse at its best, and higher praise is needless, perhaps impossible. This Peach is of the highest specific gravity, and is of that creamy-white hue which is hardly ever dissociated from the highest quality. I have not yet grown Dr. Hogg as an early Peach under glass; but Early Beatrice is far inferior to the Early York in quality; and the latter, though three weeks earlier than such magnificent Peaches as Royal George, Violette Hâtive, Noblesse, Stirling Castle, Barrington, and others, is not to be compared with any of them either as regards size or quality.—D. T. FISH.

Eradicating Buttercups.—I want to know by what means I can get rid of a very strong plantation of Buttercups which has been increasing yearly in a field in my pleasure ground, driving out all the best Grasses.—J. E. GAFF.

OBITUARY.

MRS. OSBORN, of the Fulham Nurseries, died on Friday, the 30th ult., aged sixty-one, after an illness of six months' duration. Mrs. Osborn was widely known to many of our readers, having, after the death of her husband and his brother, had sole charge of the business for several years. The nursery is now we need scarcely repeat, carried on by her son, Mr. Robert Osborn.

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

PELARGONIUMS AS WINTER BASKET PLANTS.

WITHIN the last few years Pelargoniums have been largely grown as winter-flowering plants, their brilliant colours being very effective at that dull season of the year. Conservatories, however, as a rule, do not afford them sufficient light when set on shelves or stages, and therefore, in order to remedy that evil, I grow my Pelargoniums for winter flowering in baskets. Treated in this way, and suspended from the roof, they receive a maximum of light; the air about them is kept in active circulation, and the result is a healthy flowering condition all through the winter. The baskets in which they are to be placed should be fitted with two sets of movable shelves, in order that they may be always kept gay, and they should also be dressed outside with Ferns, Mosses, or Echeverias, so as to give them a fresh and interesting appearance. First of all, place in the baskets a layer of Moss from the woods with the green side downwards; then fill in a few inches of soil suitable for the plants to grow in. Introduce the roots of the latter from the outside by making holes through the Moss with the fingers; then shake the soil through the roots and press all firmly down. If Ferns be selected the baskets should be dressed in the spring and hung up in a shaded moist stove or Fernery, and treated in the ordinary way until they are well furnished. The Pelargoniums for winter blooming should be propagated in April or not later than May, when cuttings of them should be inserted singly in 3-in. pots. The number required should, of course, be calculated beforehand, and when they are rooted, if the baskets be not properly furnished with Ferns, or whatever else has been used, the Pelargoniums may be given a shift and kept growing on. Meanwhile, the plants used for dressing the outside of the baskets will have established themselves and will be in a fit state to be gradually hardened, so as to withstand a lower temperature, by which time the Pelargoniums will be ready to be transferred from the pots to the baskets. The first row should be planted so as to lean over the sides, and each succeeding row should have a more vertical position, so as to give the basket when finished a globular form, but not so much so as to appear too formal. It was later than this (September 12) last year when I filled my baskets, but, nevertheless, the experiment proved eminently successful. The conservatory in which they were placed was kept quite cool up to Christmas, during which time the Chrysanthemums were in flower, and the baskets of scarlet Pelargoniums played no unimportant part in its decoration. Even after the turn of the year, when a variety of other subjects took the place of the Chrysanthemums, and when the temperature of the conservatory had to be raised a few degrees, the Pelargoniums with the increased warmth seemed to improve so much in appearance, that they were quite fresh in February. The varieties used were Lord Derby and Jean Sisley, both of which did equally well, the latter being even more conspicuous than Lord Derby, owing to its charming white eye—a striking characteristic belonging to it.

W. HINDS.

Otterspool.

MARIGOLDS AS AUTUMN BORDER FLOWERS.

IN writing of the African and French Marigolds it is necessary to dissociate them from the yellow biennial kinds that are so common in cottage and old gardens, and that are so gay in the early part of the summer. These have not hitherto been classed as florist flowers, but the annual kinds have long been so designated, and well deserve that distinction. There are few double flowers that display more fullness, rotundity of form, and evenness of petal than is seen in a good African

Marigold, whilst the pretty French kinds have flowers in which the petals are so evenly and neatly arranged that no expert in dressing could find one out of place or improve upon the form of the flower. As exhibition flowers the Marigolds are not now largely encouraged. What they get in that way is chiefly found amongst the old florists in the north, where the Marigold is yet cherished, but in the southern districts it would, indeed, be a rare case to find prizes offered for flowers of either kind. In the African Marigold the essential features of show flowers are size, form, and evenness of petal; the larger the blooms, if of perfect form, the better. A stand of twelve flowers admits of little variety, and probably that is a weak point in an exhibition sense. Shades of yellow only are found, but these vary through pale lemon, straw colour, yellow, and orange, some half-dozen shades at least, and therefore if all these be included, and the flowers be good, a stand need not lack attractiveness. It is as an autumn border flower, however, that the African Marigold is valuable; here it is brilliant and effective, not planted in masses, but in twos and threes. Where supported with sticks, to keep their heavy blooms from being blown to the ground, they serve to light up dark-coloured shrubs and surroundings admirably. It is simply impossible to avoid admiring a fine African Marigold bloom; but when a plant has several large flowers on it fully expanded, it commands attention. The French Marigold not only affords more variety of colour, but also variety of habit, the old, coarse-growing, strong kinds sprawling about all over the ground and needing, at least, a yard square of space for growth. These are very useful to plant out amongst shrubs where there are large vacant spaces that look all the better when filled with something, and they do well for the filling of large beds in old gardens or public parks, and thus growing as they list make a good show. In these tall-growing kinds have hitherto been found the maroon and yellow-striped flowers so favoured in the north for exhibition purposes. That these, though small, are the prettiest of all the French flowers there can be no doubt, the markings being so distinct and beautiful; but a good strain of these is by no means common, if what are generally seen growing in gardens afford correct evidence. The Marigold wants plenty of keeping up to the proper standard of excellence, as it soon runs back, though those who grow it only as a garden plant are not concerned about the quality of the flowers. The most beautifully striped blooms I have seen this year are found not on the old tall form, but upon plants of medium height and less robustness, every flower on which presents the true striped form; if these can be fixed to come true from year to year they will prove a great advance over the old kinds. But beyond these there is growing up steadily a striped strain, the plants belonging to which are dense and compact; they form stout, erect bushes about 12 in. in height, and as much through. The flowers in this case are not yet quite so perfect as are those in the previous named section, but when fully fixed, as a season or two will inevitably effect, this strain will supersede all others, as the flowers are larger and fuller, and the plants much more ornamental. Exhibition striped Marigolds are selected not for size, but entirely for marking, and I am not sure that the expert in dressing does not here occasionally display his manipulating powers and remove petals, in order that only a certain number may be seen, and these the best marked. Those who admire the French Marigold solely for its decorative qualities will find in these dwarf forms capital border, and even bedding plants. In this last respect they have one drawback, as let the strain be ever so good, the best that can be had, at least one-fourth of the plants will produce single or semi-double flowers, and these should of course be destroyed. If planted out singly in borders this defect is of less moment. The beautiful yellow kind called *aurea floribunda* gives, perhaps, the least number of single flowers, and as a yellow bedding plant this Marigold is unrivalled; the plants are even and they produce a mass of golden flowers. Seed may be sown in any cool house, or frame, about the middle of April, and the seedlings will be ready to transplant about the third week in May; the stronger the plants are before being dibbled out the better, as slugs have a decided liking for the stems. If lifted from the seed bed and laid in by the roots

first for a week or ten days in the open ground, they harden, and when planted out are less liable to be eaten off. A. D.

USEFUL PLANTS FOR CARPET GARDENING.

In planting the flower garden according to the arrangement required by carpet gardening, which is so much in vogue at present, the filling in of the groundwork, and the materials of which that groundwork is formed, constitute an important, although to a certain extent subsidiary, part. For this purpose the Gibraltar variety of *Mentha Pulegium* has been much used and strongly recommended. My experience, however, is that it is liable to grow irregular and tufty. Now we have amongst our British plants, though by no means a common one, in the *Herniaria glabra*, a plant not only infinitely better adapted to this purpose in its perfectly prostrate growth, but in its much neater and smaller foliage, added to which it possesses a permanent character, and has not the habit of dying out in the centre of the patch, even though cultivated for years in the same place. As regards propagation, possibly it may not be as rapidly increased as the plant I name or some of the others used for this purpose, but its increase is by no means difficult either by division or by means of cuttings, and, once established, it may take part alike either in spring or summer gardening. Its flowers are small and green-coloured, and consequently do not interfere in the least with its value for carpet gardening.

Another plant nearly as useful is *Veronica læta*, or Milky-white Speedwell. This is equally prostrate in growth, and has equally small foliage of a slightly darker green, but, though quite devoid of blossom during the summer, it is in the spring suffused with myriads of its white flowers, which give it a special value as a flowering plant for the spring garden. Unlike the *Herniaria*, it should be divided and replanted every season when the summer filling of the flower beds is being carried out. Both of these plants I have recently seen put fairly to the test in a little terrace flower garden recently formed at Brantinghamthorpe, in our neighbourhood.

Another plant which I would strongly recommend for a similar purpose is the *Acæna microphylla*, more generally known under the specific title of *Novæ Zealandiæ*, not, however, as a green, but as capable of forming a beautiful bronze groundwork—a sort of neutral zone—such a zone as would contrast charmingly with the light, glaucous green foliage of the *Echeverias*; and not only would it be acceptable for its neat foliage, but equally so for its singular flower heads, produced in abundance throughout the latter part of the summer—each head bristling with miniature blood-stained bayonet points. The introduction of such a plant, wherever the soil is of a light, sandy character—an essential which, if not naturally present, can always be expediently—would assist by its novelty to remove that stain on carpet gardening, namely, that universal sameness, which every one must admit to be its great defect. The *Acæna* may be raised from seed, which it produces in abundance, or increased by division. J. C. NIVEN.

Hull Botanic Gardens.

Succulents in the Flower Garden.—I can well conceive that the bedding plants in Hyde Park or anywhere else, where *Polygonums*, *Lobelias*, *Verbenas*, and others are used, must for some time past have looked wretched. With rains of a heavy character and absence of sunshine comes a miserable and bedraggled appearance that puts an end to all beauty. I have often expressed a belief, and this season has the more convinced me in the same, that the most effective and constant designs are those in which succulents are largely used, aided by such fine foliaged plants as will remain constant and regular throughout the bedding season. The most beautiful effects at Heckfield—where bedding plants are, if possible, even better than usual—is found in the use of such plants as *Sedums*, *Echeverias*, giant *Sempervivums*, and *Mesembryanthemums* amongst succulents, and of *Golden Feather*, *Alternantheras*, and the dwarf *Penny Royal* in leaf plants. Where plants such as these are chiefly in use, the weather affects the bedding only in the smallest degree; indeed, such plants usually look brighter after rain than at any other time, and the labour needed to keep these plants in neat order is but little. Weeds can hardly find foothold, so well is the ground covered, and there are no dead leaves or flowers to gather up. Beds so planted look as charming at the end of October as at midsummer. A small grave garden planted with such hardy plants has for a long time, and will for some time yet remain very pleasing. A margin of dwarf *Penny Royal* over which the hand-shears is occasionally run to keep it neat, and inside of this a series of whole and half-diamonds formed with single lines of *Echeveria secunda* glauca, the sections carpeted with *Sedum lydium*, green; glaucous, silver; and acre

elegans, cream, will, with a few large pot plants of *Echeverias* and *Pachyphytums*, have a fine effect.—A. D.

Clove Carnation Miss Arkey.—This fine variety was sent to me last spring, from Bedale, by the raiser of it (Mr. W. Culverwell). Its flowers are pure white, with smooth, stout petals, of excellent substance and agreeably fragrant. The plant possesses a good constitution, and is in every respect a most desirable variety to cultivate. This, and an unnamed variety from Rassis, bearing bright, rosy-salmon flowers, are my favourite Cloves. The latter has large and very stout petals, somewhat slightly serrated on the edges; it is remarkably free, and possesses an excellent constitution. It is known in my garden simply as the *Rose Clove*.—D.

Apios tuberosa.—Than this there are few hardy plants better suited for covering arbours or for rambling over shrubs, &c.; the fragrance of its flowers, which much resemble that of *Violas*, pervades the atmosphere round it, especially after a shower. The blossoms are of a reddish-brown colour, densely arranged on spikes 3 in. long, produced freely from the axils of the leaves in which the leaflets are in three pairs with one terminal. The roots assume a tuber-like appearance, and afford a ready means of propagation.—A.

Wallflower Seed.—If the experience of growers of the Wallflower in large quantities elsewhere is the same as that of growers for market and for seed here, the seed crop of the Wallflower will this year be a small one indeed. It is worthy of note that a comparatively mild open winter resulted in almost entire destruction to large breadths of this hardy plant; but it is probable that the actual mischief was done when the severe frosts of March so greatly injured the early fruit blossom, although the effects were not seen until long afterwards. Of two pieces of yellow Wallflowers grown here in a warm, sheltered place, and which flowered freely, not a plant was left alive to carry a pod of seed; and amongst the dark blood-red plants the damage was almost as bad here, and quite as bad in many other gardens. It is further possible that the heavy rains of the spring assisted to produce this evil, as the Wallflower certainly thrives better in drought than excessive wet. It is to be desired that such a misfortune to one of our most favourite hardy plants will not again occur.—A. D., Bedford.

Indian Balsams.—At this season these beautiful annuals form a very attractive feature. If left to themselves they seed freely, scattering their seeds far and wide, and they will germinate and establish themselves freely unaided. For shrubberies by the side of woodland walks, or amongst dwarf kinds in borders, they will be found invaluable. The best kinds are, the gland-bearing Balsam (*Impatiens grandiflora*), which attains a height of 6 ft., and bears numerous flowers varying in colour from white to a deep rose. This kind will soon take possession of shrubberies if not checked, but it is seen to best advantage as isolated specimens. The Lung-horned Balsam (*I. longicornis*) is very beautiful. It has the habit of the last, but the lower part of its helmet-shaped flowers is of a bright yellow marked by transverse lines of dark brown; the upper part is rose colour. The spur, as its specific name implies, is much longer than that of its neighbours, which marks it distinctly. Royle's Balsam (*I. Roylei*) is a much dwarfer kind than the preceding, and has blossoms of a deep rose colour. The Crested Balsam (*I. cristata*) is very distinct in its leaves being very sharply toothed; it has light rose-coloured blossoms.—W.

Border Pentstemons.—Mr. Douglas (p. 216) seems in doubt as to the original species from which the present race of garden Pentstemons have sprung. I presume they are from the old *Pentstemon gentianoides*, a fine border plant in days gone by, the first good forms of which were *occinea* and *alba*. Now the family is a wondrously varied one, the flowers large, of fine form, and beautifully coloured and marked. I do not agree with Mr. Douglas as to the time of sowing the seed, as the *Pentstemon*, if it flowers ever so early, seldom ripens its seed before the beginning of September, and it would be too late to sow them, except to be troubled to keep the plants in a frame or house all the winter, whilst to plant such small plants in the open border late in the autumn would be to court certain destruction. If seed be kept over the winter and sown in a pan or box under glass early in spring, and the plants got out into the open ground in May, they will begin to bloom in August, and will be full of flower up to the end of October or later. Next year these same plants will bloom in great profusion from May to August, and thus, with a succession of seedling plants, the flowering time of the *Pentstemon* may be made a long one. Seed strains of the *Pentstemon* are now so good, that it is useless to trouble oneself about named kinds. A good strain will invariably reproduce all the qualities of the seed parents. A rich soil, moreover, is not necessary. I have grown them in masses for years in common garden soil, and they will even thrive in ordinary mixed borders. In short, where the Snapdragon will grow so will the *Pentstemon*.—A. D.

NOTES OF THE WEEK.

Odontoglossum coronarium.—We have received from Sir Trevor Lawrence a magnificent flower-spike of this *Odontoglossum* furnished with twenty-five blossoms. It measured 6 in. in width and 12 in. in length, and the flowers, which are of a warm cinnamon brown colour with a yellow lip, were arranged closely but gracefully on the spikes. Though not particularly rare, this *Odontoglossum* is seldom seen in flower—much less in the beautiful condition which the specimen in question presented.

The Three-leaved Bouvardia (*B. triphylla*).—One of the best greenhouse plants in flower at the present time, and, indeed, almost continuously is this Mexican Bouvardia. It is seldom met with in gardens, but a more useful shrub would be difficult to find, as it is easily grown in a cool house where actual frost is excluded in winter. It grows from 1 ft. to 3 ft. high, and has lance-shaped leaves arranged in whorls of three on the stem. The blossoms are borne profusely in terminal clusters, and are tubular, about 1½ in. long, and of a bright orange-scarlet colour.—W.

Brownea erecta var. princeps.—This is about to flower at Lakelands, near Cork, for the first time, it is believed, in Europe. The inflorescence, or flower-spike, differs in form altogether from that of any member of this family that has hitherto bloomed in our stoves, being, when I saw it about ten days ago, a straight stem with many lateral branchlets of apparently white woolly-looking buds of some 18 in. to 24 in. in height, and likely to grow still higher, rising out of the centre of a whorl of handsome leaves on the top of a straight stem of more than 20 ft. in height. This novelty will not be actually in bloom for a week or more to come, when I may have something more to say thereabout.—W. E. G.

Arundo conspicua.—There are some superb tufts of this now in bloom in Mr. John Waterer's nursery, at Bagshot, where it seems at home in the peat soil. The plumes are as high as those of the Pampas Grass when full grown. This New Zealand *Arundo* is indeed a precious gain for our gardens and well worth growing as a conservatory plant in tubs where the climate or soil will not permit of its healthy growth out-of-doors.—V.

Argemone hispida.—This fine, new, hardy plant is now in flower at Kew. It resembles *A. grandiflora*, figured some time ago in the "Botanical Register." It grows about 2 ft. high, and has glaucous, light green, spiny leaves. The blossoms are borne in succession from the tips of the branches, and are about 4 in. across, with broad divisions of thin texture and snowy whiteness, a tuff of bright yellow stamens being in the centre. It is a very desirable plant, and one which, when less rare, will inevitably become popular. It is a native of California, and, doubtless, will prove quite hardy.—A.

Canna iridiflora hybrida.—This is one of the noblest of Cannas. Its leaves are as large as those of a young Musa, and it is dwarfier and more compact in habit than most Cannas. Its flowers are large, drooping, and of a bright rose-magenta colour. It is, as yet, scarce, having been lost to cultivation for some years. It grows well at Chiswick, both in pots and in the open ground. Isolated groups of plants of it on lawns, or standing out boldly in front of shrubberies or in similar positions, would be most effective.

Showy Hardy Flowers.—We have received from Mr. Ware, Tottenham, cut blooms of some of the most showy hardy flowers now to be found there. Amongst others are branching spikes of *Helenium autumnale*, furnished with upwards of thirty bright golden blossoms, each nearly 4 in. in diameter; also the golden-flowered *Aplopappus ciliatus*, the white variety of *Chelone obliqua*, and *Eriogonum racemosum*. In addition to these we have strong spikes of *Polygonatum verticillatum*, furnished with bright claret-coloured berries; also handsome spikes of the coral-coloured fruit of the common Lily of the Valley. With these were likewise *Asclepias incarnata*, well furnished with rosy-purple flowers, and *Leucanthemum lacustre*, with showy white flowers, a plant well worth a place in shrubby borders or in the wild garden.

Tropeolum speciosum in Devonshire.—Much has been written about the growth and flowering of this plant, which in some places seems to be somewhat uncertain. With me it grows most luxuriantly amongst *Rhododendrons*, over which it scrambles. This year I had some tops of young Larch trees about 8 ft. or 9 ft. high placed for it to climb up, and from which it now hangs in beautiful festoons, its purple-coloured berries forming a fine contrast to the flowers. Than this no plant can be more easily propagated. This year I raised about 100 from one plant. About the beginning of May, as soon as the young shoots are well through the ground, carefully take them up with a steel fork, following out the underground stem as far as possible; this will branch off into other stems.

Take up the required quantity, cut them up into pieces about 1½ in. long, and plant them in light, rich soil in pans or boxes (the same as one would bulb of *Gesnera*), and place them in a cold frame. In a fortnight or three weeks they will have grown up strongly, and should be potted off in 4-in. or 5-in. pots before they become entangled. Put a stick 15 in. or 18 in. high to each plant, which will be fit to finally plant out the same summer or autumn. The young tops when taken up should be at once potted off with 1 in. or 2 in. of root. It is difficult to get much seed unless daily watched, as birds eat it as soon as it changes colour. This *Tropeolum* is, in short, a plant that only requires to be better known to be generally grown.—JOHN GARLAND, Killerton, Exeter.

We have received a further consignment (Parts VI., VII., and VIII.) of Mr. Mehan's "Native Flowers and Ferns of the United States," noticed by us (p. 122), and are glad to see that so interesting a work progresses satisfactorily. It is excellent in all ways.

A Good White Bouquet Dahlia.—For vases or bouquets the pure white flowers of *Dahlia Little Beauty* are among the most useful at this season of the year. The plant grows rather tall, but blooms with great freedom until late in autumn.—C. S.

Chrysanthemum frutescens aureum.—This yellow-flowered form of a well-known plant is remarkable for its abundance of bloom when well grown either in pots or in the open ground. It does not grow quite so strongly as the type, and its flowers, which are of a delicate sulphur colour, are well adapted for cutting for vases or bouquets. It is now blooming in quantity in Messrs. Veitch's nursery at Chelsea.—S.

Tillandsia zebrina and fulgens.—Both these *Tillandsias* are now being grown in large quantities by Mr. Wills, at his Anerley Nursery, for decorative purposes. Their foliage, which is in itself effective, withstands the heat of rooms lighted with gas without sustaining much injury, and when furnished with large brilliant scarlet spathes and blossoms, they are reckoned amongst the most effective and useful of decorative plants.

The Rockwork at Chiswick.—The rockery recently made in front of the large Vinery in the Royal Horticultural garden at Chiswick is a great improvement. It is now well planted, and when the different plants get well established it will form one of the most interesting features in the garden. The plants with which it is furnished are not wholly rock plants properly so-called, for, in addition to *Sedums*, *Saxifrages*, and other plants usually grown on rockwork, choice small-growing *Conifers* and other plants which succeed best in an elevated position are introduced here and there in suitable places. Tuberous-rooted *Begonias* also are planted on the sunny side, and the stately-looking *Lobelia cardinalis* and *L. speciosa* seem quite at home on the summit of the mounds. Rock gardens such as this are highly interesting, and much better adapted for small places than beds filled with scarlet *Pelargoniums* and *Calceolarias*.

Phlox Drummondii.—Messrs. Carter & Co. have sent us a collection of blooms of this useful garden annual. In size, colour, and variety they excel any we have hitherto seen, some of the individual blooms being as large as a florin. The flowers vary in colour from white, yellow, mauve-purple, and rose, to the deepest crimson, and there are also some very beautiful striped kinds. The easy culture, as well as the long-flowering qualities and attractiveness of *Phlox Drummondii* and its varieties, should gain for them more extensive culture in both large and small gardens than they at present receive. Nothing scarcely can equal a good mixed bed of dwarf *Phloxes*, and, if planted in rich soil, they will flower from June till frost sets in.

A Good White Pelargonium.—White flowers amongst zonal *Pelargoniums* are always valuable for bouquet making, and they may be had, with little trouble, every month in the year. The greatest difficulty, however, has hitherto been to obtain a kind which would flower freely, as most white *Pelargoniums* of the Madame Vaucher type are strong growers and shy bloomers, especially in a young state. Jean d'Arc, now finely in flower in the Chiswick collection, however, promises to supply this want. In habit and leaf it closely resembles the well-known pink *Christine*, whilst its flowers, which are produced in great profusion, are large, well-formed, and of the purest white. During winter this *Pelargonium* would be especially valuable, and any one having good plants of it, the wood of which is well ripened, would have no difficulty in obtaining a good supply of bloom during the dullest months of the year.

Delphinium Victory.—Under this name we find a beautiful double-flowered *Delphinium* in Mr. Parker's nursery, Tooting—indeed, one of the best of double-flowered *Larkspurs*; its racemes of flowers are 2 ft. in length, the blossoms themselves being very double, and of a brilliant blue, shaded with purple.

NOTES FROM KEW.

Hardy Shrubs.—Somewhat similar to *Escallonia floribunda*, which has already been noted as a most valuable flowering shrub, is *E. montevidensis*, from La Plata; the leaves are very finely serrated, and the white flowers are produced in large panicles, the individual blossoms, however, being hardly so large as those of the first-mentioned sort. The late-flowering season of *E. montevidensis* also adds to its value. *Solanum jasminoides*, a climbing, shrubby kind from Rio Grande, has pleasing, light green foliage, and twigs terminated by pendulous clusters of pure white blossoms, in the centre of each of which is a golden-yellow cone formed by the stamens. This is an elegant and graceful plant, well worth a sheltered spot on a wall, &c., in any of the southern counties, where it cannot but do well and be much admired. A pretty Myrtle (*Myrtus mucronata*) is now in flower on one of the walls; the small, dark green, pointed, Box-like leaves afford a good contrast to the white flowers. *Grabowskia boerhaaviifolia*, from Peru, is a bush belonging to the *Solanum* family; the small leaves are very glaucous—in some specimens almost as much so as those of *Atriplex Halimne*—and the flat flowers are whitish, with a bluish or dark-coloured mark at the base of each of the five divisions of the corolla. *Gaultheria nummularioides*, a pretty little creeping shrub from the Himalayas, is a much less plant than the well-known Partridge-berry of North America (*G. procumbens*); it has round, oiled leaves—the under surface of which is covered with hairs—and shortly-stalked, bell-shaped, pendulous flowers of a deep red colour. *G. carnea* has very small, glossy, toothed leaves and white, fleshy berries. *Heimia salicifolia*, a Mexican shrub of erect habit, has pretty, smooth, Willow-like leaves and yellow blossoms; at times this gets killed down to the ground by wet and frost during winter, but it always springs up again readily from the root and flowers freely.

Hardy Herbaceous Plants.—Climbing amongst low shrubs on the dwarf wall of one of the houses are some specimens of a Cape bulb (*Bowiea volubilis*). This very strange plant, although allied botanically to the *Drimys* and *Scillas*, is totally unlike them; indeed, in general appearance, it exhibits no resemblance to any other plant whatever. Possessing little beauty, it is one of the most curious plants ever introduced into Europe, and consists of little more than a round, fleshy, green bulb, from the apex of which springs yearly a slender, twining, light green flower stem, 6 ft. or 8 ft. in length, which, below, throws off an abundance of much branched, curving, flowerless branches, and above bears numerous small, greenish-white flowers. For the rafters of the cool greenhouse the long, twining flower stems of this plant will excite attention, even if only for their being so totally different from anything else in the vegetable kingdom. *Ophiopogon spicatus*, from China and Japan, is another Liliaceous plant worthy of mention; it has narrow, sword-shaped leaves and spikes of violet-blue flowers. The type attains a height of about 1 ft., but a stout-growing variety is nearly double that height. *Oxalis lobata* is one of the most charming of a lovely class of plants; it has prettily-marked leaves and bright, deep, orange-coloured blossoms, which are freely produced; it does not grow more than 3 in. high. *Galatella dracunculoides* is a lovely Siberian Aster, between 2 ft. and 3 ft. high, extremely floriferous, and of good habit. The flowers are of a pleasing bluish-purple colour. *Diplopappus rigidus*, a United States perennial, is a charming plant of excellent habit, and with mauve-coloured blossoms; it grows about 1 ft. high. *Helipterum floribundum*, 3 ft. to 4 ft. high, has deep, orange-coloured flowers, and is an excellent autumn-flowering plant. *Isotoma secocioides*, about 6 in. high, is a beautiful annual with prettily-out leaves and star-like, mauve-coloured flowers, borne singly on rather long flower stalks. *Colechicum speciosum*, from the Caucasus, figured in THE GARDEN (Vol. XI., p. 548), is by far the most handsome of the genus, and apparently of as robust a constitution as our own indigenous Meadow Saffron (*C. autumnale*). *Polygonum sachalinense*, a Siberian perennial, is a magnificent plant with large leaves borne on somewhat arching branches and short, dense, drooping panicles of greenish flowers. *P. Sieboldi*, from Japan, forms a very compact plant and grows to a height of 6 ft. or 8 ft.; the branchlets and leaf-stalks are red, and the panicles of white flowers are produced in such profusion from the axils of the leaves as to give the plant a most feathery appearance; this makes a fine object as a single specimen on a lawn. A variegated form of *P. Sieboldi* is not nearly so robust as the type, but the coloration of the foliage is very constant and extremely pretty; it only grows about 2 ft. high. *P. cuspidatum compactum* is a neat-growing dwarf form about as high as the last named; at present there are in flower few more lovely hardy plants.

Greenhouse Plants.—*Thibaudia pulchra* is one of the loveliest greenhouse shrubs we have seen for a long time; it has neat, leathery, glossy leaves, and large, drooping, wax-like tubular

blossoms which are bright red, with the exception of the whitish mouth. *Cotyledon ramosissimum*, from the Cape of Good Hope, is a handsome, shrubby succulent with short, roundish, glaucous leaves and large, pedulous reddish flowers.

Stove Plants.—*Ravena spectabilis* is a showy member of the *Rue* family from Cuba; from the axils of its stalked leaves, made up of three leaflets, spring clusters of beautiful rose-coloured, salver-shaped flowers. *Hymenocallis expansa* has fine dark-green, glossy leaves and tall scapes bearing umbels of pure white flowers, the segments of which, as well as the corona, are very narrow.—†

THE OLD YELLOW PROVENCE ROSE.

PERMIT me to thank "C. T." (p. 218) for his liberal offer to send me some plants of this grand old Rose next November, as well as some cuttings of a Rose stock that withstands drought. I need not add how pleased and grateful I shall be to receive both, and to defray expenses of transit, &c. I have also to thank others, and especially Mr. Gilbert, of Burghley, for his promise of buds or plants and useful hints on the best means of growing this beautiful old Rose. "C. T.'s" hints on budding are also very useful, though I have found, after trying such Roses as Maréchal Niel on all available stocks, and also double-budded, that it does best on its own roots. Possibly most Roses will get back to this natural state in the end. Meanwhile, however, a stock, such as that to which "C. T." refers, that will withstand the heat and drought of the northern and eastern counties of England better than the Brier would prove invaluable. The month's intense heat and drought that we had during the past summer killed about 500 Roses here; not that the plants died outright, but they have been dying ever since. Such losses are serious and most provoking. They have also become so common that for many years past we have been in the habit of budding 500 Briers annually merely to keep up our collection. Among so many fatalities, one almost envies "C. T." being able to write of Roses lasting for ever. In fairness to the Brier, however, it must be added that part of this alarming death rate must be laid to the constitution of the Rose; for while we have Compe de Hèbe, Charles Lawson, Baronne Prévost, and Madame Hardy on the Brier twenty-five years old, Beauty of Waltham, Duke of Edinburgh, and General Jacqueminot hardly live for five years. The mortality among Roses on the Brier and the Manetti seems a growing evil, and advances apparently in proportion to the improvement of the Rose in size, colour, and substance. A stock that would lessen or reduce the death rate would therefore prove a great boon to British cultivators. Seedling Briers will doubtless do something to mitigate this evil. The Manetti has also sensibly reduced the numbers of deaths in many localities, but there is a brilliant future for the Portuguese stock, referred to by "C. T.," if it will abolish it or render budded Roses as long-lived as those on their own roots. The latter, however, will doubtless become more and more the Rose of the future, though it will take considerable time to change the current of trade and the fashion in Roses to such a degree as to banish standards from our gardens.

D. T. FISH.

The Japanese Rose.—This has been largely propagated by some Paris nurserymen; we noticed handsome standards and large bushes of it at the Exhibition. There is also what is supposed to be a double variety of it grown about Paris, but though this seems nearly allied to the single forms we grow, it does not seem exactly the same, having smaller and less beautiful foliage.

Blue Gum Tree in Fruit.—Mr. H. Fox (see p. 190), in his notice of the fine specimens of *Eucalyptus globulus* growing in the open air at Penmere, omits one interesting fact in connection with them, viz., that one of them at least perfected seeds last year, and that it is again bearing a crop this season. I have raised a batch of plants from its seeds given to me by Mr. Alfred L. Fox, of Penmere.—JOHN D. MITCHELL, Falmouth.

Myrtles on Walls.—The Myrtle is scarcely hardy enough to withstand our severest winters as an exposed bush, but on walls it does well in most parts of the kingdom, and is most effective. Its sweet-scented evergreen leaves are welcome at all seasons for mixing with out flowers, and at this time of the year it will in most places be beautifully in blossom. Beyond firmly nailing the strongest shoots to the wall, no training is necessary, as it looks best growing freely with its spray-like growth loose and unfettered.—J. GROOM.

Vigorous Rose Shoots.—I have a Gloire de Dijon, planted last year against my house on a north-east aspect, which this year has made a shoot 15 ft. 2 in. in length.—W. E. LAYTON, Cranbourne, Windsor.

THE FLOWER GARDEN.

FROM THE BIRTH TO THE DEATH OF THE LILY.

THIS paper was prepared to follow my last one (p. 140) as a supplement, but has been delayed in consequence of an accident having happened to the photographer. The subject to which I drew attention in my last was early lifting and re-

Old Lily Stem and Roots and New Bulb.

planting, and the decay and death of the parent bulb. The accompanying woodcut is taken from a photograph, sent by me, of a bulb of *Lilium candidum*, which was lifted out of the ground one month after it had bloomed in the present year, 1878. A shows the scar or site of the stem of 1877; B the old stem of 1878; C the remains of the roots of the old stem of 1878; D D the new bulb, having a large slice cut off it to lay open its interior formation; E the roots of the new bulb; these were from 5 in. to 7 in. long, with fine, fibrous rootlets, but they were unavoidably broken off in the lifting; F the

radical leaves, peculiar to this Lily, being the precursors of the stem of the new bulb, which was destined to bloom in 1879. These leaves, springing up so early and so close to the remains of the old stem, now decaying, gave rise to the mistaken idea that this Lily is an evergreen. G, H, I are scales of the old bulb which were left in dissecting in order to show how the new bulb sits in the midst of them until they decay and wither off; K shows the remains of the scales of the old bulb which were picked off to uncover the new bulb. As to early lifting and replanting, that is to say, early after blooming, I would direct attention to the progress which this Lily has made in only one month from the time when the flowers of the parent bulb had faded. The new roots had penetrated from 5 in. to 7 in. into the soil, and, as seen in the woodcut, the radical leaves had grown $2\frac{1}{2}$ in. above the apex of the new bulb. Even at this early period the roots were broken in lifting the bulb out of the ground. Yet it is laid down as a general rule by some Lily growers in their catalogues that "they (all Lilies) should be planted from October to March." In catalogues this Lily is classed with *L. croceum*, *bulbiferum*, *testaceum*, *Thunbergianum*, *tigrinum*, and some others as blooming in June and July; and, as regards growth, they may all be classed as represented in the woodcut, with the exception of the radical leaves, which are, as I have said, peculiar to *L. candidum*. If, therefore, all these Lilies cannot be lifted one month after blooming without injuriously damaging the roots, what state would they be in if allowed to grow three months longer? A mere beginner might be able to answer this question, plainly as I have put it. Therefore, the man who can recommend all kinds of Lilies, bloom when they may, not to be planted or transplanted before October, can know nothing correctly of their organic structure.

Let me now add one or two remarks on the annual decay and death of the plant. M. Max Leichtlin says: "If 'Dunedin' has a correspondent in California who can send him a bulb of *L. Washingtonianum* carefully taken out, he will observe that his theory cannot be applied to that species, for he will find inserted in one long sideway-growing bulb the accumulated growth of eight or ten years." Now, to me, there is nothing extraordinary in this, for the climate and soil of California are peculiarly favourable to the preservation of the phenomena alluded to. Compare the equable temperature of California with the land we live in. In this country we have the temperature of summer and winter differing by 50° or 60° , liable to great extremes, such as long and variable winters and short, uncertain summers. Yet with all these disadvantages I have found Lily bulbs in my underground explorations with an accumulated growth of four or five years upon them. As to the "sideward growth" of *L. Washingtonianum*, which seems to have struck M. Leichtlin as something remarkable, he will yet find, on close examination, that this is characteristic of all true Lilies. Let your readers look at the woodcut. We have at A, on our left, the scar or site of the stem of 1877; on our right side of it we have B, the stem of 1878; and at C, immediately under K, the remains of its roots. On the right side of B and C we have D, the new bulb, which was destined to bloom in 1879; and if the new bulb were further cut away, we would find, by microscopic observation, on the right, but close to the stem of the new bulb, the germ or seed-bud which was destined to grow up and bloom in 1880—all moving by a "sideward growth" to the right, one year after the other, as M. Leichtlin describes *L. Washingtonianum*. Here, then, before us in that woodcut we have an accumulation of three years' growth presented to our view at one glance, the germ or fourth being unseen by the naked eye. Now let the reader picture to his mind what I have seen in my underground explorations, namely, an extension to the left of two more scars like A, being the sites of the old stems of 1876 and 1875. This would make in all five years' distinct growths, besides the germ, all moving in a "sideward-growing" direction to our right. Before, however, the reader can realise this satisfactorily, let us examine the composition of that part of the plant which we see before us. The old stem B and the old scales G H I (the old roots being already gone) will shrink up and be entirely lost in our cold and damp soil before the spring comes round, leaving no traces behind but the site in the core of the old stem of 1878, as at A. Then, what becomes of

the core itself? This is, in reality, the question in difference between M. Leichtlin and myself. I need not explain to the reader what the stem is composed of, as he can see for himself that during this short month it has been fast hastening to decay, especially near its base, where it is greatly shrunk up. With respect to the old scales, the walls of the cells in which the sap has been stored being composed of what is termed cellular tissue, resist for a time, but even these have to give way in a very few months to the all-powerful effects of decay, the commencement of which is easily recognised on the points of the scales. We now come to the core. In the new bulb the core has the appearance of a fleshy substance, but in the old bulb it resolves itself into a kind of woody fibre, and then it becomes almost fossilised, somewhat like the hardened rootstock of *Zingiber officinale*, or common Ginger. The scar A was left on the core in 1877, more than twelve months ago, but a double one I met with three weeks ago, in the presence of a friend, showed that the outer one must have been the scar of the stem of 1876 left there more than two years ago. If, then, in our own country we sometimes meet with four or five years' growth ranged sideways—and this is the invariable rule with all true Lilies, malformations excepted—is it anything to call forth wonder that, in a land so highly favoured as California, there should be found inserted in one long, sideward-growing bulb (successional bulbs) the accumulated (successional) growth of eight or ten years, like the rhizoma of *Diphylleia cymosa*, which often shows six years' growth and a new bud for the seventh, a scar being left, like that at A in the woodcut, by the decay of the annual stalk of the year before and the scars of previous years? Instead, therefore, of bringing forward proofs to show that my theory, as M. Leichtlin calls it, cannot be applied to *L. Washingtonianum*, he has placed before the readers of THE GARDEN the very strongest evidence, when carefully considered, that can be urged to prove the correctness of my doctrine, viz., that in all true Lilies every year witnesses a birth and a death.

DUNEDIN.

LILIUM SPECIOSUM ROSEUM OUT-OF-DOORS.

ABOUT twenty years ago a Lily bulb was planted in my garden in November; the person who planted it had little knowledge of Lilies, and believed that they were all hardy. The bulb in question was left, therefore, in the open garden to the mercy of the weather, which that winter proved to be very severe. Early in the following May, having ceased to remember the planting of this bulb, I was puzzled with the appearance of a plant which had come up, and was showing foliage, which appeared to be strange to me. It was not long, however, before I saw that the plant was a Lily, and I then remembered the planting of it. Well, it grew most vigorously, and in due time—I think in the first week of September—the first bloom appeared, and when I saw it I was not a little surprised to find that my Lily was *L. speciosum* (*lanceifolium*) *roseum*, which I had hitherto seen under glass only, coddled and petted as a tender plant, and not able to resist the rigours of a Scottish winter. After this my Lily received due attention, and the second bloom that is, the bloom of the following year, and the vigour of the plant, convinced me that this Lily was hardy, and one of the finest of plants for the out-door garden. From a single stem, my plant increased year by year till the stems numbered about thirty, but by this time they had begun to grow weaker, and the blooms were growing smaller. It occurred to me that the soil was exhausted, so I resolved on seeing what was at the root, and in making the shift I found deep in the soil quite a nest of bulbs; I forget the number, but there were more than a dozen. They were separated and planted in fresh soil, and now I have bulbs by the hundred, and blooms of the greatest beauty by the thousand. So far as my experience goes, *L. auratum* is equally hardy, and has the advantage of blooming earlier; I had it in bloom in July, but the bulb was planted out early in spring. My garden rests on a porous rock which affords perfect drainage and greatly helps to keep tender plants in the open air sound during winter.

R. C. R.

Bank House, Ayrshire.

Lilium eximium.—Last autumn I purchased a bulb of this Lily, potted it in a 6-in. pot, and treated it in all respects as my other Lilies. It produced one stem with two buds, only one of which came to maturity, blooming about the middle of July last. Scarcely had this bloom fallen, when I observed two strong shoots coming away on

either side of the old stem. These have grown strongly since, and each now shows three buds enlarging rapidly, and, with a continuance of the present fine weather, they will no doubt bloom in about ten days. I have never had a similar thing happen with any of my other Lilies, and I should much like to know whether it is a peculiarity of *L. eximium*. Perhaps some of your readers can throw some light on this point. Since May, when I removed them from the frame, my Lilies have been outside my sitting-room window, which faces the south.—FRED. J. ALEXANDER, *Fernlees, Gunnersbury*.

Cheap Lily Bulbs.—"Danedin" wishes to know the fate of the one shilling Lily bulbs about which I wrote in the spring. Some, of course, have died; but a large majority, four out of five I should think, are doing admirably and flowering now with from five to sixteen flowers on a stem. They have been left out in the beds in which they were planted all the winter. I think this shows that cheap Lily bulbs may be relied upon if purchased from a respectable person.—J. STEWART GATHORNE HARDY.

Transplanting Lilies.—"Danedin" assumes (p. 216) that I had not seen Mrs. Newall's Lilies, but the fact is I did see them in growth as recently as last summer; he assumes, too, with about equal correctness, that Mrs. Newall's Lilies "are dwindling away for want of proper cultivation." I read Mrs. Newall's letter shortly thus: "A correspondent in THE GARDEN insists on the necessity of frequent removal of Lilies. You know the position of our Lilies; I will describe their treatment and its results, and then, knowing that you have grown Lilies for many years, and have made them, rather a speciality, if you advise removal I will move them." I think Lily growers of experience will agree with me, that when the results of Mrs. Newall's treatment are that *Lilium speciosum album*, in an exposed situation not far from the borders of Yorkshire, will, after sixteen years, grow and yield flowers, as described in Mrs. Newall's letter (p. 200), and have stems showing "robust health," that the only advice to be given was, "let well alone."—GEORGE F. WILSON, *Heatherbank, Weybridge Heath*.

SPECIES OF HYPERICUM.

I do not find the following beautiful kinds of St. John's-wort given in the list (Vol. XII., p. 280). They are all, without exception, highly ornamental plants, either for pot culture or for outside borders. They are all natives of South Europe, and are quite hardy in sheltered and rather dry situations. Though a century has elapsed since they were first introduced to cultivation, yet even now they are but seldom seen in gardens, and certainly not so often as they well deserve to be.

The Egyptian St. John's-wort (*H. ægyptiacum*) grows to about 1 ft. high, and is furnished with minute glaucous leaves, densely arranged in pairs on the numerous slender, glaucous branches. The blossoms are about $\frac{1}{2}$ in. long, of a sulphur colour, and are borne in profusion from the axil of each leaf on the upper half of the branches. It forms neat and well-shaped specimens, and when seen in full flower, of which there is a continuous succession for a long time, it is one of the most striking of hardy plants.

The Balearic St. John's-wort (*H. balearicum*).—This beautiful kind is taller in growth than the preceding, sometimes attaining a height of 1½ ft. It is also more sparingly branched. The dark green, spoon-shaped leaves, about 1½ in. long, are arranged in alternating pairs, and are thickly covered on the under side and edges, and also the stem with wart-like excrescences, which give the plant a very peculiar appearance. The blossoms are borne singly at the tips of the branches, and are 1 in. across, of a deep yellow colour.

The Empetrum-leaved St. John's-wort (*H. empetrifolium*).—This very distinct kind forms a dwarf evergreen bush from 1 ft. to 1½ ft. high. Its branches are stiff and erect, on which are arranged in closely-set whorls of three the narrow, blunt-tipped leaves. The flowers, which are borne on terminal spikes, are from 3 in. to 6 in. in length, and are about $\frac{3}{4}$ in. across, and deep yellow in colour.

The Coris St. John's-wort (*H. Coris*).—This so closely resembles the last, that it is often confused with it. It is distinguished by not being shrubby, but having herbaceous procumbent branches, and moreover the leaves and stem are very glaucous. Altogether, it is a very distinct kind, but rare in collections.

The Olympic St. John's-wort (*H. olympicum*).—This is one of the largest-flowered kinds in the genus, though the plant does not grow more than 1 ft. high. It is at once recognised by its very glaucous foliage and erect single stems, with terminal flowers about 2 in. across, and of a bright yellow colour. It forms handsome specimens that flower early in the season, and that last a long time in

good condition, and its value as a choice border plant can scarcely be over-rated.

All the above kinds may be propagated easily by means of cuttings, which should be put in in the present month, as the shoots are now fully ripened, and will become well established before winter. In favourable seasons they also produce seeds abundantly, which afford a wholesale means of propagation.

W.

THE VARIABLE ARROWHEAD.

(SAGITTARIA VARIABILIS.)

This very elegant Arrowhead is a native of North America, where the genus *Sagittaria* is represented by a large number of widely different forms, which have puzzled botanists who have attempted to classify them. After Mosses and Ferns, aquatic plants have, perhaps, the widest area of distribution of any class of plants. Thus, Bullrushes are found nearly all over the world; and Arrowheads, though not so widely dispersed, are common in the temperate and sub-tropical regions

Sagittaria variabilis.

of the Northern Hemisphere, and nearly throughout South America. Both in the Old World and in America there are numerous forms differing from each other in size, outline of leaf, and other particulars; and in a large series of dried specimens we find every gradation between plants 6 in. to 8 in. to 6 ft. to 8 ft. high. Many of the variations are, doubtless, due to the conditions under which the plant is growing—whether in running or stagnant water, in deep, rich mud, or shallow soil, or sub-terrestrial. On the other hand, there are variations in the foliage, &c., which appear to be wholly independent of external influences. It is noteworthy, too, that nearly the same range of variation is exhibited by the Old World *S. sagittifolia* and the North American *S. variabilis*. Some botanists, it is true, regard them as one species; but Dr. Engelmann, who has made a special study of the North American Arrowheads, says that *variabilis* differs from its Old World congener in not having a purple centre to the flower, in the relative length of the flower stalks, shape of carpels, &c. The most striking difference, then, is in the colour of the flowers; the varieties of *S. variabilis* having them pure white. The variety represented in the accompanying engraving is distinguished as *S. variabilis* var. *angustifolia*. Some of the leaves of young plants are long and narrow without any lobes at

the base, and in the lobed ones the divergent lobes are nearly of the same form and size as the terminal portion of the leaf. The leaves are from 6 in. to 12 in. long, according to the vigour of the plant, and the flowering scape from 1 ft. to 3 ft. high. Messrs. Henderson, of the Pine-apple Nurseries, have introduced and are cultivating this variety. It is spread over the eastern side of North America, from Texas to Ohio, and further north. A variety called *gracilis* is a miniature of the foregoing, usually about 1 ft. high, with exceedingly narrow leaves on relatively long stalks. Another variety, named *obtusa*, has large, broad leaves, the broad lobes being sometimes as much as 6 in. wide, and the terminal part nearly double that width. Some years ago this variety was found wild, supposed to have been introduced in ditches near Bordeaux, where it grew to the height of 8 ft. This extreme height is probably ascribable to the extraordinary vigour displayed by some plants when first introduced into a fresh country with favourable climatal conditions; but even if this stature were not maintained, there is no doubt that this variety would be a very effective plant for the margin of a lake.

W. B. HEMSLEY.

NOTES AND QUESTIONS ON THE FLOWER GARDEN:

Nymphaea odorata minor.—This is the variety named by Pursh as roses, to which name it may justly lay claim, as the plant which we noticed in flower lately in the Kew collection confirmed. It is much smaller in every part than the type; it has the same dark purple colour on the under side of the leaf and attenuated lobes. The blossoms, which are about 2 in. across, have the outer petals deeply tinged with rose, a colour which contrasts finely with the fringe of golden stamens. Though much inferior to the recently-introduced rose-coloured variety of *N. alba*, it is, nevertheless, a distinct and valuable kind.—W.

Orchis latifolia.—Some weeks ago I made a rather invidious comparison between some flowers of *Orchis foliosa*, which I had seen in a nursery garden, and some of *Orchis latifolia* which I had seen growing wild. I stated that on particular occasions I believe I had seen well-furnished spikes of the latter 1 ft. long. I must admit that the statement was made somewhat loosely, and that I never measured them, but my impression remains the same. This year I dug up a number of roots to try what could be done with them under cultivation. Botanical synonyms are sometimes confusing, but I before said that my remarks referred to the common marsh *Orchis* figured in Sowerby's "British Botany" under the name of *Orchis incarnata*. As for Miss Hope's plan of nipping off the flower-head when withering, I can only remark that *O. latifolia* grows abundantly near Eton in a meadow which is mown every year when they are either in flower or just over, and the bulbs do not seem to suffer from it.—C. W. Don, Eton.

Salvia patens in Mixed Beds. — Amongst blue-flowered ordinary garden plants few equal this beautiful Sage. Being quite hardy and of a perennial character, it will, when once planted, continue to produce yearly its beautiful spikes of lovely blue, even after Delphiniums and similar plants in mixed borders are nearly over. Perhaps the best effects, however, of which it is capable are obtained in mixed beds, as, for instance, when the spikes of this plant are allowed to mix freely with those of *Calceolaria amplexicaulis* or with golden-leaved *Pelargoniums* or *Abutilons*, the whole being edged with *Colens*. The roots, like those of *Dahlia*s, are quite safe in winter left in the ground under a covering of coal ashes. If lifted they should not be exposed to a dry atmosphere for any length of time, as being only of moderate size they are not capable of withstanding so much exposure as *Dahlia*s. It is difficult to get any quantity of soft shoots fit for propagating in autumn, as nearly every shoot made runs to flower. Therefore, the principal effort to increase the stock of this plant, which is never very abundant, should be made early in spring. If the roots be packed in boxes of light soil and introduced to gentle heat in March, abundance of young shoots will be produced in April, which, if struck in the ordinary manner, like *Dahlia* cuttings, make good plants for placing out-of-doors in May, and when once a good supply of roots is obtained, it is an easy matter to make good any deficiencies in beds or borders that may occur. The combinations in which this plant may be successfully employed are unlimited, and may be varied according to taste.—J. G.

Helianthus multiflorus fl.-pl.—This fine double perennial Sunflower is very effective when planted in large masses along with *Dahlia*s, *Hollyhocks*, *Tritomas*, or other tall flowering plants. It looks extremely well, too, in shrubby borders or in mixed beds in which bold and striking colours are desired.—J. Groom.

TREES AND SHRUBS.

THE KENTUCKY COFFEE TREE.

LONDON, in his "Arboretum Britannicum," gives a list of the trees and shrubs introduced into Britain at various periods during the last century, and in the list of those brought to us between 1741 and 1750 we find the Kentucky Coffee tree (*Gymnocladus canadensis*), said to have been introduced by the Duke of Argyle. Almost a century ago we find it figured by Michaux in his beautiful work, "The North American Sylva" (Vol. I, p. 122), and although subsequent authors have described it, their descriptions have all been a copy of those of Michaux. I had supposed, after so long a period, that it was a tolerably common tree in England, though Mr. Sargent, who visited the leading places a few years ago, says he does not remember seeing it; and I do not now, after so long a time, recollect seeing many specimens at the time of my visit many years before. There are, however, some fine specimens of it around London and on the Continent. Loudon enumerates several; one at Whitton was 60 ft. high in 1835. In the Mile-end Nursery was one 35 ft., and in the Jardin des Plantes, in Paris, another equally high. Though growing over such a vast extent in our own country, from Canada to Tennessee, it is yet very rare to find it planted in the Atlantic States; and it is doubtful if there are trees of any size, except in some of the old half-botanic gardens. It is so unlike almost every other hardy tree, and so tropical in aspect, that it is difficult to convey a good idea of it, except by some comparison. Imagine, therefore, a tree 50 ft. high, with the graceful foliage of *Acacia lophantha*, but ten times as large, and of the soft glaucous hue of *A. dealbata*, and you have a slight knowledge of this Coffee tree in summer. In winter, however, this is all reversed; the immense double-compound leaves, 3 ft. long, have fallen; and dangling at the very tips of a few large, very rough, blunt, awkward, irregular branches, are the huge reddish-brown legumes or pods, 6 in. to 10 in. long and 2 in. wide, slightly crescent-shaped, filled with a kind of pulpy juice, and containing from seven to ten large bean-like seeds. At that season, compared with other trees, it appears to be only the remains of some old and decrepit tree which storms had stripped of its spray, appearing exactly what its Canadian name (*Chicot*) implies—a stump tree; yet there is a rare kind of beauty even at that season, for its very barrenness arrests the eye and singles it out as a curiosity among tree vegetation. Loudon, as usual, gives a drawing of a tree ten years planted, but it is then too small to show its characteristics. He also gives another drawing of the old tree at Syon, 54 ft. high, and this again from position or injury by winds does not portray its fine, erect, feathery head. It is not until it has somewhat lengthened out its few branches that it develops the masses of tufted foliage, almost like bouquets of Fern leaves, which give it such rare beauty. Its growth, which is very slow, appears to be about 1 ft. a year. The several trees of it which Loudon names as 35 ft. to 45 ft. high, had been planted thirty to forty years. Our own tree is about 35 ft. high, and has been planted thirty or more years. Last autumn, in walking under the tree after the leaves had fallen, I picked up two or three of the large pods which had been blown off. It was the first time I had ever noticed it in fruit. Looking up at the tree, I saw a large number of the pods, but having no means of reaching them, except by climbing, I thought another day would do to gather them. The few seeds picked up were planted in a pot in the greenhouse, but I forgot all about gathering the others until one day I noticed the seed had begun to grow. This, however, was the latter part of March; it at once reminded me of my intent to gather the remainder in the autumn. The snow had just disappeared, and, upon examination, we found the pods all upon the ground and the seeds already swollen and nearly ready to vegetate. We had them immediately planted in the house, and in a few days they began to push up the earth just in the same way as Scarlet Runners, pushing themselves quite out of the soil, and in a few weeks they were as large as those planted in November. Michaux says that the male and female flowers are borne by different plants, and Mr. Sargent asserts that "both sexes of this tree should be grown near each other" to produce seeds. It would appear

great presumption in me to doubt this, yet I wish to state that I have but one single tree of the *Gymnocladus*, and I know of no other tree within two miles, and am not sure there is one within ten or twenty miles, yet I had plenty of fertile seeds, from which I now have fifty or a hundred plants 4 in. or 5 in. high. If diœcious, how is this to be explained? I have never noticed the flowers, but eminent botanists have, I presume; and, if strictly diœcious, how could I have fertile seeds? Thirty years ago I described this tree in the "Magazine of Horticulture," and, with the increasing growth of the tree since that time, my appreciation of it has in no way lessened; on the contrary, as I look at it now there are few, if any, of all our hardy American trees, not even excepting the *Magnolia* or *Tulip* tree, which have the unique, semi-tropical, and light, feathery aspect in summer, or the sombre and weird, yet singularly attractive, appearance in winter that this Coffee tree possesses.

C. M. HOVEY.

Boston, Mass.

NOTES ON CONIFERS.

SCIADOPYTIS VERTICILLATA.—This, the Umbrella Pine, is a singular species. It is said to be the finest Conifer in Japan, growing to a height of 150 ft. It is well worthy of trial in this country, for although it appears to be of slow growth here, it has been with us too short a time to enable a fair judgment to be formed of its merits.

SEQUOIA SEMPERVIRENS (the Californian Redwood) is a giant of scarcely inferior size to the *Wellingtonia*. Although of doubtful repute in the North for hardness, I have seen it growing luxuriantly in very cold districts. It is a far more beautiful tree than the *Wellingtonia*, both from its graceful foliage and habit, and the deep ruddy colour of the trunk. It requires the same conditions of soil and shelter, but should be planted, if possible, in a north aspect, where it is less likely to be tempted into late autumn growth. It is frequently known in nurseries as *Taxodium sempervirens*.

TAXODIUM DISTICHUM (the Deciduous Cypress) is a very beautiful tree, of a bright and peculiar green in summer, which changes in autumn into gorgeous gold and brown. It should only be planted in sheltered, swampy places, near lakes and rivers if possible, where it forms a beautiful object.

THUJA GIGANTEA (known also as *T. Lobbi* or *Menziesii*) has been in this country about twenty years, and already promises to become of great importance as a forest tree. The annual growth is very vigorous, the habit of the tree drooping and graceful, and the olive-green foliage is healthy-looking and plentiful. The timber is said to be valuable, hence this tree may be safely used both as an ornamental and forest tree. It stands moderate exposure, and is not at all particular as to soil.

CRYPTOMERIA JAPONICA.—A rapidly-growing hardy tree, but one that will not bear exposure to high winds. It is very ornamental, the foliage being of a rich green, and somewhat Fern-like or Moss-like in character. Although planted in quantities in the Azore Islands and elsewhere for light packing-case timber, it is not likely to be sought after in this country as a timber tree. The wood is very light and soft. It likes a somewhat damp soil. Of the other species, *C. elegans*, I cannot speak except in the character of a shrub. It is a very beautiful plant, and should it grow to the dimensions of a forest tree in this country, will be a very striking object in the landscape, from the coppery tint assumed by the foliage in winter. In its native country, Japan, it grows to the same size as *C. japonica*.

SALMONICEPS.

THE LABRADOR TEA PLANT.

THERE are several plants that are rarely to be found, except in the damp cold peat swamps and dark moist woods of our Northern States. Comparatively few have seen this aspect of vegetation, where the Sphagnum or peat Moss covers the surface for acres, the upper portion of the Moss being alive and growing, while the lower portion is decaying, and undergoing a gradual change into peat. In this wet mass a number of plants find a congenial home, one of which is the Labrador Tea (*Ledum latifolium*), a shrub which sometimes reaches 5 ft., but is commonly not more than 2 ft. high. It belongs

to the Heath family. Its alternate evergreen leaves are of a pale, dull green; as looked at from above they present no remarkable appearance, but the under surface shows a singular contrast; in the first place, the edge is neatly turned over all round, revolute, as the botanists call it, though a lady might compare it to a hem, and the whole lower side is covered with a thick brownish or rust-coloured coating of down or wool, reminding one of a piece of felt; we do not think of any other native plant that presents in its leaf such strong contrast of colour and texture; the new growth of the stem has a similar down, which soon disappears. The flowers appear in May and June in umbel-like clusters at the ends of the branches, and proceed from large scaly buds, which are formed the previous season. The annexed engraving shows the end of a flowering branch of the natural size. The corolla consists of five white petals, and the stamens, usually of the same number, but sometime six or seven;

Labrador Tea Plant (*Ledum latifolium*).

the fruit is a dry oblong pod. The plant, though not so showy as some of its relatives, is an exceedingly neat and interesting one. Like the Rhododendron and similar plants, this would no doubt reach the greatest perfection in a specially prepared peat soil, but we have on two occasions removed the plant from its native locality to a very sandy garden soil, with very satisfactory results. In European nurseries this plant is raised from seeds and by layering. A much narrower leaved species, *L. palustre*, is found far north in British America. The English name refers to the use made of its leaves (which are slightly fragrant when bruised) by the people of Labrador as a substitute for Tea.—“American Agriculturist.”

Chestnut Sports.—Mr. Joseph Newton has shown us a singular sport taken from a Sweet Chestnut growing in Kensington Gardens. The normal size of a leaf taken from the same tree is about 8 in. long and 3 in. wide, while that of the sport is from 14 in. to 15 in. in length, and little more than $\frac{1}{2}$ in. in width.

THE FRUIT GARDEN.

PROTECTING EARLY VINE BORDERS.

THE time is close at hand when the protection of early Vine borders will require attention. In the early forcing of either fruits, flowers, or vegetables, forethought forms the principal part; for unless attention has been paid during the summer months to keep the roots and foliage in a healthy condition, so as to well ripen the wood and produce fine plump buds, no amount of labour afterwards will insure success. This remark holds good also in the case of early Vines, the foliage of which must be kept clean and free from insects, and the wood well ripened. Different opinions are held respecting the protection of Vine borders with leaves or litter. Some say that this covering will ferment and heat, but this never happened in my case. I have placed trial sticks in every position, and I could never find any difference between these in the litter and those in the border; but whether leaves or litter are used, both should be in a dry condition. Previous to 1862 I adopted the old system of using fermenting material on my early Vine borders outside, and added a little fresh material about every three weeks, according to circumstances. This necessitated extra work, which I thought returned but little profit, so I discontinued the practice. We commenced cutting Grapes the first week in May, and for five successive years I only protected with from 9 in. to 12 in. of leaves and litter, covered with wooden shutters to throw off the rain; and the Vines continued to produce good crops quite as early as before, and retained their foliage longer, which is always beneficial in early Vines. I now force much earlier, and commence cutting the third week in March; but all our early Vinerias have the better half of their borders inside, which is, in my opinion, the most suitable plan in the case of Vines that are forced early, the greater part of the roots being comfortably inside, where they can receive a regular supply of weak manure water at a temperature of 80°; and by the time the leaves begin to unfold the roots inside are ready for action, while those in the outside border remain quiet till the fruit arrives at the stoning period, and move just at the time when they are wanted to finish off the crop. In this way, too, the foliage is kept on the Vines much longer than if the roots were all inside, as roots inside get sooner exhausted than those outside, and in very early forcing year after year, every care is required to keep the foliage clean and healthy as long as possible, for if neglected, every eye on the Vine will break from top to bottom during the month of August, and will ruin the crop for the following season. The protecting material should be put on the borders as early in October as possible, so as to inclose, as it were, the summer heat. If rain should now set in, place the shutters on the border to prevent saturation, as the roots soon perish when wet and dormant.

Waterdale.

J. SMITH.

MANAGEMENT OF SHY-SETTING GRAPES.

In the cultivation of plants or fruits, the plodding enthusiast devotes his attention to what are termed “difficult subjects,” and prides himself on his success in moulding them to his will. For some years I have been engaged in the cultivation of the different kinds of fruit usually found in an English garden. In this department it is quite unnecessary for me to say that Grapes of various kinds always occupy the first place in the front rank, and, judging from the magnificent examples of cultivation we frequently see at exhibitions, as well as in private gardens, the horticulturist’s sheet-anchor is well worthy of that place. As a cultivator and observer, I have always been curious to ascertain the causes and conditions which have led to extraordinary success, and I have also paid some attention to the causes of failure in the management of difficult subjects. Many of our finest sorts of Grapes, both black and white, being shy-setters, we do not, as a rule, see them so well grown as they ought to be. Either the bunches are thin and straggling, with here and there a properly-fertilised berry, or, as is often the case with that grand old Grape, Black Morocco, better known as Kempsey Alicante, we see fine, vigorous Vines a complete failure through imperfect fertilisation. A short time ago I walked through an extensive range of span-roofed Vinerias. The Vines, on the extension principle, were growing with a luxuriant, fruitful-looking kind of vigour, by no means objectionable to the man who knows how to handle the reins; but what was the state of affairs? Hamburgs, Lady Downe, and Mincats had set badly, and a splendid Kempsey Alicante, capable of carrying a quarter of a ton of Grapes, was running rampant for the want of something to do. I was told it carried a heavy crop last year, and required rest. We often hear of the elip between the cup and the lip. To me, the most annoying elip would be the loss of the crop, after having succeeded in bringing finely-formed bunches up to the flowering period.

If we turn to a good weekly calendar, we find instructions to keep the house dry, warm, and well ventilated while the Vines are in flower. Many people follow this advice, and fail; so to make sure of our point, we will go back to the beginning, *i.e.*, the border. On all soils for Vines on the single rod, the bottom should be concreted and well drained with clean broken bricks or stones. The border should be made piecemeal, and underdone rather than overdone with soil, an abundance of live active roots within a limited space being more easily excited when the Grapes are coming into flower, and being capable of taking a great deal more tepid liquid when swelling-off the fruit, than if spread over a larger area. In all cases where practicable, I give my Vines the benefit of inside borders, if only 3 ft. wide, as I can then lift and relay the external or internal roots alternately, for the purpose of keeping up lively root action, without losing a crop.

Assuming that we are about to start, in January, a house that has been well planted with Muscats and Alicantes, with room for extending the inside and outside borders as the roots advance, instead of filling up the border with a mass of compost, I should prefer circumscribing the roots by means of turf walls, some feet within the space set aside for the border. The trench thus formed I should fill with fermenting Oak leaves as soon as the Vines had broken. In the course of three weeks these leaves would be cast on the top of the border, covered with shutters, and the trench having been refilled, root-action would be secured for the season. Meantime, the inside trench would be filled with a mixture of horse manure and leaves, and the surface of the border, slightly mulched, would receive moderate supplies of water, at a temperature of 90° to 95°. Under this treatment, growth being free and quick, fine shows might be expected at from two to four buds on every shoot.

So far the Vines have not been distressed, the warmth applied to the roots having assisted them before the stored-up sap became exhausted. The great point now to be considered is a good set. To ensure this, we usually see every bunch left to exhaust the Vines by the flowering process, at a time when they require all the assistance that can be given; the result is a number of imperfectly fertilised bunches, from which, with a great deal of trouble and anxiety, 25 per cent. of the best are saved for the crop, and the others are cut off and thrown away as useless. After a narrow escape of this kind, the selected bunches will contain many stoneless berries, which obstinately refuse to fill up the space they ought to fill. The result is ragged bunches, through which a rifle ball might be fired without touching them; and light cropping being almost as fatal as heavy cropping, the Vines lose their balance, the wood becomes gross, ripens badly, and the second year is worse than the first. Now, had the 75 per cent. of bunches removed been cut off before they approached the flowering period, those left would have set like Hamburgs, probably without artificial fertilisation, certainly with the aid of the camel-hair pencil passed over every flower once a day. Muscats contain plenty of pollen, and some Grape growers draw the hand down the bunches; but it is not a good practice, as many of the outside berries show a small brown spot at the apex when ripe, caused no doubt by pressure or perspiration. Kempsey Alicante, even after the surplus bunches have been removed, requires a little more care than the Muscat, and well this noble Grape repays all that can be done for it. Having often noticed that Grapes invariably set well when the points of the bunches are drawn up by accident or otherwise to the glass, I pay great attention to the position of these when in flower, the more so as the Alicante often produces a moist, adhesive kind of matter, which prevents natural fertilisation; but by the daily use of the pencil, well furnished with Hamburg or Muscat pollen, which is carried on a sheet of paper, this matter soon gives way, and the Alicante then sets as freely as any other Grape. Artificial fertilisation to some may appear a very tedious process, but having cleared the Vines of the bulk of the surplus bunches, the operation is quickly performed; indeed, half an hour each day while the Grapes are in flower will ensure a large house of well-set Grapes. Of the varieties in general cultivation that require artificial fertilisation I may name the Muscats, some of the Sweetwaters, Mrs. Pince's Muscat, Black Morocco, Venn's Seedling, and Muscat Hamburg. The Frontignans, Lady Downes, and the Hamburg, on imperfectly ripened wood of the past year, will also repay the care bestowed upon them.

From the foregoing remarks, your readers will gather that many years' practical experience has taught me that moderate-sized borders, well filled with active roots, bottom-heat in proportion to that of the house in which the Vines are growing, combined with the early removal of surplus bunches, and the artificial fertilisation of those intended for the crop, will lead to success in the most difficult subjects; while treatment the reverse of this is attended with but partial success or failure. I have not made any allusion to the ripening of

the Vines, as amateurs, to whom these remarks are addressed, know that good Grapes cannot be obtained from imperfectly matured wood.—W. COLEMAN, in the "Florist."

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

Victoria Plum.—This Plum has been so laden this year with fruit as in some cases to be literally borne to the ground with its weight, unless supported by props. The Victoria is not a first-class dessert Plum, but selected, well-ripened fruit are very good-eating nevertheless, and, being a freestone sort, it is all the pleasanter. As a culinary Plum it stands high, and it makes a delicious preserve. I have purchased here a fine sample at 7s. per bushel, the selling market price. A strike costing 2s. 6d. gave, when stoned, 15 lb. of good flesh for boiling, which was just 2d. per lb. The "Fruit Manual" classes this Plum as ripe in the beginning and middle of September. Here the bulk of the fruit is ripe and marketed at this date, August 31. I may add that a strike is about 3 gallons or one-third of a bushel. It is a common fruit measure in the London market.—A. D., *Bedfont*.

Treble-rooted Vines.—An interesting experiment in Vine culture may now be seen at Heckfield. Those who have visited these charming gardens are familiar with the large span-roofed Lady Downes house, the pitch of which on either side touches the ground. On the one side are planted twelve Vines, eleven of which have two rods each, and these are carried up on the one side and down to the bottom of the other, a distance of about 30 ft. Last year Mr. Wildsmith layered the shoots at the extremity of these twenty-three rods, and all rooted. The wood beyond was taken off in the winter, and now may be seen the interesting spectacle of Vines having three distinct sets of roots. What the ultimate effect upon the plants may be it would be difficult to say, but at present the crop is at once the best and heaviest which the Vines have borne. The bunches are fine, and the berries large and getting as black as Sloes. There are upwards of 400 bunches in the house, presenting a probable weight of about 600 lb. This is a heavy crop for such a kind as Lady Downes, which is the very best late-keeping Grape, the larger portion of the produce there being cut in January and kept good in bottles until April and May.—A. D.

In the Orchard.—In these modern days men have lost the pleasures of the orchard; yet an old-fashioned orchard is the most delicious of places wherein to idle away the afternoon of a lazy autumn day, when the sun seems to shine with a soft slumberous warmth without glare, as if the rays came through an aerial spider's web spun across the sky, letting all the beauty but not the heat slip through its invisible meshes. There is a shadowy coolness in the recesses under the trees. On the Damson trunks are yellowish crystalline knobs of gum which have exuded from the bark. Now and then a leaf rattles to the ground, and at longer intervals an Apple falls with a decided thump. It is silent save for the gentle twittering of the swallows on the topmost branches—they are talking of their coming journey—and perhaps occasionally the distant echo of a shot where the lead has gone whistling among a covey. It is a place to dream in, bringing with you a chair to sit on—for it will be freer from insects than the garden seats—and a book. Put away all thought of time: often in striving to get the most value from our time it slips from us as the reality did from the dog that greedily grasped at the shadow: simply dream of what you will, with Apples and Plums, Nuts and Filberts within reach. Dusky Blenheim Oranges, with a gleam of gold under the rind; a warmer tint of yellow on the Pippins. Here streaks of red, here a tawny hue. Yonder a load of great Russets; near by heavy Pears bending the strong branches; round black Damsons; luscious egg Plums hanging their yellow ovals overhead; Bullace, not yet ripe, but presently sweetly piquant. On the Walnut trees bunches of round green balls—note those that show a dark spot or streak, and gently tap them with the tip of the tall slender pole placed there for the purpose. Down they come glancing from bough to bough, and, striking the hard turf, the thick green rind splits asunder, and the Walnut itself rebounds upward. Those who buy Walnuts have no idea of the fine taste of the fruit thus gathered direct from the tree. Surely it is an error to banish old-fashioned orchards from the pleasure-grounds of modern houses?—"Pall Mall Gazette."

Blackberries.—These are most abundant this year. I have lately observed amongst them several distinct varieties, that vary considerably, both in leaf, fruit, and time of ripening. Blackberries, I need scarcely remark, are extremely well adapted for tarts or preserves, as although by themselves they are somewhat insipid in taste, that may be readily improved by the addition of a sharp Apple or two or a little Lemon juice.—J. Groom.

THE INDOOR GARDEN.

CONFINING THE ROOTS OF STEPHANOTIS.

ALTHOUGH specimen plants of *Stephanotis* are not uncommon, yet it is much more generally grown wholly for the sake of its flowers in a cut state, their pearly whiteness and delightful fragrance rendering them favourites for nearly all kinds of indoor decoration. When its blossoms are required in quantity the best plan is to plant it out in brick compartments or narrow borders, and to train the shoots tolerably close to the glass, for unless a maximum amount of light and air be given it, it will not flower freely. The most floriferous plant of *Stephanotis* which I ever had was planted in a narrow border, not more than $1\frac{1}{2}$ ft. wide, in a compost of fibry turf, peat, and sand, resting on a quantity of brick rubbish, which acted as drainage. Here it had abundance of water, both at the root and overhead. It is very liable to be attacked by mealy bug, but copious deluges of tepid water will dislodge it. The shoots were trained horizontally on wires 8 in. apart, and the same distance from the glass of a span-roofed pit, where they could receive abundance of heat, light, and air, but where they were at the same time carefully shaded from the direct rays of the sun, while the foliage was in an immature condition during the early summer months, and while the principal flowering season lasted. During the autumn months they received all the light and air possible, with but an intermediate temperature, and, during the winter months, the temperature was seldom more than 50° at night and sometimes even lower than that, but as sun-heat increased with the lengthening days in early spring, and more fire-heat was applied for forcing purposes, the flower bunches appeared at the axil of every leaf, so that by the time they began to expand, each wire looked like a bridal wreath, densely furnished with waxy flowers of great substance. While in that condition it was copiously supplied with weak liquid manure to help the crop of bloom and to promote some early growth, that usually flowered well later in the summer. As this plant was confined to the portion of roof over the central pathway, it occupied space that could not well be otherwise utilised; but if trained thinly over an entire house or pit, the majority of plants, such as Ferns, that delight in partial shade might be grown under it with advantage. Where a narrow border is not available, brick compartments would be preferable to planting it in a large body of soil, more especially where it happens to be associated with stronger-growing plants. Thus treated, the roots are more under command as regards the applying of moisture, and when any lack of vigour is observed, the old soil can be carefully removed from the surface and replaced with fresh, well-enriched compost; any pruning required should be done after the flowering is over. It should consist in cutting any old, bare pieces away in order to give light and air to the new growth; overcrowding, above all things, must be avoided. Plants grown on circular wire trellises frequently fail to flower freely, owing to the young wood being trained so thickly as to be unable to get ripened. In that case it should be trained up thinly on wires until thoroughly matured, and then be replaced on the trellis, when it will be almost certain to produce an abundant crop of flowers.

J. G.

WINTERING HALF-HARDY PLANTS IN FRAMES.

ALTHOUGH the system of heating houses and pits with hot water has greatly simplified the keeping of tender plants through the winter, and, to a great extent, superseded cold frames and pits for that purpose, yet it frequently happens that small cultivators have no heated structure of any kind, and, therefore, necessarily fall back on the somewhat antiquated, but by no means to be despised, two or three-light frame, that, during summer, is usually devoted to Cucumbers or Melons. I have seen a good many plants safely wintered as follows: As early as cuttings are procurable, say in the end of July, commence propagating *Pelargoniums*. Get some boxes 4 in. deep, and of lengths most convenient for storing purposes, and fill them with tolerably fine, sandy soil; in this insert the cuttings, prepared in the usual manner, about 2 in. apart. These will root freely in a fully exposed position if moderately supplied with moisture, and they will be well established in the

boxes before winter sets in. During August such tender, soft-wooded cuttings as those of *Lobelia*, *Alyssum*, *Verbena*, &c., may be readily propagated in store pots under hand-glasses or cloches set in a tolerably shaded position, giving a little air at night, picking off any decayed leaves, and giving water sufficient to keep them from flagging. The pots should be well drained; at least, they should be one-third full of potsherds, over which should be put a covering of rough soil, finishing with finely-sifted soil and clear, sharp sand. As soon as they commence to grow, which will be in about three weeks from the date of insertion, give more air, and after another week remove them to an open situation, but sheltered from rough winds. The growing points and all flower buds must be kept pinched close, in order to induce a dwarf, sturdy habit. About the end of September, or early in October, set the frames on a good, hard foundation of well-trodden coal ashes that will keep worms down, and superabundant moisture from rising. A sheltered position fully exposed to sun and air is best, as at all seasons, when there is not actual frost, plenty of ventilation should be given, as stagnant damp is more frequently fatal than frost. The latter, however, must be guarded against by means of dry litter put over the glass, and the sides may be securely protected by dry leaves packed firmly about $1\frac{1}{2}$ ft. thick all round. If the boxes and pots be elevated on a hollow stage all the better, and only sufficient water to prevent flagging should be given until the days begin to lengthen. Then any which it may be desirable to increase may be removed to closer quarters to promote young growth for cuttings, as where means for propagating are at hand, spring-struck plants from those kept in store pots, such as *Verbenas* and *Lobelias*, are the best. *Pelargoniums*, however, are best struck in the autumn. Where space will allow, these should be potted off early in spring, and as soon as they have become well established under glass, they may be hardened off under some temporary protection. If intended to remain in the boxes until they are planted out, strong-growing varieties must be allowed more space.

About the middle of March a hotbed should be made up for a one-light frame, and as soon as the heat has fallen to a safe temperature all the cuttings fit for use should be taken off and inserted moderately thick, and the pots in which they are put should be plunged to their rims in spent tan or Cocoa-nut fibre, keeping them pretty close up to the glass. The cuttings should receive a good watering through a fine rose when first put in, and they must not be allowed to become dry enough to flag at any stage of their growth. If the lights be kept close and shaded from bright sunshine during the day, a batch of cuttings may be struck off rapidly and successfully. In fact, where convenience for hardening off the plants as soon as struck exist the numbers that may be propagated under a single light, by renewing the bed and adding linings for successive batches, would not be credited by those who have not tried it. For ordinary growers one or two batches of cuttings will be sufficient, and by raising some *Cucumber* plants with the earliest lot they will be ready for planting out as soon as the propagating is over. Pans or boxes of annuals available for bedding may also be raised during the earlier stages of growth, or before all the space is required. *Petunias*, *Golden Feather*, *Lobelias*, *Asters*, *Perillas*, and similar plants, if sown thinly in boxes and just given a start under glass, may be afterwards sheltered by temporary coverings during any ungenial periods that occur before they are planted out.

There are in addition to the above many very useful plants that are hardy enough to stand a moderate amount of frost without any protection, and for which a turf pit, with a temporary covering of reed-mats during severe weather, is all that is needed. *Calceolarias*, *Gazanias*, *Santolinas*, *Violas*, *Golden Thyme*, and similar plants now so extensively used, are better kept during winter in the hardiest condition possible, as nothing predisposes plants of a hardy character to disease so much as unnecessary coddling during winter in a higher temperature than that which they require, thus necessarily keeping them growing when they ought to be at rest.

J. GROOM.

Aspidistra lurida variegata.—This is one of the best plants that can be grown either indoors or in the conservatory, being of easy

culture and rapid growth, and making fine, healthy foliage, which, when well matured, will continue in good health in ordinary dwelling-rooms for a lengthened period; being of a smooth, shining character, too, it is readily divested of dust by sponging or syringing. This *Aspidistra* will withstand a wide range of temperature, varying from that of the hot stove to that of the coolest greenhouse, but it retains its foliage best in an intermediate house.—J. GROOM.

CONTINUOUS FLOWERING OF BOUGAINVILLEA GLABRA.

AMONG climbers, the blooms of which adorn the roofs and walls of our plant houses, there is none more beautiful than this *Bougainvillea*, owing to the large size and profusion of its mauve or rather pink bracts. *Bougainvilleas* inhabit the warm, semi-tropical valleys lying along the upper tributaries of the Platte River, the banks of which are clothed with an infinite variety of tropical productions. Skirting the forest, the *Bougainvillea* may be seen growing rampant among the branches of some trees, which it festoons in a gay but artless manner, not without injury, however, to a sapling. This luxuriance, which lasts in greater or less abundance about nine months, is promoted by copious rains, clear sunshine, atmospheric influences, and decayed vegetation, but with winter comes a check; sometimes the leaves fall entirely, but in ordinary seasons they are partially retained and the dormant state quickly passes into one of active growth. These conditions indicate that we should grow the *Bougainvillea* in a brisk-growing temperature, on the one hand, followed by a decided rest on the other—treatment which experience verifies, judging from the behaviour of *Bougainvillea glabra* during a series of years. It is grown here in a 20-in. pot or tub, placed on a stone table 2 ft. above the pipes, at the warm end of an intermediate house, the thermometer often falling to 45° in midwinter. It is at present one mass of bloom. The entire plant covers an area of 100 sq. ft. With the departure of bright sunlight and the approach of winter, growth reaches a minimum. In January the ripened shoots are pruned to short spurs; after a few weeks more the roots are examined, some new soil supplied, and the stem tied up horizontally near the glass. During the resting period water is not entirely withheld, because I consider the "dry-as-dust" practice injurious to the roots; the atmosphere is also somewhat moist. In March the buds break with renewed energy, root action follows, the vigorous nature of the plant becomes apparent, a fact which appears to me to form the basis on which success or failure, as regards continuous flowering mainly depends, for if the advancing shoots be not first thinned and afterwards pinched at every lateral, the annual result is an exuberance of immature growths with very little bloom. But let the shoots be kept evenly apart and trained carefully to the wires, as one would do with a Peach tree on the frame method, and the sun will not fail in perfecting the growth, in strengthening the whole plant, and indicating abundance of blossoms. Supplies of water and liquid manure, shading from the direct rays of the sun, frequent syringings, and clean glass are also indispensable to secure good results.

Edinburgh.

JAMES SCOTT.

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Musa zebrina.—Where room plants are required, this might be grown with advantage. Plants of it in 6-in. or 8-in. pots would become large enough for the purpose, and, when well furnished with graceful dark green, brown-blotched leaves, and the pots covered with *Club Mosses*, they make effective subjects in vases set on pedestals or in similar positions.—C. S.

Cordylina indivisa from Seed.—It is satisfactory to find that, after many failures, this excellent decorative plant can be obtained from seed sown in this country. Comparatively few plants of it have hitherto been obtained in this way, but Mr. Williams has succeeded in raising a large batch of it in his nursery at Holloway.—C.

A Good Pelargonium.—There are now so many new zonal *Pelargoniums* that to select the best is a difficult matter; but one in the Pine-apple Nursery, named *Comte de Gomer*, appeared to be worth notice on account of its close resemblance in habit to the well-known and much-valued kind called *Vesuvius*, whilst its flowers are double the size of those of that sort, and of fine form and colour. It might with advantage be termed *Vesuvius Improved*.—S. C.

Greivillea robusta from Seed.—This is one of the most useful of green-leaved plants for decorative purposes, and it is now largely grown for market. Seed of it sown early in spring will, if properly attended to, produce fine, graceful-leaved plants, from 12 in. to 18 in. high by August. We lately saw a large houseful of similar-sized plants in Messrs. Rollisson's nursery, Tooting, the result of seed sown at the time named.—S.

PLATE CXLV.

DENDROBIUM GOLDIEI (RCHB.).

THIS beautiful species, at one time thought to be *D. superbiens*, but now found to be distinct, was discovered by Mr. Goldie, in the neighbourhood of Torres Straits. It is undoubtedly one of the most charming of all *Dendrobies*, and is a most profuse bloomer, as many as fifteen spikes having been found on an imported bulb, a fact which fully proves its free flowering qualities. Its blossoms, which are produced on gracefully-drooping, slender stems for a long time in succession, are most useful in a cut state for bouquet-making. The plant grows freely and succeeds well under the same treatment as *D. nobile* and similar kinds. It may be added that the longevity of the flowers of this *Dendrobe* is very remarkable; blossoms which opened on plants in Mr. Williams' nursery early in December, lasted in good preservation until early in March; therefore, plants of it kept in a moderately cool, dry temperature, would be attractive objects for at least two months in the year, and this during a season when good flowering plants are in most request. The plant from which our figure was prepared flowered for the first time last summer in Mr. Williams' nursery at Holloway.

SUCCESSIONAL FLOWERING OF EUCHARIS AMAZONICA.

MOST cultivators who have liberal demands for the more choice flowers for cutting, and who have not, now-a-days, will readily endorse "J. P.'s" high estimation of the value and beauty of this plant. No doubt he is also right in condemning starving modes of culture that he affirms causes it to flower but scantily or not at all, but it is equally certain that the plant may be fed or forced into a flowerless condition. An excess of heat, or of food, and a constant uninterrupted supply of either, are likely to result in little or nothing but leaves. The secret of continuous, or rather successional, blooming of this fine plant consists in subjecting it to a series of sudden changes. So much has recently been written on the life history of *Lily bulbs* that one hesitates to dogmatise almost the life or flowering of any bulb without subjecting it to a series of experiments more searching and exhaustive than most of us can find time to devote to such purposes; but whether the same bulbs flower a second or a third time, or other bulbs produce the successive displays of bloom, the practical results of a chequered treatment of this fine plant are the same. Sudden and severe checks from moisture to drought, from feasting to starvation, from heat to cold, bring forth fresh crops of bloom. By this is not meant a few spikes sent up, as it were, in succession to a full harvest of beauty, but rather a second and a third harvest equal or superior to the first. To obtain such brilliant results there must be a forced rest or interregnum to growth, brought about by some such checks as those here indicated. Thus the application of a high temperature and liberal treatment brings forth yet other crops of blooms. Three or even four crops of flowers a year are thus possible, the plants being always under treatment, and never losing their foliage. Some of our finest plants have had six weeks' rest in the open air this summer, and responded to the genial temperature of the stove afterwards with a perfect forest of flower stems. The same plants are grown in the open air, and will be in flower again early in October. They also flowered in February and March, right up to May, and went out-of-doors immediately after a rest. Some of the plants remained out until the flowers opened, and flowers and foliage seemed all the more vigorous in consequence. It will thus be seen that a high stove temperature throughout the season is by no means necessary for the flowering of these grand plants in succession. On the contrary, severe changes of condition and treatment are the simplest, but most effective, means used to force the plants to flower freely several times a year.

D. T. FISHER.

Acanthuses in Shade.—Where plants for indoors have to be largely provided, the *Acanthus latifolius* and *mollis* will be found to be most useful, not only on account of their beautiful green foliage fitting them so well for large vases, but from the fact that they retain their health and vigour, and continue to produce fresh foliage in positions so imperfectly lighted and ventilated that scarcely any other plant would exist for any length of time. Where sub-tropical bedding is carried on there is usually a quantity of such plants fit for lifting at this season, and which, if carefully potted and kept in partial shade for a few days, will remain serviceable during the whole of the ensuing winter.—JAMES GROOM.

DENDROBIUM GOLDIEI.

GARDEN DESTROYERS.

HYLOTOMA (TENTHREDO) ROSARUM.

(THE ROSE SAWFLY.)

THE Rose sawfly is about three-fourths of an inch long and seven-tenths of an inch across the wings when fully outstretched. The head, thorax, and antennæ are of a brownish-black. The antennæ have only three joints; the wings are large and transparent, the upper pair being the longer, with the front margin much thickened, particularly at a point called the stigma, about two-thirds of the length of the wing from the base. The body is broad and flattened, and of a yellowish-brown colour, that of the female being furnished with saws, as described below. The eggs, about twenty-five in number, are laid in the spring, and placed each in a separate slit in the young wood of the Rose. The larvæ are hatched in about eight or ten days; their bodies are composed of thirteen segments, nine of which each bear a pair of legs. The head is yellow, with black eyes; the body is yellowish on the back, greenish-yellow on the sides, and white beneath; both back and sides are sprinkled with small, shining black tubercles, from which spring a few fine hairs. They increase in size

The Rose Sawfly—*Hylotoma (Tenthredo) rosarum*.

very rapidly, and change their skins four times; they attain their full size in about a month, when they are about $\frac{3}{4}$ in. long. They then descend to the ground, bury themselves, and construct a double cocoon in which to undergo their change to the pupa state; the inner cocoon is of a much closer and more compact texture than the outer one. The larva remains in this cocoon for nearly a month before becoming a pupa, after which another month elapses before the perfect insect appears. The larvæ of this second generation in due course bury themselves in the ground and form their cocoons, in which they pass the winter as larvæ, not changing into pupæ until the following spring.

The sawflies belong to the natural order Hymenoptera (or membranaceous-winged), from the Greek *hymen*, a membrane, *pteron* a wing. This order comprises all the bees, wasps, ants, ichneumons, gallflies, sawflies, &c., all of whom (with the exception of a few wingless species) are furnished with two pairs of wings, both of which are used in flight, and are long, transparent, and veined. The larvæ or grubs are legless, with the exception of those of the sawfly. When in the pupa or chrysalis state, the limbs of the perfect insect can be seen cased in sheaths and folded over the breast. The sawflies derive their name from the very curious and

interesting organs with which the end of the bodies of the females are furnished, and by means of which they cut slits in the leaves and young shoots of plants, in which they deposit their eggs. These organs consist of a pair of saws placed side by side, contained in a sheath formed by a pair of flattened plates. These saws are somewhat curved, are very finely-toothed, and their sides are grooved transversely. When in use they are protruded from the sheath and worked rapidly and alternately, one being pushed forward whilst the other is withdrawn; in this manner a slit is very quickly made, the egg is then passed between the saws into the slit, and the insect prepares to form another slit. Each egg is accompanied with a drop of frothy matter which, it is imagined, prevents the wound in the leaf from closing.

This insect in a perfect state is very common and may be found from May till August; as it only feeds on the nectar and pollen of flowers, it is quite harmless in the garden. The larvæ, on the contrary, do a great amount of injury to Roses and Briers by eating their leaves, at times only the midrib and larger veins being left. They attack all kinds of Roses, but the Banksias and Tea Roses suffer less than others. Some Rose growers on the Continent plant Parsley near their Roses, as the larvæ are particularly fond of that plant, in order to attract them from their Rose trees. I am unaware if this has been tried with success in England. Birds and wasps destroy great numbers, many are attacked by a small parasitic insect (one of the Chalcididæ), which lays its eggs in the larvæ, the grubs from which eventually kill them. The perfect insects should be destroyed whenever they are found, particularly in the spring, when they are sluggish and may be easily caught.

S. G. S.

FERN CASES AND FRESH WATER AQUARIA.

THE following remarks on this subject were made by Mr. J. C. Niven in a lecture lately delivered to the Hull Literary and Philosophical Society. He said that the important principle in the Fern case consisted in the fact that as rapidly as the moisture was evaporated from the soil it was condensed on the inner sides, and trickled down to its original source, but he here pointed out the fallacy of the popular idea that plants grown under these conditions never require watering. This was found in practice to be a mistake. It would be obvious to all that as the water condensed on the glass it ran down the sides into the drainage of the stand, and that a large percentage of it would thus be placed far beyond the influence of the soil; the latter would, therefore, become too dry to support vegetation in a healthy condition, and in his experience the failure of not a few attempts in the management of these cases had been distinctly attributable to this erroneous, but very general, impression. By way of answer to the query, Why are Ferns, Club Mosses, and their allies so well adapted to these confined conditions of culture? Mr. Niven drew attention not only to the position they generally affect at the present day in our deep ravines and caverns, but also to that ancient period of time—so charmingly depicted by Hugh Miller, when the surface of our earth was enshrouded in a cloud of misty evaporation, a condition under which our small Club Mosses were represented by giant trees of the same type, whose silicified and carbonised remains might be seen in nearly all museums. The lecturer then dealt with the conditions of successful culture under three heads; first, the nature of soil best adapted for the purpose; second, the sorts of Ferns, or, at least, a selection of them best adapted; and third, some general hints as to after management. In the matter of soil nothing was superior to the Loudon peat, with its dense texture. This, with a mixture of silver sand, some burnt soil, and charcoal—the latter two materials acting as valuable anti-septics—constitutes the best elements of successful culture. The soil should have below it a good open space of potsherds for drainage. The lecturer then referred to the kinds of Ferns best adapted by their small size of growth, and various other qualifications, for culture under a glass shade, and then said, with respect to after management, that he strongly recommended the giving of air to Fern cases by the complete removal of the shades for, say, a quarter of an hour or more, selecting the morning as the best time for this operation, and thereby the growth of a fungoid character, which readily developed itself on decaying particles of the fronds, would be checked. He further cautioned people against sudden changes, such as were frequently and thoughtlessly made in the depth of winter, when possibly the Fern case would be removed, say from its usual position in the warm temperature of the dining-room to a cold hall table, or, worse still, to a landing window, where, possibly, before morning, the frost would have made itself visible in a lovely, but fatal, crystallisation on the inside of the shade. Some cases, he said, were supplemented by an aquarium, which occupied the centre, containing that popular water plant the Vallisneria, with sundry small fishes; this arrangement had added additional interest. He stated that many attempts at the cultivation of the Vallisneria had failed from the erroneous idea that it needed no soil. True, the American Water Weed is independent of an anchorage of any kind, but the Vallisneria dearly loves a rich alluvial clay, wherein to perfect its growth.

GARDENING FOR THE WEEK.

Flower Garden.

Auriculas.—Old plants of these should have been established in their blooming pots before this month; still, if they have not been potted it will be desirable to do so rather than allow them to remain in the same pots another season. Offsets that were put into small pots, five or six in a pot, must now be potted off if they are well rooted. Offsets are sometimes very small, and, therefore, small pots must be used for them. I use what are termed thumbs, but they are deeper than usual in proportion to their width. The object in using such pots is to be able to accommodate a larger number in a certain space than could be done if the pots were shallower and wider; it may be as well to state that Auriculas thrive well in such pots. Plants that are throwing up trusses must have the flower-buds pinched out before they open; autumn trusses exhaust the plants if the flowers be allowed to expand. Green fly must be destroyed by fumigating, broaching them off, or dusting with fine, dry Tobacco powder. All offsets that have formed roots should be carefully removed from the parent plant with a sharp knife and be potted in light soil with a little sand placed at the base of the offsets.

Carnations and Picotees.—From the middle to the end of the month the earliest-rooted layers may be taken off, and if the weather be warm and sunny, some shading should be placed over them. Place the frame in which they are to be put with its back to the south, which will farther tend to maintain a cool atmosphere round the plants. It is not desirable to remove the layers when the soil is wet and sloppy.

Dahlias.—At this, the height of the blooming season, the cultivator will be daily amongst his plants. These will now be of large size, and if the blooms have been thinned out, lateral growths will continue to be formed, and must be pinched out with the finger and thumb. It is bad management to have an over large proportion of leaves to that of flowers, which the removal of the lateral growths tends to improve. Exhibitors must select the best flowers and shade them by drawing their stems through a slit in a board about 9 in. square; a 7-in. pot with a bit of potsherd placed over the hole answers well as a shade.

Hollyhocks.—Continue to take cuttings from eyes formed on the side growths, or from shoots thrown up from the base of the plants. If it be intended to save seeds, the decaying flowers should be removed before they injure the seed pods; fading flowers spoil the effect of the spike, and it is best to remove them before they have become unsightly.

Gladioli.—It is now almost too late to hybridise any of the flowers of these for seeding; but if any desirable sorts intended to be crossed did not flower sooner there can be no harm in setting the blooms. If October should be a fine month, warm and dry, some few seeds might be matured. Plants still throwing up their flower spikes should have sticks placed to them, and the hoe should be kept at work between the rows; the bulbs ripen better if this is done. Seedlings in pots should be watered cautiously; allow the soil to become dry before watering, but it is not well to dry it so much that the small plants are checked in their development. The seed pods should be gathered as they ripen and be placed in an airy room to dry.

Phloxes and Pentstemons.—It is a good time to put in cuttings of the last-named; the small succulent shoots are the best. They should be inserted in small pots, and they will strike roots in a few weeks if placed in hand-lights or in a cold frame behind a north wall. The flower spikes should be fastened to sticks as the first blooms open. They will be found to be very useful in a cut state. Cuttings of Phloxes may also be put in and managed in the same manner. As those in pots go out of bloom the stems should be cut over at once, and the pots placed out-of-doors on a hard bottom.

Pansies.—Cuttings of these may also be put in. Small slips with small roots attached to them can now be obtained from the centres of the old plants, and if pricked out in fine soil out-of-doors they will soon become established. They may be either put into boxes or pots, whichever the cultivator prefers. Plants in beds intended to bloom well in October should now be surface-dressed; all the flowers ought to be removed and the growths pegged down close to the ground. Sow seeds to produce plants that will flower from the end of April all through the season. Seeds may also be saved by gathering the pods and drying them in an airy room.

Tulips.—The ground for these should be prepared this month. Trench it 2 ft. deep at least, and mix some rotted manure with the soil. Prepare some fibrous turfy loam, place 3 in. or 4 in. of it on the surface of the beds, and in this the bulbs should be planted. Place some sharp river sand round each root at planting time, which should be in November.

Pinks.—If the ground be ready for these they may be planted out at once. The soil should be in good order, from being turned over several times. If this has not been done, better delay the planting a few weeks. It is a good plan to place some decayed turfy loam on the surface of the beds before putting out the plants.—J. DOUGLAS.

Wigandias, Ricinus, Cannas, Maize, and other fine-foliaged plants of gross feeding habits should be well supplied with manure water, and in sufficient quantities to soak the whole of the soil, as their principal feeding roots penetrate far down and derive little or no benefit from mere surface wetting. Autumnal gales may now be expected, and, in order to prevent injury occurring to such plants as the above, they should at once be securely staked and tied, or the force of wind, with the hold it has on such a mass of leaf surface, will soon commit sad havoc amongst them.

Indoor Plant Department.

Stoves.—Reduce the shading here to a minimum, but do not remove it altogether, for sometimes we get extremely bright weather even up to the end of the month, by which very much injury is done by scorching, especially as it is necessary now to use much less moisture in the atmosphere, as well as to admit more air, both of which render the foliage more liable to scorch. The object of the cultivator in this matter ought to be to just shade sufficiently to prevent injury, but no more, not even for a single hour. This is a point the importance of which I would urge, as so much depends upon the manner in which stove plants are treated in this respect during this and the following month, with a view to their flowering freely the ensuing season. From Allamandas, Clerodendrons, and Bougainvilleas gradually withhold water, allowing them to flag for a day or so before giving any, and then only give it in reduced quantities; by continuing this treatment the soil in the pots will gradually get to that (at this time of year) necessary condition as to moisture, that it contains just sufficient moisture to maintain the roots in health without inducing any disposition in the plants to form more wood. Stephanotis requires to be kept after this time comparatively dry; but, unlike the preceding plants, being evergreen, it will not answer if the soil gets too dry, as the leaves would suffer and drop off. Dipladenias should also be kept drier than when it is desirable to encourage active growth, yet not so dry as Stephanotis. Ixoras, again, must be kept at this season drier than when their growth is most active, but must never be allowed to get too dry, or they will suffer to an extent that will take the best part of a season to recover them. Nothing adds more to the good appearance of a stove than a few suspended baskets of such things as Hoya bella or the different varieties of *Aschmannthus*. Of the latter, *A. splendens* and *A. Boschianus* are most desirable plants, of graceful, drooping habit, brilliant, and free flowering, growing freely in an equal mixture of loam and peat, with sufficient sand to ensure porosity.

Azaleas.—The late-blooming plants will now be setting their flower buds, and should be no more shaded. The syringe should also be withheld, simply throwing a moderate amount of water about the floors and paths, at, say, four o'clock, when the house should be closed, allowing the temperature to rise by sun-heat, which is at once the most genial to the plants and the most economical. Continue this practice until the flower buds are up as large as small *Camellia* buds. If their inveterate enemy, the thrips, makes its appearance, give it no quarter; any delay in this matter entails a serious after expenditure of labour. Get all the plants, large and small, tied before they have quite completed their growth and the wood becomes hardened thoroughly, as, after this, they are too stiff to regain the natural position of their shoots after tying.

Solanum capsicastrum and **S. pseudo-capsicum** that were planted out-of-doors in spring in a warm, sunny position, although not so forward as they would have been had the weather been warm earlier, should now be lifted and potted, as it is necessary to get them established before the season gets too far advanced, or the berries will not colour so well, neither will the plants retain their foliage satisfactorily until the spring. Except in the case of large plants above the size that these Solanums can be grown to be propagated from cuttings or seeds in a single season, 6-in. pots will answer well, for if the roots can be got into them without much pressure they are sufficiently large. Soil in which Cucumbers have been grown will answer the purpose just as well as new loam. It will require sand enough added to it to keep it from getting impervious to the liberal quantities of water which these Solanums need. Put 1½ in. of cracks in the bottom of each pot with a little half-decomposed leaf-mould on the top; pot them moderately firm, and do not fill the pots too full. The day before lifting the plants they must be well soaked with water, which will prevent their roots from being so much broken in removal; take them up with a fork carefully. It will be necessary to shake a good deal of the soil from them to admit

of their going into pots of the size just named; as soon as they are potted they must be thoroughly soaked so as to make the soil quite moist; this advice may appear very different from that which is generally prescribed for most plants, but the nature of these Solanums is such that they will bear it with impunity; and if not done the leaves will flag, when they are certain to lose the deep green colour that adds so much to their appearance, to secure which and a greater quantity of berries, they are recommended to be thus planted out in preference to growing them in pots through the summer. If a pit or frame can be spared so as to keep them close with little air admitted and shaded from the sun until they have got established, that will be a suitable place for them. If they cannot be so treated, they must be placed at the north side of a wall or close hedge, so as to prevent the sun from shining upon them for three weeks, by which time they will have made new roots sufficient to support them. During this time sprinkle with water overhead every evening whilst the weather is dry. Examine closely in order to see that no aphides infest the leaves, for if only a few of these exist they will increase apace when taken indoors. If it be desirable that a portion of the stock should have their berries coloured early they ought to be placed in a little heat; about 50° in the night will soon give them their bright orange tint. The remainder under ordinary greenhouse warmth will form a succession. If managed in this way these most useful decorative plants can be had in better condition than by any other method. Nothing will bear confinement in a room better, or will be more suitable for the purpose when the berries are ripe.

Herbaceous Calceolarias should be pricked out in seed-pans as soon as they are large enough to handle; there are many good "strains" of these plants now in existence that are not nearly so delicate in constitution as those with more finely-formed flowers that were grown some years ago; those to which I allude make plenty of large leaves, are of a dwarf, compact habit, producing profuse heads of bloom, and are very desirable to grow; the principal points needing attention are to keep them scrupulously free from aphides, and to feed liberally with manure water in the spring when they are making active growth; they delight in rich open material from their first stage onwards. For this first pricking out sift the soil, and add to it one-fourth of fully decomposed manure and leaf-mould in equal parts and a sixth of sand; the pans used may be from 8 in. to 12 in. in diameter, with 1 in. of crocks in the bottom, and a little fibrous material over to keep the loose soil out of the drainage; on this put the prepared soil, pressing it moderately, but not too close, filling up the pans to within 1 in. of the top; put in the plants about 1½ in. apart, and sprinkle overhead when each pan is filled. Calceolarias are moisture-loving plants, and must never be allowed to get dry at the roots or be subjected to an over-dry atmosphere. Keep them near the roof of the pit or house in which they are placed during the autumn; when they require more room they must be potted off singly.

Hyacinths, Tulips, Crocuses, and Narcissi.—These should now be potted; it is not well to defer procuring them until the stocks are somewhat run through. Where any considerable quantity of forced flowers are required early, a good supply of Roman Hyacinths should be used. These are smaller than the ordinary type, but very handsome. They should at once be potted, putting five or six in a 7-in. pot. All the above varieties of bulbs ought to be potted as soon as they are obtained, as they will very shortly evince a disposition to grow, and the sooner they are in the soil under these circumstances the better. A few directions may be useful to those who have not had much to do with this class of plants. For Hyacinths 6-in. pots are the most convenient, and look the best. Ordinary loam, wherein is a moderate quantity of sand, leaf-soil, and rotten manure is the most suitable material in which to grow them. Put at the bottom of the pots ½ in. of broken crocks; on this place 1 in. of dry, rotten manure, and fill up to within ¼ in. of the rim, making the whole moderately firm; then take out of the centre as much of the soil as will allow three-fourths of the bulb going below the surface, pressing it firmly round on all sides. Narcissi require to be similarly dealt with. Three Tulips may go into each pot of the above size, placing the bulbs just below the surface. For Crocuses, half fill the pots with soil, pressing it firm; then put in half-a-dozen bulbs, and fill up with soil. The reason why Crocuses require to be potted deeper than the others is that each year they form a new corn, or bulb, on the top of the old one, the latter decaying; and if there was not a sufficient depth of soil over them, this natural process could not occur. When all are potted, plunge them out-of-doors, as close as the pots will stand, in a bed of coal ashes, covering them with 6 in. of the same material; and here allow them to remain until they have made a good quantity of roots.

Chrysanthemums that are planted out in the open ground with a view to layering the shoots and afterwards transferring them to pots for blooming should now be layered. When the soil of the site in which the plants are growing is of a loose, sandy character, they may be layered in it without any addition, but when it is of a strong, adhesive description, it will be necessary to use some purposely prepared. Such as has been employed in Cucumber or Melon beds will do, provided it has enough sand added to it and a little rotten manure or leaf-mould sifted; this should be laid in hills in the manner in which Carnations are treated for layering. The shoots must be bent down and the leaves stripped off at the place where they are intended to be layered, which may be a little below where the flowering growths branch out. Tongue the shoots, that is, split them longitudinally upwards for about 2 in., passing the knife half-way through them, and then bury the tongued part for about 8 in. of its length in a little hill of soil, already described, securing it with hooked pegs strong enough to keep it firm in its place; let the soil be regularly watered, and in a few weeks the shoots so treated will form a mass of roots, after which they may be severed just below where they are layered and potted. It is necessary, as has been stated, to have the soil of a light character, or the roots will get broken when taken up, in which case the blooms will suffer. By this method a very large quantity of flowers can be obtained from pots of a small size.

Indoor Fruit Department.

Peaches and Nectarinss.—Trees trained to wires or upon walls under glass should be examined as soon as the leaves are all cleared off; and, if it be found that scale has in any way affected their bark, measures should at once be taken to stamp out this pest. If the trees be thoroughly ripened, they may be pruned, taking care to save all natural spurs, leaving the best placed young wood, and cutting back only when three buds are discernible. Single buds are, as a rule, flower buds only; but the centre buds of the triplets are wood buds, and lead up the esp when growth commences. Laying the shoots in thickly is an evil which should be guarded against. With healthy, well-ripened trees, we never found it difficult to get a fruit to each square foot of surface. Cut out every particle of dead wood or decaying spurs, and, when this is done, commence the destruction of the scale. Get a quantity of warm water, and mix soft soap in it till it is frothy; then let careful hands, with short-haired brushes, commence at the trunk of the trees, and wash every part of the bark, both of old and young wood. Let the loosened branches hang suspended, so that the whole of the woodwork may be washed and the soapy water enter every crevice. We have used turpentine and other destructive agents for cleansing, but if the structures are to be painted, this washing is unnecessary. The washing of the trees may have to be repeated before forcing begins. All the surface soil inside the buildings may be taken away, and the trees kept cool and airy.

Figs may be washed in the same way as Peaches after any wood which is crowding the tree is cut away; when the leaves have fallen naturally off pot trees, they may be placed in a position where the sun will have full power on them; but depriving them of water will injure the trees materially. Crops, to ripen in November, may have a good soaking of manure water, the surface being kept loose and open afterwards.

Cucumbers may be planted when the plants are strong enough; rotted turves, mixed with decayed leaf mould, suits them well. If bottom-heat is supplied by hot-water pipes, there should be provision made to prevent the roots being scorched, as if the pipes come in contact with the soil, a dry unhealthy position will soon be occupied by the roots. Little soil may be given at first, but pieces of turf should be added as the roots appear.

Hardy Fruit.

Peach Borders.—Should there be dry weather, it will be necessary to apply water freely to outside Peach borders much later than they usually receive it; if this be not done, the leaves will suffer and fall off sooner than they ought to do, which in all cases has a prejudicial effect upon the strength of the trees, and on their bearing another year. The application of water to these trees will be most needed where any kind of vegetable crop is grown on the border, and which from the moisture it extracts from the soil renders the trees in a worse condition as to root moisture than where the border is unroppered; do not confine the application of water, as is too frequently done, merely to a few feet round the stem of the trees, where it is really least wanted, but apply it over the whole extent of the border occupied by the roots; keep all the shoots required for next year's bearing laid in close to the wall, a position in which they will get ripened much sooner than if left hanging loose; this is most necessary in late localities where there is a difficulty in getting the growth matured.

Kitchen Garden.

Potatoes.—Late crops should now at once be taken up, as after this time there is nothing gained by leaving them longer in the ground. Where considerable quantities are grown, it often becomes a difficult matter to find room for storing them without resorting to clamping; but, unless where unavoidable, this method of keeping them should never be practised, more especially in a season like the present, when disease has been so prevalent, rendering it necessary to go over them several times during the autumn to remove any that may be affected.

Planting Cabbages.—A good piece of ground, upon which to plant early Cabbages, should now be dug over. Those sown in July will, by this time, be large enough to plant out. It is not well to manure heavily at the time of preparing the ground; for, if much is put in for this crop, it has the effect of inducing over-luxuriant growth, which should be avoided. Although the Cabbage is very hardy, yet, if the plants are forced into rank growth, they are often cut off in severe winters; consequently, it is better at this season to plant on soils that have been manured well for some previous crop. Ground where Onions have been grown, and which by this time will be cleared, will, if simply dug over, answer all purposes. In planting at this season some distinction should be made in the different kinds; small-growing sorts, such as the Cocos-ant, may be put in 9 in. apart in the rows with intervals of 2 ft. between the rows. In the spring, as soon as they are at all fit for use, every other one can be taken out, leaving the remainder to develop more fully. Larger kinds, like Enfield Market, should be put in 1 ft. apart in the rows, in like manner taking out in the spring every alternate Cabbage; these larger growers should also have 2 ft. between the rows. When putting them out use a little soot and lime to each plant; for, although this autumn-planted crop is not liable to suffer through clubbing in the way that the spring and summer plantings do, still these have the effect of keeping away slugs. In planting all the Brassica family, amateur gardeners are apt to err in either not putting them in sufficiently deep, or to the other extreme of half burying the leaves. If the former mistake is made the wind blows them about in a way that does much mischief; and if too deep they do not do well. Whatever size the plants are they should be planted so that the bottom leaves will be on a level with the surface; this does away with the necessity for making the ridges too high in hoeing up. If the land is moderately dry it is a good plan to make with the hoe shallow trenches, 5 in. or 6 in. deep, planting in the bottom of these. The advantage of this is, that a portion of the soil in the so-formed intervening ridges can be drawn to support the plants before winter, and the remainder, thus a little elevated, acts as a protection from cutting, frosty winds, and in the spring can be put to the plants, still leaving them nearly on a level with the surface, thus enabling the whole of the roots to receive fuller benefit from rain than if placed on a high ridge that throws off the water. In ground that is insufficiently drained this plan will not answer for autumn planting, as the crop would be liable to suffer from too much wet. All the Cabbage family are surface-rooting, and do not push their roots down to any considerable depth, consequently, unless where the soil is extremely shallow, the above practice may with advantage be followed. For the summer crops this system can also be recommended, as it admits of the plants being earthed up sufficiently without a ridge of any consequence being formed, and which, for the reason above stated, is better absent. When the space intended for the principal crop is filled, it is advisable to prepare a small corner in which to put some plants for a reserve; these may be pricked out about 6 in. apart, and will come in for filling up any gaps that may occur through the effects of a severe winter.

Cauliflowers that were sown in the middle of last month will now be ready to prick out, and those intended for early use next spring, and which are to be protected during the winter by hand-lights, ought to be pricked out in them at once. Double or even treble the number of plants intended to stand may be planted in them and drawn out as growth progresses, and transplanted in other favourable positions as soon as the severity of winter is past. Of course, the covers of the hand-lights will not be required for use till there is danger of injury from frost. A batch may also be pricked out at the bottom of a south wall and left to stand the winter in that position.

Lettuces.—Make a last sowing in the open air of Lettuces. The Tom Thumb is a beautiful little Cabbage Lettuce for sowing now for framework by-and-by. It is very hardy, occupies but little space, and turns in rapidly. The brown Cos should also be sown now for spring planting. A last sowing of Endive may also be made now on a dry, warm border.

Extracts from my Diary.

September 16.—Sowing Red and White Turnip Radishes in cold pits. Pricking out Cauliflowers and Red Cabbage plants. Clearing

off a piece of Turnips, and heavily manuring and digging the ground for Coleworts. Clearing out Melons from pits, adding a little more soil and manure, and planting them with dwarf Beans for winter bearing. Tying up Lettuces and covering up Endive to blanch. Cutting back all young growth on Tomatoes, and exposing the unripe fruit to the sun. Turning a large heap of manure, and adding a little salt and soot to it for general use. Clearing off the surface of early Vine border, and giving it a top-dressing of loam, horse manure, and oal ashes.

Sept. 17.—Potting Dutch bulbs in a mixture of loam, manure, charcoal, and sand. Filling up all spare frames with Lettuce and Endive. Dressing Early Black Hamburgh Vines with composition to kill insects. Erecting a temporary frame over pot Strawberries on which to place spare lights to throw off heavy rains. Rolling newly-made gravel walks. Looking over all young fruit trees, and applying new ties and stakes where necessary. Gathering Hawthornden, Cellini, and Golden Pippin Apples; also a few Golden Drop Plums.

Sept. 18.—Potting off variegated Pelargoniums. Putting in another batch of Osborn's forcing French Beans and Ashleaf Kidney Potatoes that have been previously started in pots for forcing. Roping Onions. Washing woodwork in houses, and, when wet, cutting shreds and making labels and flower-sticks.

Sept. 19.—Putting in cuttings of Cerastium under hand-lights. Potting off Centaurea candidissima as soon as rooted; also putting a few Primulas and Cinerarias into their flowering pots for early blooming. Weeding and thinning out all overgrown Parsley. Hoeing amongst all late-planted Endive and Lettuce. Putting bay-bands round Cardoons and earthing them up.

Sept. 20.—Putting in Tomato cuttings to furnish plants for early fruiting. Shaking out and repotting old plants of tricolor Pelargoniums. Thinning out Endive and Lettuce. Manuring and roughly digging the ground previously occupied by Cauliflowers. Weeding and cutting the runners off pot Strawberries. Preparing frames for Cauliflower plants by putting a thick layer of green turf Grass side downwards, and then 1 in. of good mould in which to prick out the plants, which are placed 6 in. apart each way. Gathering Berberries, Reine Claude de Bayay, and Cos's Golden Drop Plums.

Sept. 21.—Putting in Tom Thumb and Indian-yellow Pelargoniums in large store boxes and pots. Earthing up Celery when the soil is dry. Thinning autumn-sown Carrots and Turnips. Weeding Box edgings. Gathering Gansel's Bergamot, Citron de Carmes, and Dunmore Seedling Peare, and Ribston Pippin Apple. Fruit in use for dessert: Pines, Grapes, Melons, Peaches, Nectarines, Figs, Plums, Peare, and Apples.—W. G. P., Dorset.

The Wild Garden in America.—One of the most interesting features of this place (Brookline) was the wild garden, that is, a wooded dell all growing over with Vines, shrubs, Ferns, and the like, the most enjoyable part of the garden in spring. In this place are naturalised hosts of Crocuses, Daffodils, Joaquims, Squills, Tulips, Irises, English Primroses, Phloxes, and many other flowers that come up and blossom in perfection in spring, while their location is open and sunny, owing to leafless trees growing overhead. During the summer time they are sheltered, shaded, and undisturbed, just as they prefer to be. It is not the winter's severity so much as the summer's sun that, in this country, proves fatal to so many European woodland plants. For instance, English Primroses growing in a shady rocky here live throughout the winter and blossom splendidly in spring; but in the open garden border they invariably die.—"Moore's Rural."

TO THE FINEST OF FRUITS.

(Sung in August by a Sub-Editor.)

Let others praise the mellow Peach,
The luscious Grape, the golden Pie;
But oh! within my modest reach,
I know a fruit that's more divine.
'Mid fragrant groves of Orange flower
Let bridegroom roam! But weave my crown
Of Gooseberries that, sweet or sour,
Bloom when the world is out of town!
When silence holds the Lady's Mile,
And daily sheets, grown empty too,
Hail, with a glad and greeting smile,
The little earthquake from Peru—
The avalanche—the hot pursuit
Of luggage lost—all things that bore!
Say, what can match the cheery fruit
That blooms till Town is full once more?

—"Punch."

GARDEN BOTANY.

(Continued from p. 229.)

The Fruit.

DEFINITION.—As understood by most botanists, the fruit of a plant in a botanical sense is much the same as the popular conception, with the addition that any seed-vessel, edible or otherwise, is a fruit. Generally speaking, the fruit affords characters by which the order, genus, and sometimes even species of a plant may be determined; hence the importance of comprehending the nature of the principal modifications. The fruit is the mature pistil of a flower and whatever has grown around it, as a Pea pod or an Apple; or it is the mature pistils of a number of flowers in a state of cohesion, as the Pine-apple; that is to say, in the Apple we have an example of a fleshy fruit the product of one flower; in the Pine-apple an example of a fruit consisting of the consolidated fleshy pistils of a number of flowers. When the mature pistils are free (separate) from each other, although they may be closely appressed, as in a cluster of Grapes, each berry is a fruit. The terms superior and inferior, apocarpous and syncarpous have the same signification as when applied to the immature pistil. The wall or shell of the fruit, or whatsoever encloses the seed or seeds, is the pericarp, which dehisces (bursts or splits open) in some way to free the seeds, as the seed vessels of Poppy, Wallflower,

THE BERRY.—This term is popularly applied to fruits of the most diverse nature and structure, but in its more restricted botanical signification a berry is a fruit in which the whole substance of the pericarp, excepting the outer skin, is fleshy. Occasionally the walls of the cell or cells (for a berry may have one or more cells) containing the seed or seeds is of a different texture, though never stony. Sometimes the berried fruit resulting from a pistil having an ovary with more than one cell becomes one-celled by the abortion or obliteration of the other cells. The Gooseberry and Currant (fig. 564) are familiar examples of berried fruits. These fruits, as well as that of the

Fig. 567.—Fruit (drupe) of Cherry.

Fig. 568.—Section of a Cherry, showing the solitary seed within the stony endocarp.

Indian Fig (*Opuntia vulgaris*—figs. 565 and 566), are inferior in the botanical signification of the word, and the seeds are embedded in the pulp. The fruit of the Barberry is also a true berry, and likewise the Grape, though both of them result from superior ovaries. The Melon, Cucumber, Gourd, and indeed nearly all the members of the Cucurbitaceae, have fruits of the berry type, though the term pepo has been proposed for the fruits of this family. In its nature a Melon is as much a berry as a Gooseberry, and clashes only in size with the general notion of a berry, but the Red Bryony (*Bryonia dioica*), the only member of the same family native of this country, has a genuine berried fruit not larger than a Black Currant. We may conclude this paragraph by observing that the Strawberry, Raspberry, Blackberry, Mulberry, &c., are fruits belonging to wholly different types from the berry, and their nature is explained under other heads.

THE DRUPE.—The chief distinction between a berry and a drupe is that the inner layers of the pericarp of the latter become very much hardened, so that after the fleshy part of the fruit has been removed the seed still remains enclosed in a shell. To be more explicit, the term is applied to the stone fruits of gardeners, as well as to some others described below. What is commonly called the kernel is the seed, and the shell or stone a part of the pericarp. When the pericarp is thus differentiated into distinct layers the stone is termed the endo-

Fig. 565.—Fruit (berry) of *Opuntia vulgaris*.

Fig. 566.—Section of the fruit (berry) of *Opuntia vulgaris*, showing the numerous seeds immersed in a fleshy pulp.

Antirrhinum, &c.; or it remains closed until it decays, as the Apple, Gooseberry, &c.

CLASSIFICATION OF FRUITS.—It is no easy matter to establish a sound and intelligible classification of fruits, inasmuch as many pistils which are identical in nature and almost alike in a young stage develop into very dissimilar fruits. Furthermore, external forms are characters of only secondary importance. Some writers have distinguished nearly fifty different kinds of fruits by special names, but many of these modifications are restricted to a single family, and in a few cases to a single genus. Such a classification, therefore, is unnecessarily cumbersome; indeed, very few distinctive terms are now employed in descriptive botany, it being more convenient to use as few as possible and describe their modifications where necessary. Fruits may be primarily divided into simple (proceeding from one flower) and collective (proceeding from two or more flowers). It is understood that a fruit is simple in all cases where the contrary is not stated.

SIMPLE FRUITS.—These present a great variety in external form, size, and other particulars, but, with few exceptions, they may be referred to one or the other of the following types. They may be subdivided into dry and fleshy fruits according as the pericarp of the ripe fruit is dry or fleshy.

SIMPLE FRUITS HAVING A FLESHY PERICARP.—This subdivision includes many familiar fruits, familiar because they are edible. They may be referred, excluding a few modifications peculiar to certain species or small groups of species, to three or four types, all of which do not split open to release the seeds, or what is called indehiscent.

Fig. 569.—Fruit (drupe) of *Cornus mas*.

Fig. 570.—Transverse section of two-celled two-seeded drupe of *Cornus mas*.

carp, the fleshy portion mesocarp, and the outer skin epicarp. To this category belong the Peach, Almond, Apricot, Plum, Cherry, &c., each and all of these having normally one-celled and one-seeded fruits (see figs. 567 and 568). The Walnut, too, is a drupe, though the fleshy covering is removed before the fruit is brought to the table, except when pickled, and in this state the true nature of the fruit can be recognised. The Cornel (figs. 569 and 570) has a drupaceous fruit containing two stones, and the Medlar (figs. 572 and 573) is a fleshy fruit containing five stones. *Cratagus Oxyacantha*, the Whitethorn, has a similar, though smaller, fruit. The Raspberry (fig. 574) has an apocarpous pistil consisting of numerous carpels, each

of which becomes a small drupe, and the ripe fruit is a cluster of drupes crowded upon a cylindrical receptacle. It is of the same nature in the Blackberry and its allies, and totally different from the Mulberry, which is described under "collective" fruits. Drupes, or drupels as they are sometimes called, of an

Fig. 571.—Fruit of Medlar.

Fig. 572.—Fruit of Medlar, with a part of the flesh removed to show the five stones.

apocarpous pistil differ only in having a fleshy mesocarp from the achenes of some apocarpous pistils (see the paragraph on the achene).

THE POME.—This can only be regarded as a modification of a drupaceous fruit, differing from a true drupe in the endocarp, or inner layer of the pericarp, being leathery or cartilaginous,

Fig. 573.—Transverse section of five-celled five-seeded drupe of Medlar.

Fig. 574.—Fruit of Raspberry, consisting of a cluster of one seeded fleshy drupels.

not of a woody or bony consistence: we need only name the Apple, Pear, and Quince.

W. B. HEMSLEY.

Liberian Coffee.—The transplantation of this plant from its native soil to Ceylon and other countries has been attended with such good results, that the tree is likely to supersede the *Coffea arabica*, the species now usually cultivated. Of little importance in its native country, the Liberian Coffee becomes astonishingly productive when placed in the best plantations alongside or very close to its better-known rival; and it has this peculiarity, that, whereas the Arabian Coffee flourishes at an altitude of from 2000 ft. to 6000 ft. above the sea-level, the Liberian variety thrives at from sea-level to an elevation of 1000 ft. It is not certain, however, that it cannot be cultivated at a considerably greater altitude, in which case its value will be greatly enhanced. On an estate in Ceylon, where the African plant has been tested, the enormous crop of two tons of Coffee to an acre has been yielded. The plant is being tested in several other countries beside Ceylon. In Brazil, Venezuela, South Australia, Guatemala, Queensland, Fiji, Jamaica, and other lands the seeds have been planted or young trees introduced. It is curious that hitherto England has been the principal centre of its propagation. Large numbers of seedlings and many thousands of seeds have been distributed from London, where the tree has been cultivated under artificial heat. The seeds travel well if packed in damp Moss. One important feature presented by the Liberian Coffee is its power of resisting the leaf disease, which is so fatal to the planters' hopes in Ceylon; so far, at least, the plants grown in that colony have shown no signs of contracting the disease. There is little doubt that the Liberian Coffee is destined to take an important place in the list of important vegetable products, and that it will be the means of introducing a valuable industry into countries which would otherwise not have thought of entering into competition with the Coffee districts of South America and the East.—"Colonies and India."

Bitter Cucumbers.—A writer in the "Monatschrift für Pomologie" states that the occasional bitter taste of Cucumbers is entirely due to immoderately slow growth. It may readily be prevented, therefore, by judicious watering when the slowness is dependent on drought, but when cold is the origin of the mischief no means of prevention has as yet been discovered.

THE KITCHEN GARDEN:

REPORT ON SAVOYS GROWN AT CHISWICK.

The Savoy (*Brassica oleracea bullata major*).—A species of Cabbage, distinguished by having the leaves blistered or curled. It is the Chou de Milan of the French, but differs from the Chou de Milan of the English. A collection of all the known varieties was secured from various seedsmen. These on examination by the committee were arranged into three classes as follows:—

1. **EARLY OR AUTUMN SAVOYS.**—Early Dwarf Vienna, Early Joulia, King Koffee, Little Pixie, Tom Thumb, Tours, Ulm, and Vienna.
 2. **SECOND EARLY OR MID-SEASON.**—Dwarf Green Curled, Dwarf Early, Golden Savoy, Golden Globe, Golden Yellow, Green Globe, Large Green Curled, and Sugar Loaf.
 3. **LATE OR WINTER.**—Cape, Drumhead, Des Vertas, De Pontoise, Impériale, Limay, Norwegian, and the following
- BASTARD VARIETIES.**—Chou de Milan Suisse, Feather Stemmed, and Sprouting Ulm.

The varieties named being considered distinct are here described; and correct photographs of most of them have been secured for future comparison. The variation in appearance of different stocks of the same variety was in some cases very remarkable, and where very decided these have been given as distinct. But very few of the stocks received were so pure but that more than one variety could have been selected. The classification arrived at was determined by the average appearance.

CAPE (Nutting & Sons; Carter & Co.).—Plant of splendid habit, from 14 in. to 16 in. high, and from 2 ft. to 2½ ft. in diameter, with a short stem. Leaves rather small for size of plant, of a bluish-green colour, faintly tinged with brown on the outer edges, coarsely curled and leathery. Heart roundish, from 6 in. to 7 in. in diameter, very firm and solid. A late and very hardy sort, but of coarse and inferior quality.

DU CAP (Vilmorin & Co.).—A very curled variety of the preceding.

CHOU DE MILAN SUISSE (Carter & Co.).—This is properly a Broccolo of strong growth, forming no heart; leaves somewhat curled like the Savoy, very hardy, and useful in severe winters.

COURT HÂTIF (Vilmorin & Co.).—Plant dwarf, height 10 in., the heads almost resting on the ground, diameter from 22 in. to 24 in. Leaves large, spreading, rounded, of a light green colour, very curled near to the heart; hearts of medium size, flattened, from 6 in. to 8 in. in diameter; tolerably firm and solid, of a pale green colour. A very early sort of the mid-season section, but soon decays. Inferior.

COMMON SAVOY (Carter & Co.).—See Green Globe.

CHOU TRES FRIES DU CAP (Leroy).—See Cape.

DE PONTOISE (Vilmorin & Co.).—Similar to the Vertus, but much coarser and hardier.

DWARF ULM.—See Ulm.

DWARF EARLY DRUMHEAD.—See Court Hâtif.

DWARF GREEN CURLED.—Plant from 12 in. to 14 in. high, with a short stem, and a diameter of 24 in. Leaves spreading, of medium size, finely curled throughout, of a pale green colour. Hearts rounded, at times a little pointed, from 6 in. to 8 in. in diameter, solid, very finely curled, and of a beautiful light green colour. An exceedingly pretty Savoy, and stands the winter well. The best variety for general use.

DES VERTUS.—Plant almost resting on the ground, from 12 in. to 15 in. high, and from 2 ft. to 3 ft. across. Leaves spreading, large, rounded, of a light glaucous green colour, coarsely curled. Heads flattened, from 10 in. to 11 in. in diameter, very firm and solid, of a light green colour, the outer edges of the leaves tinged with brown. This variety hearts early, growing frequently to a large size, and having few outer leaves, does not stand severe frost so well as the ordinary Drumhead. Fine quality.

DRUMHEAD.—Plant almost resting on the ground, from 14 in. to 15 in. high, and from 2 ft. to 2½ ft. in diameter. Leaves large, broad spreading, coarsely and slightly curled, of a deep green colour, with faint tinges of brown on some. Hearts large, from 8 in. to 10 in. or 12 in. in diameter, not much curled, very firm and solid. A very fine Savoy for winter use; very hardy.

DRUMHEAD (Veitah).—A very curled selection of finer quality, but not so hardy as the ordinary form.

DWARF DRUMHEAD.—See Drumhead.

EARLY DWARF ULM (Dippé Bros.).—See Ulm.

EARLY DWARF VIENNA.—See Vienna (Stuart & Mein).

EARLY DWARF VIENNA (Benary).—Plant of very small, close, compact growth, smaller than the *Ulm*, with very finely curled leaves of a very pale green colour. Hearts small, roundish ovate, from 3 in. to 4 in. in diameter, very close and firm, fleshy, crisp, and tender. Comes early into use. This is the finest and most curled variety of any.

EARLIEST SMALLEST VIENNA (Benary).—See *Little Pixie*.

EARLY JOULIN (Vilmorin & Co.).—Plant small, of close, compact growth; height from 9 in. to 12 in. with a short stem, and from 20 in. to 24 in. in diameter. Leaves of a very deep green colour, and very coarsely curled, giving it a very distinct appearance. Hearts small, roundish ovate, much but coarsely curled, very firm and solid, crisp and fleshy. Comes early into use. Inferior.

EARLY LIMAY.—See *Limay*.

EARLY VIENNA.—See *Vienna*.

FEATHER STEMMED (Carter & Co.).—Plant partaking of the character of *Brussels Sprouts*, the stem being covered with half open sprouts, and having a small head, like a *savoy*. Leaves much curled. Worthless.

GREEN CURLED (Nutting & Sons).—see *Dwarf Green Curled*.

GREEN GLOBE (Vilmorin & Co.).—Plant of low spreading growth, height 12 in., with a diameter of 24 in. Leaves roundish, rather coarsely curled, of a dark green colour. Hearts roundish or flattened, from 7 in. to 8 in. in diameter, very firm and solid. A mid-season variety. Good stock.

GOLDEN SAVOY (Vilmorin & Co.).—Plant from 20 in. to 24 in. high, and from 2 ft. to 3 ft. in diameter, somewhat spreading. The outer leaves pale green, much curled. The hearts large, rather loose, conical, about 7 in. in diameter, of a deep golden colour; very handsome and ornamental, of excellent quality.

GOLDEN GLOBE (Nutting; Carter; Minier & Co.).—A dwarfier form of the preceding, forming round and more solid hearts.

GOLDEN YELLOW (Benary).—A very fine dwarf form of the preceding. Leaves finely curled. Hearts roundish ovate, about 6 in. in diameter; very firm and solid, of a beautiful golden yellow. This variety hearts early, and then opens out in mild weather, becoming very ornamental.

IMPERIALE (Carter & Co.).—See *Des Vertus*.

KING KOFFEE (Harrison & Sons).—A very finely curled selection of the *Vienna*. Larger than the *Early Dwarf Vienna* of Benary.

LARGE VERTUS DRUMHEAD (Vilmorin & Co.).—See *Des Vertus*.

LARGE GREEN CURLED (Minier & Co.).—Plant from 17 in. to 18 in. high, with a stem of about 6 in. Hearts somewhat conical in shape, about 6 in. in diameter, moderately firm and solid, and finely curled. This may be termed a tall growing variety of the *Dwarf Green Curled*, and inferior.

LARGE LATE ERFURT (Benary).—See *Green Globe*.

LARGE LATE VERTUS DRUMHEAD (Vilmorin & Co.).—See *Des Vertus*.—"Journal of the Royal Horticultural Society."

ASPARAGUS FROM SEED WITHOUT TRANSPLANTING.

As is well known, the usual way of getting up *Asparagus* is by sowing seed and afterwards transplanting the crowns. In all works on kitchen gardening this plan, and no other, so far as we are aware, is recommended. That the plan succeeds well enough, when managed skilfully and carried out under favourable conditions, there can be no doubt; but it is also true that transplanting throws the plants back considerably, and that it is often the cause of great losses amongst the plants, thereby causing much loss of time in filling the beds. *Asparagus* is one of the most troublesome subjects to transplant that the cultivator has to deal with. Seeds grow freely enough, and there is never any difficulty in raising young plants; but moving from the seed bed to the permanent bed is a very different matter, particularly when the plants have to be transported any distance—as, for example, when they come from the nursery, where they are not always so carefully lifted as they should be. Several plans have been suggested to prevent losses in transplanting, and one of the best is to move the plants just when they begin to grow, and not before, as is frequently done. Whichever plan is adopted, however, there are sure to be losses, causing blanks in the beds, and which have to be filled up the following season.

By sowing the seed where the plants are to remain, however, and simply thinning them out to the proper distances apart, all trouble and losses are avoided. Perhaps a little more seed is used at first, and a little more space occupied for the first year or two; but these considerations are nothing compared with the advantages obtained.

There are other objections that might possibly be offered to the plan, but they are not worth considering. It is well known that, by transplanting, the plants that grow lose a year or more, owing to the check they receive. The first year their growth is usually as weak or weaker than it was the year previous in the seed bed, where, had they remained, it would have been increasing in strength, and the plants would have yielded a crop proportionally earlier. To sow seed to transplant when the seedlings are two years old or more, and afterwards wait for four or five years longer for a crop, is a long while, when perhaps a third of the time might be saved by sowing seed only, as has been recommended. A few years ago the writer was asked by a gentleman to go and see a plantation of *Asparagus* which he had made some distance from his own place, because the situation and soil were favourable—a market gardener contracting to look after the plantation, under the supervision of a friend of the gentleman's. About an acre of good ground was inclosed, great quantities of manure applied to it, including many tons of bones, and the whole was trenched over 3 ft. deep. At the proper season young plants were procured from the nursery and the beds planted. It happened to be rather a dry time, and the plants were nothing the better for their journey from the nursery, and, though as carefully and as quickly got into the ground as possible, about one-third of the crop perished during the summer. The second year the blanks were made up again from the nursery, and again a large proportion died, but not so many. It was in the autumn of the same year that we visited the beds; the gentleman was anxious to have them in good yielding condition as soon as possible, and also to have plants for forcing. We suggested that the spaces in the rows should be ready where possible, and sown with seed, and that the remainder of the ground should be laid out in beds and also sown. This was done, and the following autumn there were no blanks on the ground, and by the third year the seedling plants were about as good as those which were several years older, and that had come from the nursery. The old market gardener received our suggestions about seedling beds rather contemptuously at first, but he acknowledged in the end that the plan answered well. This, however, was not the only example of seedling plantations we had seen, for we had learned the plan in an extensive Scotch garden, where it was found to answer, and was carried out on a considerable scale. In a large quarter there, not one blank was to be found, and at the end of the third year, thanks to timely thinning and subsequent good culture, the plants were as fine and strong as we have seen transplanted ones at the end of five years or more from the time of sowing. Beds for seedling plantations may be made in the usual way, either raised or sunk according to circumstances, and afterwards dressed and cultivated in the ordinary manner.—"Field."

KITCHEN GARDENING IN GREECE.

LIKE all other branches of horticulture, kitchen gardening has made great progress in Greece during the last few years, and in the Athens vegetable and fruit market we meet with as large and as fine a display of salads, Artichokes, Tomatoes, Aubergines, Bamias (*Hibiscus esculentus*), Peas, Beans, and other green material as is to be found in the larger cities of Western Europe. The modern Athenian costermonger and his attendant donkey are as great institutions in the city of the *Violet Crown* as they are in London, and in the early morning our streets resound with similar cries to those that are heard in your own smoky city, but in language differing but little from that used in the days of *Thucydides*. Fruit and vegetables here are sold by the *oke* (2.82 lb. English), an old Turkish weight still used throughout Greece, at a cheap rate. I have already described the numerous wild vegetables, such as *Chioory*, *Sowthrift*, &c., which are sold in the streets, as well as the beautiful floral displays made by our flower-sellers almost throughout the year. How would some of our lovers of flowers like to have the privilege of buying a huge bouquet of *Lilies*, *Roses*, *Violets*, and *Hyacinths* in mid-December for as many pence as they would give shillings in England, or a large bunch of *Violets* for less than a penny on Christmas Day?

Fruit growing, too, is progressing, thousands of new subjects of every description being planted every year. *Cherries*, *Apricots*, *Peaches*, *Pears*, &c., are all good and cheap, as may be seen from the following price list of the best quality of fruit, which is chiefly grown at *Kermelonea*, outside Athens proper: *Pears*, 1½d. to 2d. per *oke*; *Water Melons*, 1d. to 1½d.; *Cherries*, 3½d. to 4½d.; *Morello ditto*, 4½d. to 5½d.; *Apricots*, 2d. to 3d.; *Peaches*, 3d. to 4d.; *choice Grapes*, 2d. to 3d.; *Pomegranates*, 1½d. to 2d. The best *Pears* are grown in the island of *Skupeloo*, and fetch from 3½d. to 4½d. per *oke*. Greek gardeners, I am happy to say, are doing their best to profit by the privileges which they enjoy in this beautiful home of the sun.

X. LANDERER.

Athens.

Potatoes on Waite Heaps.—Two years ago I cleaned out a pond in which the small stream flowing through it had left a large quantity of alluvial deposit. This was shot into a meadow close at hand, and formed a heap about 14 rods in area. This I planted in spring with Irish Rook Potatoes, 3 ft. apart every way. The crop which we raised last week quite realised my expectations, eight bags (160 lb.) of prime tubers coming to the scale. It is worthy of remark that they were almost entirely free from disease, while Potatoes in the kitchen garden adjacent were much affected by it. Might not many of the waste heaps which we constantly see about the country be thus advantageously utilised?—W. J. FOSTER, *Dene Court, omersetshire.*

Sharpe's Invincible Pea.—In my trial of new Peas this season I find this to be an excellent and distinct Pea. I have grown it side by side with Marvel, Dr. McLean, Criterion, and others, all excellent Peas, and I consider it to be second to none of them. It is a second crop Pea; sown April 12, it came into flower on June 20, and was gathered July 1. The pods, which are in pairs, each contain from nine to eleven Peas of a beautiful green colour. It is very productive and excellent in flavour. Its height is from 2½ ft. to 3 ft.—DAVID LUMSDEN, *Bloxham Hall.*

Mushroom Beds.—The best season for making up these is now at hand, and when a good supply of fresh stable manure is at command it should be carefully shaken over, and any dry portions thoroughly moistened, adding a good quantity of fresh turfy loam as the work progresses. The loam will moderate the heat and make the bed last longer than it otherwise would do, as the violent heating to which the manure is sometimes exposed drives off the elements most essential for the growth of the Mushrooms, and hastens the decay of the manure, thus necessarily shortening the season of production. Beds made up firmly of this mixture seldom heat too strongly, and they may be spawned almost immediately. As soon as the spawn begins to run a good coating of new loamy soil, of a rather adhesive texture, should be sifted fine and applied as a covering, beating it down as firmly as the back of a spade can make it. Beds made in this manner in situations where a moist intermediate temperature can be commanded have continued to supply abundance of Mushrooms for a long period.—J. G.

Jefferies' Little Queen Lettuce.—I can fully endorse all Dr. Roden says (p. 148) respecting this Lettuce. I have grown it this year for the first time, and I must say that it is superior to any other Lettuce for summer work. I gave it a fair trial along with a very superior strain of Paris Cos, which I have had for several years, and which I thought could not be surpassed until I compared it with Little Queen. The two sorts were sown on three occasions under precisely similar conditions; their after treatment was also similar, and the result in each case was that the Little Queen was superior to the Paris Cos. At first I thought it slow in growth, but when I pulled one up, its firmness, weight, crispness, and good flavour convinced me that Paris Cos was eclipsed, although larger and much more showy looking. If all new introductions were to be tested by some standard sort, as in this case, much disappointment would be avoided.—J. GADD, *Thorndon.*

Crowbar-planted Cabbages.—I have not the number of THE GARDEN to which Mr. Gilbert (Vol. XIII, p. 407) refers, but I do not remember having condemned the crowbar system of planting either Cabbage or any other of the Brassica family. I remember, however, having questioned the advisability of extending the practice to early Potatoes and similar crops. I have for years planted Broccoli and winter greens on Mr. Gilbert's system.—J. GROOM.

Cucumbers and their Use in the East.—One of the most favourite vegetables in the East of Europe is the common Cucumber (*Cucumis sativa*), or Anguria, as it is called in Greece and Turkey. It is sometimes eaten as salad with oil and vinegar, but more often with salt alone, and, with bread, often forms the evening meal of the Greek or Turkish labourer, with a few Tomatoes or a bunch of Grapes as the second course. Cucumbers also play an important part at the tables of the rich, and are often eaten at dessert with fruit. In the month of April, when they are scarce, they cost in the market from 2d. to 3d., but late in June and July the Athens costermonger does a thriving trade in them at a halfpenny apiece for the largest and best. The peel is much used as a cure for headache, and is bound on the forehead with a handkerchief. There is also a peculiar superstition that if a piece of the peel of the first Cucumber eaten is bound round the head the person will be free from fever during the whole of the year. The ancient Greeks called the Cucumber Sikya, but the moderns use the Turkish word Angouria. The Cucumber must be eaten when it is young and fresh, otherwise it is apt to be unwholesome, and the ancient Greeks had a proverb to the effect that Cucumbers produce illness, except eaten with strong wine, but this saying, like many others, is not borne out by fact.—X. LANDREER, *Athens.*

PROPAGATING.

MIKANIA SCANDENS VARIEGATA.—This beautiful climber may be readily increased by means of cuttings either made of the tops, as shown in fig. 1, or single eyes, as seen in fig. 2. The soil usually used for soft-wooded plants will suit the Mikania admirably. Insert the cuttings, sprinkle them over with a fine-rosed watering pot, and place them in the cutting box on bottom-heat, when they will emit roots in a fortnight. They must be shaded from sunlight, as they very soon flag, and if too much moisture be given overhead, it is liable to affect injuriously the tender parts of the foliage. The best plan is to

Fig. 1.

Fig. 2.

Cuttings of *Mikania scandens variegata*.

tilt the glasses or lights after watering for a couple of hours, an operation which should always be done early in the morning.

H. H.

LAW.

INJURY TO VEGETATION CAUSED BY CHEMICAL WORKS.—The plaintiffs in the case of *Brooke v. Wigg*, recently before Vice-Chancellor Sir James Bacon, in the Chancery division of the High Court of Justice, Sir Richard Brooke and his eldest son, are owners of Norton Priory estate in Cheshire, and the Cherdley estate in Lancashire, the former consisting of about 5600 acres, and the latter of 1200 acres, and the object of the suit was to restrain the defendants, who were owners of a manufactory which had originally been erected for the manufacture of creosote and pitch, but was now used as alkali works, from damaging the estates and crops thereon. The plaintiffs complained that in addition to the manufacture of alkali, the defendants had carried on vitriol, copper, soda, and other works, and that the effect of the fumes from such works was deadly to the vegetation, and generally destructive to the plaintiffs' property. It was also said that the defendants could have prevented this result by the use of proper means of condensation. The principal defence of the defendants was that besides their own works there were numerous other works for the manufacture of alkali and similar substances, which had been in operation for more than twenty years without any complaint or interruption on the plaintiffs' part, and that much of the damage was caused by these other works. They contended that they had used the best processes known for condensing the vapours, under the inspection of the Government. They admitted that deleterious vapours had escaped from their works in rare and accidental circumstances, but they denied that such damage was continuous. The trial occupied a great many days and a great quantity of evidence was given on the plaintiffs' part to prove that on account of the proximity of the defendants' works to the Norton Priory estate the greater part of the damage caused to that estate was due to the defendants' works, as they were within a mile of the estate, while the other works at Widnes and Runcorn were at a much greater distance. Vice-Chancellor Bacon said that every man was entitled to the free and uninterrupted enjoyment of his own property, and any interference with such enjoyment was a wrong for which the law gave a remedy. In the special circumstances of this case it was necessary for the plaintiffs to bring home acts of damage to the special defendants whom they had selected for their attack. The evidence on both sides had been very voluminous, and much time had been necessarily expended in cross-examination; and in his opinion the result of the evidence was to establish the deleterious nature of the vapours complained of, and to bring home a considerable part of the damage done to the plaintiffs' property to the defendants' works. The defendants had proved by their evidence that large quantities of similar vapours had come from other works, similar to those of the defendants, at Widnes, and for a period previous to the

erection of the defendants' works, and they had brought witnesses who said that the damage done by the defendants' works could not be distinguished from that done by the numerous surrounding works of the district. Against the theories and opinions of such witnesses he had to set the positive statements of the witnesses of the plaintiffs, who had with their own eyes seen the vapours from the defendants' works settle on the property of the plaintiffs. If they had also suffered from other manufactories, that was no reason why they should suffer more from the defendants' works. Therefore, he held that the plaintiffs were entitled to an injunction to restrain the defendants from conducting their manufacture to the injury of the plaintiffs; but, as it would not be possible to distinguish the damage done to the plaintiffs by the defendants' works from that done by other works, he should make no order for an inquiry as to damage.

ANSWERS TO CORRESPONDENTS.

The First White Fuchsia.—In THE GARDEN of July 27 (p. 98) I saw an enquiry about various Fuchsias, one of which was Venus Victrix. Mr. Cripps, of Tunbridge Wells, has kindly given me the date of its purchase by him. Venus Victrix was the very first white Fuchsia ever brought out and the parent of all the others. It was raised by John Gulliver, gardener to the Rev. W. Smith Marriott, of Horsmonden, Kent, and was bought from him by Mr. Cripps in 1841.—W. MARRIOTT, *Down House, Blandford.*

The Crapè Myrtle.—The enclosed has been given to me as the flower of the Crapè Myrtle. It came from New Orleans. Can you tell me what the real name of the plant is?—KATE RILEY, *Southport.* [The red-flowered greenhouse shrub which you have sent is *Lagerstroemia indica*, a native of the East Indies.]

Prince Albert Pine.—This, I believe, was raised in the same batch of seedlings as Black Prince by Mr. Foden, then gardener to Mr. Entwistle, The Foxholes, Lancashire. My informant is a son of Mr. Foden, who resides in this neighbourhood.—H. LINDEY, *Huntroyde.*

Epilobium obcordatum.—This is one of the most difficult plants I have to propagate from cuttings. Can any one give me a hint in order to ensure success?—W. [Cuttings taken from ripened wood of *E. obcordatum* root freely if put in during the months of April and May. They keep well if potted after rooting in small pots, and can be planted out in the spring of the following year. Plants of it have stood well during mild winters on the northern slopes of the rockery in the Royal Botanic Garden, Edinburgh, where they flower abundantly. Those planted in level beds also flower well, but are more liable to suffer from damp during winter than on the rockery.—J. McNAB.]

Pyrus japonica.—Is the fruit of this eatable? A cluster of it is growing on a small plant in my garden.—J. K., *Glenoir, near Galway.* [The fruit of *Pyrus japonica* is certainly not poisonous, but very much depends upon the taste of the person attempting to eat it as to whether it is eatable or not. Its flavour when ripe is not absolutely disagreeable, but, for my part, I never cared for more than one bite. The Japanese, I believe, make it into a preserve.—T. S.]

Eradicating Buttercups.—I want to know by what means I can get rid of a very strong plantation of Buttercups which has been increasing yearly in a field in my pleasure ground, driving out all the best Grasses.—J. E. GRAY. [Sulphuric acid is a sure cure for Buttercups. Women or boys should carry it in old blacking bottles, to the necks of which should be fastened a piece of strong wire, long enough to hold them by; have a stick 12 in. long by 1 in. in diameter, with a long, sharp point, dip the stick into the liquid and then place its point on the crown of the plant; the effect is instantaneous. I have seen this plan practised successfully in one of the best kept gardens in this county.—JOHN GARLAND, *Killerton, Exeter.*]

Garrya elliptica and other Hardy Shrubs.—What is the best season for pruning and taking cuttings from the *Garrya elliptica*, and also the best season for transplanting it? I would ask the same question respecting *Arbutus* and *Holly*, and whether the variegated and hedgehog *Holly* are less manageable as to transplanting than the common *Holly*?—J. E. GRAY. [Garryas should receive what pruning they require in spring after they have flowered. Spring is also the best time to prune both the *Arbutus* and *Hollies*. Cuttings of the *Garrya* and *Holly* may be put in now; in some localities they will strike root in a shady border in the open air, but in others they require a frame. It is useless putting in cuttings of *Arbutus*. These shrubs may be all safely transplanted at the present time. I am not aware that any of the *Hollies* are more difficult than others to move, but if the *Garrya* has been more than one year established, as a rule, its removal should not be attempted. Better get it in a pot from some nursery.—T. S.]

Early Peaches.—If I were going to plant a house with Peaches I should employ few, if any, but the old varieties. I am not at all sure that of those mentioned (p. 210) any but *Early Beatrice* are earlier than the old early kinds, and even *Beatrice* with me this year was not gathered before the *Early York*, which is a larger and better fruit. It is said, nay, claimed for new varieties, that they are improvements on old sorts, not so much in the character of the fruit as in the constitution of the tree, which is stated not to be so subject to mildew, &c.; but those that have come under my observation are subject to all the ills of the old sorts. As to

being earlier, to-day I have gathered some excellent fruit of *Grosse Mignonne*, *Barrington*, *Early Savoy*, *Acton Seat*, *Bellegarde*, *Dr. Hogg*, *Early Alfred*, and *Early Louise*, and I gathered fruit from the same varieties last week, with the exception of *Bellegarde*. I should have added *Crawford's Early*, which is worthless, except for show. Indoors some time since I gathered *Early York*, *Early Beatrice*, *Early Alfred*, and *Royal George* all at the same time, *Royal George* being by far the best. Plant plenty of the well-known sorts is my recommendation, and afterwards the new kinds might be added if thought proper.—JOHN TAYLOR, *Hardwicke Grange, Shrewsbury.*

Lilium auratum.—What number of blossoms does this Lily usually bear? I have one now in flower, 6 ft. 6 in. in height, which is bearing thirty-two blooms on a single stem, all of good size. On another plant the blooms were very large, but they remained cup-like, and the petals would not reflex; can any of your readers explain this? I feed my plants liberally with Stauden's manure, and plant the bulbs on the top of the soil, like Hyacinths, in order to give more root room.—F. H. E. [It is difficult to reply definitely to the question asked, viz., How many blossoms does this Lily usually bear? Much depends on the mode of culture and the variety—for there are many—some never exceeding from twelve to fourteen blossoms, and others a much larger number. I presume the enquiry relates to the blooms on a single stem. I have had forty and upwards, and on fasciculated stems, a mode of growth not uncommon in the case of this Lily, sixty, seventy, and eighty; a clump, originally one bulb, of five stems, two large and three smaller, produced upwards of 300 blooms last year. I cannot say what may be the cause of the petals of the Lily described not fully opening. It is possible that it may have received a check from spring frosts, which, although not remarked at the time, is now developing its effects.—J. W. S.]

Names of Plants.—*R. L. D.*—*Clethra alnifolia*, from North America. *Miss T., Belfast.*—*Maurandia Barclayana*. *F.*—*Odontoglossum Andersonianum*. *Inquirer.*—*Hedychium Gardnerianum*. *Anon.*—As far as can be judged it is a kind of *Asclepias*. The shrub is *Neillia thysiflora* from Nepal.

Names of Fruits.—*J. M.*—117, *Beurre Diel*; 19, common *Bergamot* (standard); 92, the true *Marie Louise*. *Bradford.*—*Alberge* or *Portugal Peach* and *Magnum Bonum Plum*.

Earwigs.—"S. G. S." (p. 230) seems to doubt the fact that earwigs creep into people's ears, but I can assure him that they occasionally do so. When a lad one crept into my ear, and I have known the same thing to happen in the case of others. A slice of Apple pressed against the ear is said to induce them to come out.—B., *Highgate.*

Scottish Horticultural Association.—At a recent meeting of this Society Mr. A. McKinnon, Melville Castle, read a paper on the culture of the Peach. He described its early history and introduction into this country, and referred to the many difficulties that attended the growing of Peaches in Scotland. He concluded by stating that after taking into account all the facts of Peach culture it was necessary to have a heated glass house in order to ensure a crop each season. A spirited discussion followed the reading of the paper, some of the members contending that artificial heat was not needed in ordinary seasons to produce a crop, each side citing instances of failure and success with and without the application of artificial heat. Mr. John Davidson, of Messrs. Dicksons & Co., next read a paper on the culture of fruit trees generally pursued in nurseries. He described the system of budding and grafting, mentioning the different stocks required for different trees, and the adaptability of certain stocks for various soils, and urged the more general planting of fruit trees for profit. Mr. R. Munro made a few remarks on autumn-flowering *Chrysanthemums*, and exhibited twelve sorts at present bearing a profusion of bloom. Miss Hope, Wardie Lodge, sent some beautiful flowers of *Dianthus atropurpureus*, raised from the Chiswick strain of seed. Messrs. Downie & Laird exhibited two fine new *Phloxes*, named *Lady Belhaven* and *Mrs. Bowyer*; and Mr. W. Black exhibited a curious *Lobelia* with blue and white flowers on the same plant. Mr. A. McIntosh, Paxton House, received a certificate for an excellent new round Potato named *Premier White*.

International Show of 1880.—There need be no fear that this will be a great success provided the matter be fairly ventilated, and to do this effectually I would suggest to those who have the matter at present in hand the advisability of at once communicating with some leading horticulturist in all the large towns in the provinces, preparatory to forming a small working local committee in each place for the purpose of getting subscriptions and guarantees. I feel satisfied that if such steps were at once taken, they would be much more effectual for the furtherance of the cause than any circulars that could be sent from a central committee; I have little faith in such appeals, and can speak from experience. For example, we all know that much more should be done, and can be done if we have willing workers, for that valuable charity, "The Gardeners' Benevolent Institution." A short time ago, a few gentlemen formed themselves into a committee here with the ostensible purpose of furthering the objects of this institution by individual efforts. A fair amount of success has been achieved, which could never have been done by appeals through circulars; hence, I think that if something of the same plan were adopted to collect funds for the "International," it would be widely and liberally responded to. A further suggestion crops up in my mind, viz., that if the show is not, strictly speaking, international, it will assuredly be national, and why should not a representative chosen from these

local committees be selected and placed upon the general committee? By this means we give a fair representation of national horticulture.—ROBERT TAIT, 43, Corporation Street, Manchester.

OPENING OF KEW GARDENS.

It is to be regretted that some of our great national institutions are national more in name than in reality, and that they are not sufficiently open to the public, for whose benefit they were in a great measure founded. This injudicious conservatism may be partly due to the majority of the community being indifferent to the matter, and to the small minority, interested in the pursuit of science, or in the study of Nature, not being strong enough to secure those privileges to which they may justly lay claim. But it is also due to the selfish and monopolising spirit of those local authorities to whom the Government has given much power, and whose opinions carry great weight in any deliberations the Government may enter upon with respect to the management and needs of the institutions over which those authorities have so much control. Kew Gardens have long held a high position among these public places that are devoted to the pleasure or instruction of the public. In a sanitary point of view alone they are, as a place of recreation and amusement, a great boon to everyone within reach of them. They were formed at an enormous cost, and are supported with a revenue of over £22,000 a year; while, as a large field for the study of horticulture, botany, and vegetable physiology, they are second to none in the world. And yet those magnificent and useful gardens are closed to the public throughout the best part of the day, and for seven or eight hours after the time all other botanic gardens are open to the public. In the early morning of summer, in the early hours of a spring or autumnal day—periods equally favourable for study or recreation—these gardens are absolutely closed. Such an arrangement must appear to most people both unaccountable and indefensible, and certainly the arguments adduced in support of that arrangement are so flippant and sophistical, that it is surprising that the present management of the gardens has not been challenged more often than it has been. First, we are told that the earlier opening of the gardens would interfere with the pursuit of science. This would be, if true, a serious allegation, considering that one of the chief purposes of the gardens is to develop and encourage a taste for botany and the sciences allied to it. But the fact is, neither would the free opening of the gardens interfere with the pursuit of science, nor is there, unfortunately, much science going on to be interfered with. If the opponents of any change in the present arrangements mean such scientific work as is done in books or reports, it is done in the officers' rooms, in the library, or in the herbarium, with none of which the public wish to interfere; and with regard to such horticultural work as sending plants to the colonies, that is done in the propagating houses or packing sheds, which are always private. Even were the gardens more used, as they ought to be, for educational purposes, and the botanical classes held which are supposed to be held, the free and unrestricted admission of the public could not in the least interfere with either public teaching or private study. The gardens are large enough, as everyone knows, and there are plenty of places in them where lectures could be given, where the student could study, and scientific researches be conducted, without any hindrance from public interruption. It has even been alleged that the public would interfere with the gardeners doing their proper work! When the authorities have to resort to such an absurd argument as this, they only show the weakness of their case. It is also urged that the people have more time allowed them in Kew Gardens than at any other gardens in the world; and that the general public do not desire to be admitted earlier than the present time. Neither of those allegations can be substantiated. Besides, even were this statement correct, it does not follow that, because other countries adopt a faulty plan, we should do the same. Nor are they correct in saying that the public are indifferent on the subject. There are few of us who do not hear people constantly complaining that gardens, so far away from London, are not open till one o'clock, when the best part of the day for either recreation or instruction has gone, and the hot summer afternoons, or the short hours of a spring or autumnal day are alone left to them. With regard to another argument that has been urged, viz., that the proposed change would entail extra police and expenditure, it may be doubted whether much more expense would be incurred, provided the large funds at present at the disposal of the managers were economically administered. But while the considerations that have been advanced in support of the present arrangement at Kew Gardens are such as cannot be for a moment entertained, the arguments in favour of the unrestricted opening of these gardens are, as might be gathered from the foregoing remarks, such as no unprejudiced person will attempt to disprove. It is evident that if the gardens, for the maintenance of which the public have to pay annually a large sum of money, were open in the forenoon, the

advantages which the public derive from them, both from a sanitary and an educational point of view, would be far greater than they are now. On account of the short time now allowed either for study or recreation, the gardens are, except during public holidays, almost deserted. But were a different arrangement adopted, hundreds would take the place of the few visitors that are now to be daily seen there. It is, however, from a moral and educational standpoint that we would insist upon every facility being given for visiting these gardens, and every encouragement being held out to students to take advantage of the fine opportunity offered them for the study of botany and horticulture. What Mr. Ruskin has so well said of "art intellect" may be also said of science intellect. "A certain quantity of art intellect," says that eloquent writer, "is born annually in every nation. . . . You may lose it, or you may gather it; you may let it lie loose in the ravine and buried in the sands, or you may make kings' thrones of it, and overlay temple gates with it, as you choose." In the same manner we may say that a certain quantity of science intellect and nature-loving intellect is born to us every year. We may lose much of this also, or we may gather it. We may let it lie buried in obscurity or blighted by indifference and neglect. Or we may let it expand the intellect, improve the taste, and even mould the character of thousands. We may make out of it discoveries that never would have been made, and diffuse widely a taste for the beautiful that never would have been diffused, but for the fostering influence of popular education, and the help and encouragement of all who are interested in the moral and intellectual advancement of the community. By all means, therefore, let these gardens be opened the greater part of the day, and let classes be held and lectures delivered, and every other means taken to attract the visitor, whether in search of health or of knowledge. Then, out of the thousands that will be annually flocking to them, there will be less chance of science intellect and nature-loving intellect running to waste, and more chance of adding largely to the many eminent botanists we have amongst us.—"Medical Press."

Monstera deliciosa in the Conservatory.—When the old stove space of the conservatory in the Botanic Gardens, Regent's Park, was thrown into the cool and larger part, some large plants of this that grew on rockwork were subjected to a much lower temperature. They seem, however, to thrive fairly well, thus proving that this remarkable and graceful plant is available for winter garden embellishment in the cooler class of structures of this kind.

Cineraria maritima.—This, though an old inhabitant of our gardens, is not so often seen as it ought to be. The whole plant is of the purest silvery white, with the exception of the upper surfaces of the leaves, which are greenish, although in a degree covered with wool, and perhaps in the whole vegetable kingdom no leaf is more beautifully cut. This ought to be pre-eminently a park plant, and where freely used would give life and character to ornamental grounds. It is of a shrubby habit and may be freely used in the outskirts of choice masses of shrubs; those, too, who edge their masses of shrubs with some particular plant will find this a very striking plant, as it may be kept to any height that may be required, and a mass of this plant edged with some dark green dwarf shrub would be a sight, and, if properly attended to, would equal, if not excel, any of the Centaureas. It is a fine plant for toning down masses of blue or purple; and, mingled with the Perilla, crimson Beet, or the dark Celens, it would be effective; a few plants might also be introduced with advantage into the conservatory. In short, from its peculiar whiteness, it is attractive in any place, and is a most charming window plant.—THOS. WILLIAMS, Ormskirk.

Adiantum Farleyense from Seed.—This, the most distinct and beautiful of all the Maiden-hair Ferns, and one which has hitherto either not seeded at all, as some assert, or, if it has, has not reproduced itself true from seed, has recently come to me as a chance self-sown seedling in the gravel underside shelf of my stove house, a fact which may be interesting to some of your readers who grow stove Ferns.—W. E. G.

Lemon Seeds Germinating Inside the Fruit.—A few days ago on cutting open a Lemon that seemed to be sound, I found that many of the seeds were more or less in a growing condition inside the fruit, the roots being in some cases $\frac{1}{2}$ in. long, and the cotyledons expanded. This I considered more singular than Melon seeds germinating inside the fruit, as few seeds start sooner into growth than those of the Melon where the necessary heat and moisture are applied.—J. G.

Clabbing in Cabbages.—This, according to a Russian Government enquiry, is not the work of an insect, but that of a parasitic vegetable called *Plasmodiophora Brassicæ*. Some of the means adopted by way of remedy are sowing the ground, before planting the crop, with common salt, wood ashes, or, before all, soot.

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare*.

AUTUMNAL ROSES AT WALTHAM CROSS.

ALTHOUGH there have long been what are termed autumnal Roses or Hybrid Perpetuals, which produce a second crop of flowers in autumn, yet it is seldom at this time of year that one can meet with a really good display of blossom. The flowers always open in succession, not simultaneously, and it is not often that a really good stand of Roses can be shown in September, unless the collection to choose from be an extensive one; and doubtless it is for this reason that prizes are so seldom offered for Roses at flower shows in the autumn. It was not without some surprise, therefore, that we found at Messrs. Wm. Paul & Son's the other day a really fine display of Roses. Most of those, producing a good bloom, are dwarf, or pillar Roses, and their disposition is different from that usually found in most nurseries. Although it is necessary to have square quarters and long lines in many instances, yet some parts of the ground, besides being devoted to ordinary nursery purposes, are also converted into a really ornamental garden; large pillars of Roses are introduced among low-growing shrubs or stately Conifers; Tea Roses on their own roots are grouped together in round beds on the edges of shrubberies; whilst the outside walls of glass houses are concealed beneath free blooming Teas which have now a gay appearance. The best kind just now is Belle Lyonnaise. The plants of it in this case are not formally trained, as too often happens in nurseries; on the contrary, they are allowed to grow almost at will, and in that way they are much more effective and enjoyable than in any other.

Madame Berarde, planted on a large bank near the entrance to the nursery, forms a striking feature; it is "worked" on De la Grifferaie, which is used here as a stock; it is pegged down every year, and, thus treated, it yields an abundance of flowering shoots. As an autumnal Rose this is one of the best in its way. Its flowers somewhat resemble those of Gloire de Dijon, but they are richer in colour and different in shape. Here, indeed, it is thought to be superior even to Gloire de Dijon.

Duchess of Bedford is a fine new Rose which blooms well in autumn. It was shown this year for the first time by Mr. W. Paul at several of the London and other shows, where it was much admired. It somewhat resembles Charles Lefebvre in habit of growth and shape of blossom, but in colour the flowers are deeper and brighter than those of General Jacqueminot.

Countess of Rosebery is another new Rose now finely in flower. It resembles Etienne Levet, but is much freer in growth and blooms more profusely. Its blossoms are of a bright rosy-salmon and handsome in shape. This, when well established, will make a fine Rose for autumnal blooming.

Dwarf Roses on the seedling Brier (*Rosa canina*) do remarkably well at Waltham Cross, and on that account this stock is now as largely used as the Manetti. Large breadths of all the best autumn blooming Roses are almost as attractive now as one would expect to find them in July. Among the best we may name La France, one of the finest Hybrid Perpetual Roses in cultivation. Rows of it now represent quite hedges of blossom. La Rosière is producing abundance of dark velvety maroon flowers almost fit for an exhibition stand; and Mons. E. Y. Teas, a well tried Rose only in cultivation a few years, is also of great value both for summer or autumn flowering. Gonsoli Gaelano is a pretty variety which flowers freely in autumn; it is dwarf and admirably adapted for grouping in beds or raised banks; its flowers are of a lively salmon-blush, and large in size. Bessie Johnson, Imperatrice Eugenie, and Eliza Boelle, all excellent white Roses, are now finely in flower, and Avocat Duvivier affords an abundance of brilliant scarlet flowers all through the season. Among other kinds now in

good bloom may be named Star of Waltham, Countess of Oxford, Eugenie Verdier, and Charles Lefebvre. Captain Christy is one of the best and freest blooming of autumn Roses, and Mons. Pillion, of the Jules Margottin type, makes an excellent pillar Rose. Madame Sophia Fropot is a strong grower, and bears abundance of clear pink flowers. Jules Margottin and Triomphe de l'Exposition bloom well as pillar plants; and La Duchesse de Morny, Alfred Colomb, and Sir Joseph Paxton rank amongst the best of perpetual blooming garden Roses. Acidalie, a fine old white Rose of the Bourbon section, is now profusely in bloom; indeed, in good soil it flowers without intermission all through the summer and autumn. Round beds filled with dwarf plants of Souvenir de la Malmaison on its own roots in the central avenue are very attractive, every shoot being surmounted by numbers of buds and fine blossoms. Large beds of plants of the beautiful Tea Rose Sofrano turned out of small pots into rich soil fifteen months ago have made remarkable growth, many of them being 3 ft. high, bushy, and well furnished with buds and cream-coloured blossoms. Hundreds of seedlings are to be found here in all stages of growth, from a strong flowering specimen down to small plants a few inches high, which have been raised from seed saved with much care from hybridised flowers in the hope of still gaining something new to add to the already lengthy list of good Roses grown here. A quantity of Hybrid Perpetual Tea and other Roses struck from cuttings last autumn are now furnishing a fine display of bloom. The cuttings were inserted in a raised border on the north side of a hedge, and nearly 60 per cent. of them struck root freely. They were afterwards transplanted at distances varying from 1 ft. to 1½ ft. apart in the same border, into which had been dug a large quantity of road sand. The plants are now bushy and strong, and full of bloom and buds, and where flower beds are required to be kept gay from July to October, plants raised in this way will be found to be acquisitions.

The stock De la Grifferaie, already referred to, is a variety of *Rosa multiflora*, sent out by a French Rose grower many years ago. Its flowers are rosy-purple, changing to pinkish-purple as they advance in age, and they are produced in very large clusters. It is, in fact, in itself a good climbing Rose, both as regards foliage and flowers, but its great value at the present time is its proved suitability as a stock for some kinds of Roses. Among others the strong-growing varieties of the Tea scented, especially the Gloire de Dijon race, grow on it with surprising vigour, and produce very fine flowers quite up to the end of autumn. Madame Berarde, Maréchal Niel, climbing Devonensis, and Gloire de Dijon here growing on the seedling Dog Rose, have only made shoots from 4 ft. to 5 ft. this year, while the same varieties on the De la Grifferaie have made shoots from 8 ft. to 10 ft. The shoots of the latter, too, are stout in proportion to their growth and well ripened, being provided with laterals now producing an abundance of well-formed flower buds. This stock is found to strike readily from cuttings, and buds take most freely on it. For standards it is probably not so well suited, inasmuch as it is rather tender, and therefore, if allowed to grow to a great height above ground, it would be liable to be injured by frost. Whilst kept beneath the surface, however, it makes an excellent stock for climbing Roses.

Dog Rose cuttings are also struck here and used for stocks. They are put in during autumn, and consist of young shoots torn from the old wood with a "heel." The following summer, like the Manetti, they are budded near the ground, and for some kinds of Roses they are found to be superior to any other kind of stock, and they are much more easily procured than seedling plants.

Pot Roses, of which there are thousands now to be seen in this nursery, are exceptionally strong and healthy; they are plunged in raised beds of Cocoa-nut fibre and manure in a sunny position. Thus situated they grow vigorously and ripen their wood thoroughly.

C. S.

Early and Late Budded Roses.—In budding Roses, one of the principal points in order to ensure successful results is to bud early, so that the buds will push shoots sufficiently early in the season for the wood to get matured enough to withstand the winter, or so late that the buds, after maturing, will remain dormant until the following spring. I prefer the early system, as in light soils if drought sets

in the bark does not rise so freely, and success is not so certain as while the sap is abundant. It is also a saving of time to get a moderate growth matured in the same season in which the buds are put in.—J. G.

TREES AND SHRUBS.

TREES AND SHRUBS FOR AVENUE AND LANDSCAPE PLANTING.

The season for making alterations in pleasure grounds and park lands being at hand, a few practical notes on planting and selecting the different varieties of trees for that purpose may, perhaps, be of service to intending planters. Of course, in a single paper it is impossible to do full justice to the subject in all its bearings. I shall therefore, for the present, confine my remarks to the varieties of trees and shrubs which I have found to produce the best results. One of the first principles to be observed is winter effect. Woodland aspects in summer will, to a certain extent, take care of themselves; but winter—cold, bleak, and dreary—requires all the warmth that can be imported into it, by which I mean plenty of evergreens, variegated and berried plants, coloured bark and gracefully-branched deciduous trees. With this principle in view, therefore, the following trees and shrubs will be found best adapted for the varied purposes named:—

To begin with evergreens, for home avenues no Conifer can exceed in beauty *Thujaopsis borealis*. It is a plant of free growth, perfect in symmetry, graceful in habit, excellent in colour, thoroughly hardy, and very cheap. Yet how rarely do we meet with it! Another plant, almost equally good, though of different habit of growth, is *Thuja Lobbi*, which, being more conical in habit, might suit some tastes better than the *Thujaopsis*. As to *Wellingtonias*, which are now so much in vogue for avenue planting, graceful as they are in a young state, I think them anything but well adapted for small avenue planting, but for large parks or extensive avenue planting, at great distances apart, no plant can be better suited, though personally I should prefer *Picea nobilis*, or the Douglas Fir. The latter has proved itself such a free grower in our climate, and its timber being also very valuable, those on the outlook for avenue trees would do well to plant it. *Picea nobilis* is of slower growth and less graceful, but is superior to the Douglas Fir in point of colour.

As a deciduous avenue tree I would recommend the Spanish Chestnut; first, for its gracefulness in winter, and, secondly, for its flowers in spring, its grand foliage in summer, and its fruit in autumn. Next in order come the Lime, Horse Chestnut, and Elm. In giving a list of trees that produce the best landscape effects, it must be borne in mind that the grouping system is the one which I prefer, *i.e.*, from three to seven or more trees of one kind, according to the distance from the mansion, the formation of the ground, &c., should be placed together. Of course, single specimen trees play an important part in all landscapes, but the groups should, in all cases, be formed first, and the finishing stroke, as it were, be given by planting a columnar-habited tree there, a pyramidal one yonder, a drooping one in another spot, and so on, to complete the picture. The copper-coloured Beech must be first on our list, next the green form or type, then the Birch and the Oak, some of the Turkey varieties of which have foliage equal to that of the best sub-tropical plants. As evergreen companion groups the best are the common Spruce Fir, the Douglas Fir, the Scotch Fir, and Evergreen Oaks. As single specimens for associating with this grouping, the best are the Robinias, Lombardy and Aspen Poplars, Silver Birch, Green Hollies, Deodar and Cedars of Lebanon, Cryptomerias, and Wellingtonias. For scenery nearer home, and for general "gardenesque" effect, the following are the most striking plants, *viz.*, green and variegated Hollies, common and variegated Yews, Junipers, and *Retinosporas*, and, indeed, all the compact and dwarf-growing Coniferae. As deciduous companion trees I would select the Laburnums, Ailantus, Japanese Maples, and Robinias, all of which will be found to blend harmoniously and look best when grouped, as to colours, &c., as above suggested.

So many handsome, compact, and dwarf-growing hardy shrubs have of late years been introduced from Japan and other

countries, that the idea has more than once occurred to me that an entire garden of dwarf, columnar, conical, and pyramidal-growing shrubs (no artificial distortion or clipping to be attempted), arranged with a view to permanent effect, would be interesting. Who, therefore, will establish such a garden? I would be only too glad to do the practical part connected with it. W. W. H.

FOREST WORK FOR SEPTEMBER.

As the time is fast approaching when planting operations will demand attention, all works necessary for the preparation of the ground should be pushed forward as rapidly as possible. These consist of fencing, draining, trenching and holing. One of the first requisites to successful planting is a fence impervious to sheep and cattle; and unless rabbits and hares can also be kept out, but little can be done in rearing plantations formed of small trees. Where the land has not been trenched the advantages of early holing are great, as the excavated soil becomes ameliorated by exposure. Moch of the nursery stock intended for woodlands may now be raised and afterwards carefully bedded upon a dry, warm soil until it can be placed in its permanent situation. If this operation be well performed, and a proper soil and position be chosen, the growth of the small rootlets will continue and the plants may afterwards be removed under circumstances most favourable to their rapid development. Injured roots should be carefully pruned back at once, but the less the knife is used, either upon these or upon the head, the better. The layering of a deciduous coppice should be finished as early as possible. Select two years' shoots, peg them firmly in the ground, cutting the layer half-way through on its under side, if necessary, to bring it well to the ground; cover with from 4 in. to 6 in. of soil, and bring the head into an upright position; also cut away from the parent stool layers of two or three years' growth. Layering may be practised upon almost every kind of hard wood, as, for instance, on the Elm, Ash, Oak, Sweet Chestnut, Alder, Poplar, Birch, Plane, Lime, Willow, Mountain Ash, and Hazel. For filling up thin and neglected coppices, it is at once the cheapest and by far the most expeditious way. The transplanting of evergreens should be finished as quickly as possible. Where large deciduous trees have been previously prepared by trenching round them, now is the time for their removal. Take up the roots as entire as possible, preserve the bark uninjured, and avoid cutting or pollarding the top. Secure a firm bed on which the tree may rest, but avoid treading the soil around its roots when in a wet state. By dashing on water with some force during the filling in, and heaping up sufficient soil to allow for a gradual subsidence, more good may be done than by treading, and thus encasing the delicate rootlets in an impenetrable mass of hard clay or other soil. In looking through the plantations all trees requiring support should at once be staked and tied, and, where early transplanting has been done, watering may now be necessary. Mulching should not be neglected, as any substance which prevents evaporation will prove beneficial to the trees. Trim all wood rides preparatory to the shooting season, and remove the trimmings at once. If any timber remain in the woods it should be speedily removed before wet weather sets in. Select stock for filling up the home nursery, and also such as is required to supplement the home supply in filling up the woodlands. Finish the trimming of all hedges, and see that those adjoining pastures are kept in good repair. Wherever the pruning of forest trees has been neglected they should now be attended to without delay; but this should have been finished much earlier in the season. A. J. BURROWS.

Pruning Conifers.—I noticed the other day a fine plant of *Pinus Pinsapo*, the lower branches of which had a few years ago become rather straggling and bare, and which were therefore pruned back in order to get them to make fresh growth. This plan has resulted satisfactorily, for the branches at the bottom are now as dense as at the top, and equally green and healthy. No one need therefore fear to prune *Pinus Pinsapo* should such an operation become necessary.—S.

Jasminum nudiflorum aureo-variegatum.—This is one of the best golden-foliaged wall climbers at this season of the year that we possess. It is a vigorous-growing plant, and one which ought to be cultivated by every one who values a contrast of colour on open walls, and it is as hardy as the type.—J. G.

The Broad-leaved Spindle Tree (*Euonymus latifolius*) is very brilliant in copse in the Alps now. With the curious *Fuchsia*-like effect of the fruit, it deserves to be more popular. In some of the gardens the Snowberry bushes of America bear their fruit in thick-set racemes in such abundance, that the shoots are all bent and the half-standard bushes white with them.

NOTES OF THE WEEK.

Salvia splendens Out-of-doors.—We have lately noticed handsome pyramidal bushes of this in South German gardens, the plants reaching a height of nearly 6 ft. We remember seeing this plant flowered in the same way at Bicton by the late Mr. Barnes, but the bushes were not so tall. The plant has a singularly brilliant effect in the autumnal garden.

Sweet-scented Cyclamens.—Those thinking of planting gardens of sweet-scented flowers would do well to include the autumn-flowering Cyclamen, which is now in abundant bloom on the hills in Switzerland and North Italy. The fragrance is delicious, and yet of a refined and delicate character. When gathered in bunches with a few leaves around, as *Viola*s are gathered, its fragrance is more apparent than in the case of single blooms.

Single Dahlias.—Mr. Cannell, Swanley, showed at South Kensington, last Tuesday, a Dahlia with a single row of broad, velvety, maroon, purple-shaded petals and a large tuft of bright yellow anthers in the centre; the whole somewhat larger than a crown piece. It was called Paragon, but it looks very much like an original species. It quits took the committee by surprise, who collectively pronounced it to be one of the most beautiful plants brought out for some time, either for borders or for cutting. There was a yellow one with it, almost similar in all respects, except in colour.—T. B.

Desmodium racemosum in September.—As grown among the herbaceous plants in the Botanic Garden at Berns, this is a peculiarly beautiful plant. The shoots are tied to a stake for about 4 ft., but grow free for several ft. more, and droop in the most graceful manner laden with numerous pretty purple flowers. As it comes at a season when plants that bloom freshly and well are not plentiful, it is all the more welcome.

Adiantum Hendersoni.—This new Fern may now be seen in the Pine-apple Nursery. It has gracefully-arched fronds, resembling those of *Pteris serrulata*. The pinnæ are of a bright bronze colour, and the young fronds are especially pretty. For growing in pots or vases it will be found very useful, being a distinct and free-growing variety.

Gentiana asclepiadea in Autumn.—This tall and graceful Gentian is now a beautiful object in many Alpine woods and copses. Sometimes, where it is plentiful, one may see it dotted through the long Grass and coarse herbs of a little glade in the wood; sometimes leaning out from small bushes, singly or in small groups, in all cases the Willow-like shoot bearing its handsome spike of flowers. The height of the plant makes it quite at home in long Grass and such herbage as occurs in woods and copses or unmown spots. Therefore it will prove one of the very best of all wild garden plants. It has long been a favourite with lovers of good border flowers. Our gardens contain many places where it can be grown as we suggest. It and the Grass of Parnassus, and the autumn-flowering Cyclamen are among the few flowers now in bloom on the Alps that remind one of the beauty of the flora there before scythe, and herd, and time have done their work.

Dianthus as Bedding Plants.—While much labour is bestowed in obtaining *Palargoniums*, *Verbenas*, and similar plants for flower garden embellishment in summer, comparatively little attention is paid to the beautiful *Dianthus Heddswigi*, which can be made to form a fine display from early in June to the beginning of September. At Chiswick there has been all through the summer a grand display of these *Dianthuses*, the result of seed sown early in May. Their blooms are large, and possess a brilliancy and variety of colour afforded by few other plants. Rich, deep soil and plenty of water constitute the chief conditions of success. They seed with tolerable freedom, and when once a good strain is secured it can easily be kept and improved by yearly weeding out indifferent flowers.

Orchard Trees Everywhere.—It is very instructive to notice the effect of the orchard trees dotted over the landscape in various parts of Switzerland. It is noticeable that as trees they are often as effective in the landscape as any of our so-called ornamental trees. They are scattered over the land without the slightest attempt at inclosure or fencing of any kind, and the country is covered with them in many parts. Where the climate is not unfavourable they attain such stately dimensions, that one accustomed only to our pruned trees would not suppose these to be fruit trees at all. It must be charming to see the land when these trees are in flower in spring. In America and England we count our acres of orchard. Here the orchard is everywhere dotted over the Grassy slopes and pastures. These seem none the worse for it. It is most unfortunate that with us so few people plant a fruit tree without a wall or hedge (both expensive and useless objects in this case) around it. And not only

this, but even the old-fashioned habit of planting an orchard of any kind has gone out of fashion in many places. The orchard at Preston Hall is the only good one we have seen for years in a private place. All this should be changed if we are to do justice to either the land or the people in it. We ought to have good orchards, and we ought to plant fruit trees as we now plant Privet and Laurel.

Phlox Mrs. Hunter.—This is one of the best of the light-coloured class of herbaceous Phloxes. Its flowers, which are borne in large pyramidal trusses, are pure white with a clear pink eye, and are quite as large as a half-crown piece. We lately saw it in fine condition in the Tottenham Nurseries.

Michaelmas Daisies on Walls.—The *Asters* may be added to the many plants that will grow on walls; there are handsome colonies of them now on some by no means old or mouldering walls in Berns. The seed, no doubt, fall from some plants in the garden above.

New Varieties of Liliun speciosum.—In the Tottenham Nurseries may now be seen several new varieties of *Liliun speciosum* roseum and album, all great improvements on the types. Their flowers are very large and the petals broad, and in form more like those of *L. auratum* than the *speciosum* section, from which they originated.

Datisca cannabina in Autumn.—The female or seed-bearing form of this plant is a very fine thing with me now, the herbaceous stems of the year having a growth of nearly 10 ft., and bending gracefully towards the ground owing to the weight of the fruit. It is a fine subject for the wild garden, or for a place on the turf near a shrubbery—H.

Odontoglossum grande.—Now, when Orchid houses are almost flowerless, this *Odontoglossum*, familiar to every one, is doubly valuable. It is very effective just now in Mr. Williams' nursery, Holloway, where there may be seen fine varieties of it. Of these some of the flowers measure upwards of 6 in. in diameter, and they are richly barred and spotted with yellow and chocolate.

Two Good Nerines.—The best scarlet-flowered Nerine now to be found blooming in the London nurseries is *N. Fothergilli* major. Its flower-spikes are very strong and its trusses of blossom large, as are also the individual flowers, which are of a waxy substance and brilliant scarlet. *N. Planti*, a deep rose-flowered variety, is another equally good kind. We lately saw both sorts finely in bloom in Messrs. Henderson's nursery, Pine-apple Place.

Tillandsia Lindenii vera.—This is now in flower in Mr. Williams' nursery, Holloway. In habit it is dwarfer than *T. Lindau*, and its flower-spathe is broader and shorter. Its flowers, which are of a rich satiny blue, open in succession for many weeks together.

Griffinia hyacinthina and Blumenavia.—Both these *Amaryllids* may now be found in bloom in the Victoria Nurseries, Upper Holloway, where, associated with Ferns and ornamental-leaved plants, they are very effective. They are easily grown, much more so, indeed, than many of the *Amaryllis*, and might be cultivated more largely in private gardens than they are at present. The plants in question are well supplied with healthy foliage—rather a rare occurrence in the case of *Griffinias* at the time of flowering.

Cryptogamic Society of Scotland.—The fourth annual conference of this Society will be held in the Royal Botanic Garden, Edinburgh, on Oct. 9, 10, and 11 next, to which all interested in cryptogamic botany are invited.

Destructive Gales in Ireland.—We were visited by severe gales of wind on Sunday and Monday last, which have done a great deal of damage to kitchen, fruit, and flower gardens in this district. Dahlias, which at the time were at their best, perhaps suffered the worst, being literally broken to pieces and rendered useless for the remainder of this season. In the kitchen garden all the Brassica family, with the exception of Cabbages, were blown about and lying in every direction, although none, so far as I have seen, are actually uprooted. Jerusalem Artichokes, which have made good growth this year, are laid low, and most of their leaves are as black as if they had been struck down by frost. In the fruit garden standard Apples and Pears are nearly stripped of their fruit, which is, of course, rendered useless as regards keeping. Forest trees here and there are uprooted, and many of them have lost large limbs. Shrubs, where much exposed, have also suffered severely.—S. KEVAN, *Castle Upton, Templepatrick, Antrim.*

Grapes Shown at Edinburgh.—At the Royal Caledonian Horticultural Society's show, held the other day in the Waverley Market, Grapes were shown in great quantities. Probably only on the occasion of the international show in Edinburgh, four years ago, has such a fine collection been brought together. For baskets of Grapes alone some 3 cwt. were sent in, and in one case as much as 30 lb. had been cut from one rod. Mr. Johnstone, Glamis Castle carried off the first prize in this class.

NOTES FROM KEW.

Hardy herbs.—One of the Witch-hazel family, *Hamamelis virginica*, a North American shrub, is now in flower; the colour of the blossoms, which are freely produced, is yellow, and the corolla is composed of four long petals; the foliage is much like that of the common Hazel. Although long known to cultivation, this interesting shrub is not so often met with as it deserves to be. *Cassia marilandica* has elegant pinnate leaves; its stems (about 4 ft. high) are crowded with axillary racemes of yellow flowers, the reddish-brown stamens giving them, at a short distance, a variegated appearance. *Eugenia Ugui*, a Chilean member of the Myrtle family, is well worth a sunny place on a wall, where it is sure—at any rate in the South—to produce in abundance its small but agreeably-flavoured and perfumed fruits; the white flowers are also fragrant, as are the leaves when bruised. *Ceanothus azureus* is a very useful late summer or autumn-flowering shrub; the genuine plant, with dark blue blossoms, is to be had in more than one London nursery, although a much inferior one, with lavender-coloured blossoms, generally does duty for it. *Desmodium pendulifolium* is a charming plant of graceful habit, and belongs to the Pea family; the stalked leaves, composed of three leaflets, are green above and very glaucous beneath; the drooping or arching branches bear a profusion of showy, reddish-purple flowers in long-stalked racemes. *Lespedeza bicolor*, from 4 ft. to 6 ft. high, and a near relation of the last-named, is of totally different habit, being erect and having upright racemes of flowers somewhat less in size than those of *D. pendulifolium* and rather lighter in colour. *Bupleurum fruticosum* is a remarkable plant in many ways; e.g., it is an excellent example of a shrubby umbellifer, an enormous majority of the plants belonging to this family being of herbaceous habit; and, again, its leaves, of a sea-green colour, are entire, and not compound, as in most umbellifers. This shrub is a native of the south of Europe, and is worth a sheltered place, as the strange appearance afforded by its numberless umbels and peculiarly tinted leaves is different from that of any other outdoor shrub. The Chaste tree (*Vitex Agnus-castus*) ought to occupy a place in the gardens of the curious; the long-stalked leaves, made up of three leaflets, are of a very light green tint, and the plant is sufficiently striking even without the flowers, which are rather inconspicuous; the leaves, when dry, have a powerfully aromatic odour. *Aralia japonica*, with its noble, compound leaves of immense size, and its proportionately large inflorescence, made up of very numerous panicles of small, whitish flowers, furnishes a sub-tropical aspect hardly equalled by any other hardy shrub.

Hardy Herbaceous Plants.—*Potentilla ambigua*, a creeping sort from the Himalayas, has small leaves with three-lobed leaflets, and long-stalked, solitary, bright yellow blossoms; this is a distinct and handsome little plant. *Cimicifuga japonica* grows about 2 ft. high and has showy panicles of white flowers, the white stamens of each flower being so numerous as to form a dense, bush-like mass. Some of the more remarkable and rarer of the Michaelmas Daisies, which are so important as autumn-flowering herbaceous plants, are those hereafter mentioned. *Aster Herveyi*, a new kind from North America, is very distinct; it grows about 3 ft. high and flowers very freely, the colour of its blossoms being lavender. *A. sikkimensis*, an equally distinct sort from the Himalayas, has pale blue blossoms, and grows about 2 ft. high. *A. grandiflorus* attains a height of 3 ft. and is a handsome blue, the very leafy character of its involucrel bracts giving it quite an appearance of its own, and rendering it different from any other *Aster* which we call to mind at the present moment. *A. turbinellus*, 3 ft. high, is a beautiful plant with graceful and airy habit and handsome blue flowers. *A. ptarmicoides*, a rare sort, grows about 18 in. or 24 in. high, and bears most abundantly rather small flower-heads of a white colour. *A. longifolius ramosus* is a densely-branched and free-flowering plant growing about 2 ft. high and bearing pale purple flowers. *A. mutabilis*, 4 ft. or 5 ft. in height, is one of the best of the white kinds, the individual flower-heads being a good size. The Golden-rods form an important feature at the present time in all general collections of herbaceous plants; although all are yellow-flowered, many exhibit extreme differences in size, habit, and general appearance. We have selected the best from the large selection at Kew. *Solidago odora*, about 3 ft. high, is a light and extremely graceful plant. *S. nemoralis* is a most floriferous sort about 2 ft. high. *S. rigida*, 3 ft. in height, has large, broad leaves and bright yellow blossoms. *S. sempervirens*, with large, strap-shaped leaves, grows about 3 ft. or 4 ft. high, its foliage and erect pyramidal panicles giving a totally different aspect from most of its relations. *S. altissima*, a tall-growing sort 6 ft. high, is a free-flowering and handsome plant which would make a striking single specimen plant on a lawn, &c.

Greenhouse Plants.—*Trio binium Maaglesi* is a very ornamental Swan River Amaranth, which, we believe, was first introduced to English gardens by Mr. Thompson, of Ipswich; the pale purple

flowers are borne in a dense, rather woolly spike. *Bransevigia Josephinae* is an extraordinary bulbous plant from the Cape of Good Hope; the bulb is very large, and the leaves are not developed at the same time as the flowers; the stout scape supports a very large umbel of dull, dark red flowers. *Mesembryanthemum pallidum*, a shrubby sort with small leaves, flowers freely and produces an abundance of handsome purple blossoms.—†.

THE SPECIES OF EUCOMIS.

THESE Cape bulbous plants, though not very showy, present a peculiar aspect not generally met with in other kinds of the Lily family, the broad, handsome foliage, more or less spotted at the base with purple, from which rise the tall cylindrical spikes of blossoms, surmounted by a crown-like tuft of leaves, renders them very attractive objects, and well deserving of general cultivation, either for the greenhouse or the outdoor garden, as they have proved of sufficient hardiness to survive our ordinary winters on light and dry soils, as in the case of many other Cape plants. There are but four species, all of which are in cultivation, and all were introduced previous to the present century.

Wavy-leaved *Eucomis* (*E. undulata*).—This kind has leaves 18 in. long, from 2 in. to 4 in. broad, and pointed, rather concave and wavy at the margins. They are profusely marked with dark purple blotches on the under surface, which, in the variety *striata*, assumes the form of stripes. The flower-spikes are 2 ft. to 4 ft. high, spotted below. On the upper half are densely arranged in a cylindrical manner the very numerous blossoms about $\frac{3}{4}$ in. across, greenish-white with purplish centre, and the spike is crowned by a tuft of narrow green leaves.

Spotted *Eucomis* (*E. punctata*).—This, the largest growing kind, has leaves $1\frac{1}{2}$ ft. to 3 ft. long by 2 ft. to 4 ft. wide, nearly flat, and pointed. It differs from the last in the margins of the leaf not being wavy, less spotted, taller spikes, and the more lax arrangement of the blossoms. There is also a striated form of this kind.

Tongue-leaved *Eucomis* (*E. regia*).—This is rather dwarfer than either of the preceding; leaves 12 in. to 18 in. long by 4 in. to 6 in. wide, rather blunt at the tip, crisped at the edges, and slightly spotted on the outer base. The raceme of flowers is very dense, about 1 ft. high, with no intervening naked portion between it and the leaves. The tuft of leaves at the top is larger than in the other kinds. It is also known under the names of *E. microphylla* and *E. clavata*.

Dwarf *Eucomis* (*E. nana*).—This, the smallest kind, much resembles the last in habit, but the leaves are not so large and not crisped at the margins, and the flowers are greener and the crown of leaves not so large. As in *E. regia*, the leaves are spreading and lie horizontally, whilst in the others they are more erect. W.

A Good White *Pelargonium*.—I observe Joan of Arc strongly recommended in THE GARDEN (p. 235). I do not grow that variety, but am much pleased with White Vesuvius, by far the finest white *Pelargonium* I have yet met with. It is a capital white, with all the good qualities of Vesuvius, from which it is a sport. I hope to grow it largely for pot culture, and also as a bedding plant. I quite agree with all that is said of the value of white *Pelargoniums* for bouquet making and other purposes. A good pure double white is still a desideratum, though Madame Amelia Ballet goes a very long way to meet it.—D. T. FISH.

***Sericographis Ghiesbreghtii*.**—This is one of the most serviceable of winter-flowering plants. It is easily grown and it flowers freely in a small state. It has good foliage, and light, feathery, scarlet flowers that last long in good condition in plant stands. Cuttings of it put in in April or May strike freely, and make excellent plants for the ensuing winter. The young plants will succeed in a mixture of peat, loam, and sand. Plunge them in a gentle bottom heat in a cold frame during the summer, keeping it tolerably close and moist while they are making their growth. Being of erect habit, they should be stopped early in order to induce the formation of side shoots in proportion to the sized specimens required, but when growth has been nearly completed, plenty of air should be admitted, and they should be kept quite cool from this date forward. They should be introduced in succession into gentle heat, and they will flower all through the dull months.—J. GROOM.

GARDEN DESTROYERS.

BERGMANN'S TORTRIX.

(CRÆSIA BERGMANNIANA.)

THIS pretty little moth is one of the Rose grower's greatest enemies. Unfortunately, it is very common and widely distributed. Its caterpillars feed on the buds and leaves of Roses, and in this way are most destructive, spoiling the flowers and destroying the foliage. They curl up or fasten together the leaves, and live within the so-formed shelter. They may best be destroyed by carefully going over the Roses, and pinching

Bergmann's Tortrix (*Cresia Bergmanniana*).

all the leaves which are curled up sufficiently hard to crush the caterpillar inside. This requires doing with a certain amount of care, as they are very active, and may drop out if you pinch the wrong part of the leaf. When the Roses are pruned, the shoots which are cut off should be burned, as there may be eggs on them. The moths can be caught in a common butterfly net after sunset, when they may be found flying round the Rose bushes. The perfect insect measures about 6-10ths of an inch across the wings when they are fully extended; the upper pair are yellowish, finely reticulated, with reddish-brown lines, and with three transverse, silvery bands; the lower wings are dark grey, with their margins almost black. The caterpillars have fourteen joints, including the head, and eight pairs of legs, one pair being placed on each of the first three joints of the body, and on the sixth, seventh, eighth, ninth, and last joints. The head, the first three pairs of legs, and a shield-shaped spot at the back of the first segment of the body are black; otherwise the caterpillars are of a transparent

Rose Tortrix (*Lozotania rosana*).

greenish-yellow, with a few fine hairs of the same colour on each joint. They grow very fast, and change their skins several times; when full grown, they are about $\frac{1}{2}$ in., or perhaps rather more, in length. The chrysalis is dark brown, and the edge of each segment of its body is furnished with two transverse rows of fine spines. The female moth lays her eggs singly at the base of Rose shoots. In very hot weather the caterpillars are sometimes hatched in about a month, and the second brood of the moth appears in September, but generally the eggs are not hatched until the following spring, towards the end of April. The caterpillars attain their full size and assume the chrysalis state about the end of May, in the meantime living on the leaves and buds, which they much injure. They have the power of emitting from their mouths a glutinous secretion, which, when drawn out, forms a silken thread; apparently whilst drying these threads contract, for, as soon as the caterpillar has placed a few across a leaf from one side to the

other, the leaf begins to curl up, and at last assumes the curled and rolled forms so common on Rose bushes. Sometimes they will fasten two or more leaves together in the same manner; in these leafy shelters caterpillars live, letting themselves down by threads. If disturbed when full grown they line the interior of their habitations with silk, and in a few days become chrysalides. At the end of about a month the chrysalides, with the help of the rows of spines before alluded to, work their way to the end of the rolls, and the perfect insect makes its appearance, having forced its way through the chrysalis case which splits open at the head. This moth belongs to the family Tortricidæ, a family of small moths, the caterpillars of which are very destructive to various trees and plants, particularly to fruit and forest trees and Roses, by eating their leaves and fruit. They may generally be distinguished from other moths by their upper wings being wide, with the upper and lower margins almost parallel, and the side margin being nearly straight. The upper margin is much curved near the base of the wing, forming quite a shoulder; the upper wings are more or less marked with transverse bands, and the lower ones are usually grey, somewhat darker at the outer margin. *Lozotania rosana*, or the Rose Tortrix, is another member of this family, which gives much annoyance to the Rose grower. It is considerably larger than Bergmann's Tortrix, measuring eight-tenths of an inch across the wings, but it varies very much in size. The upper wings are of a grayish-brown, marked with dark brown somewhat transverse lines, some of which are much shorter than the others. The lower wings are of a pale ochreous-yellow, with the margin nearest the body blackish. The economy of this insect is much the same as that of Bergmann's Tortrix.

S. G. S.

A TRAP FOR WASPS, ANTS, AND OTHER INSECTS.

THE ingenious inventor who discovers a trap that will effectually put an end to the ravages of ants, wasps, and

Trap for the destruction of Wasps, Ants, and other Insects.

similar garden pests will earn the gratitude of all fruit and flower growers. Numberless devices already exist which are waunted by their inventors to accomplish this purpose, but although they seem to succeed well enough at one time, they are comparatively useless at another. The contrivance figured above

is stated by M. E. A. Carrière in one of the last numbers of the "Revue Horticole" to fulfil its purpose most admirably. Its construction is founded on a knowledge of the habits of the wasp. There are two varieties of the common wasp (*Vespa vulgaris*), one of which, *Vespa parietum*, is larger than the ordinary kind. It attaches itself more especially to buildings, and takes up its habitation in the nooks and crannies of brick or stone walls, whence its specific name. The common variety, which is familiar to everybody, affects the soil; and as it is incapable of hollowing out a nest for itself, it generally takes up its dwelling in an abandoned molehill, or one from whence it has possibly driven out the late proprietor. Here they build their well-known paper comb and send forth their fertilised females to found fresh colonies. It is, therefore, necessary to attack the enemy before this emigration takes place; we must not, however, commence operations before the colony is complete, which generally happens just about the period when the Grape begins to ripen. The trap, as will be seen from the figure, consists of two parts, the upper being made of glass, the lower of tin or zinc; inside the glass globe is a hollow provided with a rim which contains the bait. The method of using this trap is most simple. We need only place it over a wasp's nest or anthill so as to cover the opening. In the case of wasps, the bait holder must be filled with benzoline, the vapour of which will suffocate the insects. Ants, on the other hand, must be attracted with some toothsome bait, such as sugar, or honey and water, stale beer, beer and water, &c. The trap may be purchased of the inventor and maker, M. Pelletin, 20, Rue de la Banque, Paris, but an ordinary bell-glass, from the interior of which an egg-cup or other small vessel is suspended by means of a piece of string and some cobbler's or grafting wax, and a tin vessel of the form shown in the cut, easily made by any tinman, ought to serve the purpose of a more expensive apparatus.

C. W. QUIN.

THE FRUIT GARDEN.

GATHERING APPLES AND PEARS.

IN keeping these sound for the longest period much depends on the care with which they are gathered, and also on each kind being gathered at the right moment. Every one is capable of gathering carefully, but a certain amount of practical experience is indispensable as regards the second requisite. Imagine Williams' Bon Chrétien Pear and a Winter Nelis gathered at the same time! yet such I have known to have been done. It is well known that Apples or Pears gathered before growth is complete shrivel and dry up prematurely, or, if this does not happen, they are "sticky," and never so thoroughly mature as to be usable. More Pears are made bad than are bad naturally through this one cause of premature harvesting; therefore I would recommend grumblers about "sticky" Pears to this season leave them longer on the trees. Unfortunately, no one rule is applicable to every case as to when an Apple or Pear is fit to gather, as soil, position, exposure, and shelter have much to do with the season of fitness to gather. But, as a sort of guide to the inexperienced who may be in uncertainty, I would say, if the fruit be very gently moved upwards and part readily, without the slightest pull, from the tree, then it may safely be gathered. Another good test is to cut open a fruit, and if the seeds or pips be quite brown or black, then the crop is fit to gather. Another test, in the case of the earlier ripening kinds more particularly, is when birds or wasps begin to attack them; these depredators are too good judges to make mistakes. Apple gathering in some parts is looked upon as a very ordinary operation, capable of being performed by anybody and anyhow, a plan which might answer if the fruits are to be ground into cyder or used forthwith, but if they are to be kept in sound condition for any length of time, too much care cannot be bestowed on gathering them, as the slightest bruise induces decay; and the same remark is applicable to Pears, with the addition that, if possible, even more care should be taken with them. The manner of storing in fruit rooms is also of importance. If space can be spared, the fruit should be put in single layers only, and certainly in no case should it be two layers deep. The room ought previously to have been

well cleansed and dried, and for the first two or three weeks after the fruit is gathered all the air possible should be given, as when first housed a moisture is given off by the fruit, which, if not driven out by free ventilation, lays the foundation for decay. Specky, bird-pecked, or wasp-eaten fruit should not be put in the same room with that which is sound. If it cannot be used at once, better throw it away than allow the fungus which it engenders to spread to the fruit which is good.

W. W. H.

PINES FRUITING PREMATURELY.

It often happens where Pines are grown in quantity that some of them fruit when they are little more than suckers, and before they have been put into their fruiting pots. In some places I have seen the whole stock nearly lost in this way. A general impression prevails that when Pines fruit prematurely they are of no further use. This spring, however, many of our last autumn suckers fruited immediately they were placed in their fruiting pots. To have thrown them away would have reduced our stock too much, and to have allowed the fruit to have ripened would have caused a blank next spring. By way of experiment, therefore, the fruit was removed without disturbing the plants. Soon afterwards two and three suckers pushed from the base of each fruiting stem, and after these had grown, until it was seen which was likely to be the best, all were removed but that one, and any one seeing these plants now would never know that they had borne fruit or had been dealt with in the manner just described, as they are as fine as they possibly could have been had no mishap occurred to them. The varieties were chiefly Queens, with a few smooth-leaved Cayennes and Jamaica amongst them. Although the smooth-leaved Cayennes do not produce suckers freely, as a rule when the fruit was cut off they threw up suckers as freely as the Queens; therefore, in that case, their fruiting prematurely has been a gain to us. Some consider the cause of Pines fruiting prematurely to be neglect, and it may be so in some cases, but not in all. Ours fruited from want of both top and bottom-heat, as the structures in which we grow them can scarcely be said to be heated at all. In summer they do very well, but in winter they are half starved compared with the conditions under which Pines are generally grown. Being kept so cool and quiet in winter, they bolt into fruit immediately warm weather sets in in spring. We have never any difficulty, therefore, in getting our Pines to fruit, and when any of our fruiting plants have large suckers on them in spring they produce fruit also. We have lately had Queens bearing four fruit at the same time, and all ripening together. The centre fruit weighed about 2½ lb. or 3 lb., and the three others on the suckers over 1 lb. each; therefore, there was not less than 6 lb. of fruit on the plant altogether, and the four were a great deal more useful than one fruit 6 lb. in weight would have been. Unless for exhibition purposes, large Pines are not desirable. In many places the dessert is not placed on the table, unless on special occasions, and then the Pine is cut up on the sideboard. It, therefore, matters not in that case whether the fruit is large or small. Small fruits 2 lb. and 3 lb. in weight are, on that account, much more useful, as a rule, than those double that weight, and small fruit can be more profitably produced. We have had a good many plants this season each of which has produced two fruits, and that is the way in which we now intend fruiting a good many of our Pines, *i.e.*, taking two and three fruit from each plant. Some affirm that suckers weaken the parent plants, but I do not think that they do so, as some of our plants, furnished with vigorous suckers, are bearing as large and finely-swelled fruit at the present time as those on which there are no suckers. Small Pine suckers take a long time to become large plants; they make far more progress when left undisturbed. Our smooth-leaved Cayenne plants have produced suckers freely this season, on some of the plants there being four and even five. This we attribute to watering them well at the axils of the leaves.

CAMBRIAN.

Coe's Late Red Plum.—I find this to be a useful variety when very late Plums for culinary purposes are required, and when grown and ripened on a wall it is even good for dessert. If netted and kept

secure from the attacks of insects it will hang very late on the trees. While speaking of late Plums I may remark that, although rather a thin crop in this locality, their hardier relations the Bullaces are particularly abundant and fine.—J. GROOM.

PROTECTING EARLY VINERY BORDERS.

AN admission has been made on this subject by Mr. Smith, of Waterdale, which calls for some comment. Your readers may recollect that in the discussion which has only lately taken place in THE GARDEN and elsewhere between myself and others on the subject of covering Vine borders with fermenting materials, allusion was several times made to Mr. Smith's practice, which was cited as an example of the successful production of early Grapes without the aid of fermenting materials, the reader being left to infer that the roots of Mr. Smith's Vines were principally under the said fermenting materials and outside—Mr. Hinds, of Otterpool, who has visited Waterdale, having perhaps done more than any one else to convey this impression. Now, as I have before stated, I only recommended fermenting materials to warm the outside roots of the Vines to a reasonable extent where the roots were all outside, and I stated so plainly, over and over again, not wishing to be misunderstood. The early Vineries at Waterdale were cited against me by my opponents, whom Mr. Smith has himself written to support. But now we get at the facts; observe Mr. Smith's statement in last week's GARDEN. He says, speaking of his early Vineries, "but all our early Vineries have the better half of their borders inside, which is, in my opinion, the most suitable place in the case of Vines that are forced early, the greater part of the roots being comfortably inside, where they can receive a regular supply of weak manure water at a temperature of 80°, and by the time the leaves begin to unfold the roots inside are ready for action, while those in the outside border remain quiet till the fruit arrives at the stoning period, and move just at the time when they are wanted to finish off the crop." Now here, in one sentence, the whole of the facts come out, and at one blow Mr. Smith destroys the evidence which he and his friends have before furnished in regard to his practice. First, Mr. Smith does not depend upon fermenting materials at all; the most of his Vine roots are "comfortably inside," where they are made still more comfortable by the "regular" application of water some 15° or 20° above the mean temperature of the inside border; and, secondly, Mr. Smith does not expect or wish the outside roots to come into action, but to "remain quiet" till they begin to move naturally about the beginning of summer, when the fruit is beginning to ripen. Comment is needless.

Wortley.

J. SIMPSON.

TOP-DRESSING VINE BORDERS IN AUTUMN.

IN many instances Vine borders are top-dressed in spring just when the young roots are beginning to push, and I am of opinion that more harm than good is often done by top-dressing at that time. Scraping the points off the young roots must give the Vines a check, and that at a very critical time. For a good many years we have been in the habit of top-dressing all our borders before the Vines have shed their leaves, and I am convinced that this is better than top-dressing when the Vines are just starting into growth. Early Vines are top-dressed sooner than this, but late ones may be done any time during September. All manure which may have been lying on the borders during the summer should be cleared off and the surface soil carefully removed down to the top roots. A layer of good substantial material should then be put on; loam and cow manure in about equal proportions, with a quantity of charred refuse in a rough state mixed amongst it, make a good compost for a surface dressing. After it has been applied, it may be trodden down firmly on the roots while it is dry, as in that condition the roots strike into it more freely than when it is loose. When this is done in autumn many of the roots enter the new soil before the Vines lose their leaves, and the advantages of this in spring are apparent, as the new roots in a healthy state are revelling amongst the fresh material and ready to assist the Vines in their growth from the very commencement. I have been told that Mr. Fowler, of Castle Kennedy, is in the habit of top-dressing his Vine borders in autumn, and if so, the advantages of this system have there been amply confirmed. I am of opinion that in many cases too much manure is employed on the surface of Vine borders. All who have need much of it will have observed that roots push into it freely, but what becomes of them? The manure cannot be left to form part of the permanent border; consequently it is annually cleared away, and fresh material substituted, and most of the roots in it are cut off and removed also; therefore a host of fresh roots have to be made. The removal of these roots must be injurious to the Vine, and I am satisfied that to put a surface-dressing of good substantial material on when it is required

would be better. A mixture, such as that which I have recommended, applied now does the Vines lasting good, and two or three good waterings with liquid manure when they are growing and swelling their fruit will give them as much nourishment as they would get from a surface-dressing of decayed manure. If the border be not thoroughly drained, or the least inclined to be retentive, nothing does it more harm than loading the surface with manure. It is then impossible for the soil underneath to dry, and, not being exposed to the air, it soon becomes cold, damp, and sour. This is just the kind of border in which Grapes will shank and fail to finish properly. With an open surface this could never occur, because the soil is naturally dried from the top, and then it can be seen when to give water, which is seldom the case when the surface is hidden under manure.

CAMBRIAN.

RASPBERRIES ON LIGHT SOILS.

THE Raspberry is difficult to manage on light soils, especially where the climate is very changeable; under such circumstances the Raspberry requires a deep moist soil, a shady situation, and plenty of water during the growing season, *i.e.*, while the young fruit-bearing canes are being formed. Where the ground is gravelly or light, it may be improved by removing a portion of the natural soil and adding fresh compost, such as decomposed vegetable matter, mixed with the refuse collected from the potting bench, or other similar material. On our light sandy soil here, the dry weather of the past summer brought growth to a standstill; the fruit was plentiful enough and of good quality but small, and the young canes were so weakly that anxiety was felt for the next year's crop. A crop of Cabbages planted between the rows was removed early last month, the old canes were cut away, and the young ones reduced to from three to four to each stool. The surface of the soil was then loosely forked over and a heavy mulching of horse manure, from the stable yard, was spread over it, and in addition to all this the ground has been thoroughly soaked two or three times since with liquid manure. The result is, the canes are growing apace and thickening, and by the end of the season they will be good for this locality. Too much importance cannot be attached to the position allotted to Raspberries where the soil and climate are naturally unfavourable. I have never seen such Raspberry canes as I once saw in the north of Scotland in a deep light soil in a low-lying district naturally shaded by trees from the fierce rays of the sun. Conditions such as these do not, however, exist in every garden, but they may to some extent be imitated. A cool position, surface mulching, and copious supplies of liquid manure will go far towards counteracting unfavourable conditions both of soil and climate.

W. HINDS.

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

Warner's King and Devonshire Queen Apples.—One of the finest Apples in the orchards here this season is Warner's King. From a fine young tree re-grafted in 1875, I have just gathered upwards of 160 fruit, eighteen of the finest of which weigh 15 lb. 3 oz. It is first-rate as a culinary Apple and for market purposes. The tree is a strong grower and a good bearer; that just alluded to is ten or twelve years old. Devonshire Queen Apple is also a useful kind. Being large and having a deep red skin, it makes a handsome dessert Apple for this month and October.—J. GARLAND, *Killerton, Evesham*.

Gathering Early Pears.—Although it is not advisable to gather late-keeping Pears a day sooner than the inclemency of the season compels us to shelter them, it is quite different in the case of early kinds, such as Williams' Bon Chretien, Citron des Carmes, &c. These are much improved by being gathered a week or a fortnight before they are required for use and ripened in the fruit room. This early gathering is also a means of lengthening the season of such kinds as are but a very short period fit for dessert if left to ripen on the trees.—J. GROOM.

The Argenteuil Figs.—I should be glad to know if any of your readers have tried any of the three following sorts of Figs, and with what results, *viz.*, Dauphine de Argenteuil, Violette Dauphine, very like the first, and also from Argenteuil, perhaps the same, and Noir Dauphine. I saw these three at the fortnightly horticultural show at the Paris Exhibition a few weeks ago, and was very much struck with them. They were shown in great quantities, as many as 200 or 300 on a dish; also on the trees and on branches cut and brought to the Exhibition literally smothered with fruit, which was also unusually large, three to the pound perhaps. They surpassed anything I ever saw at any British exhibition, with the exception of fruit of the Castle Kennedy variety, once shown by Mr. Fowler at Edin-

burgh, the only time in which I ever saw that Fig in its true character. The Castle Kennedy is, however, a shy bearer, and quite unlike these Argentei Figs, and I was not a little surprised to find such grand sorts, evidently extensively cultivated in the neighbourhood of Paris, unknown to us, at least, by name. I have looked over the "Fruit Manual" (old edition) but cannot find any of these three Figs alluded to. The Black Genoa seems to answer to the description of the Noir Dauphine, but one cannot be sure from description only. The three Figs named are at all events grand sorts, and I have purchased them all; but, meanwhile, I should like to learn if they are cultivated in this country.—J. SIMPSON, *Wortley*.

Canvas Shutters for Covering Vine Borders.—Where it is desirable to keep ripe Grapes hanging on the Vines as late as possible, if the roots be in outside borders, some provision should shortly be made for throwing off excessive rainfalls. After trying several different coverings I find one which allows a free circulation of air over the surface of the border to be better than any close covering that comes in contact with the soil; evaporation in that case is rendered almost impossible; the border benefits little from any drying intervals that occur, and in some cases the soil becomes even more sodden and uncongenial to the roots than when no covering is used. Vine borders should never be positively dry, but cold rain and snow water should be kept from the roots while they are comparatively dormant. A form of covering that is easily put on and taken off is stout canvas stretched tightly on a light wooden framework, made in widths of 4 ft. and 5 ft., and of lengths sufficient to cover the border. This kind of covering should have two or three coats of paint, oil, or waterproof composition, and if high enough at the back to give a good fall, heavy rains will be effectually thrown off, and during bright weather the covering may be removed altogether. In spring such shutters are exceedingly useful for covering bedding plants while being hardened off, or for protecting the blossoms of wall trees; in fact, they are always serviceable for some purpose or another, and a coat of paint every year preserves them for a considerable time if used with care. I must add, however, that if made of lengths sufficient to cover a wide border, several cross bearers must be introduced in order to hold the framework securely together.—J. GROOM.

How to Lengthen the Strawberry Season.—It is well known that Strawberry plants which have been forced early will, if planted out, generally bear a second crop in autumn, and if the early crop be heavy, the late one will be proportionately light, and *vice versa*. A number of the variety La Margherita, commonly known in Covent Garden as Marguerite, were accidentally injured when in flower and were removed to the open air. This occurred in March. As it happened, they were kept in pots, and in June they began again to throw up bloom. They were then set out to a growing distance, and allowed to root into the soil through the holes in the bottoms of the pots. Under these conditions they flowered and fruited during the whole summer and autumn. There was always a dish of fruit to pick. The French, as a rule, do not care much for the large fruited Strawberries that we in this country prefer. They like better to grow a sort which gives a picking the summer through. By employing the Alpine, and judiciously cultivating it, they are enabled to attain this object. Could we not do something in the same way with some of our own varieties? The Strawberry is just one of those fruits of which the last gathering is even more relished than the first, and the only complaint that I have ever heard concerning it was that its season did not last long enough. If we wish to have Strawberries late in the year, we shall have to adopt some method of retarding their bearing season, as we cannot expect to get any variety to produce fruit much later than the kinds which we possess. That it is possible to accomplish this I firmly believe; all that is required is system, in order to ensure a supply of Strawberries during the summer, autumn, and even winter. Two years ago, at housing time, many plants of Sir C. Napier were full of fruit. They were put in a cold frame where but few could ripen; had they been placed in a warm house, there would have been plenty of ripe fruit in December. I remember, too, a beautiful basket of fruit being gathered at Christmas from some plants which had stood in pots during the summer. Perhaps some of the readers of THE GARDEN may be inclined to act upon these few hints. I should recommend that the plants be allowed to flower, then have the trusses picked out and the plants placed in the open air. They thus receive a partial rest, and then start anew into growth. If planted out the yield would, of course, be greater.—J. CORNHILL, *Byfleet*.

Strawberries in September.—We are now gathering daily fine fruit from Vicomtesse Hericart de Thury in the open air—plants that were forced first and planted out as soon as they were hardened off in March. The runners were removed, and the first flowers were also picked off, and now we have a batch of fruit scarcely second to the crops of the same fruit in June.—W. H.

THE FLOWER GARDEN.

EULALIA JAPONICA.

THIS beautiful Grass, as its specific name denotes, is a native of Japan, but it is by no means restricted in a wild state to that country, being found in China, India, and many of the Polynesian Islands, &c. The variety *zebrina* reached Europe by way of America; and although the inflorescence of that variety is very handsome, it is chiefly for its ornamental foliage that it will be grown. There are, however, some magnificent varieties waiting to be introduced, notably one from the Himalayan Mountains, which possibly may prove to be a distinct species. Instead of a digitate inflorescence it has dense, narrow, plumose panicles. The late Mr. R. Oldham collected specimens of a plant, very much like the one in cultivation, on hillsides in Japan. He describes it as growing from 3 ft. to 4 ft. high, which would also tally with our plant, and from the situation in which he collected it should be hardy with us. The varieties which grow in warmer parts, if varieties they be, are plants of much larger stature, attaining from 6 ft. to 8 ft. or more in height. A panicle in the Kew Herbarium of one collected at Hong-Kong is upwards of 18 in. long and nearly 12 in. broad. Some of these grand Grasses should be introduced for associating with Lilies, &c., in aquaria. W. B. HEMSLEY.

ARE LILIES ANNUALS, BIENNIALS, OR PERENNIALS?

THE solution of this question suggested itself to me on reading "W. J. T.'s" note of August 24 (p. 177), in which he says: "If this bulb had been perennial, *i.e.*, dependent upon itself for existence, and not upon a successive and distinct growth, as maintained by 'Dunedin,' I cannot think that it would have survived the treatment above mentioned, or, at all events, that it would have had strength enough to flower at this season." The beauty of the flowers, says M. Duchartre, "has attracted the attention of horticulturists to these plants for a good many years, but by botanists they have been somewhat neglected." I will go further and say that some professors of botany, both at home and abroad, have published theories that have no foundation upon which to rest. Some also tell us that the Lily is a perennial, and pass on without saying more. Our own countryman, Mr. Baker, has, however, gone into the subject at great length, and, if I may be allowed to say so, in a most admirable manner, in his "Generic Characters of all the Lilies" in the "Journal of the Linnean Society," a translation from which may be seen in THE GARDEN of April 10, 1875. But even he, it appears, has found this particular part of the subject to be somewhat of a stumbling block in his path. Out of a list of forty-six Lilies, he describes twenty-nine as perennials, four as annuals, one as an annual or biennial, and to twelve he gives no name. In framing his synopsis he says in a contemporary: "If, in attempting to do this, I overlook or misunderstand any characters which are valuable for distinctive purposes, I hope that your horticultural readers will not fail to correct what I have mistaken, or to add what I have omitted, as this is a genus in which there is an especial need, in order to put it upon a sound botanical footing for botanists and horticulturists to work together." An invitation so freely and frankly given should be responded to in the same spirit. I therefore accept it with the view of simply stating that, in my opinion—founded upon experimental facts—he is mistaken in thinking that Lilies are either annuals, biennials, or perennials. Then, what are they? This is what I propose to explain. All true Lilies partake more or less of the rhizomatose character, that is, the underground portion of the stem, commonly called the bulb, moves year by year in its new growth, or in the growth of the new bulb, further away, in a direct line, from the scars or sites of the growth of preceding years, unless unnatural growths interfere. M. Max Leichtlin makes a slight mistake in saying of *L. Washingtonianum* that I would find inserted in one long sideward-growing bulb the accumulated growth of eight or ten years. He should have said "straightforward-growing," though, from the manner in which he held the specimen, it

might have appeared to be growing "sideward," as in the case of my own specimen (p. 237). But mine was simply held so to enable the photographer to take in the greatest number of important points at one view. This is clearly illustrated by the artist (p. 135) of THE GARDEN, February 17, 1877, by a sketch of *L. Washingtonianum* itself. There the artist places the specimen bulb as growing to the left. But this matters not, for it all depends on how the specimen bulb is held, as the change of position cannot alter the growth in a "straight-forward" direction.

In this case it is to be regretted that the artist did not pick off the old scales, so as to uncover the new bulb. At page 155, February 24, 1877, the same artist gives a very fine illustration of the same direction of growth in *L. Hansonii*. On our left we see the new bulb springing up from amongst the old scales, and on our right we see the old stem. If "F. W. B." had just taken the trouble to pick away all the old scales from around the new bulb and the old stem, he would have laid open the new bulb, the old stem, and the scar or site of the stem of the previous year—a view which would have been well worthy of his pencil. If he had done this, he would have saved me a great deal of writing. I know of no other plants which can be compared in their underground action with true Lilies, and, therefore, there need be no difficulty in marking the difference. We have an annual bloom, but not from the same bulb. The bulb that flowers one year will never bloom again. This is an incontrovertible fact, all attempts to prove the contrary having failed. While one bulb is flourishing in its first and only bloom, a new bulb within the old scales is progressing in its growth, so as to be enabled to bloom next year in place of the one now blooming, which will then be dead—thus keeping up a yearly bloom from successional bulbs for an indefinite number of years, if successfully cultivated. What I have now stated, it will be seen, is contrary to Mr. Baker's theory. He says, "A new bulb, whether grown from seed or from bulblets developed in the axils of the aboveground leaves of the floriferous stem, or produced in the axil of one of the bulb-scales, takes not less than three years,

under the most favourable circumstances, before it develops a flower-bearing stem." So far I quite agree with him, but it will be seen that he entirely ignores the legitimate seed-bud, which, instead of taking "three years," grows up, and is ready to flower the very next season after the parent bulb has bloomed. Mr. Baker then proceeds: "The first season we get an ovoid mass, perhaps $\frac{1}{4}$ in. in thickness, composed of half-a-dozen tightly imbricated scales, which sends out three or four slender, radicular fibres from its base. At the end of

next summer we have a bulb as large as a Hazel nut, with a copious development of strong radicular fibres from its under side, and the half-dozen scales prolonged above the soil into a rosette of ob-lanceolate leaves." This is all true enough, but it can only have reference to the growth of bulblets, small off-sets, or to adventitious buds. It can have no reference whatever to the legitimate or successional seed-bud, which is always out of sight until the middle of the summer, when, if the blooming bulb be lifted out of the soil, it will be seen to be a grown-up, fully-developed bulb, bursting up from among the old scales. Mr. Baker goes on: "Next year, if circumstances be favourable, the flower-bearing stem is developed, and then, if nothing untoward happen, the bulb goes on living for an indefinite period, sending out each year a flower-stem from its centre and shredding off old scales with buds from their axils—more copiously in some kinds, less copiously in others—from the circumference all round." Such is, or was, Mr. Baker's belief. But it is now proved beyond a doubt that the same bulb does not "go on living for an indefinite period, sending

out each year a flower stem from its centre." It is due to science that he should reconsider the matter, and amend his theory, or strike it out altogether, so that, in his own words, "this genus may be put upon a sound botanical footing for botanists and horticulturists to work together." *L. candidum*, or the White Lily—though certainly not a perennial, as Mr. Baker describes it—I look upon to be a correct type of a true Lily—the radical leaves being

The Zebra-striped Eulalia (*E. japonica zebrina*).

excepted—for whatever leading principles may be traced in its bulb, may also be traced, with ordinary care, in the bulbs of all true Lilies. It is the best known, being one of the oldest inhabitants of our gardens. The bulb is large, cheap, and plentiful, and is, therefore, well suited for dissection in any number at comparatively little expense. On this account, and in order that all who have a few white Lilies may be enabled to follow me, I have shown by photographic representations, and by the dissected bulbs themselves (drawn by THE GARDEN artists), the progress of growth in the reproductive organs in all stages. At p. 143, February 16, 1878, I have shown the seed-bud in a dissected bulb taken up on the 1st of January, the seed-bud being somewhat larger than a canary seed. At p. 263, April 7, 1877, I have shown the seed-bud, now a young bulbule, about $\frac{1}{2}$ in. by 5-12ths in. in diameter, taken up in March. In this case the artist made a mistake in showing the bulbule in front of the stem, instead of by the side of it, which would have shown that they were distinct from one another. At page 61 (July 20) I have shown another, marked No. 33 of the specimens, about $1\frac{1}{2}$ in. by $1\frac{1}{4}$ in. in diameter, taken up in the beginning of May, and at p. 237 I have shown the same, now fully developed, about $2\frac{3}{4}$ in. by $2\frac{1}{4}$ in. in diameter, the bulb having been taken out of the ground on August 6 last, showing with what rapidity the new bulb grows, according to an increased ratio, between January 1 and August 6, during which time the parent bulb, unlike a perennial, has been preparing, and has actually bloomed. No one in the slightest degree acquainted with the true nature of Lily bulbs can look upon these representations without seeing that the bulb of the season can only send out one flower stem, and then by successional, but distinct, new bulbs send out afterwards, year by year, one flower stem each, the bulb that blooms one year being dead by the time its successor blooms next year. As to being perennials no one can say with truth that these bulbs "live and flower for more than two years," this being the definition of the term "perennial." Nor can they say that there is anything to distinguish them as annuals or biennials. With regard to the bulb "shredding off old scales," as Mr. Baker says, "with buds from their axils—more copiously in some kinds, less copiously in others—from the circumference all round," many of the readers of THE GARDEN seem to have been misled by this passage. Mr. George F. Wilson, at p. 252, March 23, says: "I have always believed it to be an acknowledged fact that when *L. giganteum* flowered, its bulb decayed, leaving a circle of root bulbs to carry on the race." It is true that the bulb of *L. giganteum*, like all true Lilies, decays and dies after flowering, but the circle of root bulbs—or small offsets—cannot carry on the race in a direct successional line, as they are only fit to be picked off and planted out for "not less than three years," as Mr. Baker remarks, before they can develop flower-bearing stems. These small offsets may be found on the outside, or circumference, of many Lily bulbs, but it is more correct to call them "adventitious" buds, as the exact spot where they may present themselves cannot be foreseen, nor can it be known beforehand whether they will appear or not, nor in what numbers; whereas, the legitimate successional seed bud (which has been altogether overlooked by Mr. Baker), being unseen, will grow up and bloom the second season after it has been generated, after which it decays and dies. Though unseen until it becomes a fully-developed bulb, the expert knows at all times where to find the seed bud. In my paper, p. 237, when referring to the new bulb marked D in the woodcut, I said that if the new bulb were further cut away, we should find on the right, but close to the stem of the new bulb, the germ or seed-bud which was destined to grow up and bloom in 1880. Three days after I had written this I took the specimen bulb, at the request of a visitor, and picked off the scales on our right side until I had laid bare this same germ or seed-bud, which is now lying before me, adhering to the core close to the new stem—looking like a small disc of white wax, about the thirty-sixth part of an inch in diameter.

DUNEDIN.

The Black Snakeroot (*Actæa racemosa*).—This is both a graceful and a pretty plant, though not very showy. When well grown it forms fine specimens, with thrice-divided root leaves 2 ft. in length. Its flower stalks are from 4 ft. to 6 ft. in height, much

branched, on which are arranged, in long, dense racemes white feathery blossoms, which retain their freshness a long time, and are well adapted for cutting. The blossoms are succeeded by small green fruits, which remain on the plants for two or three months. Taking it altogether, it is a strikingly attractive hardy plant, suitable either for the ordinary border, for margins of shrubberies, or as isolated specimens on lawns, the latter being preferable, as in that case it is shown to the best advantage. It thrives best in partial shade, as it inhabits the shady woods extending from Canada to Georgia and the Western States of America. Nearly allied to it, and equally as fine a plant, is the Fetid Snakeroot (*Cimicifuga foetida*), but the seed vessels are different, being longer and membranous, whilst in *A. racemosa* they are nearly round and berry-like.—W.

LILY CULTURE AT ROCHDALE.

MRS. NEWALL has just sent me a few words of comment on "Dunedin's" letter (p. 216). She writes as follows: "'Dunedin' misunderstands my letter a little. I do not say that my plants degenerate and that the flowers grow smaller and the stems dwindle every year. I simply mean that, contrasted with what they were when only put out for the summer, they are smaller. Against that I set the great gain that, becoming acclimatized, the flowers appear earlier each year, and the stems, strengthened and hardened, if shortened, require no props. My friend, Mr. Wilson, has seen my Lilies. I am no botanist, only a lover of flowers, and act from experience and observation. I garden, too, under great disadvantages; the smoke from mills, brickkilns, and tile works comes between my flowers and the sunshine; even the trees are hide bound, and smother up the pores of their leaves. When the wind blows from the direction of the tile works you can trace its pathway through the blighted foliage. If we have much rain there is too much leaf, too little flower; if there is little rain everything is black with soot; so black, that Nature when she brings her rain clouds so low over our hills intends us a kindness, for the rain deluges are needed to wash off the accumulated layers of dust and soot. Last year the frost came unusually early and nipped my Lily buds; this year they are flowering earlier and will escape. In 1876 (December), long after the Dahlias hung blackened and rotted on their stalks, my dinner-table was decorated with specimen glasses full of the lovely scented flowers of my *L. speciosum*. I generally cut the large buds before they open, because our sooty atmosphere blackens the petals, and its rains and winds rob the stamens and powder the pure white blossoms with their orange pollen. About transplanting, I cannot help thinking there are two sides to the question, and that many plants, both bulbous and tuberous-rooted, flourish best undisturbed. Have you never noticed and envied in old-established gardens clumps of Martagon, of *L. candidum*, of Scillas, Lilies of the Valley, Frillillarias, and Hellebores, growing in a luxuriance into which no cultivation can coax them in our own garden borders?" I have often quoted Mrs. Newall's Lilies as showing what can be done by loving care in unfavourable situations, but I hardly before realised the difficulties with which she had to contend. G. F. WILSON.

Heatherbank, Weybridge Heath.

— I am sorry if I have said anything (p. 216) to annoy Mr. Wilson, but certainly I could not help being surprised at the advice which he gave to Mrs. Newall, as I thought he must have overlooked certain important points in her letter which at once caught my eye. But now he seems to make matters worse, for in his explanation (p. 238) he admits that, "as a fact, he did see Mrs. Newall's Lilies in growth as recently as last summer;" and yet, when she tells him that the flowers are smaller this summer, and also that the plants are dwarfing—one of the worst complaints to which the Lily is liable—he says: "My advice was short—'leave well alone.'" Mr. Wilson must have known that Lilies may do very well one season, and go off all of a sudden next year; therefore, "leaving well alone" should have no place in the Lily grower's memorandum book. In fact, to use Mr. Wilson's own words, Lilies should be attended to with the most "intelligent and loving care," and not be left, at least in this country, to take care of themselves. He says he thinks Lily growers of experience will agree with him that he was right. I think not. If he will look at "R. C. R.'s" letter, on the same page with his own, he will see that "R. C. R." says: "From a single stem my plants increased year by year till the stems numbered about thirty, but by this time they had begun to grow weaker, and the blooms were growing smaller," almost the very words Mrs. Newall makes use of. "R. C. R." then goes on: "It occurred to me that the soil was exhausted, so I resolved on seeing what was at the root, and in making the shift I found deep in the soil quite a nest of bulbs; they were separated and planted in fresh soil, and now I have bulbs by the hundred,

and blooms of the greatest beauty by the thousand." This is strong confirmation of the correctness of my doctrine when I said, in reference to Mrs. Newall's Lilies, that "they were dwindling away for want of proper cultivation, being clotted together, and living on one another, instead of being lifted, separated, and transplanted into fresh and better soil." Mr. Wilson says that I am not correct in assuming such a thing. My experience is my authority for saying so. Many years ago, when Mr. James Carter first offered *L. speciosum* (then called *lancofolium*) for sale, I procured a supply, and planted them out of his grounds into my own garden on the same day. Every three or four years I lifted and transplanted them with the same results, that is, the first year they bloomed best, the second year very well, but the third and fourth years they evidently deteriorated. I have the successional bulbs now in my garden (for, remember that the parent bulbs die every year), where they have been left undisturbed for the last four years, for experimental purposes. But now they are fewer in number and dwarfer—a sure sign that the successional bulbs are degenerating, their constitutional organisation being affected through the want of generous diet and proper culture. Many thanks to Mr. J. Stewart Gathorne Hardy for his communication (p. 238).

DUNEDIN.

SALVIA PATENS BEST LIFTED IN AUTUMN.

I WELL recollect the time when this lovely blue-flowered *Salvia* was first used for planting out-of-doors, and the unqualified praise which it received from all who saw it. When the ribbon style of summer bedding was first introduced it formed one of the most charming objects in such combinations, relieving them somewhat of their objectionable formality made still more conspicuous when the close-growing plants selected for ribbon work in later years came into use. It is equally suitable for planting in masses amongst herbaceous plants, or in any position in gardens where flowering subjects of a like stature are admissible. In fact, it can hardly be spoken of too highly, with the exception that it is not of much use for cutting, as the flowers fall off quickly; yet, even with this drawback it is difficult to understand why this *Salvia* is now so seldom seen. The fact can only be accounted for on the ground that, in the never-ending crave for novelty, there is not room for all, and that it, along with no small number of most deserving plants, is consigned to oblivion to make way for new-comers. But communications such as that of "J. G." (p. 239) respecting this plant lack the caution necessary in writing upon the cold-resisting powers of half-hardy subjects like this, and are calculated to lead to serious disappointment, for, except in the most exceptionally favoured spots in the kingdom, a severe protracted frost will reach and destroy the roots when under the ordinary protection of ashes, tan, leaf mould, or anything applied in the manner in which these are used. The real fact is, that the recent mild winters which we have had have induced many to look upon the cold-resisting abilities of a considerable number of plants from a point of view which the first severe continued frost that we experience will dispel in anything but an agreeable way. So little trouble is involved in taking up and storing away the roots of this *Salvia* and other plants of a similar character, that it is unwise to risk them out-of-doors, and the superior manner and long period during which it, and other plants of a like nature, will flower when taken up and divided, so as to confine them to fewer shoots than when left in an undisturbed mass, with the opportunity given for fully incorporating manure with the soil, render their being taken up in the autumn preferable in every way to risking their destruction in the open ground.

T. BAINES.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Hardiness of *Physianthus albens*.—When visiting an old fashioned garden belonging to some lady friends, in this neighbourhood, the other day, I was much surprised to see a most luxuriant mass of the above-named plant from Buenos Ayres, figured in Vol. LIX. of the "Botanical Magazine" (published in 1832), tab. 3201, and usually supposed to require the temperature of a stove, or, at least, of a warm greenhouse, covering the garden wall to a height of 9 ft. by 12 ft., where, my friends informed me, it had grown unprotected for these last twenty years, proving itself to be almost perfectly hardy, only severe frosts ontng back and injuring those shoots that overtop, and so are deprived of the protection afforded by the wall. It is deciduous in winter, and occasionally produces handsome, large, deep orange-coloured fruit, the size of a turkey's egg, but somewhat longer, and resembling the fruit produced by some *Passifloras*. My friends had never heard any name for this plant, but had named it for themselves The Cruel Flower, from the fact that the blossoms, which seem very attractive to all sorts of insects, and especially to the humming-

bird moth, have within them some viscid or glutinous matter, to which the proboscis, when inserted into the flower, seems to adhere so firmly, that they are unable to withdraw it, and, being thus detained prisoners by it, flatter about till they die.—W. E. G., *Queenstown*.

Phlox Drummondii a Continuous Flowerer.—Not the least amongst the many good properties possessed by this beautiful annual is that of its flowering continuously late in autumn; when most of the occupants of the summer flower beds begin to fade this is even more floriferous than in the height of summer.—J. G.

Flower Gardening at Lambton.—This has been very brilliant this season. Conspicuous amongst Pelargoniums may be named Robert Fish, a variety which seems to do extremely well in the North. It has a sturdy habit, and the flowers are borne upon stout foot-stalks well up above the foliage. Amongst Lobelias, St. Martin's Blue appeared to be the best; it is a dark, bronze-foliaged variety, of an effective shade of colour. Another plant which succeeds well at Lambton is Harrison's Musk, which the extreme drought experienced there this summer did not affect nearly so much as it did other bedding plants; and so persistent are its blooming properties, that the heavy rains which we had in August did not impair its appearance for more than a day or two.—TYNEDALE.

Protecting Tall Chrysanthemums in Windy Weather.

—The situation in which we place our pot plants is sheltered by walls on the north and south, and by bothouses on the east and west, but it is otherwise fully exposed to sun and air. The plants are arranged in lines across the plot of ground, and a strong stake is driven down at either end of the line; cords are then run between the stakes at from 1 ft. to 2 ft. apart, and made fast at each end. The base of the stem is made quite fast to the bottom cord, but as the extremity of the shoot is approached the ties are made gradually looser, the last one, which is within 2 ft. of the extremity of the shoot, having an inch or two of play. The consequence is, that in windy weather the whole mass moves to and fro with the wind with little or no breakage; whereas, before this plan was adopted, though to every stem there was a stake, a sharp gust of wind used to break the tops off the shoots where they were made fast to the stakes. No plan is so safe as leaving plenty of space for vibration, whether upright stakes be used or not.—W. HINDS.

Useful Plants for Carpet Gardening.—Allow me to thank Mr. Niven for his note (p. 234) on this subject. I shall certainly obtain the two plants which he names, viz., *Veronica læta* and *Acœna microphylla*. The other two—*Mentha Pulegium gibraltaria* and *Herniaria glabra*—I grow largely, but my experience of them is the very opposite of that of Mr. Niven, as the *Mentha* when cut weekly with hand-shears is the most perfect sheet of emerald green it is possible to conceive. The *Herniaria* is a duller green, and, as a matter of course, not nearly so effective, but it has this advantage, that it requires no clipping, as it naturally grows quite flat on the ground. The best cream-coloured or whitish-yellow plant for such work is *Sedum acre elegans*; we have used it in lieu of *Mesembryanthemum cordifolium variegatum*, and with decidedly better effects.—W. WILDSMITH, *Heckfield*.

Creepers for Training over Cottage Doors and Windows.—It is a simple matter, the planting a Honeysuckle, Clematis, or Jessamine beside a cottage doorway, or the placing of a potful of earth on the window-sill outside, and sowing a few seeds of the Canary creeper or *Convolvulus* in it; and yet what a large amount of pleasure it is capable of affording, not only to the actual possessors, but to passers-by—indeed, from my point of view, the latter is one of the greatest benefits it confers. Example is better than precept, and the lesson taught by a chastely decorated cottage front is carried home to many hearts. Some time ago I was passing a cottage that gave evidence that more than ordinary pains had been taken in ornamenting its doorway and windows with living plants. Over the doorway were trained Clematis Jackmanni and *C. Flammula*, mixed and blended together; and as the former became thin of flowers the latter opened its numerous small white sweet blossoms, which scented the atmosphere round. Round the windows were trained Canary Creepers and blue *Convolvulus* mixed, planted in boxes, which were also furnished in addition with Mignonette. I waited a few minutes beside the house to see what notice was taken of it by the people passing, and the effect was magical; not a single face but wore a pleased look as the eyes glanced upward and took in the view. And, after all, the trouble and expense was a mere nothing; at the most, two or three shillings would buy all the necessary requisites to begin with, and many a man spends that or more in a single week without deriving the least benefit from it in any sense.—E. HOBDAV.

Phytolacca decandra.—At this season there is scarcely a hardy herbaceous plant to equal this. Its large handsome fruits are quite ornamental, and the plant will keep in good condition until it is cut down by frost.—J. G.

NOTES FROM "THE PINES."

In a fairly large collection of ornamental shrubs, I know of none that is more desirable than the

Double-flowered Deutzia crenata.—I refer to the shrub first introduced under that name, and which has been in our collections for several years. In the first place, it fills a gap, by coming along just after the Weigelas and other early-blooming shrubs have done flowering, and makes its display about the middle of June. It first gives us a few days of promise, and these show the outside of the petals with a most charming tinge of purplish rose. The few days it remains in this state, are, in my opinion, the best; but after this it comes into full flower, and the bush is a sheet of white, as, by opening, the interior petals quite hide the outer coloured ones. After this excellent shrub had become well established, the nurserymen offered, with some flourish.

Deutzia crenata alba fl.-pl., which, being interpreted, means the White Flowered Double Deutzia crenata. This has flowered with me this season, but it is in no respect preferable, indeed, not equal to the older variety. It is true that the flowers are pure white throughout, but give only pure white, while the older kind gives us both the purple-rose tinge before it fairly opens, and at length as good a white as the other. In former notes I have mentioned our

Native **Wistaria frutescens**, as a much neglected climber. It does not flower until the vine is in full leaf, and its flowers are not so large or of so deep a purple as the more generally cultivated Chinese species. It is for the very reason that it flowers later that I value it. The Chinese is good in its way; still, if I could have but one, I should take our native, as it gives foliage at the same time with its flowers. Having cultivated the ordinary purplish-flowered form, and also the white variety for several years, I was quite surprised to find, in conversation with horticultural friends around Boston, to learn that

The **White American Wistaria** was quite unknown at that centre of horticulture. This led me to "hark back" on the plant, and trace its origin. I found that my plants were sent me, the season that I came to "The Pines," with a very generous contribution of other hardy shrubs, from my not very distant neighbour, Mr. A. S. Fuller, and that he procured his original plant from Mr. W. R. Prince, of Flushing, who had in his time a most remarkable collection. Beyond this it is not possible to trace its history; but those who knew Mr. Prince in his younger days, are aware that he spared no pains in procuring any new and strange plant that he might hear of, in any part of the country. Several years ago a gentleman in Tennessee (I think) sent me some small trees of

The **Dyehouse Cherry**, so called because it originated on the place of a person by the name of Dyehouse. When they came, I, to save them, put them in temporarily where they grew a year or two, and were then set out where they were to remain. This is the first year that they have borne anything of a crop, and though the trees are not over 6 or 8 ft. high, they were fairly filled. The fruit was ripe at least a week or ten days before the Early Richmond, heretofore the earliest Cherry I had, and while about the size of that, is a palatable fruit. The Early Richmond, even when dead ripe, is, to my taste too sour for anything but cooking.

New Varieties of Japan Iris.—Mr. Thomas Hogg, who was the first to introduce Iris Kämpferi, has selected 20 of the finest varieties of this charming plant, which he has named as follows: 1. Ichiban, light reddish purple, pencilled with white; double; dwarf; medium early. 2. Prof. Thurber, purplish blue, mottled and spotted with white, fine yellow eye; double; early; first-class. 3. Princess, lilac, finely pencilled with blue; double; dwarf; fine. 4. Robert Buist, dark indigo blue, fine yellow eye; double; first-class. 5. Mr. Buchanan, light indigo blue, fine yellow eye; double; large; extra fine. 6. Emperor of Japan, maroon; first-class. 7. Pearl, pure white; tall; early; first-class. 8. Daimio, dark pink, pencilled with white; medium height; early. 9. Fusi-yama, white, pencilled with purplish stripes, purple centre; tall; early; first-class. 10. Mr. Chotars, light blue, striped and mottled with white; tall; early. 11. Minister Mori, white, deeply laced with pink; early; first-class. 12. Ieyas, purplish blue, solid colour; tall; early. 13. Murnsaki, purple, wavy petals. 14. Water Nymph, white, deeply laced and shaded with lavender; tall; early; distinct. 15. Diabertz, deep indigo blue; semi-double; dwarf; medium early; first-class. 16. Imperial Standard, purplish pink, mottled with white; tall; early; first-class. 17. Oentossma, light purple, slightly mottled with white; tall; very early; handsome. 18. Empress of Japan, lavender, pencilled with white; tall; medium early; first-class. 19. Perfection, white, pencilled and mottled with purple; dwarf; medium early; fine. 20. Virginialis, double white; extra fine.—"American Agriculturalist."

PLATE CXLVI.

DWARF ALPINE ARMERIAS.

(WITH A COLOURED FIGURE OF A. SETLCEA)

CONSIDERING the large amount of attention that has been paid for some years past to Alpine vegetation, it is somewhat surprising that this interesting class of plants has not become more plentiful than they are. To all true lovers of such miniature forms of vegetation the following will, I feel confident, be truly welcome, and will prove valuable additions to their gardens.

Armeria setacea.—Of this the accompanying figure will give a good idea. Its little globose heads of pink flowers are produced so plentifully as almost to conceal the other portions of the plant. The leaves are flat on the upper surface with a distinct depression down the centre; they are very narrow, and about $1\frac{1}{2}$ in. in length. The flower stems vary from 1 in. to 3 in. high. This and *A. juncea*, mentioned below, were found on barren, stony mounds, on elevated table-land, in the south of France. They have been cultivated for two years in the nurseries at York, and have proved to be quite hardy and of easy culture. They grow freely in sandy or stony earth, either in the open border, on rockwork, or in pots, and their neatness and compactness of habit fit them for association with the choicest of Alpine flowers.

A. alpina.—This is found at from 2000 ft. to 8000 ft. elevation on nearly all the European mountain ranges. It is rather dwarfer than the common form *A. maritima*, and, if possible, more compact. The colour of the flowers varies considerably from deep rose to pure white. I have grown the variety for the last few years called *rosea* on a rock plant, and very pretty it is when planted in a dry and somewhat poor soil.

A. cæspitosa.—This is a very handsome rose-coloured species from the south of Europe, where it is found growing at an altitude of from 5000 ft. to 8000 ft. above the sea level. Its flower heads each measure from $\frac{3}{4}$ in. to 1 in. in diameter, and are borne on slender stems from 1 in. to 2 in. high, from June to September. The leaves are narrow and flat on the upper surface, with a slight depression down the centre. They are from $\frac{1}{2}$ in. to $\frac{3}{4}$ in. long, in dense tufts, with a branching, woody rootstock. It is as yet seldom met with in cultivation.

A. juniperifolia.—Some consider this to be synonymous with *A. cæspitosa*, but the two are quite distinct, not only in habit, but in other respects. *A. juniperifolia* is a diminutive plant, forming hemispherical little tufts from 2 in. to 3 in. in diameter, composed of small rosettes from $\frac{1}{2}$ in. to $\frac{3}{4}$ in. across. Its leaves are very minute, only being from $\frac{1}{4}$ in. to $\frac{1}{2}$ in. long, with a small spine at their extremities. The flowers I have not yet seen. It thrives well in smashed granite and sandy loam.

A. juncea.—This is another pretty little species that resembles tufts of miniature Rushes, about 1 in. high. Its flowers, which are pale pink, are produced in great profusion in dense heads $\frac{1}{2}$ in. across, set on slender wiry stems from 4 in. to 6 in. in height.

With regard to culture, I may just remark that they thrive freely in any well-drained, rather poor, sandy loam. I have noticed that if the soil in which they are planted be too rich, they thrive most luxuriantly for a time, but in wet weather they are liable to damp off between the foliage and the root. The different species named above range, as regards the time of flowering, from May to September. The dwarfer kinds are propagated by means of seed, and the more vigorous sorts by division early in spring or in autumn.

R. P.

[For the plant from which our figure was prepared we are indebted to Messrs. Backhouse, of York.]

Half-hardy Shrubs in Pots.—It is surprising that the common Continental practice of growing certain shrubs in tubs and wintering them in cellars has not been adopted among us. Of the shrubs useful for this purpose, the Oleander, the Maple, the Pittosporum, and the common Fig may be named. The practice is only worthy of a lotion in towns and other places where plants may not be easily had in the usual way. It is not worth carrying out as regards hardy shrubs that grow in the open air with us, particularly as there is a variety of fine half-hardy shrubs that require winter protection. Given that, they flower well out-of-doors in summer, and with their aid a pretty little garden may be made in a hot courtyard in front of a house on a

ALPINE CAMPANULA

balcony, and in various other positions where gardening in the usual way is out of the question. Would not other fruits be worth growing in this way as well as the Fig?—V.

PROPAGATING.

BOUVARDIAS.—In order to increase these successfully, they require a box in the propagating house to themselves. Plants of them for propagation must be cut back to the ripe wood, and got into a house, the temperature of which is 65°, in March, when they will push young growths quickly. Keep them well syringed two or three times a day, and when the shoots are sufficiently large take them off, and make them into cuttings as shown at fig. 1. Insert them in sandy soil (peat and loam), with sand on the surface, and plunge them in a brisk bottom-heat in the cutting box. In about ten days roots will be emitted; they must be occasionally moistened overhead and kept close. As they begin to show signs of growth air should be gradually admitted, but not so much at once as to give them a check, as their aftergrowth depends very much upon how they are treated when young. As the wood gets harder, the cuttings should be made as seen in fig. 2. Where roots are employed, select some strong plants in March, shake away the soil, and cut off all the strongest and freshest-looking roots, avoiding such as look in any way decayed; cut these up into pieces 1½ in. long, as represented in fig. 3; place them flat in pots or pans filled with the same soil as that used for the tops, and cover them over to the depth of ¼ in. with soil, or they

Fig. 1.

Cuttings of *Bouvardia Humboldtii corymbiflora*.

Fig. 2.

Fig. 3.

may be placed singly in very small pots; give them a good watering, and place them in bottom-heat, but without any covering over them. As soon as they begin to push through the soil, water sparingly, and as soon as they have made sufficient growth pot them off and set them in a humid atmosphere. If the roots be not stout and strong, they will not be likely to make strong plants; weakly-rooted varieties are, therefore, best increased by means of ordinary cuttings. H. H.

Hall's Honeysuckle (*Lonicera Halleana*).—In the general confusion in which the genus *Lonicera* is at present, I will not undertake to say to which botanical species this belongs, but as it is in several catalogues as *Lonicera Halleana*, there can be no difficulty in getting it under this, its horticultural name. Any one who knows a good plant when he sees it, cannot fail to appreciate this as a most valuable climber. Its lithe slender stems make it a most manageable plant. I have it growing flat upon the ground, and running up upon what is part fence and part trellis, and also under pot culture. It is one of those easy-going plants that will grow anywhere, and bloom whether 2 ft. or 20 ft. high, and—what is more to the purpose—keep on blooming. It blooms right along all summer. Its flowers, when they first open, are of the purest white; a little while later they are of a delicate buff colour, and before they are done with, become darker still—almost an orange colour. All the while they have a most pleasing perfume.—“*American Agriculturist*.”

GARDENING FOR THE WEEK.

Indoor Plant Department.

Sobralias.—These Orchids, though remarkable for the size of their individual blooms, do not find favour with cultivators to the extent to which their merits entitle them. One reason alleged for their being not so much grown is the short-lived character of the flowers, as they do not last more than three days, but against this it must be borne in mind that they are amongst the most certain of free-flowering plants. Every fully-developed shoot of the preceding year's growth, with the most ordinary management, may be considered certain of blooming, producing in succession from three to six flowers, so that with a good-sized plant from six to a dozen blooms will be in perfect condition daily for several weeks. If required for cutting, where any of the many slightly different forms of March stands are employed, nothing that I have ever tried is more effective for placing in the base of these than *Sobralia* flowers. The plants will now be in active growth, and if the old bloom stems have not been cut away from such as flowered early in the spring they may now be removed, but I have found it in practice much better not to follow the course frequently pursued in removing them as soon as the flowering is over, for, as might be supposed, they exert a good deal of influence in imparting strength to the young shoots now progressing, which spring from eyes immediately at their base. In place of cutting them away early, particularly with young plants which it is desirable to grow to a larger size after blooming, tie them out at a considerable angle from the centre of the pot so as to give the rising shoots room and prevent their being drawn up, which the old bloom stems will be apt to cause if allowed to overhang the young growth. There is no position in the Orchid house that suits these plants better than the extreme end of the structure, where this, as it always should, consists of glass, in place of the too often introduced brick wall. In such a situation, their clean, healthy-looking shoots form a pleasing contrast to the dwarfer-growing plants, and do not overshadow them; so placed, the *Sobralias* themselves do not become drawn up too tall, a disposition to which is objectionable. There are several varieties, especially of the *marantha* section, differing little, except in their dwarf or tall habit. It is well to select the lowest growing kinds, of which Woolley's dwarf variety with its large intensely-coloured flowers is one of the most desirable; *S. Liliastrum* is another fine kind, as also *S. violacea* and *S. virginalis*. All the family are very strong-rooting plants, and now whilst making their growth should be plentifully supplied with water, syringing them freely once a day overhead, by which means they will be kept quite free from thrips or red spider, which will sometimes attack them where sufficient water is not applied to the leaves. From their strong-growing disposition they require a good deal of root room, and although early in the spring is the most suitable time for repotting, yet where they are manifestly suffering from want of root space, they may be shifted at any time, simply being careful not to injure the roots, which will now be growing freely, more than can be avoided.

Sophrontis.—This, especially the brilliant scarlet *S. grandiflora*, deserves a place in every collection; in fact, half-a-dozen or more specimens suspended in the house tend to liven it up during the dull, winter months in a way that few other plants of such small growth are capable of. They are the most effective when grown on blocks hung up, or on pieces of cork; but in this way now, when making active growth, they will, in common with other subjects similarly grown, need to be well supplied with water, to retain sufficient of which, for the sustenance of the roots, a moderate amount of *Sphagnum* should be used. Where this has become detached from the blocks, or removed by constant use of the syringe, a little fresh should be added.

Phalænopsids.—These will now be in their full season of growth, and should be accommodated with the best light position in the warmest house. Their extremely free-flowering disposition frequently causes the production of bloom-stems at all times of the year, but it is by no means advisable to encourage their flowering whenever inclined to do so, and in the case of plants that it is desirable to grow on to a larger, stronger condition, any flower stems now produced may, with advantage, be rubbed off as soon as they make their appearance.

Propagating Phalænopsids.—When the plants have got strong and after blooming the extremities of the flower-stems alone were removed, leaving the lower portion adhering to the plants, these will sometimes form young plants from the joints left remaining; they should not be disturbed until they consist of a couple of small leaves, and have formed roots. When these exist they may be taken away from the plant that has produced them, put on blocks, and treated like the older examples. The handsome *P. Lindemanniana* increases freely in this way. If, instead of increasing the number

of separate individual plants, it is deemed more desirable to have larger masses, the shoots bearing these young plants may be bent round and secured to the back or surface of the pot in which the old specimen is grown, allowing the young ones in this manner to become established, and go on with the crown that has made them. This may be encouraged until the plant consists of several, say six crowns, in which way, when the whole have acquired sufficient strength, they will produce a proportionately increased number of bloom stems, having a much more imposing appearance when in flower than is possible with a single crown however strong. Young Orchid growers will do well also not to allow such species as *P. amabilis* and *P. grandiflora* to continue blooming so long or so often as they are frequently disposed, otherwise the requisite amount of leaf growth, which should be formed each season, will be non-existent, the result of which is that the plants, with their natural disposition to cast off a portion of their lower leaves, will do this without forming a corresponding or a greater quantity of new, in which case the specimens, instead of increasing in size and strength, become reduced in both.

Schomburgkias.—These drier-atmosphere-requiring plants should, through the rest of the autumn, be placed where they will get the least amount of shade, with correspondingly less moisture, and the most air that is admitted, without which, however strong the growth, their flowering is doubtful; for, as I have frequently urged in respect to these and some other Orchids that do not bloom freely with the usual Orchid house treatment, their flowering is very much more dependent upon the conditions they exist under whilst the growth is actually being made than to any amount of drying up or pinching process which they may afterwards be subjected to. These *Schomburgkias* are distinct growing plants with extremely stout, thick, leathery-textured leaves, very easily kept clean, and tenacious of life, bearing strong, tall, flower stems, the individual blooms very distinct and lasting an unusual length of time in a fresh condition. *S. tibicinis*, *S. nodulata*, and *S. crispa marginata* are well worth attention by those desirous to avail themselves of one of the greatest charms possessed by the Orchidaceous family—that of producing flowers distinct in form and general character.

Odontoglossum grande.—This really grand Orchid, with its several forms, is one of the best autumn-flowering plants in existence. According to the conditions under which it has been grown, it will now be in bloom or progressing in that direction. There is one peculiarity in the plant, that is, the extreme partiality which slugs and snails have for the advancing flower stems; if there happens to be in the house even a single individual of the large brown slugs that so often and so mysteriously find their way into Orchid houses, it will almost be certain to get to any advancing spikes that there may be of this *Odontoglossum*, and in a single night will, most probably, destroy every flower. To avoid such disappointment these pests should be continually sought for. Their existence may often be detected by the slimy track they leave for weeks before they are met with. Nothing I have tried they are so fond of, or to which their sense of smell, instinct, or whatever it may be, so soon attracts them, as good sweet Apples sliced. If these be put about amongst the plants and looked over two or three hours after dark for a few nights, the intruders are nearly sure to be met with.—T. BAINES.

Greenhouse Plants.—Preparation must now be made for immediately getting in hard-wooded plants, such as Heathes, Epacrises, Genistas, and all others of a similar character. These will not suffer injury out-of-doors so long as there is no frost or excessive rains; but on the appearance of either, all subjects like the above-named should be housed at once. A little judgment should be exercised in arranging them in their winter quarters, for, although they all need as much light as can be afforded them, the Heathes should have the lightest, most airy, and coolest end of the house; and any of the more delicate hard-wooded subjects should have plenty of light and be put where the temperature will be somewhat warmer than that in which the Heathes are placed. Genistas and Epacrises will thrive where there is not quite so much light as required by the former plants. Examine all before they are taken in the house to see that they are free from aphides, red spider, and thrips, for if any of these insects only exist in small numbers they will ultimately leave quantities of eggs that will come to life in the spring. Washing with weak Gishurst water (about 2 oz. to the gallon) will be found the best means to get rid of red spider and thrips; Tobacco fumigation is the most convenient remedy for destroying aphides on all hard-wooded plants.

Camellias should also be at once got into their winter quarters; they likewise will succeed in a position where there is less light than many hard-wooded subjects. Nothing adds more to the appearance of these plants than keeping the leaves clean; it is also essential to their health that no accumulations of dust be allowed upon them, for

if they be affected at all with brown scale the dirt will stick to the glutinous excrement of the insect, and this, if not removed, will cause the foliage to turn yellow and fall off. If infested with white scale, the best implement for removing it from the wood is an ordinary tooth-brush, after which sponge the leaves one by one on both the upper and under surfaces. Wash the pots of all plants as they are taken inside, and remove any Moss that may have accumulated upon the soil.

Pelargoniums, both large-flowered and fancy varieties, may yet remain out in cold pits or frames; but the soil must not be allowed to get too wet through the lights being off; the latter should now be on during the night and day, tilting them as the plants require air.

Kalosanthes should be taken in; however well these have ripened through the summer they should be placed well up to the roof, or the under leaves near the base of the branches are liable to suffer; give them no more water than what is necessary to keep the roots in a healthy state, but do not let them be so dry as to cause the plants to flag; they are easily struck at any season, rooting from the smallest slip. If cuttings be now put in they will get established before winter, and make growth next summer considerably in advance of those struck in the spring; some of the weaker inside growths that are not likely to flower, the removal of which will in no way interfere with the next year's bloom, will answer for cuttings. Take them off about 5 in. or 6 in. long, strip the leaves from 2 in. of the bottom of the stems, and insert five or six of them close together in 4-in. pots filled with sifted loam to which has been added one-fourth of sand; the pots must be well drained for either large or small specimens of *Kalosanthes*, as they cannot bear anything approaching stagnant moisture; give a little water, but do not cover the cuttings at all in the usual way under propagating glasses, or they will be liable to damp. They will root in an ordinary greenhouse temperature, but if there be a frame or pit a few degrees warmer the plants will thrive all the better. In the spring the points should be pinched out, and each pot of cuttings shifted entire into larger pots, as in this way they will make fair-sized plants for flowering the ensuing year.

Celosias for autumn flowering that are now fast filling their pots with roots must be well supplied with manure water, the use of which for almost all plants that are required to bloom in comparatively small pots is not sufficiently understood. Keep them turned round to the light, which is not only necessary to preserve a uniform shape, but also to allow every part of the plants their full share of light, without which the leaves of those that are of a soft nature and short endurance are liable to fall off before the flowering is over, in which case the beauty of the plants is lost, for, however full of bloom a plant may be, without a sufficiency of healthy foliage it is shorn of half its attractiveness.

Fuchsias.—Cuttings of these that were put in to strike some weeks ago for flowering early in spring will be now ready for potting off singly. Put them in 3-in. or 4-in. pots, according to the quantity of roots they have made. They should have good ordinary loam in which to grow, new if it can be had; if not, such as has been used during the early part of the season for growing Cucumbers will do. Fuchsias do not require quite so much sand in the soil as most quick-growing subjects, but they like it pressed moderately firm in the pots. These summer-struck cuttings are greatly preferable for early flowering to those rooted in the spring, however early they are then put in, but they thrive best when they can be accommodated through the winter with a night temperature of from 45° to 50°; the latter suits them better than the former. Placed near the glass they make steady progress, and not only bloom before the old cut-back plants, but are much nicer looking. If the young plants show any disposition to form flowers during the autumn, these must be nipped off as soon as they make their appearance. Keep each plant tied up to a small stick. Fuchsias are so easily struck and easily grown, that the old, naked-stemmed plants so often met with should never be tolerated.

Lilies in pots of the lancifolium section, and any plants of *Lilium aratum* that have flowered late, should be set out-of-doors after they have done blooming, in a sunny situation, and sufficiently but not over watered, until the leaves have turned yellow and fallen off naturally. The unsatisfactory condition in which these and similar plants are so frequently met with is often traceable to the comparative neglect which they undergo after flowering, through being thrust into any out-of-the-way place, and either prematurely dried off for want of water, or deluged with rain if the weather happens to be wet. The longer the leaves keep fresh and green the stronger the bulbs will be next year. It sometimes happens that odd plants of these Lilies in a collection, through some cause or other, lose their leaves prematurely, even before they have ceased

flowering; if these be marked so as to identify them the following season, it will be seen that, instead of improving in size and strength, they have become weaker. If the plants have not sufficient sustenance through their being too many in a pot, insufficient light in the early stages of their growth, or not enough water at any time whilst growing, the leaves come thin, and have not strength to remain on the plant the allotted time. Lilies that have flowered early, and the tops of which are already dead, should be placed where they will not be exposed to drenching rains, or suffer from the opposite extreme, either of which is fatal to the bulbs increasing in size and ability to produce flowers as they ought to do.

Chrysanthemums in Pots should now receive their final tying, being sticks enough to support the plants and keep them from being broken by the wind. As soon as the flowers are set thin out the shoots; it is a mistake, even for ordinary decorative purposes, to allow the lateral flowering shoots to remain crowded, as the size of the blooms is thereby much reduced, and in texture they are so much thinner as not to last nearly the length of time they do when no more flowers are left on the plants than they can properly support. When the pots are plunged, or even if standing on the surface of the ground, they will root through the bottom if not moved occasionally; to prevent this it is a good plan to turn them round once a fortnight, for if the roots be permitted to take much hold of the soil on which they stand they must necessarily be broken when the plants are taken indoors, and ruptures in that way give them a check which causes imperfection in the flowers. The open centres that badly-managed Chrysanthemums so often exhibit are mainly attributable to the checks which the roots receive, or being allowed to bear too many blooms. Give plenty of manure water now; they will bear it in large quantities, and stronger than almost any other plants.

Flower Garden.

Bedding Plants.—If any trace of mildew existed on the plants from which Verbena cuttings were taken, it will have been almost certain to have made its appearance whilst they were kept close for the purpose of rooting. They should now be carefully examined, and, if any be found, dust them at once with flowers of sulphur; the white varieties are most subject to it, but if care be taken through the autumn to apply sulphur as soon as the mildew is discovered, the pest may be completely eradicated before spring propagation commences. The liability of these plants to suffer from mildew has caused many to give up their cultivation, yet they are more continuous in their blooming and less objectionably formal than many bedding subjects that have taken their place, with the additional advantage that they are most useful for cutting all through the late summer months when flowers are not superabundant.

Indoor Fruit Department.

Vines.—All late Grapes should now be nearly ripe, and a dry air should be allowed to circulate freely about them when they have arrived at this state. Lady Downes, Alicante, Gros Guillaume, and nearly all late varieties improve considerably in flavour after they are, to all appearances, quite ripe. We have seen the last-named kind in fine condition lately, and where it succeeds well, it is a first-rate black late Grape. Lateral growths should now be cut off. Vines of all descriptions; late rods, with plenty of healthy foliage, will still produce these shoots, but they must not be allowed to grow more than 1 in. or 2 in., and should then be removed. Be particular to keep Vinerias clear of decayed leaves; if they be left lying about where ripe Grapes are hanging, they induce damp among the fruit. Vine wood, in both early and late houses, is fast becoming hard, and, where green sappy wood still exists, it should be ripened as quickly as possible, with the assistance of a little fire-heat at night and on dull days. Keep a little air on at the same time or the berries will shrivel in the close, warm atmosphere. Where the wood is shaded with a great quantity of leaves (and this is often the case with the leading shoots of young Vines), thin the largest of them out; do not break the leaf stalk close to the wood, but where it joins the leaf. The wood on early Vines should now be ripe and ready for pruning.

Pines.—Late varieties swelling fruit should have a night temperature of 70°. The second batch of Queens must now be gradually prepared for winter, and the atmospheric moisture about them should be reduced, especially during the day, and less water at the root should be given. Later plants, which were placed in their fruiting pots in June, most still be kept growing. Bottom-heat is not of so much importance to these as a bracing atmosphere; and all kinds of shading should be removed without delay. The last of the suckers must now be taken off and potted; they do not root freely or winter well when potted later on. No shading should be used in protecting them from the sun when rooting; the hardier they can be grown the better; 5-in. pots are large enough for these

late suckers. Any late Queens which may be in fruit should be ripened speedily, as high flavour is never induced in November or December.

Hardy Fruit.

Peaches.—In damp localities, where there is a difficulty in getting the wood of Peach trees to ripen on open walls, it becomes necessary to give them every assistance possible. In such places the shoots should be kept much thinner than is requisite in more favourable situations, so as to allow the sun to get to them; they should also be kept closely nailed in so that they may receive the full benefit to be derived from the heat of the bricks. Shoots nailed in now will mature their buds much better than if they are allowed to stand away from the wall. These remarks do not of course apply to the southern counties, where the wood will ripen under almost any conditions; but in parts of the kingdom where the Peach can only just finish its wood, in ordinary seasons, it sometimes happens that the shoots are left detached from the wall under the impression that the buds are matured by the extra air they get in such a position. In this respect, however, the influence of the heat derived from absolute contact with the face of the wall is much greater.

Strawberry Ground should now be cleared, all the runners being cut away and removed to the refuse heap; but, in doing this, the old mistaken practice of cutting off a large portion of the leaves should by no means be followed, for, whilst they retain any vitality, they continue to impart strength to the crowns, and, when dead, they afford a natural protection to them through the winter. After clearing away all the runners, let the ground be well hoed, and the weeds (if any exist) raked off, care being taken not to remove any soil with them. This often happens where a negligent, careless system of gardening is followed and weeds are allowed to attain a large size, and is always damaging, but especially so amongst surface-rooting plants, such as Strawberries. A good thick mulching of littery manure applied in spring to Strawberry beds is most beneficial in its effects in keeping down weeds. Where fresh plantations are required, and the land did not happen to be at liberty in August—the best time for planting—rooted runners may now be taken up and planted, 6 in. apart, on a piece of ground previously prepared by digging. These can remain thus for the winter, and be removed in spring to the positions which they are to occupy permanently.

Kitchen Garden.

In most gardens at this season there are usually numbers of spare pits or frames, some of which should now be prepared for Lettuce and Endive, so as to have a supply under cover in the event of sharp frosts occurring in October or November. Pits which have been used for Cucumbers or Melons, if the manure is not immediately required for digging in the land, will require to have the soil on the top thoroughly stirred, all roots taken out, and, if dry, moistened, so as to have it in a thoroughly healthy growing condition. In thus making provision for autumn and early winter salads, every one, of course, must be guided by the demand they will have to meet. It is advisable, however, in planting a pit of several lights to select plants of different ages and sizes, for the sake of the successional character such a mode of planting will give—thus a light or more may be planted with half-grown plants that have been once transplanted, and the remaining space filled with the smaller and later sown plants. It will be found a better plan to plant now, where they can easily be protected when necessary, half-grown plants (as the check giving in moving them will be an advantage rather than otherwise) than to wait, as is commonly done, till frost is apprehended, and then hastily taken up large full-grown Lettuces, and stow them away thickly in frames, where the most careful management often fails to preserve in them that full flavour and succulency generally observable in plants that retain all their roots until they are required for use. I should, however, say that Endive is much more manageable in this respect than Lettuce. As regards varieties of Lettuces for winter, the Bath Cos should always be one of the varieties grown, and the Tom Thumb Cabbage, owing to its excellent flavour and quick growth, is also a very useful variety. Referring again for a moment to the question of transplanting: since the recent copious rainfall very rapid growth is observable in all kinds of green crops, and a certain grossness of over-luxuriance is not unlikely to take place, which will make them less able to stand a cold winter. This tendency can at any time be checked by partially lifting each plant with a steel fork; and wherever Broccoli are planted too thickly, half the plants may be lifted to form another plantation, and probably the transplanted plants will turn out the most satisfactory crop. There is no occasion to use any protection to Lettuce in frames at present; give them all the air possible, and it would be as well to have stored somewhere a quantity of dry wood ashes, or dry dusty peat, to scatter round and amongst the

plants when the short damp days arrive, to counteract any tendency to damp or mildew. Mustard and Cress should be sown under hand-lights during the present month, after which it will be as well to sow in boxes in a warm house or pit.

Turnips.—These sown about the beginning of August are an important crop, as upon them principally depends the winter supply; when sown earlier it is difficult, in many parts of the kingdom, to preserve the young plants from the Turnip beetle. To get a satisfactory return from these late sowings it is absolutely necessary to allow them plenty of room by thinning sufficiently and in time. At this season they make larger tops than earlier, and, unless given space enough, they will not make roots of a useful size. Where the first thinning was insufficient they should at once be again gone over and more pulled out; a space of 15 in. between the plants every way is not too much.

Spinach.—A little more winter Spinach should now be sown at once on a dry piece of ground, and will come in for use in the spring. This late sowing will not have a disposition to run so soon to seed as that put in at an earlier period. It is a good plan to go over the rows, and to partly thin them out, leaving the plants so that they will not become drawn; and to complete the thinning by removing more as they are required for use. Ultimately, those that are left should be about 6 in. asunder. This vegetable, like all others, cannot stand a severe winter when crowded. This method of partial thinning admits of a supply both for the present and future time being supplied from the same ground. Whenever an opportunity is offered by the land being dry, let the entire surface, where there is room amongst growing crops, be gone over with the hoe and well stirred, in order to destroy the weeds. This saves much labour, by preventing the seeding of such annuals as Groundsel, Chickweed, &c., which will otherwise keep on flowering and maturing seed to the end of the year. It also has the best possible influence upon the present crops, and upon the land, by keeping it more open for the winter; but, in order to effect the greatest amount of good, the soil should be quite dry when stirred.

Carrots, especially the Horn varieties, will, in most places, be ready for pulling. A dry day should be chosen for the work, the tops being cut off as it proceeds, and the roots, being allowed to remain on the ground, exposed for a few hours to the sun. They should then be put in an airy shed for a short time until they have discharged a portion of the moisture which they contain, but not so as to cause them to shrivel. After this they should be stored in thin layers in moderately dry coal ashes, which should lie beneath and surround each separate layer and cover the whole. The previous exposure to the sun and air in open quarters or in a shed is necessary to prevent fermentation, which would otherwise be apt to occur.

Extracts from my Diary.

September 23.—Potting *Humea elegans*, *Coleus*, and scented-leaved *Pelargoniums*. Filling up all frames and cold pits as they become empty with Lettuces and Endive. Planting early border with August-sown Cabbage plants. Cutting turf to stack away for potting purposes. Hand-weeding Strawberry quarters, and cutting off all runners, afterwards mulching the ground with well-rotted manure.

Sept. 24.—Sowing Mustard and Cress for succession. Taking up *Alternantheras* and potting them; also a few *Coleus* for stock. Removing all cuttings struck in heat to a cold frame to harden. Giving first-spawned Mushroom bed a little warm water. Pricking out on a large border Carters' Hartwell Early Marrow Cabbage plants to stand the winter. Watering Pine-apples with manure water; also late Peas, Cauliflowers, and Celery.

Sept. 25.—Potting variegated Ivy and a few Carnations. Rearranging Fernery. Earthing up French Beans in pots. Lifting a portion of the main crop of Carrots and stacking them away in dry sand in an open shed. Moving pot Vines out of pits and placing them against a south wall, to finish the ripening of the wood and fruit buds. Examining all fresh-planted shrubs and putting a few stakes and ties to those likely to be injured by wind. Turning manure for Mushrooms, and salting terrace walks. Gathering Louise Bonne of Jersey and Marie Louise Pears; also Wormsley Pippin Apples.

Sept. 26.—Taking up plants of *Mesembryanthemum cordifolium* and potting them for stock. Giving a top-dressing of soil to Cucumber beds. Storing away *Caladiums* on dry shelves. Earthing up Celery. Clipping hedges, and cleaning shrubbery borders. Gathering Coe's Golden Drop Plums and Barrington Peaches; also Ribston Pippin and Cornish Gilliflower Apples; and Flemish Beauty and Brown Beurré Pears.

Sept. 27.—Potting double white Primulas, *Cinerarias*, and *Solanum capsicastrum*. Clearing off a piece of Turnips, and manuring and digging the ground for other crops. Transplanting Early White Naples and Giant White Tripoli Onions. Gathering all unripe Tomatoes, and hanging them up in Vineries in a sunny position to finish ripening; also picking Cucumbers, Bolton Mushrooms, Cauliflowers, hard White Cabbage, and *Capsicums* for pickling.

Sept. 28.—Potting Hyacinths and Tulips; also Osborn's early-forcing French Beans. Taking up and potting Mrs. Pollock and Tom Thumb *Pelargoniums*. Gathering Passe Colmar, Danmore, and Doyenné du Comice Pears; also Lucombe's Seedling, Court of Wick, and Cockle Pippin Apples. Fruit in use for dessert—Pine-apples, Grapes, Peaches, Plums, Pears, and Apples.—W. G. P., Dorset.

GARDEN BOTANY.

(Continued from p. 250.)

SIMPLE FRUITS HAVING A DRY PERICARP.—Fruits of this class are primarily divisible into dehiscent and indehiscent. The latter present fewer modifications, so we will treat of them first.

THE ACHENE.—A term applied to any dry, one-seeded, indehiscent fruit, or dry, one-seeded carpel of an apocarpous fruit. From this definition it will be seen that an achene sometimes means

Fig. 575.—Fruit (achene) of Dandelion.

Fig. 576.—Fruit of *Mirabilis jalapa*; an achene enclosed in the indurated base of the perianth. Enlarged.

an entire fruit, sometimes a single carpel of an apocarpous fruit; but the important and constant character is, that it is always a dry (not fleshy) one-seeded body which does not split open to release the seed. The seed of an achene is either free from the pericarp, or the ripe seed and pericarp closely adhere. In the Dandelion (fig. 575) and most members of the *Compositæ*, the seed is adherent, and, as has already been mentioned, we sow the fruit, pericarp and seed, of such plants as *Asters*, *Marigolds*, *Zinnias*, &c. The fruit of the Marvel of Peru (*Mira-*

Fig. 577.—Longitudinal section of the fruit of *Mirabilis jalapa*, showing the single seed.

Fig. 578.—Section of a single carpel (achene) of *Thalictrum* (Meadow Rue), showing the solitary pendulous seed free from the pericarp.

hilis jalapa—figs. 576 and 577) is an achene enclosed in the indurated perianth-tube, and the seed is adherent to the pericarp. Achenes with free seeds are also not uncommon. Thus, the fruit of a Buttercup and of a Meadow Rue (fig. 578) consists of a number of achenes crowded upon a small, short, conical receptacle; and in the Strawberry (fig. 579) the receptacle

grows into a large fleshy body, with the minute achenes scattered over its surface. The mature fruit of a Rose (fig. 580) very much resembles a miniature Apple, but on cutting it through vertically, we find that it is a hollow receptacle, in which are seated a number of achenes, as represented in fig. 581. The fruit of a Calycanthus (figs. 582 and 583) is of a similar nature.

THE FOLLICLE.—When the separate carpels of an apocarpous pistil are dry and contain more than one seed, they commonly dehisce down the inner or central suture, and are then termed

Fig. 579.—Fruit of Strawberry, consisting of a number of achenes on a fleshy receptacle.

Fig. 580.—Fruit of a Rose.

follicles. The fruit of the Columbine and of the Larkspur (fig. 584) is follicular, as well as that of the tropical genus *Sterculia* (fig. 585).

Fig. 581.—Section of a fruit of a Rose; one-seeded achenes in a persistent fleshy receptacle.

Fig. 582.—Fruit of Calycanthus, consisting of a number of one-seeded carpels (achenes) crowded together in a hollow receptacle.

THE LEGUME.—This is the name given to the pod of the Leguminosæ (Pea, Bean, Vetch, &c.). It closely resembles a

Fig. 583.—Longitudinal section of the fruit of Calycanthus, showing the free carpels.

Fig. 584.—Fruit of Delphinium, consisting of three many-seeded free carpels, called follicles.

follicle, but it dehisces along both sutures, and there is never more than one in a fruit proceeding from one flower. *Acacia* (fig. 586) belongs to the same family.

THE SILIQUA.—The pod of the Cruciferæ (ex., Stock, fig. 587, Radish, Turnip, Cabbage, &c.) is called a siliqua. This differs from a legume in the valves dehiscent from a framework to which the seeds are attached along both sutures, and in other

particulars. It is more fully described in one of the paragraphs relating to the gynœcium. When it is as broad or broader than long, as in the Shepherd's Purse, it is termed a silicula.

THE SAMARA.—A name given to winged fruits, like those of the Maples and Sycamore (fig. 588), and sometimes applied to

Fig. 585.—One follicle of a fruit of *Sterculia platanifolia*, dehiscent on the inner side, where the seeds are attached.

Fig. 586.—Fruit (legume) of an *Acacia* (Leguminosæ), dehiscent into two valves, each bearing one row of seeds, along the upper margin.

the fruit of the Elm (fig. 589), which has a circular wing. Other botanists restrict the application of the term to the

Fig. 587.—Capsule (siliqua) of Stock, showing the two valves dehiscent from below upwards, and leaving the seeds attached to the framework (replum).

Fig. 588.—Fruit (samara) of Sycamore.

hulls into which such fruits as that of the Sycamore eventually split.

THE CAPSULE.—This includes a great variety of dry, dehiscent seed vessels, characterised by the manner in which they dehisce,

Fig. 589.—Fruit (samara) of Elm.

Fig. 590.—Three-lobed capsular fruit of Tulip, dehiscent loculicidally, or through the back of the cells.

the number of cells they contain, and other particulars. From the more striking modifications we select the following: The capsule of a Tulip (fig. 590), when ripe, opens by three longi-

tudinal slits, each slit being down the back of a cell and midway between the walls. This kind of dehiscence is termed loculicidal, because the cells themselves open. It will be better understood by comparison with *Flindersia* (fig. 591). In this the capsule, which is five-celled, splits into five parts between the cell walls, so that each part resembles a follicle of an apocarpous fruit. The fissures being between the walls of the cells,

to the axis. In Orchids the placentation is parietal, there being three placentas in each capsule, which, however splits longitudinally into six pieces, the alternate ones only bearing seeds.

Fig. 591.—Fruit of *Flindersia*, showing septicial dehiscence, i.e., between the walls of the cells.

Fig. 592.—Fruit of *Lancretia*, dehiscing septicially.

leaving the cells themselves intact, this kind of dehiscence has been called septicial, literally partition-splitting. Each valve or portion of the opened capsule of a Tulip bears the partition of two contiguous cells down the centre, and consists, therefore, of portions of two cells or carpels, whereas in septicial dehiscence each portion is an independent carpel or cell. The

Fig. 597.—Fruit of *Hypericum*, from which the valves have fallen away, leaving the placentas covered with seeds.

Fig. 598.—Fruit of an Orchid.

Fig. 598 does not very clearly illustrate this point. Many capsules open only at the apex, as Chickweed (*Stellaria media*—fig. 599) and many others of the same Natural Order. In splitting open the top of the capsule parts into as many, or twice as many, small teeth as there are styles. Mignonette

Fig. 593.—Capsular fruit of *Convolvulus*.

Fig. 594.—Capsule of *Convolvulus*, just as the three valves are falling away and revealing the three cells with the seeds attached to the axis.

dehiscence of the capsule of *Convolvulus* is also longitudinal (fig. 594). The capsule is three-celled, and the outer wall falls away in three valves, leaving the partitions of the cells attached to the axis or centre. This mode of dehiscence is termed septifragal, literally breaking from the partitions. The capsule of the Thorn Apple is another familiar example of septifragal

Fig. 599.—Fruit of *Stellaria media*, a capsule dehiscing at the top into six valves.

Fig. 600.—Capsule of *Hyoscyamus niger*, enclosed in the persistent calyx.

offers a familiar example of this mode of dehiscence, the capsule opening long before the seeds are ripe. All the foregoing modifications of dehiscence are longitudinal. In a comparatively small number of instances it is transverse, as in the one-celled capsule of the Pimpernel, and in the two-

Fig. 595.—One-celled fruit of *Violet*, with the seeds arranged on three parietal placentas, and dehiscing into as many valves.

Fig. 596.—Fruit of *Hypericum hircinum*.

dehiscence. In all three of these modes of dehiscence, the placentation or attachment of the seeds is axile or central. When the placentation is parietal the axis is not produced above the base of the ovary, which remains one-celled, except the placentas grow inwards and meet in the centre. The dehiscence is usually longitudinal, as in the *Violet* (fig. 595), which splits into as many valves as there are placentas, each valve bearing a placenta. The capsule of *Hypericum hircinum* (fig. 597) offers a singular mode of dehiscence, the outer wall falling away in three valves, leaving the three placentas attached

Fig. 601.—Capsule of *Hyoscyamus* removed from the calyx, and showing the transverse dehiscence near the top; the cap (sperculum) at the side.

Fig. 602.—Fruit of *Poppy*, dehiscing by small pores beneath the cap-like top.

celled capsule of *Henbane* (*Hyoscyamus niger*—figs. 600 and 601). The top separates from the lower part like a lid. Another mode of dehiscence is by pores, as in *Antirrhinum*, *Campaula*, and *Poppy* (fig. 602).
W. B. HEMSLEY.

The Old White Brugmansia as a Tub Plant.—Among the plants stored away in cellars in tubs and flowered out-of-doors on terraces and other sunny places in summer, perhaps the most valuable is this old and somewhat neglected plant. It is much grown in Switzerland in tubs, and has lately been covered with its white trumpets, affording a charming effect. This plant is better worth growing in the way alluded to than most others treated in the same manner. Light is not at all essential to it during the winter, and, therefore, it may be grown where there is little or no glass. Some of the plants alluded to seem very old, and have, no doubt, spent many winters in cellars.—V.

THE KITCHEN GARDEN.

TRANSPLANTING AUTUMN-SOWN ONIONS.

SOME years ago it was the general practice not to sow the seed of autumn Onions before August 12 or 15. At that time it was thought that early sowing was fatal to the development of fine bulbs, or, to use a common phrase, that they were sure to bolt in bulbing, which sometimes happens, but autumn transplanting prevents, to a great extent, such an occurrence. Early sowing and spring planting contributed in a great degree to the plants running to seed. My attention was first directed to this matter in 1870. Most people will recollect how severe the frost was that year, and how disastrous it was to vegetation generally. My winter Onions that year were rather thickly sown, but otherwise they looked strong and healthy, and I calculated that when planting time came round in the spring I should have far more than would be required; but, alas! not a living plant was left. I blamed myself for neglecting to thin out the seedlings, and resolved that in future there should be more pains taken with seed beds which had to stand over the winter. On paying a visit to a neighbour a few days afterwards, I noticed that a brake of Onions planted out during the previous autumn had escaped unharmed, whilst the plants in the seed beds from which they were taken were sadly out of the ground, although the latter were in a sheltered corner, whilst the former were planted in an exposed part of the garden. The reason was manifest, and the lesson thus taught has been noted upon ever since. I make two sowings, one about the beginning of October, and the result is I have never had a failure since. An exposed plot of rich ground is selected, which has been heavily manured the previous spring; this is dug over one spade deep without adding any fresh manure, and after the surface of the ground is made firm by trampling on it, lines are drawn and planting is commenced. There is no greater mistake than that of coddling up young plants in seed beds; owing to their being crammed together their leaves are necessarily soft and tender and liable to be injured by frost, whereas the case is wholly different when they are sown in good time and fit to be planted out in their permanent quarters in autumn; they furnish themselves with an extra supply of roots through the cheek received through transplanting, and become firm and hardened by exposure to the action of the weather.

J. GROOM.

NOTES AND QUESTIONS ON THE KITCHEN GARDEN.

New American Potatoes.—Four new American Potatoes were put into commerce this year. Beauty of Hebron is a pale-skinned Rose, the tint being a very pale pink, but in all other respects it seems to be a Rose only, and gives nothing of any appreciable value as a market or table kind. Trophy, a new red Kidney of the same colour as Ruby, is rich red, with rosy eyes; tubers large and handsome, and produced in great abundance; flesh white, but not first-rate. This produced a grand crop this year, and far excelled all other American kinds. It is later and much more robust than Ruby; that kind is too dwarf and early, for coloured kinds are not so valuable early as late. Should Trophy retain its present form, it will outclass all the other coloured American Kidneys. Triumph is a very handsome, rich-coloured Round, with very white flesh. Whatever may be the merits of this kind this year, it is small, too small, but evidently very productive. As the best crops from America invariably come from the first seed, I scarcely expect that this kind will hold a place with us for any time. Burbank's Seedling is a large, coarse, white Kidney, deep-eyed, and ngainly when grown strong, but on medium ground it produces tubers much like those of Magnum Bonum. I think the latter, in spite of its rank haulm, is, however, preferable. An older American kind, Centennial, produces tubers the exact form and colour of Floorball; and I think it would be difficult to distinguish one from the other. Manhattan gives large purplish tubers, that bear a close resemblance to the old Farmer's Glory. Out of the fifty or more American kinds imported here, not more than half-a-dozen seem to hold their own for any time.—A. D.

New Potatoes in Autumn.—Why should we not have new Potatoes in autumn? I have tried the experiment this season, and am quite satisfied with the results. The variety planted was Myatt's Early Ashleaf. In spring I kept rubbing the buds off a limited number of tubers, which were also retarded as much as possible by being kept in a cool place and laid out singly. The buds were rubbed off them up to within a short time of planting, when they were allowed to grow to from 1 in. to 2 in. in length. The planting was done early in June, on the same border from which the early crop was taken. It was in no way prepared, beyond adding a little leaf mould on which to lay the seed when the drills were drawn. Pota-

atoes, I have always observed, turn out white and clean when there is a slight layer of leaf mould placed under and above them. The drills were drawn in an oblique direction, as the border is a south one, and thus the side of the drill was fully exposed to the warmth of the sun. The crop is now becoming fit for use, and promises to be in every respect satisfactory. The haulm is of course weak, consequent on the shoots being rubbed away so often, but the tubers are a fair size, well formed, and of excellent quality. They will not be ready for lifting for some time yet, and when they are a portion will be laid in sand, where they will keep clean and fresh for a further period. By making one or two plantings from the beginning of June to July a succession of young Potatoes might be kept up to Christmas.—W. HINDS.

Vick's Criterion Tomato.—This Tomato, recently sent out by Messrs. Carter, is one of the best croppers amongst a large collection at Chiswick. Its fruit is of medium size, very regular, and of fine form and flavour. At Chiswick the back wall of a long house is covered with Tomatoes of various kinds, and the quantity of fruit gathered from them is astonishing. At the present time there is a good crop, although the plants have been in bearing all through the summer.—S.

Spade Culture Best (p. 148).—In the Eastern Counties one might find endless cases fully illustrating the superiority of spade culture over that done by the plough. Fields hitherto comparatively barren, from which portions have been taken for cottage gardens, soon become most productive. It is not the abundance of manure that favours the cottager, for, as a rule, the amount used in such plots is but small. No; it is deeper cultivation, and confining the producing powers of the land to useful crops instead of weeds. Turning poor soil up deeply is not a profitable investment at first, but by gradually increasing the depth by means of deeper digging each succeeding year, a more productive soil will in time be obtained, and whether excessively wet or dry will be less liable to adversely affect the crop; for providing a deep root-run is the best safeguard against drought, and a ready means of exit is at the same time provided for superabundant falls of rain.—J. GROOM.

The Potato Disease.—The excessive drought which we experienced in July not only arrested the growth of the Potato crop, but, for a time, stayed the effects of the disease; but the heavy thunderstorms and downpours of rain which we had in August have caused it to break out afresh in its severest form.—J. G.

Early Peas for Late Crops.—When green Peas are wanted late in summer various expedients are resorted to in order to obtain them, one of which is sowing the very earliest varieties, such as Ringleader or Sangster's No. 1, after the crops of tall Marrows are exhausted. From experience, however, I do not much like the practice, as by making good preparation for the latest sowings of tall Peas, such as Ne Plus Ultra or Champion of England, I have invariably had them in bearing as long as the weather would permit the pods to swell satisfactorily, and in moist summers I have frequently had all the sowings made after the middle of May continue prolific until frost finished their career. Another point of importance is that most people like the late varieties better than the earliest ones, which are simply prized for that quality alone. For all late or main crops wide trenches should be taken out and well manured, and by mulching the roots, and keeping them well supplied with water during times of drought, the varieties named will prove abundant and continuous bearers.—J. GROOM.

Keeping Onions.—The way (strongly recommended by Mr. Baines some time ago in THE GARDEN) of keeping Onions by hanging them under the eaves of cottages and out-houses is extensively practised in some parts of Central Europe. Sometimes there the hanks assume the form of large rings, somewhat like, in fact, gigantic Immortelles.

Bossin Cabbage Lettuce.—This variety was found to stand best among the large number of others tried at Chiswick this season, and it was singular to note that while heads of all other varieties had bolted off to seed, the Bossin was as unbroken as when it was heading in. It is not a taking-looking Lettuce, being somewhat large and coarse-looking, with brownish, tinted-fringed leaves. Of its standing qualities there can be no doubt, and, after all, it is the inside of a Lettuce that salad eaters are most concerned about.—"Gardeners' Chronicle."

Showing and Storing Potatoes.—Mr. Peter M'Kinley, the well-known grower and exhibitor of Potatoes, who has 600 varieties under cultivation in his garden at Beckenham, stores his best samples in a large airy outbuilding, lined with tiers of small wooden bins ranged one above the other, but open at the top, each one holding about half a bushel of Potatoes. Covered up with dry sawdust, they remain clean and fresh until required for the show table. The bins are subsequently used for storing the various sorts for seed.

COCORITE PALMS IN TRINIDAD.

"At last, striking into a broader trace which came from the westward, we found ourselves some 600 ft. or 800 ft. above the sea, in scenery still like a magnified Clovelly, but amid a vegetation which—how can I describe? Suffice it to say, that right and left of the path, and arching together overhead, rose a natural avenue of Cocorite Palms (*Maximiliana*), beneath whose shade I rode for miles, enjoying the fresh trade wind, and the perfume of the Vanilla flowers. We stopped at one point, silent with delight and awe. Through an arch of Cocorite boughs—ah, that English painters would go to paint such pictures, set in such natural frames!—we saw, nearly 1000 ft. below us, the little bay of Fillette. The height of the horizon line told us how high we were ourselves; for the blue of the Caribbean Sea rose far above a point which stretched out on our right, covered with noble wood; while the dark Olive cliffs along its base were gnawed by snowy surf. On our left, the nearer mountain woods rushed into the sea, cutting off the view; and under our very feet, in the centre of an amphitheatre of wood, as the eye of the whole picture, was a group—such as I cannot hope to see again. Out of a group of scarlet Bois Immortelles rose three Palmistes, and close to them a single Balata, whose height I hardly dare to estimate. So tall they were, that though they were perhaps 1000 ft. below us, they stood out against the blue sea, far up toward the horizon line; the central Palm 150 ft. at least, the two others, as we guessed, 120 ft. or more. Their stems were perfectly straight and motionless, while their dark crowns, even at that distance, could be seen to toss and rage impatiently before the rush of the strong trade-wind. The black glossy head of the Balata, almost as high aloft as they, threw off sheets of spangled light, which mingled with the spangles of the waves; and, above the tree tops, as if poised in a blue hazy sky, one tiny white sail danced before the breeze. The whole scene swam in soft sea air; and such combined grandeur and delicacy of form and of colour I never beheld before." Such is Canon Kingsley's account, in "At Last," of this beautiful bay in the Island of Trinidad.

The Bay of Fillette, seen through Cocorite Palms.

HOME-GROWN v. IMPORTED PLANTS AND SEEDS.

THAT we are gradually shaking off a notion once conceived that imported plants and seeds are superior to those of home growth must, I think, be apparent to everybody. There could not be more conclusive evidence than that afforded by the fact that while new establishments are continually springing up, the older ones are not only enlarging the area devoted to production, but many of the largest have already special branch nurseries for each particular department, an arrangement by means of which the very best soils and situations are secured for the fruit and forest tree department, the Rose nursery, or

the seed farm or trial ground, while others devote large areas to hardy bulbs and herbaceous and Alpine plants. And as to the extent of such branches, it may truly be said that the demand creates the supply; for, whereas but a few years back it was impossible to find many really good old plants, except in botanic gardens, now we have only to visit an establishment devoted to this branch of trade to find them in abundance; while Lilies and similar bulbs that were but recently mostly procured from the Continent may now be seen delighting the eye with their gorgeous colours by the acre. Again, as regards trees of stately growth, or such as are adapted for street planting or avenues, it is but a short time since such specimens as those planted on the Thames Embankment had to be procured from the Continent; but now they can be had almost on the spot. In Messrs. Veitch's nursery at Southfield, Fulham, I recently saw thousands of as perfect specimens of such trees as it would be possible to find anywhere with clear stems bearing fine heads of luxuriant foliage. Such trees, lifted and replanted in any part of the metropolis or suburbs in the same

day, would surely be preferable to trees exposed during a long journey by land and sea. Planes, Elms, and Acacias are all equally good; and here, too, were Ivies by the thousand, plants each of which would at once cover 3 ft. wide of a wall 10 ft. or 12 ft. high. Fruit trees I also noticed under every form of training, from the simple cordon to the most complicated design. As regards Roses, the demand seems to outrun the supply, although so many growers devote their attention exclusively to the Rose. Gloire de Dijon and Maréchal Niel appear still to be the greatest favourites. Some new kinds of Roses, it is true, still come from France, but English raised sorts now equal in every respect those of

foreign origin. As regards hard-wooded plants, such as Camellias, Azaleas, Heaths, Epacris, &c., those who have been supplied with home-grown plants need no further recommendation, as respects their merits, than the success that has attended their exhibition in the form of specimens at public shows. At Messrs. Rollisson's may now be seen immense numbers of this class of plant, not shaded or brought up tenderly, but set on wide breadths of coal-ashes, and receiving abundant supplies of soft water from a pond close by, in which Water Lilies and other aquatics grow and flower profusely. Under this treatment Heaths, Epacris, &c., grow most luxuriantly. It is questionable whether we do not, as a rule, shade plants grown in pots too much, as it is a well known fact that well-ripened wood produces the largest amount of flowers; therefore to set plants of this kind in almost perpetual shade is doubtless a mistake, as even when cases of leaf scorching occur they may be as much owing to the weakly growth imparted to the plant by excessive coddling as to its natural inability to withstand the sun's rays. It is, however, in reference to plants of a bulbous character that we have been so long accustomed to look to the Continent

for supplies; but of these we can now grow many in this country. True, we cannot equal Haarlem in Hyacinths, Tulips, and others, but that Lily of the Valley and similar plants may be grown in perfection at home I feel confident. To do even this, however, successfully, some attention will be required. It is but quite recently that the dormant season, when all visible outward growth is at an end, was looked upon as being a time when it was of no consequence what kind of treatment such plants received; but we now frankly acknowledge that there is no such thing as a dormant or entirely stagnant period amongst plants. Bulb life, from beginning to end, is one continued round of progress; the fading leaf only indicates the finish of one chapter, so to speak, in its existence and the commencement of another. It is, therefore, clear that we should not treat bulbs at any season as if they were inanimate objects. As to flower seeds, it is quite possible to ripen seeds of Stocks, Asters, and similar plants in this country to equal the best Continental-saved seeds of these flowers. Travellers by the Great Eastern Railway must have observed the brilliant effect produced by the flower seed farms in Essex, where annuals and biennials form splendid masses of colour, and in the ordinarily dry atmosphere of the eastern counties their seeds ripen thoroughly. Amongst occupants of the kitchen garden, some notable examples might be enumerated; if we take Brussels Sprouts as an illustration, we find just as good produce from home-saved seed as from that imported from Brussels. Other examples might be enumerated, but perhaps the best way of removing any deeply-rooted prejudice in such matters is to constantly show plants raised from home-grown seeds at horticultural exhibitions. J. GROOM.

ANSWERS TO CORRESPONDENTS.

Striking Rose Cuttings.—Can I strike Rose cuttings in a conservatory? They have failed with me for two years outside.—SUBSCRIBER. [You might be able to strike Rose cuttings in pots or boxes in the conservatory, but there is no reason why they should fail outside, if properly treated. The cuttings should consist of pieces of half-ripened wood, taken off with a "heel." Insert them at once on a north border, which is well drained, adding to the soil a large quantity of road sand. Tread the soil firmly round the cuttings, and, if you be at all fortunate, you ought to get at least 40 per cent. to strike.—W.]

Mandevilla suaveolens.—How should this greenhouse creeper be treated? Mine grows well, but does not bloom, and many of the leaves are spotted with red. It has had rather a high temperature until lately; now no fire-heat is used and it has plenty of air.—H. [Your plant is probably infested with red spider through being kept too hot and close during the early stages of its growth. Early in spring the young shoots should be thinned out, selecting the weakly ones for removal, otherwise they become so crowded and entangled that nothing can be done with them, and if the house be kept hot and close the leaves never acquire sufficient substance to resist insect attack, or to insure a floriferous habit. All that can be done with your plant now is to clean it thoroughly by syringing or sponging with some insecticide. In future continue, if possible, to give more ventilation; from May 1 leave a little air on all night if possible.—E. H.]

Culture of Filberts.—Can you kindly give me some information as to the cultivation of Filberts?—F. G. [The following is the practice in some parts of Kent: The trees when young are cut back to within 1 ft. of the ground, which causes them to emit side shoots, which are regularly trained outwards by being tied to a wire or wooden hoop, which is placed in the centre, so as to give the tree a cup-like form. This is a capital method, inasmuch as it allows the sun to shine in the centre as well as all round the trees, and thus the wood gets well ripened, a condition indispensable to the production of large crops of Nuts. Nut trees are, as a rule, to be found alternately planted with standard Apple or Pear trees. In height they are seldom allowed to exceed 6 ft., severe pruning being yearly resorted to in order to keep them within bounds. Many of the established bushes are 15 ft. in diameter at the top, and are as flat as a table, and a crop of Nuts is generally to be depended upon.—S.]

Melons in Brick Pits.—Can I grow Melons and Cucumbers successfully in a common brick pit heated by means of a brick flue? and if so, what are the conditions needful? Should the flue be level with the border, above or below it? Must the bottom-beat be supplied by manure? or will a hollow chamber with the flue running through it answer? I have had two pits in use for years, one with the flue running along one end and along the front, the other with a hollow chamber with the flue running down the centre, and drain pipes as chimneys to give top heat, but neither of these answer well. Of course I know that hot water is best, but it does not suit me in this case to use it. My furnaces are sunk well down below the borders.—INQUIRER. [Fermenting leaves and manure are infinitely better for supplying bottom-heat than anything else.

If you were to erect a stage over the flue on which you could place from 12 in. to 20 in. deep of soil, there is no reason why you could not grow good Melons and Cucumbers; but the atmosphere of the pit must be kept very moist. During summer you could grow both Cucumbers and Melons without the aid of bottom-heat.—H.]

Painting Trees with Gas Tar.—Will painting the stems of trees with gas tar, to protect them from horses or cattle, be injurious to the trees? I should imagine that it would stop the pores, and so injure the growth.—J. G. [Gas tar put on the stems of trees would, we fear, prove injurious to them. A mixture of soot, lime, and cow manure would be equally effective in keeping off cattle, and would do no injury to the trees.—B.]

Asparagus Beetle.—Kindly name the enclosed beetle, which eats my Asparagus.—R. H. [The Asparagus Beetle is *Crioceris asparagi*. Your best way of getting rid of the pest would be to make a fresh bed in another part of the garden. As to the present bed, when the stalks have died down give the ground a good dressing of salt. This, indeed, you might do at once.—S.]

Diseased Shallots.—I have grown what I hoped would have proved a good crop of Shallots, but they are not keeping well. They were pulled too early, I fear.—E. [The samples sent appear to have been lifted before they had done growing, and afterwards subjected to heavy rains or stored away whilst damp. In future leave them in the ground until the tops show signs of turning brown; then pull them up, and place them thinly on a mat in the sun to dry. Managed thus they can be moved indoors during rainy weather.—S.]

Substitutes for the Potato.—I have been requested by some friends interested in allotment gardening to ask for advice respecting this matter. The uncertainty of the Potato crop in allotments is now such a serious thing, that we are anxious to find, if possible, what other keeping and storing vegetable can be best recommended to cottagers to replace entirely or partially the Potato.—RECTOR. [Jerusalem Artichokes, by some, been recommended to be grown more largely as a substitute for the Potato, but without any good result. Carrots and Parsnips answer better. A change of seed Potatoes obtained from a distance, and from soil of a totally different character from that in your garden, has sometimes been tried with advantage.—H.]

Names of Fruits.—T. B.—Apparently *Paradise d'Automne*.

Names of Plants.—Mrs. G. R.—1, *Eurya latifolia variegata*; 2, *Coprosma Baueriana variegata*. T.—Both *Fuchsias* are forms of *F. gracilis*. A. T.—*Oxalis Acetosella*. D.—*Spiraea callosa*. C. B.—*Euconymus latifolius*; Eastern Europe. E. D.—1, *Diplacus glutinosus*; 4, *Polygonum Bruzonis*; 2 and 3 next week.

Questions.

Maize as a Vegetable.—In the United States of America the tender ears of Maize are, I believe, much used and highly esteemed as a vegetable. Will any of your correspondents kindly inform me at what period of growth such ears should be gathered, and how they should be dressed?—DERWENT.

Mildewed Grapes and Ferns.—The Grapes in my greenhouse have been terribly mildewed this year time after time, in spite of the use of black sulphur, and when about to change colour they cracked and became bad. Some Ferns under the stage were equally mildewed, the leaves being now more white than green. What must I do?—R. S. H.

Calochorti and Cyclobothras Out-of-doors.—I should be very much obliged if one of your correspondents would give me some information about the cultivation of *Calochorti* and *Cyclobothras*. I find that it is possible to grow them on a raised border in the open air; some few have done very well with me in that way, but the percentage of successes is so small when compared with that of failures, that I feel sure I have still a good deal to learn regarding them. A few hints would be very acceptable to me.—HENRY EWANKS, *St. John's, Ryde, Isle of Wight*.

Lamp Heating.—In THE GARDEN (p. 110) mention is made of heating a small greenhouse with paraffin. Would "J. G.," or some other contributor to THE GARDEN, kindly tell me if the paraffin lamps to which he alludes can be simply burned in the greenhouse? or should they be used for heating water pipes? I was under the impression that the fumes from burning lamps would be injurious to the plants. I have a small cold greenhouse, in shape nearly half an octagon, its greatest dimensions being about 13 ft. by 6 ft. I want some heat in it, but am rather afraid of the expense of putting in pipes, and the necessary consumption of gas. Would the paraffin lamps give enough heat? I would be greatly obliged for any information on the subject, and as to the cost of lamps, consumption of oil, trouble of trimming, &c.—J. L.

Trees Difficult to Move.—I have always found the common evergreen Oak (*Quercus Ilex*) and the Hemlock Spruce (*Abies canadensis*) to be the most difficult trees to move successfully. I have now one of the former 15 ft. high and as much through, and one of the latter 13 ft. high and the same through, which, as they begin to interfere with a view, I must displace, but which, as handsome specimens, I wish to save. Can any of your readers oblige me by advising as to the best mode of proceeding? If preliminary trenching round be thought necessary, then I should be thankful for information as to the time of trenching, depth of trench, treatment, and time to elapse before moving, and also the best time of year for transplanting after preparation. The soil is a rather light sand.—EXEMPT.

SOCIETIES AND EXHIBITIONS.

ROYAL HORTICULTURAL SOCIETY.

SEPTEMBER 17.

The chief exhibits on this occasion consisted of florists' flowers, such as Dahlias, and there was also a good supply of fruit and vegetables.

First-class Certificates were awarded as follows:—

Dahlia Aurora (Keynes & Co.).—A medium-sized flower of good form, having small compact petals of a bright cinnamon colour, the centre being rich orange-scarlet.

D. Joseph Ashby (Turner).—A fine-built flower of a brilliant cinnabar-scarlet colour; very distinct.

D. Clara (Rawlings & Co.).—A purplish-rose-coloured flower, excellent as regards form.

D. Paragon (Cannell).—A strikingly pretty, single-flowered kind, having dark velvety maroon petals edged with purple and bright golden stamens.

D. lutea (Cannell).—A well-formed single flower, lemon-yellow in colour.

Nelumbium luteum (C. Green).—An ornamental-leaved plant, which succeeds well in a warm greenhouse tank.

Macrozamia cylindrica (Bull).—A beautiful Cycad, having gracefully-recurred fronds with long, deep, narrow, green pinnae.

Begonia Nellie May (Society's Garden).—A free-growing kind, producing a profusion of large, soft rosy-pink flowers.

B. Louis Thibaut (Hooper & Co.).—A semi-double scarlet-flowered kind of a very bright description, compact and dwarf in habit.

Eulalia japonica zebrina (Laing & Co.).—A Grass with graceful, creamy-banded leaves, an illustration of which will be found in another column. It promises to be well adapted for isolation on lawns or in pleasure grounds. The plant shown, the largest we have yet seen, was planted out-of-doors in Messrs. Laing's nursery at Forest Hill in the month of March last year.

Mr. Wm. Bull, Chelsea, showed a group of new and rare plants, among which were several beautiful varieties of *Odontoglossum*, the cut-leaved-*Artocarpus excelsa*, *Billbergia scapaa*, finely in flower, and several graceful Palms. The same exhibitor also sent a group of plants of *Lilium neilgherrense*, which were admired for their fine creamy-coloured, trumpet shaped flowers and delicate perfume.

Dahlias.—These were shown in good condition from both Slough and Selisbury. In Mr. Turner's collection of seedling show varieties the best were Joseph Ashby, cinnabar-scarlet; Amy Robsart, a finely-formed flower of a bright violet colour; Prince Bismarck, dark magenta; and John Bennett, bright yellow, edged with scarlet. The same exhibitor also showed Canary, a fine, bold, golden-yellow flower, and George Thomson, a fine sulphur colour; Mrs. Sanders, lemon, conspicuously tipped with white, and Lady Golightly, white, delicately-tinted with violet. Thoa. Goodwin was the best dark kind, being almost black, and James Service was remarkable for its fine form and regular outline. In the collection from Messrs. Keynes & Co. the best seedlings of show varieties were Rosy Morn, a fine, bold flower of a deep rose colour; Duke of Connaught, dark crimson; and Emily Edwards, a kind with fine, large, shell-shaped petals of a rich cream colour, delicately traced with violet. From the same exhibitors also came Barnaby Rudge, a greenish-yellow flower profusely striped and spotted with dark crimson and scarlet; Gaiety, a kind well named, its body colour being bright lemon, tipped with white, and splashed with bright scarlet and several shades of purple. Messrs. Rawlings Bros., Romford, showed several good seedling Dahlias, the best of which was Clara, elsewhere alluded to; the Rev. J. Goodday, dark maroon-crimson tinted with bright purple; and George Smith, a medium-sized well-formed flower of a bright magenta colour, were also promising kinds. Mr. G. Smith, Hedge Lane, Edmonton, likewise contributed several stands of Dahlias; and Mr. Cannell, Swanley, showed a stand of handsome Pomponé Dahlias and blooms of single-flowered kinds, which attracted much attention.

Miscellaneous Subjects.—Messrs. Hooper & Co. sent from their Twickenham nurseries several very fine double and single-flowered Begonias, and from the Society's Garden at Chiswick came well-grown plants of B. Moonlight, one of the best white-flowered Begonias in cultivation; also a collection of Abutilons. Mr. Noble, of Bagehot, exhibited a dwarf free flowering variety of *Gynerium argenteum* named *pumilum*; also blooms of Rose Queen of Bedders. Mr. Cannell, Swanley, furnished a stand of Verbenas blooms inserted in a carpet of Club Mosses, a good way of showing such flowers. Mr. Green, gardener to S. G. Macleay, Esq., Pandell, Blechningly, sent *Gloxinia maculata* bearing pyramidal spikes of large drooping blue flowers; also flowers of *Costus speciosus*. Mr. R. Dean showed remarkably large blooms of African Marigold, and finely-coloured French Marigolds came from Mr. Cannell.

Fruit and Vegetables.—Mr. Rivers, Sawbridgeworth, sent branches literally laden with fruit of several kinds of Plums, and to a new Pear, as yet unnamed, a first-class certificate was given. Several dessert Apples were contributed by different exhibitors. Mr. Walker, Thame,

Oxon, showed specimens of Walker's Exhibition Onion, a very large kind, and finely ripened. Specimens of an Onion called Paragon, shown by Mr. Taplin, Uxbridge, were almost as large and fine as those of Spanish growth, to which this kind is very similar, both in shape and appearance. In competition for the prizes offered by Messrs. James Carter & Co., High Holborn, for twelve fruits of Vick's Criterion Tomatoes, ten dishes were shown. The first prize was awarded to Mr. R. Phillips, gardener to Capt. Jackson, The Deodars, Meopham, Kent; the second to Mr. C. Roes, gardener to C. Eyre, Esq., Welford Park, Newbury; and the third to Mr. W. Scott, Pembroke Cottage, Cambridge. Prizes were also offered by Messrs. Hooper & Co. for twelve fruits of Acme Tomato. Mr. A. Hopkins was awarded the first prize, and Mr. Miller, gardener to J. Friend, Esq., Northdown, Margate, the second. Both kinds of Tomatoes were shown in good condition, and they are very smooth-skinned, of fine shape, and well worth culture.

Begonia geranioides.—This is one of the best of all the dwarf Begonias. Its habit is compact and distinct, and its blooms, which are produced in great abundance, are of a fine white colour. This Begonia was sent out by Messrs. Backhouse, York, a great many years ago, but it is seldom met with even in gardens in which Begonias are grown, and for what reason I am unable to say. It is one of those good plants lost to sight, but to memory dear.—J. G.

Lasiandra macrantha purpurea.—This deserves attention on account of its purple-marve colour, which is rich and striking, and also on account of its flowering freely during the autumn and winter months. It requires, however, a warm conservatory. It may be readily propagated by means of young growths inserted in sandy peat and plunged in a good strong bottom-heat. Being of rather a straggling habit, it requires some training in order to have good specimens of it, and if kept in quite cool quarters after it has made its principal summer growth, and returned to the stove about this season, good plants of it will supply a fine succession of blossoms during the greater part of the winter.—J. GROOM.

Exhibiting Wild Flowers.—I was much pleased with the arrangement of a collection of wild flowers exhibited at Coventry on the 10th inst., consisting of twenty-four kinds; they were arranged on stands similar to those used for Carnations, and were made up into bunches with some of their own foliage, and all named with their English names. This I consider a step in the right direction. Many who would study our native plants give up the task in despair when confronted with the botanical names. Children, more especially, ought to be encouraged to bestow increased care in the arrangement and naming of wild flowers. In local exhibitions this does not often receive that attention which it deserves.—A. HOSSACK, *Ragley*.

Opening of Kew Gardens.—Sir Joseph Hooker seems still disinclined to open Kew Gardens at an earlier hour. From Sir Joseph's point of view, the gardens could not be "maintained up to their present standard if the public were to be admitted at an earlier hour." We should like to know in what way the public would interfere with the proper management of the gardens. It appears that the morning hours are reserved in order that the staff may attend to their duties, and that scientific students and artists may prosecute their studies undisturbed. The easy answer to this is that visitors would not necessarily interfere with the workmen, and that the scientific students would be perfectly secure from molestation. Not a single case of wilful damage to the gardens has ever been brought before a police magistrate, and, as regards the students, their operations are generally confined to the museum and herbarium, which the general public does not enter. Nor would the latter do the students any harm. We can see, any day, in the British Museum or National Gallery, people pursuing their researches perfectly unembarrassed by any number of visitors. There is no reason to suppose that the case would be different at Kew Gardens. The fact is that the gardens are public property, and as such the public have a perfect right to visit them at all reasonable hours. The plea put forward by botanists and scientific men is rubbish. There are not twenty eminent botanists in England, and we should like to see a return of the genuine students for whose benefit public property is to be fenced off during the best part of the day. Sir Joseph's private objections are intelligible. For years Kew Gardens have formed a snug little preserve—a sort of happy hunting ground for the scientifically inclined members of the Hooker family. It is, doubtless, a little hard that the privileges so long enjoyed by the latter should have to give way, as they must, to public rights and convenience.—"Examiner."

Caterpillars and Dill.—A Hanoverian journal states that the steward of an estate in Hanover, having observed that one bed of Cabbages was left untouched by caterpillars, whilst others were infested with them, found that the healthy bed had a quantity of Dill growing on it, the smell of which, apparently, was obnoxious to the caterpillars. As Dill will grow in almost any soil, it is suggested that the experiment might be tried elsewhere.

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

FRENCH AND ENGLISH-RAISED GLADIOLI.

Of all our autumn-blooming plants, the *Gladiolus* must, I think, carry off the palm—the *Dahlia* and the *Hollyhock* must give way, notwithstanding their long and well-deserved popularity, to the *Gladiolus*; indeed, the *Hollyhock* seems to be taking itself out of the way, the mysterious disease which has affected it having baffled all attempts to get rid of it, and the raising of seedlings being equally fruitless, for the seedlings seem as subject to it as the old plants. The *Hollyhock*, too, is more suited for giving grand effects, and when grown in quarters by itself takes up a great deal of room. The *Dahlia* one cannot disparage. A great authority once called it "lumpish and inelegant." Judged by some standards of beauty, it may be so; but we have to recollect that there are various forms of beauty: we may admire the solid grandeur of the Egyptian temple as well as the graceful and airy form of the Gothic cathedral. In the symmetrical form, the varied colours, and the stately habit of the *Dahlia* there is a beauty which has won for it the favour and affection of many a devoted enthusiast; but the *Gladiolus* has many claims to the consideration of the lover of flowers. Its erect habit, the varied colours it displays, the small space of ground which it occupies (for several hundred sorts may be grown in a space which half-a-dozen plants of *Dahlias* would occupy), the manner in which it blooms in water after it is cut, lasting for many days and opening out its upper blossoms as the lower ones decay—all combine to make it one of the most beautiful and deservedly valued of florist flowers, while the improvement that has taken place of late years has given it a beauty which the older flowers never possessed.

Like many of our modern flowers, we owe our first advance in improvement to Continental growers—the *Aster*, the *Verbena*, the *Phlox*, the *Pentstemon*, and especially the *Rose*, were all taken in hand by the French before they were attempted on this side of the channel. So it was with the *Gladiolus*. It must be now above forty years since Mons. Souchet, then head gardener at the Chateau of Fontainebleau, now a venerable and respected private citizen, beloved by all who know him, began the improvement; and although some few others, such as Messrs. Courant, Berger, and Gardier, have followed his example, yet nearly the whole of the varieties now in commerce (as far as France is concerned) are of his raising; and not only so, but almost the whole trade is in the hands of Messrs. Soulliard & Brunelet, his successors; they supply the great French houses of Paris, by whom the bulbs are forwarded to all parts of the world. At a later period than this Mr. Kelway, of Langport, in Somersetshire, began his culture and hybridising of the flower. This year he issues his twenty-seventh catalogue, so that I should suppose it must be some thirty years since he began; and, as in many of the other cases to which I have already alluded, the English raiser has equalled and excelled his French rival. I do not know what amount of land Messrs. Soulliard & Co. have now under cultivation, but the Messrs. Kelway have about eight acres, and it will be readily imagined what an enormous quantity of bulbs that must involve, while each year gives us greater variety and larger and more solid flowers. There seems to be a different idea of what constitutes a good spike of *Gladiolus* abroad from that which prevails with us. We prefer one wherein all the individual flowers not only face the front, but where they also are so close that there are no spaces between them. Let us take, for example, such a flower as Meyerbeer, now very old, but unsurpassed in its shade of colour; there we have a spike which has twelve or fourteen blooms expanded at the same time, and without any space between each bloom, so that they are tucked in one to another, and present a solid front of colour. In contrast to this I take one of the latest of the Continental productions (*Leviathan*), which has not more than half-a-dozen blooms open at

once; these blooms are far apart, and consequently do not present the attractive appearance they might do were the blooms differently disposed, but I have heard the French growers like this style of flower as being more graceful and elegant. Then there is another point in which Mr. Kelway's flowers are superior to the French ones—their greater substance. Let us compare, for example, two white flowers recently sent into commerce—*Diamant* (of Mons. Souchet) and *Scopas* (of Messrs. Kelway). The former is as flimsy as a piece of muslin; there is no shape in the petals, which are dog-eared; and, although described as an extra large flower, and priced higher than any *Gladiolus* sent out recently by them, is really an indifferent flower. *Scopas*, on the other hand, is a large flower, indeed very large; in form it quite comes up to the standard, has a large number of blooms open at once, and is as solid as the other is flimsy. When flowers have to be cut this is a matter of some consideration, for, of course, those with good substance will remain fresh longer than flimsy ones. I think the honour of raising what I believe to be the finest *Gladiolus* in cultivation (*Duchess of Edinburgh*) must be accorded to the same firm. In colour it is a lovely rose, with a carmine stripe on the lower divisions, fine form, and of great substance and size; I have counted a dozen blooms out on it at one time, and it has then a very noble and grand appearance. While saying this I do not mean to disparage many of the very beautiful varieties which Mons. Souchet has given to us. Amongst light-coloured flowers *Norma*, *Ondine*, *Shakespeare*, *Madame Desportes*, *Psyché*, *Leda*, *Ginevra*, *Murillo*, and others; and amongst red, in its various shades, *Legouvé*, *Le Phare*, *Jupiter*, *Hecla*, *Horace Vernet*, *Le Vesuve*, and *Hercule* are grand flowers. All that I would imply is that the English grower is not behind, and that the last two years have not certainly been as productive in fine French novelties as previous years have been.

It is very much to be deplored that no opportunity of exhibiting these fine flowers, or their usual autumn companions the *Dahlia*, *Hollyhock*, and *Aster*, is now given in the metropolis, and that we have to look to the provinces for anything worthy of the name of an exhibition of autumn flowers. It has, I suppose, been found that they do not pay, or else we might have imagined that the *Crystal Palace* or the *Alexandra Palace* would have held them. Last year there was a show at the former place, but this year flowers form no part of their programme. People may decri exhibitions, and may complain of the way in which cut flowers are shown; but it is nevertheless a fact that nothing so encourages the growth of any flower as the offering of prizes at flower shows. People see them there who would never see them in the nurseries or private gardens from whence they come; they are induced to try them, and then probably the taste is engendered, and they become ardent admirers of the flower. Moreover, it tends to correct the judgment of those who have already grown them; they see flowers better than their own, and are stimulated to increased care, and go home with a more humble estimate of their own prowess. When we rest satisfied with our own advance, it is well for us to be shown that "wisdom does not dwell with us." More especially is this the case when we raise seedlings; the exaggerated estimate we are inclined to form of our own productions becomes sobered down by comparison with the flowers of others, and we return home wiser, if sadder. But if autumn shows are financial failures, it is useless to expect them to be held, and we must only look to the prominence given to *Gladioli* in our various horticultural journals to obtain for them the patronage they deserve. It is for this reason that I have endeavoured to draw attention to this beautiful flower. The stand which Mr. Kelway lately exhibited at South Kensington must have convinced all who saw them of their great merit; and it may be well to say, as showing the high standard which has been reached, that flowers which were set up for certificates were passed by by the floral committee which a few years ago would have been hailed as first-rate flowers. Let anyone, then, who wishes to attempt their cultivation obtain some of the lower priced seedlings of Mr. Kelway, and a few of the older flowers of French origin, and they will be laying up in store for themselves a great treat in the ensuing autumn, and will afterwards be tempted to higher flights. DELTA.

THE FRUIT GARDEN.

WALLS AND WALL TREES.

THE season is now at hand when tree planting may be successfully carried out, and also when, owing to the trees being leafless, the walls may receive that attention of which they frequently stand in need. One of the first considerations should be a smooth even surface, free from nail holes or inequalities of any kind, as where these exist insect pests find shelter in them in winter, and are ready to recommence their attacks in spring. Old walls should be plastered and receive a good coating of whitewash, as it not only looks clean and sweet, but white has been proved by direct experiment to be the best ground colour on which to train the trees. I need scarcely remark that any trees infested with scale should be well scrubbed, taking care to save the buds as much as possible, and then painted with some strong insecticide. As regards the manner of training, I believe that the wiring system has many advantages, if the wires be properly fixed, so that the wood is kept close to the walls; but when the wires are stretched horizontally in any considerable lengths the strong branches draw them away from the walls, and consequently the benefit arising from the latter is lost. As regards borders, I am of opinion that most of our wall trees will grow well in any soil that produces good crops of vegetables, provided the border be deeply cultivated at first and confined to the roots of the trees afterwards; or, if not the whole border, a wide alley, at least 4 ft. from the wall, should remain undisturbed and mowed during summer, and the remainder should only be employed for shallow rooting choice vegetables or salads. More attention should also be paid to the rotation of wall trees than that subject ordinarily receives, for if Peach trees have occupied a south wall for twenty or thirty years it is almost a waste of time and trees to suppose that merely trenching the border will supply their wants. No; they must have fresh soil, but in many cases the best course would be, as Peach culture under glass extends, to devote a larger amount of south aspects to the choicer kinds of winter Pears, such as Easter Beurré, Glon Morceau, Beurré Rance, &c. We have hitherto given winter fruits only a secondary position where they naturally only attain second-rate quality. East and west walls will bring to perfection most of our ordinary mid-season Pears, Plums, Cherries, &c., and north walls may be profitably occupied with Morellos and other Cherries, Currants, and dessert Gooseberries; but the south aspects should be devoted to the earliest Cherries, a selection of Peaches, Nectarines, and Apricots, and a choice collection of winter Pears. Space is too valuable to allow them to be trained horizontally; therefore, some of the many modifications of the upright cordon will be found an improvement, producing, as it does, speedier and better results.

J. GROOM.

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

Large Melons.—At Longford Castle a fruit of Duke of Edinburgh is said to have measured 25 in. round the middle, and 28 in. in length, and its weight was 11 lb. 12 oz. At Croome Court I saw the other day a fruit of Incomparable which measured 23 in. round the middle, and 29 in. in length, and its weight, when cut, was 13 lb. 10 oz. There were also here many Melons, each of which weighed from 8 lb. to 10 lb.—J. H. D.

The Sultana Grape.—Allow me to inform Mr. Quin that this Grape has been cultivated at Ashburnham Place, Sussex, for over forty years. It was so highly esteemed by the late Earl of Ashburnham when travelling in the East that he brought plants of it home with him. This Grape requires different treatment from other varieties, and should be grown in a house by itself, in order to ensure success. I never found it to force well, but when once commenced to grow naturally it ought to be encouraged with fire-heat and plenty of moisture. Being a late-keeping Grape, it ought to be well ripened in September, when the berries ought to be of a bright amber colour. Although small in berry the bunches are large, and will hang until March without shrivelling. The pruning most suitable for it is that known as the rod system.—A. HOSSACK, *Ragley, Alcester.*

Pear Trees for Avenues and Groups.—Writing lately of the need of more orchard trees, and of fruit trees scattered over the land without any relation to the orchard, we might have spoken of the stately grace of the Pear tree when mature or old. As a beautiful object it is probably before any tree planted for ornament, considering its fine form, early and profuse bloom, and the beauty of the fruit. We noticed the other day a handsome avenue of Pear trees, a line on each side of a roadway leading to a Swiss town. The trees were all laden with a small Pear used for making perry, and were more graceful in form than many of our "weeping lawn trees."

They were about 36 ft. apart in the lines; anything less would not allow of the trees attaining great size or being seen to advantage. Why not avenues of the freest-growing of the good Pears? Why not groups of them in our parks? They, at least, are not exotic and disappointing like many of the Conifers planted in avenues of late years; but trees of our own regions, which no cold we experience can destroy. We have seen them in Worcestershire and elsewhere attain the size of forest trees. Surely groups of such are well worthy of being added to the deciduous trees in our parks.

Strawberry Lucie Flament.—Among new varieties of Strawberries shown in May and June at the Paris International Exhibition, this variety occupied a prominent place. It is a cross between Marguerite Le Breton and Dr. Morère, and it possesses all the good qualities of the two kinds without their faults. The berries equal in size those exhibited last year at the Belgian Horticultural Show. For forcing it is all that could be desired. M. Flament, who raised it, has kept 800 plants in reserve for next season, and M. Godefroy-Lebeuf has purchased the stock of it.—L.

Selecting Pear Trees for Planting.—One seldom looks over a new plantation of Pears without finding a number of varieties that are in every way thriving and giving promise of good results, while an equal number is by no means satisfactory. As a rule, the aim seems to be to have as many varieties as possible, some of which might succeed on a wall, but in any other way are useless, and others are not suited to the locality. The season for planting being now at hand, I would recommend the selection of varieties that would succeed in the district in which the new plantation is to be made, for what can be more vexatious than spending time and labour on the culture of a given number of trees the produce of one-half of which turns out to be useless? Few fruits, in fact, are more variable than the Pear, or are more capricious under haphazard culture. The best way of converting vigorous, but unfruitful, Pear trees, or such as produce fruit of inferior quality, into remunerative ones, is to head them down while the sap is dormant, and to re-graft on all the extremities as soon as it begins to flow in spring with some tried sort from the neighbourhood. The double grafting will be certain to induce fertility, and in a few years the produce will exceed what it is possible to obtain by any less radical measures.—J. GROOM.

Protecting Early Vine Borders.—Allusion is made by Mr. Simpson (p. 261) to an admission said to have been made by me in THE GARDEN (p. 241), but I am at a loss to guess what that admission is, as I have not taken part in any controversy to my knowledge; I cannot, therefore, discover where I have written supporting Mr. Simpson's opponents. For Mr. Hind's omission to mention the inside borders here, I cannot surely be held accountable. All our Vineries have inside borders, and the front walls stand on pillars, beyond which there are outside borders, a system I have always advocated, from the facility which it affords for renewing the borders at any time without deteriorating the crops, as the inside border can be renewed at one time and the outside one at another, a consideration where a regular supply is required. I used to cover the outside border with fermenting material, but for these last five years I have dispensed with that, and I have merely protected the borders from rain and frost, a plan which I find gives more substance to the foliage, and puts a finer finish on the fruit. I, therefore, still support the protection system, as under it the temperature of the border declines gradually to the lowest point; and if the border be thoroughly drained, the roots will retain their vigour in a very low temperature, and when spring returns they will be found well able to supply any demand that may be made on them.—J. SMITH, *Waterdale.*

—Mr. Simpson says (p. 261) that I have done more than any one else to convey a wrong impression with regard to Mr. Smith's practice at Waterdale, inasmuch as Mr. Smith admits that the better half of his early Vine borders are inside. Here are my words taken verbatim from the July number of "The Gardener": "I have seen the borders at Waterdale, many of which are inside, but in one particular house—a lean-to—with the border outside, and in which the crop was ripe at the time of my visit, was perhaps the most remarkable crop of fruit I ever saw at the time of year." The allusion to me is, therefore, uncalled for.—W. HINDS, *Otterspool.*

Redleaf Russet Apple.—This is said to be a cross between the Golden Knob and Golden Harvey; its colour is that of the Golden Knob; the yellow colour of the flesh would seem to be derived from the Golden Harvey; whilst the growth of the tree and manner of bearing resembles both Nonpareil and Golden Harvey more than the Golden Knob. When in perfection, the flavour is delicious; and the fruit may be considered to be at its best from February until the end of May; after that, although it keeps sound until the end of July, the flavour gradually deteriorates. Messrs. Paul & Son, who showed specimens of this Apple the other day, state that though of moderate growth, it is vigorous enough to form a good-sized handsome tree.

NOTES OF THE WEEK.

The Red Water Lily.—Messrs. Fröbel, of Zurich, who have a large number of young plants of this, are not disposing of any till they have flowered each plant and proved it "true" as regards colour. Many of their plants are seedlings raised from the fine old plants they possess of this variety. A few of the seedlings have already bloomed, and proved quite true in colour. Many are expected to bloom during the coming year.

Gynerium argenteum nanum.—This new dwarf form of Pampas Grass is now in perfection, and merits strong recommendation, being suitable for even the smallest gardens, which can scarcely be said of the typical species. Throughout the whole summer its neat compact habit of growth attracts the eye. The flower panicles are about 5 ft. high, exceeding the foliage by 2 ft., or thereabouts.—W. THOMPSON.

The Flower Beds near Westminster Abbey.—We never remember to have seen the little garden near Westminster Abbey so completely flowerless in September as it is this year. The turf, on the other hand, is as fresh and green as a well-kept lawn in the country could possibly be, presenting a striking contrast to the dull, littery-looking beds which are just now objectionable rather than attractive.

Melons in Covent Garden.—This season appears to be a good one for Melons, if we may judge by the quantity now to be found in Covent Garden. The majority of them are medium-sized, English-grown fruit, which, if sold at moderate prices, will greatly diminish the demand for the large, coarse, foreign fruits which are to be found in the market nearly all the year round. Mr. Bennett, of Rahley, has had this season hundreds of Melons hanging in his houses at one time, presenting a sight, the like of which is seldom seen in the case of Melons.

Worcester Pearmain.—Specimens of this handsome early Apple, lately sent out by Messrs. Smith & Co., Worcester, have been sent to us by that firm. It is said to be a seedling from Devonshire Quarrenden, which, however, it only resembles in being very highly coloured. The tree is stated to be a free bearer, and, from the great beauty of the fruit, when better known, cannot fail to be a favourite, especially for market purposes.

Lapageria rosea.—We have received from Mr. Bernard D. Rowe, of Dinglefield, Liverpool, a truss consisting of seven blooms of *Lapageria rosea*; so compact a cluster is, we need scarcely say, of rare occurrence, more especially as the plant from which it was cut is said to have been in constant flower since May last, and still carries upwards of sixty-five fully-expanded blooms, besides an even greater number of buds.

Standard Trees of Tamarix.—These are exceedingly novel and graceful, as grown in some of the little squares in Zurich, and also in one or two towns in North Italy. The kind is *T. tetrandra*; they are trained with about the usual height of stem of ordinary street trees, and are allowed to spread into large heads. The flowers on these trees are said to be produced freely. They retain their verdure up to the present time.

Autumn-blooming Colchicums at Tooting.—Several large beds devoted to Colchicums in Mr. Barr's grounds, Tooting, have for some time past been, and still are very attractive. The kinds consist chiefly of *C. speciosum*, *C. byzantinum*, *C. b. longipetalum*, and a white-flowered form. The individual flowers of Colchicums do not, as a rule, last long, but as they are produced in succession, a long season of bloom is the result. It is, however, often destroyed on account of the plants being grown in unsuitable positions, viz., in bare beds of soil, which, splashing the blooms during heavy rainfalls, impairs their beauty. The best places for Colchicums are little grassy nooks near shrubberies and trees, where the soil is well drained, sandy, and rich. On rockwork, too, planted among dwarf Sedums and similar subjects, Colchicums would thrive well and make a show in autumn, when rock gardens are comparatively flowerless.

Remarkable Growth of Pampas Grass.—Where large clumps of this Grass are required in a short time, they may easily be obtained by adopting the method pursued by Mr. William Paul in his nurseries at Waltham Cross, by which means he has secured noble clumps, furnished with dozens of flower spikes, in little more than two years. The seed was sown in autumn, and when the plants were large enough they were potted into 5-in. pots, and from these in the following June they were transferred to the open ground. The soil in which they were planted was deeply dug and well manured, and from twenty to thirty plants were placed in a large, round bed. These have grown with such uniform vigour that one could scarcely

detect that more than one plant had been used. Much is doubtless due to the rich soil in which they were planted in the first place, and not a little is also due to the heavy rains and floods which occurred in this neighbourhood this season, thus serving to show that rich soil and abundance of water are necessary for the perfect growth of the Pampas Grass.

Large Cockscombs.—We have received from Mr. Craike, of Chapel Road, Stamford Hill, a Cockscomb, the comb of which measured 24 in. one way and 15 in. the other. The seed from which it and others equally large were raised, Mr. Craike tells us was sown thinly; the young plants were pricked off early and received no liberal treatment until the combs measured 2 in. across. They were then potted firmly in good soil, such as that in which Pelargoniums are grown, plunged in a moderate hotbed, and given abundance of air. As soon as the pots were full of roots, greenhouse treatment with weak manure water once a week is all they required. 6-in. sized pots are quite large enough for Cockscombs, and indeed in some seasons they have done well in 4½-in. pots.

Royal Horticultural Society's Preston Show.—We regret to find by a circular that has been issued by the local committee of the late horticultural show held at Preston that there is a deficit of nearly £1500 after paying all expenses. This deficiency is attributed by the committee to "the wet weather on the first two days, and the presence of the Lord Mayor of London at that time in Blackpool on the occasion of the opening of the winter gardens."

Woolhope Club Fungus Foray.—Although several deaths have already been announced in the papers—"through eating Mushrooms"—the Woolhope Club will hold its annual foray on Oct. 3, meeting at the Free Library, Hereford. Members and fungus collectors generally are requested to forward as many specimens of Mushrooms as they can find not later than Wednesday morning, Oct. 2, in order that they may be properly arranged for the evening meeting. Through the want of a little knowledge of fungi people suffer in two ways—if they let all the "Toadstools" along much valuable food is wasted, if they eat without knowledge they run serious risks.

Cassia corymbosa Out-of-doors.—This plant must be much harder than is usually supposed. I placed a small plant of it in June last year against a west wall in the kitchen garden here, where it stood last winter uninjured, and has this year made growths of from 6 ft. to 8 ft. in length, flowering from almost every axil, and even now (September 24) it is in full bloom. The flowers are much larger than when grown indoors, and the foliage of a deeper green and beautifully clean and healthy. The plant already covers a large piece of wall. I should add that last winter I placed a Yew bough in front of it.—D. UPHILL, Moreton, Dorchester.

The Old Watergate in Buckingham Street.—The Metropolitan Board of Works have purchased the Buckingham Street Watergate, which now occupies a retired position in the Thames Embankment Garden, for £5000. It is to be raised and used as an ornamental entrance to the Embankment Garden from Buckingham Street. It is said to be as old as the time of Elizabeth.

Fresh Fruits from Australia.—We understand that an attempt is about to be made to place the finest selected fruits of the Antipodes on the markets of London in such a state and at such prices as to compete with English produce. We already go far enough afield in search of choice fruits, and it is only a question of price whether Australia is to become one of our sources of supply. The cultivation of Oranges is being taken up with energy both in New South Wales and Victoria, and as this fruit can be gathered nuripe, and will mature on the voyage, there will be less risk of loss than in the transport of other kinds of fruit. As, however, the fruit season in Australia is exactly the period when fruits cannot be obtained here, the probability of remunerative prices is all the greater.

Skimmia japonica at Fulham.—One of the most striking features in Messrs. Osborn's nursery just now is a large bank consisting of many hundreds of this pretty berry-bearing shrub. In spring the plants were lifted and potted, and throughout the summer were placed close together in the open air. In this way their flowers set well, and the plants in question, which range in size from that of compact little bushes, in 6-in. pots, to large specimens, are literally covered with scarlet fruit. As a room plant the *Skimmia* is much more valuable than any of the Solanums, inasmuch as the latter frequently shed their foliage and often their berries; the *Skimmia*, on the contrary, will bear the heat of a room for a considerable time without suffering much injury, and retain its fruit to the last. As a standard for dinner-table decoration, or for mixing amongst other plants in greenhouses or conservatories, this species of *Skimmia* might be used with advantage.

NOTES FROM KEW.

Hardy Shrubs.—The South European *Cneorum tricoccum* is a charming little shrub, whose fruits, nestling amongst the dark green, box-like leaves, are at present assuming a deep red colour; these, with the small but bright yellow blossoms, produce a very pretty effect. *Lippia chamaedrifolia*, a neat-growing shrub, with rigid, dark green leaves, is flourishing on one of the walls; it bears long spikes of small, pretty lavender-coloured blossoms.

Hardy Herbaceous Plants.—*Impatiens amphorata*, an Indian annual, is one of the best of the hardy Balsams; it makes a very neat dense bush, about 2 ft. or 3 ft. high, and produces a profusion of handsome blossoms, the upper part of which is a pinkish-purple, the lower, a fine rich yellow spotted and lined with dark red-brown. *Crocus Cambessedesii*, found wild in the Pine forests of Majorca, is a rare and most lovely little plant; in colour it is white slightly tinged with mauve. *C. Kochyanus*, from Asia Minor, with very pale blue flowers, the *Orientalis* *C. pulchellus*, with fine, light purple flowers, and *C. speciosus*, from the Caucasus, with dark blue flowers and orange-red styles, are among the most desirable of the autumnal Crocuses now in flower in the Kew collection. *Cedronella mexicana*, a handsome Labiate, is a neat little bush somewhat more than 1 ft. in height; its numerous flowers are of a pleasing pink colour. *Valeraria plumbagioides*, from China, merits mention on account of its late-flowering qualities; its deep blue blossoms are very effective. *Centaurea babilonica*, an Oriental plant, grows about 4 ft. high and has large, whitish, almost entire leaves which are somewhat oval in outline, and bright yellow flower heads, which are, however, not large. *Mikania scandens*, a North American perennial, is an elegant climber with small, Eupatorium-like flower-heads and light green, heart-shaped leaves resembling in form those of the common Bindweed; if allowed to creep naturally over old logs this makes a beautiful covering; it also comes in well for partially covering arbours and similar structures.

Greenhouse Plants.—*Encnide bartonioides*, an illustration of which is given in THE GARDEN, p. 91, makes a useful pot plant for the decoration of the greenhouse and conservatory; it flowers freely in a small state, and with but little pot room, and its large, sulphur-yellow blossoms, with their long and very numerous stamens of the same colour, render it extremely attractive and different from anything else now in flower. *Astelias Banksii* is a curious New Zealand plant of the easiest cultivation; the small flowers, produced in dense panicles, are succeeded by mauve-coloured, berry-like fruits. Speaking of one of the *Astelias*, figured many years ago in the "Botanical Magazine," Sir Joseph Hooker says: "All are densely-tufted herbs, with a short, creeping rhizome, with very long leaves, more or less covered with shaggy wool or silvery hairs. The large kinds form a conspicuous feature on the lofty trees of New Zealand forests, where, growing epiphytically on branches, they resemble gigantic birds' nests." In cultivation they grow well in well-drained fibrous loam. *Echidnopsis cereiformis* is a peculiar South African succulent allied to the *Stapelias*, and does well if treated in the same manner; from its thick stem it produces numerous small yellow blossoms. *Fourcroya Selloi*, from Guatemala, and *F. cubensis*, from Cuba, are handsome, Agave-like Amaryllids, with flower stems 10 ft. to 15 ft. high. *Witsenia corymbosa*, from the Cape of Good Hope, with its Grass-like leaves and handsome, dark purplish-blue blossoms, ought to be much more generally grown; it is a charming greenhouse plant, and one, too, which is not difficult to manage.

Stove Plants.—The sweet-scented Garland-flower (*Hedychium coronarium*) is a splendid Cannas-like plant, 5 ft. or 6 ft. high; the large, fragrant blossoms are of the purest white, with the exception of a blotch of pale primrose on the upper portion. *Scatellaria violacea*, an East Indian sort, is a neat-habited and free-flowering plant with dark violet-blue flowers. *Ipomoea Selloi*, a Brazilian climber, has hairy, heart-shaped entire or lobed leaves and pink, trumpet-shaped blossoms. *Pitcairnia fulgens*, with its arching leaves, light green above and very glaucous beneath, and panicles of deep red flowers, is a useful decorative stove plant.

Orchids.—*Oncidium tigrinum*, from Western Mexico, is a noble kind with tall panicles of splendid, very delicately, violet-perfumed blossoms; the sepals and petals are pale yellow and brown, while the very large lip is a bright sulphur-yellow. *O. Harrisonianum*, a native of the Organ Mountains and other parts of Brazil, is very floriferous. In describing it, Dr. Lindley says that the dull grey horn-like recurved leaves, and most remarkable crest, render it impossible to mistake this pretty little plant, whose brilliant yellow flowers are enlivened by rich crimson linear stains. *Miltonia candida grandiflora* is a beautiful plant with large flowers, the sepals and petals being brown and yellow, and the large lip white with a purplish

blotch at its base. *M. Clowesi* has sepals and petals blotched with chocolate-brown on a yellow ground; the lip is white at the tip and violet coloured at its base.—†.

THE SPECIES OF MECONOPSIS.

The following list is restricted to the species at present in cultivation, but there are yet others to be introduced equally beautiful and interesting as those enumerated. With the exception of our common British species, the Welsh Poppy, they are all natives of Northern India, chiefly inhabiting various localities on the Himalayas; they are all of comparatively recent introduction. Of Himalayan Poppies there are four kinds, viz. :—

Wallich's Meconopsis (*M. Walliichi*).—This fine species attains the largest size of any. The leaves measure from 8 in. to 12 in. long, deeply cut nearly to the midrib, of a pale green colour, and covered on both sides with soft brownish hairs. The flower stems are said to be 6 ft. high in the wild specimens and much branched. The blossoms are 1½ in. to 2 in. in diameter, of a pale purple colour, with a central cone of bright yellow stamens; it is found at high elevations in Sikkim and Nepal.

Nepalese Meconopsis (*M. nepalensis*).—This so much resembles the last in a young state that the two are often confused. They may be readily distinguished by the leaves of this species not being so deeply lobed as those of the other; in fact, in some forms but slightly toothed. The flower stems are from 3 ft. to 5 ft. high and not so much branched as in *M. Walliichi*. The blossoms, which are produced freely, measure from 2 in. to 3½ in. across, nodding, and are said to be of a bright golden-yellow colour, though under cultivation they do not assume such a bright colour, but are of a pale golden yellow. It inhabits Nepal and various parts of the temperate Himalayas.

Prickly Meconopsis (*M. aculeata*).—This is a rare and very distinct kind. Its leaves are from 4 in. to 8 in. long, oblong or lance-shaped, irregularly lobed, of a pale green colour, and beset with numerous soft prickles. The stems measure from 1 ft. to 2 ft. high, and are crowned with numerous blossoms borne on slender stalks, the blossoms measuring from 2 in. to 3 in. in diameter, and of a blue-purple colour. It is found in Western Himalaya, from Cashmere to Kumaon, at high elevations.

Simple-leaved Meconopsis (*M. simplicifolia*).—This is also very distinct. It produces a tuft of lance-shaped root leaves, from 3 in. to 5 in. long, very slightly toothed, and covered with a short, dense, brownish pubescence. The flower stalk is unbranched, about 1 ft. high, and bears a single blossom at its apex from 2 in. to 3 in. in diameter, of a violet-purple colour.

These Poppies require to be grown on well-drained rock-work, planted in good soil, with a plentiful supply of water in summer, but they must be kept as dry as possible in winter, as excessive humidity in cold weather soon kills them. Pieces of sandstone broken finely should be placed under the leaves so as to prevent them from coming in contact with the damp soil. A piece of glass placed over the leaves in a slanting position also protects them from too much moisture. W.

Saxifraga cæspitosa.—Amongst plants used for carpeting bed I find none so effective as this Saxifrage. Its freshness of verdure, evenness of growth, and general adaptability for that purpose are certainly not equalled by such plants as *Mentha Pulegium*, which takes a good deal of trimming in order to keep it within bounds; neither is the *Herniaria glabra* so soft and pleasing as the Saxifrage in question, which I have here in a large oblong panel; and, having fully tested it on a large scale, I can strongly recommend it as a hardy plant, which will give every satisfaction in pattern arrangements with the least possible trouble.—G. WESTLAND.

Aster Novæ-Belgii var. minimus.—The object of this note is not so much to extol the beauty of this plant, which is one of the best of the numerous family to which it belongs, as to point out an error which exists as regards its nomenclature. It is known by the names of *longifolius* var. *formosus*, or *ramosus*, or *minor*, and other names, but those who possess the true *A. longifolius* will see that the dwarf plant has no affinity with it. Good distinguishing points are the oval root leaves in *longifolius* and the lance-shaped, pointed leaves in *Novæ-Belgii*. The colour of the flowers in the type is not quite the same, as it is pale mauve; in the dwarf plant it is much darker, but in all other points they agree.—W.

LOASA VOLCANICA.

SUBJOINED is an illustration of this handsome, newly-introduced, half-hardy annual. It is compact and branching in habit, and from 3 ft. to 4 ft. high, with Tomato-like leaves, which, together with the stem and the outside of the flowers, are beset with numerous, short, stinging hairs. The flowers are about 1 in. in diameter, and are borne singly in the axils of the stem leaves, each branch producing from twelve to twenty blossoms, which open in quick succession and last a long time, rendering it an attractive and beautiful object for several weeks together. The structure of the flower is somewhat singular; the five green divisions of the calyx alternate with as many pure white, boat-shaped petals, in which lie the yellow-tipped stamens. In the centre are five two-horned appendages, which are orange coloured on the outside, and crimson transversely marked with white on the surface. It requires the same treatment as that usually afforded to half-hardy annuals; the earlier the seeds are sown the better, as the stronger the

Loasa volcanica.

plants the longer they flower. Like all other members of the genus it is of South American origin, abounding chiefly in Peru and Chili. A coloured illustration of it will be found in a recent number of "L'illustration Horticole." It is probably identical with the plant lately sent out by Mr. Thompson, of Ipswich, under the name of *L. Wallisi*. W.

Fuchsias Out-of-doors.—Although the *Fuchsia* has been long grown well under glass, its merits as a hardy plant are by no means fully recognised, for the best specimens of out-door *Fuchsias* ordinarily seen consist of the very oldest varieties. *Riccartoni*, the old ripened wood of which is hardy enough to withstand ordinary winters, makes quite a beautiful bush in mild districts, but most of the newer kinds do best cut down close to the ground early in winter, and with a covering of coal ashes placed on their roots. Thus treated, such sorts as the white corolla'd *Madame Cornéliusson*, and any free-flowering sorts of good habit like *Rose of Castilla*, make most beautiful and continuous-flowering border plants. They need scarcely any attention after they are once planted, as the annual shoots look better left to grow as they like than when a forest of sticks and ties is added under the impression of improving them. The latter give them by far too formal an appearance.—J. GROOM.

TREES AND SHRUBS.

JAPANESE AND OTHER SHRUBS AT BAGSHOT.

FEW nurseries are more charmingly situated than that of Mr. John Waterer at Bagshot, and few are more favoured as regards soil, especially for what are called American plants. *Rhododendrons*, hardy *Azaleas*, and broad-leaved *Kalmias* form, as most people know, a prominent feature in this nursery, and to these may be added Japanese Conifers. *Rhododendrons*, both large and small, are this season better set with flower buds than might have been expected, considering the comparatively sunless summer which we have had. In long frames may be found thousands of seedlings, the produce of seed saved from hybridised flowers of the best kinds, in the hope of still obtaining something new; whilst large breadths of established plants of the best kinds have been layered in order to maintain the necessary yearly stock. Branches with bushy little heads are bent down to the ground, and, after the wood has been slit with a knife, are embedded and pegged down in prepared, rich, sandy soil. In this position they remain two years or so, in order to allow them to become well rooted. They are severed from the parent plants some time previous to being lifted, thus throwing them on their own resources for a time previous to moving them. When that period has arrived they are planted in lines ready for sending away as occasion may require. The old stools throw up an abundance of fresh shoots, which again furnish material for new plants. Each year afterwards the young plants are moved in order to keep their roots fibrous and render them easily transplanted; and such is the nature of the soil here, that not only small *Rhododendrons*, but fair specimens of Conifers may readily be moved from the ground, with a large mass of fibrous roots and a good ball of soil, by simply awaying the tree to and fro, and eventually lifting it without the aid of either spade or fork. Among the large breadths of *Rhododendrons* are planted standard or pyramid Conifers, which obviate that formal, nursery-like appearance often found in large nursery gardens. In planting *Rhododendrons* here a good dressing of rotted manure is often applied to the soil and dug in, and, as the ground gets too light, heavy, clayey loam from the adjacent hills is added to it. This at once does away with the theory, too long indulged in, that peat is absolutely necessary for the growth of *Rhododendrons*. They will grow well in any kind of rich, well-drained soil, excepting lime and chalk.

Retinosporas, which are among the most valued of Conifers, here receive special attention. *R. plumosa* is represented by some of the largest specimens in the country, and associated with these is the original plant of the beautiful *R. p. variegata* in good health. *R. p. aurea*, one of the most valued of golden-leaved Conifers, may be found by the hundred in all stages of growth dotted about the grounds; it has a compact habit of growth, yet devoid of that stiffness and formality characteristic of many of our Conifers; it is of a rich golden colour, and its chief value lies in the fact that its young growths do not get scorched during summer, as is the case with many variegated Japanese plants. *R. filifera*, grown as a standard, makes an excellent plant; it is grafted on the common *Arborvitæ* from 4 ft. to 6 ft. high, and its long, cord-like foliage assumes a gracefully weeping habit, which adapts it for isolating on lawns or for the centres of flower beds. *R. plumosa aurea* also makes a fine standard, its compact heads looking like balls of gold in the sunlight. *R. p. argentea* is a capital little plant in pots for windows; it is close and compact, and of a bright sulphur colour. *R. lycopodioides* grows here amazingly, its crested foliage being of the deepest green colour.

The original plant of the silvery-leaved Juniper (*Juniperus japonica alba*) introduced by Mr. Fortune, is still to be found in this nursery in vigorous health. The scarce *Abies Engelmanni* and its silver-leaved variety, *A. E. glauca*, may here be found in quantity, and *A. magnifica*, which is one of the most stately of the genus, makes marvellous growth in the Bagshot soil. *Thuja borealis aurea*, a sport which originated in this nursery, makes a fine plant; it is elegantly blotched with gold and is of graceful habit, and we found here the plant from which it was taken still bearing branches of a sportive character.

T. dolabrata variegata, a Japanese species, makes a very ornamental plant, and grows even more rapidly than the green-leaved variety, a circumstance not often found in the case of variegated plants. The Tree Ivy is largely grown, and makes fine bushes. It is not met with in gardens very frequently, but it might be planted with advantage where a good hardy evergreen shrub is needed. Standard Hollies of all descriptions are dotted about among low-growing shrubs with good effect, and we noticed that both green and variegated-leaved kinds are unusually well berried this year. Another interesting feature in these grounds is a large circular bed surrounded by a high, well-kept hedge; a magnificent specimen of the Lawson Cypress occupies the centre, whilst the remaining space is planted in panels with golden, silver, and green-leaved Conifers in miniature. These have a very fine effect, and serve to show how attractive and interesting even a small plot of ground may be made by means of hardy Conifers, which withstand without injury all weathers. *Menziesia polifolia alba* grows better here than we have elsewhere seen it; its foliage is of a dark, healthy green, whilst the flower spikes are from 6 in. to 9 in. long, and well furnished with pure white drooping blossoms. A large plot of ground planted with this *Menziesia* has been producing flowers for months past. The Japanese Honeysuckle (*Lonicera aurea variegata*), planted here and there about the grounds, makes a fine mound of rich golden foliage, and is even, if possible, more ornamental in this way than when grown on a wall or fence. *Acer palmatum* is one of the most rapid growing of the Japanese Maples, and its leaves change in autumn to a richly tinted gold and bronze; here it forms fine massive bushes. Thousands of plants of *Andromeda floribunda* are grown yearly for forcing; they form an abundance of flower spikes during the summer, and when lifted in autumn and potted they open freely in heat, and are almost equal in appearance to those of Lily of the Valley. *Skimmia japonica*, as grown here, is one of the best berry-bearing plants which we have for decoration in winter, and *Spiraea japonica* grown in this light, warm soil is quite equal for forcing to imported plants. Massive tufts of *Tritoma Uvaria*, many of them bearing fifty or more strong flower spikes 6 ft. in height, may be seen among the trees and shrubs from every part of the ground.

The old double white *Camellia* is grown here to a large extent, upwards of 4000 plants of it being grafted yearly. The stocks are all grown in the open air until grafted, when they are put into close glass cases in span-roofed houses until the grafts have taken; they are then removed to other houses in which Vines are trained over the roof, in order to afford them a little shade until they can withstand bright sunshine. In the following summer they are turned out of pots and planted out in temporary frames, where they make good growth and set their bloom buds; they are then ready for potting for winter blooming. Such plants are better than those of Continental growth, which frequently lose their flower buds, at least the first season after importation. C. S.

THUJOPSIS DOLABRATA.

EUROPEANS who have seen this broad, hatchet-leaved *Arbovitæ* in its native country generally agree in thinking it the handsomest evergreen tree in Japan; it has, indeed, been described as "the fairest of all evergreens." No wonder, therefore, that this plant, so very distinct from all its congeners, when first introduced into Britain nearly twenty years ago, was universally admired; it seemed, indeed, to have been considered sacred, judging from the way in which it was cultivated in pots and nurtured in greenhouses. Large numbers of those pot-cultivated plants, which were, as a rule, of a low, spreading habit, were turned out into the open ground, where, as might have been expected, considering how they had been previously treated, they grew only moderately well. Frosts browned the greenhouse-built leaves, and the destruction of many plants was completed by snow breaking down their branches. This naturally beautiful and really hardy tree became, therefore, for a time unpopular, and even now it is not looked upon with that amount of favour which it so much merits. Nevertheless, I am confident that cultivators who

treat this plant in a proper way will yet be fully rewarded. Of late years, as soon as plants of it are rooted, they are at once bedded, not too closely, in the open ground, where, if the soil be a good, rich, free loam, they strike root deeply and produce well-formed plants with good leaders. Grown in this way they have fewer branches, which are consequently better ripened, and therefore better able to resist the weight of accumulated snow, which never in the least injures them. A Manchester nurseryman some time ago informed me that it is one of the few Conifers that grow fairly well in the smoke-charged atmosphere of that city. The largest plant that I have heard of growing in Britain is in a garden at Exeter, and is 30 ft. in height. In Japan it is said to attain an average height of 50 ft. It prefers a rather moist to a dry soil, and if given the necessary shelter from cutting winds, which it needs and which it deserves, it will well repay all who plant it. There is a rather pretty variegated variety of it flaked with whitish leaves, and also a kind called *T. dolabrata nana*, a slow-growing miniature bush with comparatively small leaves, more resembling a Lycopod than a Conifer. GEO. SYME.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

Robinia pseud-acacia semperflorens.—Allow me to direct the attention of ornamental planters and admirers of late-blooming hardy plants to this excellent variety. Its flowers are white and sweetly scented, and are produced in succession throughout the summer and during early autumn.—G. B.

Eucalyptus globulus in Cornwall.—A good specimen of this may be seen in the garden of Mr. Magor at Penzance. Its age is about eighteen years, its height about 35 ft., circumference of stem at 2 ft. and up to 12 ft. from the ground 2½ in. I observe (Vol. XII., p. 228) a specimen is reported as growing at Killarney, which is 50 ft. high. Previously to the severe winter of 1860 two specimens existed here, one of which stood independently, but was destroyed in a gale of wind when about 15 ft. high; the other, the same height and age, grew against a wall in shelter and died in that winter; the latter flowered freely more than once. I have recently planted another in damp ground and well sheltered.—J. J. R., *Penrose, Cornwall*.

Diospyros lucida.—In the pleasure grounds at Strathfieldsaye there is a beautiful specimen of this, I believe, very rare tree. It is about 65 ft. high, and has a stem which girths 4 ft. 2 in. at 5 ft. above the ground, and which is clear of branches for a height of 10 ft. Its habit is peculiarly graceful; the branches up to two-thirds of its height assume quite a drooping character, the tips of the lower ones sweeping the turf with as much grace and beauty as a Weeping Birch. The foliage is bright green, smooth, and glossy, and changing in autumn to the richest tints of crimson and scarlet. What a charming object this tree would make on a lawn near a mansion, or, indeed, anywhere planted for ornament it could hardly be out of place. Probably it will succeed best in sheltered situations, and perhaps if tried too far north it might hardly thrive. I should be glad of more information as to the hardness of the different species of *Diospyros*. Can any one tell me where another good specimen of this interesting tree may be seen? I have a notion that the one in question is the best in England.—G. BERRY.

The Weeping Wellingtonia.—I have a Weeping Wellingtonia the height of which is about 32 ft., and its circumference is 7 ft. 2 in. at 1 ft. from the ground. It is no more than 7 ft. or 8 ft. in width at the widest point, but the short, drooping branches are very thick and well furnished. I got this plant just sixteen years ago, a three-year-old seedling from a friend of mine who took the seed out of a cone sent to him from California. I mention this to show how fast this Conifer has grown, three times faster, in fact, than what an ordinary Wellingtonia of mine has grown in the same time. Is there any tree of the kind 32 ft. high elsewhere in this country.—F. HAMILTON, *Coolayna, Carbury, Enfield, Ireland*.

Flowering of *Paulownia imperialis*.—A single plant of this, about 15 years old, flowered here partially this summer, and once previously a few years ago. Not more than three or four flowers opened on each spike. Are other growers more successful?—J. R.

Pernettya candida.—One of the neatest and prettiest of recent acquisitions to the rock garden, according to the "Irish Farmer's Gazette," is unquestionably this charming little trailing shrub. Its prostrate habit and neat foliage would alone be sufficient to recommend it as a rock plant, but when at this season its branchlets are terminated by clusters of pure white or occasionally purplish-tinted berries, much larger than those of the more familiar species of *Pernettya*, it looks quite a little gem in its way.

THE INDOOR GARDEN.

HEXACENTRIS MYSORENSIS AND ITS CULTURE.

THERE are few handsomer plants, and none more distinct, than this *Hexacentris*, which, when it first flowered with Messrs. Veitch, produced quite a sensation; the curiously-shaped individual crimson and yellow flowers, of which its long, pendulous racemes are composed, show themselves to the best advantage when seen drooping from the roof of a moderately cool stove. It is one of the freest of free growers, and will thrive under indifferent conditions of treatment such as would be fatal to plants of a more delicate constitution; but, although a free grower, it is easily kept in reasonable bounds, inasmuch as it will bear the knife better than most plants. There is one reason to which, perhaps, is assignable its not being more generally cultivated than it is, and that is, from being a native of Mysore many have been led to suppose that it required more heat than has proved conducive to its flowering freely. With it, as has frequently occurred in the case of other plants, cultivators have been left in the unfortunate position of knowing nothing about the altitude where the plant is found growing wild; but I should suppose, from its evidently doing better under somewhat cooler treatment than many plants we have from the same country, that it must have come from an elevated district. When well grown its drooping flower spikes will extend to as much as 15 in. in length. It is best adapted for draping the rafters of the house in which it is cultivated, or it may be trained during the growing season on thin twine near the glass, where it will be fully under the influence of light, and then trained on a trellis similar to the twining *Clerodendrons*. It is a quick grower, and can be got to a considerable size in a single season. It may either be planted out or grown in a large pot; the latter I prefer, as, under such conditions, it will attain a size sufficient for all ordinary purposes, and, being a very free rooting subject, it consequently quickly exhausts the soil, which, under pot culture, can be more readily renewed than when planted out. It appears to be a plant that under cultivation has no fixed season of flowering. I have seen it bloom well through the winter and early spring months from growth produced the preceding summer, well ripened up during the autumn, and slightly rested. I have succeeded in flowering it equally well through the late summer and autumn months from the current season's growth without any previous rest; but, to effect this, it must have a thoroughly light house with little shade, more air, and less moisture than the majority of stove plants need, and also not too much heat, otherwise it seems to keep on growing without having time to flower until checked, and the ripening process should be effected by a drier state of both the atmosphere and soil. Plants that have been rested through the autumn or winter in a temperature of about 55° at night, when subjected to 5° or 10° more warmth soon commence to grow, producing abundance of cuttings. These should be taken off, with a heel of firm wood attached to them, when about 6 in. long, inserted singly in small pots, drained, and two-thirds filled with sandy loam, the remaining portion being pure sand, kept moist, and covered with a propagating-glass in a temperature of 70°. They will root in a few weeks, when they may be gradually inured to the full air of the house, and when sufficient roots have been formed, which will be by the beginning or middle of May, they may be moved to 6-in. pots, well drained, and filled with good fibrous loam, to which should be added enough sand to allow the water to pass freely through it. I may here note that the plant appears to grow equally well in either peat or loam, but I prefer loam through all stages of its growth, as in it it has a less disposition to make wood and is more inclined to flower.

When the plants have attained 1 ft. in height, pinch out the points to induce the production of several shoots, which should be kept regularly trained round four or five tall sticks inserted in the pots for the purpose. Keep them now tolerably near the glass in an ordinary stove temperature day and night; or, if they can be accommodated in a temperature a few degrees cooler, all the better. From 65° to 70° at night is sufficient, with 80° in the day; but a few degrees either way matters not, provided the plants are where they can receive a little more

air, with a drier atmosphere, than the generality of stove plants get at the present day. Syringe freely overhead every afternoon, and use a slight shade in the brightest part of the day, if the leaves are found to scorch, not otherwise. By the middle of July the roots will have filled the pots, when the plants can be moved to others 3 in. larger, using the soil now a little rougher than before, but of a similar nature. Keep the shoots regularly trained round the sticks; if this be not done, they are sure to get entangled. Continue the same treatment as before until the beginning of September, when syringing should be stopped; more air should be given now, and less water at the root, so as to gradually induce a state of rest. Keep them through the winter at about 55° at night, and a few degrees higher in the daytime, with no more water than will just prevent the leaves flagging. About the middle or end of February increase the temperature 5° day and night, and as soon as the plants begin to grow they may have a large shift—a 16-in. or 18-in. pot will not be too much—using the loam in a lumpy state; if destined to be grown as roof climbers, the shoots should be trained under the rafters, or in whatever position they are to occupy. Be careful not to over-water, as it will take some time for the roots to fairly enter the larger body of new soil. Give sufficient air during the day through the spring, but avoid cold draughts, syringing freely at the time of closing the house in the afternoon. As the sun's power increases give a little more heat, but no more shade than seems absolutely necessary.

Continue to train the shoots as they advance in growth, treating the plants in other respects through the summer as in the preceding year; in autumn give more air, withholding atmospheric moisture, as well as reducing it at the roots so far as can be done without injuring the foliage. Let the treatment during the winter be the same as before. Again, as the days lengthen in spring, increase the heat and give more water, which will at once induce the plants to break freely from the greater portion of the last summer's shoots, from the points of which, before they extend far, the flower-spikes will make their appearance. From this time, liquid manure twice a week will considerably benefit the plants. The syringe must now be used with caution, or it may cause the flower-buds to fall off. Do not keep the plants too hot whilst flowering, and when the blooming is over, allow them to get dry at the root sufficient to cause the leaves to flag at intervals for a fortnight or so, after which they must be cut freely back, at once turning them out of the pots, removing half the old soil, and cutting in the roots freely. This, from its free-rooting character, the plant will bear as well as an *Allamanda*. They may be either returned to the same pots, or, if required to fill a large space, transferred to other pots a size or two larger, after which encourage them to make plenty of growth during the summer, to stimulate which give manure water once a week. Manage through the autumn and winter as before. Again, when the spring flowering is over, repeat the cutting back and partial disrooting with renewal of the soil. Should the plants be required to flower on a trellis, all that is necessary is to take the shoots down from the position where they have been grown near the roof, and train them on the trellises before growth commences in the spring. After flowering, cut back and re-pot, and place them where the shoots can be again trained near the glass as before. It is a plant so easily raised and quickly grown to a considerable size, that it is not advisable to keep old specimens too long, younger examples being far more preferable.

This *Hexacentris* is somewhat subject to red spider if the syringe be used insufficiently; but if the plants be freely damped overhead every day during the growing season, as advised, this insect will have a little chance of gaining a footing. If affected with mealy bug or scale when the plants are cut back after flowering, dip and wash in strong solution of insecticide. "Field."

Plumbago capensis in 6-in. Pots.—This, when grown in pots, is usually trained over a balloon-shaped trellis, and little is thought of it until it attains an exhibition size. When planted out, it does a wall or rafter with excellent effect, but it is seldom one sees well-flowered plants of it in 5-in. or 6-in. pots. In the Royal Horticultural Society's Gardens at Chiswick there are just now some

twenty or thirty plants of this description, remarkably showy. They are in 6-in. pots, and each plant is furnished with from two to four shoots, each of which bears in succession or otherwise from three to five handsome clusters of blossom, the colour of which no other plant in cultivation can supply. These plants are not more than from 12 in. to 18 in. high, pot included, and for vases or mixing with other plants in small conservatories, and similar purposes, they are admirable. After flowering the plants should be rested and the wood well ripened, and if dwarf plants are required they should be cut down to within a few inches of the base, when they will send out shoots in spring, and yield abundance of flowers during summer and autumn. If large specimens are required, there is no reason why they could not be grown into a bush as well as other plants, and in this way they would be much more effective than formal trellis-trained plants.—S.

HONEYSUCKLES IN POTS FOR FORCING.

ALL the Honeysuckles—especially the deciduous kinds—will force easily and flower freely under glass in winter and early spring, and the common species that climb about the hedges by the wayside is as useful as any for this purpose. I have had them in bloom at Christmas, and delightfully sweet they are, either in the shape of cut flowers or otherwise. In fact, although rarely used for the purpose, Honeysuckles force much easier and are more useful than many other plants that cost much more to produce. They may be readily increased from cuttings in autumn, planted firmly in a partially-shaded position. If good thick truncheons or stems can be secured in September, and planted firmly in some shaded place, they will form roots during winter, and the following season make good useful plants. A very good way of training them is to keep the stem clear of branches, but have a whorl of falling, drooping shoots from the top—dwarf standards, in fact. When the flowering is over the longest of the shoots should be cut back, so as to get a new growth from near the base to flower the following year, and when the growth is made and is getting firm, the plant should be plunged out-of-doors to ripen it. There is no fear of plants so treated not forcing well. If any plant shows signs of exhaustion at any time—a very rare occurrence, as the plant is so hardy—simply pruning it hard back, and planting it out for a year or two, will bring it round.

The best time to pot up fresh plants for forcing is, of course, in early autumn, and if placed in a cold pit—just merely sheltered—and supplied with water, they will begin making new roots immediately, so as to enable them to undergo the strain of forcing. Plants lifted and placed in the forcing house directly cannot be expected to do so well. The second year, when the wood has been made under glass and ripened early, the plants will bloom earlier with less forcing. In short, it makes all the difference between the result obtained by a special preparation or training for any particular purpose or event and the mere trusting to chance without any preparation at all. In addition to their usefulness for forcing, Honeysuckles trained in the way I have suggested (and they readily and easily assume this shape) make delightful specimens to plant among climbing Roses, Clematites, Jessamine, &c., and they should be treated in what I may call a rough-tidy sort of way, i.e., permitting no weeds or rubbish to grow, but otherwise leaving them pretty much to themselves.

Of course a group of this kind is not adapted for the immediate neighbourhood of any elaborate system of carpet bedding, but there are retired spots or banks in most gardens where informal groups of sweet-scented flowers will be highly appreciated. Besides it is almost impossible to cut a bouquet from those highly-wrought flower beds, however exact and beautiful they may be as works of art; therefore, it becomes a necessity to plant somewhere a number of plants for that purpose, and long sprays of Honeysuckle and Clematis for hanging over the sides of the tall drawing-room glasses commonly used now are very beautiful and effective.—“Horticultural Record.”

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Harrison's Musk as a Town Plant.—This will shortly play a prominent part in the decoration of windows in town houses, little front gardens, and similar places. It grows well either in a shady or sunny situation, and in any kind of soil. It yields a mass of bright blossoms from early in summer until late in autumn. As a bedding plant, too, where *Calceolarias* will not succeed, this Musk would form an excellent substitute.—S.

Rivina humilis as an Indoor Wall Plant.—Although usually grown as a dwarf bush, this looks exceedingly well as a wall plant, being a continuous flowerer and berry-bearer. I recently saw a fine plant of it, covering a large space, on the back wall of a stove house with very good effect. The small, spray-like branches were covered with bunches of brilliant red berries, which, during winter, harmonise even better with the season than flowers.—J. G.

Sedum spectabile.—This, when grown in pots, answers well for window boxes, and Messrs. Rollisson are said to supply large quantities of it for that purpose.—G.

ROSES.

PRUNING MARECHAL NIEL.

CONSIDERABLE diversity of opinion has been expressed from time to time as to the best method of growing this Rose, some asserting that it does best on its own roots, others being equally sanguine that it succeeds most satisfactorily on the seedling Brier or some other stock. Leaving these differences out of the question for the present, permit me to allude to another peculiarity in the cultivation of *Marechal Niel*, and that is the time at which it should be pruned, and also how that operation ought to be performed. When in a semi-dormant state this Rose dislikes much knife work. Several examples of it planted out here two years ago, and which were unusually strong (one having made a main rod from 25 ft. to 30 ft. long last year) got infested with green fly, and in fumigating it some of the more tender leaves got injured through the Tobacco smoke. This was when the buds were about half developed last spring, and, of course, wherever the leaves were most injured the flowers suffered in proportion. After flowering, I decided on heading back some of the plants with a view to strengthening them when they began to push. I find, however, that the rods that are strongest at the base are the weakest in pushing, and one or two of the plants are so weak that they will have to be replaced; other plants of moderate growth have pushed vigorous shoots from their base. It is hard to get over facts like these, which point directly to the Rose doing best on its own roots. Had our plants been worked on the Brier or any other stock, the probability is that most of them would have died, whereas every succeeding shoot that is produced from the base is a degree stronger than its predecessor, and tends to increase and invigorate the roots. I would recommend, therefore, that all pruning, or rather thinning out, necessary in the case of this Rose, should be done when the plants are in full growth, and not before they start after flowering. The strongest shoots should be selected, and the weaker ones rubbed off with the fingers at an early stage of their growth, and if further thinning be necessary it should be done before the season of growth is very far advanced. It is so easy to propagate a few fresh plants every season that those who desire to cultivate this Rose by the simplest method should be prepared for the loss of an old plant from time to time by having young ones ready to take its place.

W. HINDS.

Planting Roses.—This, according to the author of “Roses and their Culture,” is an operation requiring considerable care and patience. In the first place, the roots should be carefully examined. Every bruised portion and every damaged root must be cut clean away with a sharp-edged knife, lest they should rot and develop fungoid growth. Suckers, and even incipient suckers, on Briers, must be carefully removed. In addition, where the *Manetti* is the stock used, every eye below the planting line ought to be scooped out, to minimise the chance of suckers stealing up from below the soil amongst the shoots of the genuine Rose, from which, when young, it takes a keen and experienced eye to distinguish them. As soon as such are perceived they must be traced to their source, even if scooping the earth away is necessary to do so, and the intruder extirpated. One of the greatest faults in planting is, that a careful expansion of the roots is not attended to before filling in. The hole being previously prepared with some extra good soil where the roots are to be placed, the latter should be carefully spread abroad in their natural position. It will be a great encouragement to the speedy emission of new roots if they are previously plunged into a liquid compost of fine loam and powdered cow manure about the consistency of mortar. Two hands ought always to be employed in planting or transplanting—the one to manipulate the plant during the process, the other to spread out or disengage the roots and fill in and tread down the mould, so that every interstice amongst the roots is thoroughly filled up. Plants on their own roots and those worked on the Brier must never be sunk deeper than the collar, but *Manetti* ought to have the work from 3 in. to 4 in. below the ground level—never less than 2 in. Roses require firm planting, that is, the earth ought to be trodden down two or three times while planting is going on until the task is complete. After all is finished give a good watering, lay on a few inches of manure or other mulching material, and in the case of standards, put in a stake to tie them to, to as to secure them from the action of the wind.

Rose Souvenir de la Malmaison.—Few Roses are more effective just now than this, all the strong shoots of which are crowned with lovely bunches of the most delicate flesh-colored blossoms. Beds of this kind, in which *Tritomas* and other autumn flowers have been planted, have a fine effect at this season of the year.—J. GROOM.

THE FLOWER GARDEN.

DOUBLE AND SEMI-DOUBLE BUTTERCUPS.

Few plants are more useful and ornamental in our spring and early summer gardens than the various species of double and semi-double Buttercups. The time was—and, I hope, will be again—when our cottage gardens were full of those "White Maids of Kent" and "Golden Bachelor's Buttons," and many another lovely perennial well-nigh extirpated by the insensate rage for flaming, staring bedding plants, now happily passing away. It is scarcely necessary to sing the praises of the various varieties of *Ranunculus asiaticus*, Dutch, Scotch, Persian, and Turkish, and sporting every colour of the rainbow and ever so many more. I will only say that I have found the hardest variety, and the one most easy to grow to be that known as *Ranunculus asiaticus superbissimus*. The flowers, though semi-double, are of very large size and very bright in colour, and the tubers are much less particular about soil and situation than the other varieties of the species, which require more or less care to cultivate, and in some localities cannot be cultivated with success at all. The finest of the double yellow

Bouquet of Double and Semi-double Buttercups.

species is *R. bulbosus* fl.-pl., the large bulb-rooted Buttercup of our English meadows. I have seen the blooms as large as a florin and as double as a Pæony Aster. On some soils the petals are slightly tipped with green, and the blooms occasionally come crown upon crown, two or three flowers rising one above the other, like three acrobats standing upon each other's heads.

RANUNCULUS REPENS.—Of this there are two double varieties, one very neat and tidy in its growth, the other rambling and weakly, and requiring to be kept in order. *Ranunculus acris* fl.-pl. is perhaps the most useful of the class. Its tall, numerous-flowered heads of yellow buttons last for weeks and weeks; indeed, by cutting down the stalks before they have quite ceased to bloom you may have a succession of flowers the whole summer.

RANUNCULUS SPECIOSUS is a very handsome species, but on some soils it refuses to grow, and I have hitherto failed to acclimatise it in the chalk and clay of Bucks.

RANUNCULUS LANGUINOSUS FL.-PL. I at present know only by name, but I hope soon to make its personal acquaintance. It

belongs to a good sort, of which the more you know the better. The double yellow variety of *Ranunculus ficaria* (*Ficaria verna*) is exceedingly pretty on a bright sunny day in early spring. I have heard that there is a double form of the silvery white variety, but I have never yet had the good fortune to see it. Last, but not least, comes the beautiful little pure white *Ranunculus aconitifolius* fl.-pl., the "Fair Maids of Kent" of our old English gardens. I know of nothing more pleasant to look upon than a well-grown plant of this delicate and beautiful flower, and I trust the time may never come when she and her bright sisterhood will cease to ornament our beds and borders with their fair and pleasing presence.

H. HARPUR CREWE.

Drayton-Beauchamp Rectory, Tring.

THE POT MARIGOLD.

(*CALENDULA OFFICINALIS*.)

THERE is no reason why this excellent old plant should not be "classed as a florist flower" (p.233), but more useful is the fact that it can be had "gay" late in autumn, not merely "in the early part of summer." Truly its generic name is correct, for we have gathered flowers from it in ordinary seasons (with proper attention to leaving seedlings undisturbed and sufficiently thinned out) every month, with the exception, perhaps, of February. Our beds of it early in May were dazzling, and the flowers were double to the centre—such a blaze of colour could not, at that season, have been had with any other plant. After saving sufficient seed, we cut down the plants to the ground, thoroughly soak the beds when needful, and in about three weeks the "evergreen tufts of leaves," to use Mr. Ellacombe's words, are again in full growth, and by the end of August the second crop of flowers begins to appear. A top-dressing of fine soil helps the shed seed, which produces plants in abundance, and we will have now, I expect, a constant succession of flowers. As we have evergreen edgings to all our beds (silver variegated *Vinca* in this case), a bed when cut down is not strikingly bare, and the little seedlings coming on by degrees furnish fresh verdure. We have selected and saved our own seed for eighteen years. I can only add one point of interest to what Mr. Ellacombe tells us in his delightful "Plant-lore" about the Marigold, and that is that occasionally it throws out proliferous flowers, like the Hen and Chickens in the case of Daisies. It has been suggested to me that I should see if this freak would be reproduced from seed, and I saved a few and they were sown; but the experiment was not carefully carried out; I went abroad, and nothing came of the seedlings. This year I have saved a little more seed, and will try again. All who have seen our Marigold beds have begged for a pinch of seed, and all shall have some, for I am anxious that so meritorious a flower should be again a "great favourite in our gardens," to quote Mr. Ellacombe once more, and that "gardeners should no longer pass it by as beneath their notice." Had I not so many irons in the fire, I am positive that we might have got still better flowers than we have (in a florist point of view), and certainly three distinct shades of colour, viz., orange, yellow, and fawn. Foolishly, I cannot make up my mind to discard a little patch of the true single flowers, of course grown far from our double florist beds; still it would be wiser not to have such a shabby, thin flower in the garden at all. But it is very interesting to have, if possible, both the original single plant as well as its double form, and we are always collecting and completing our sets as it were. The late severe storm has been hard on the Marigolds, as well as on everything else. *Salix reticulata* is the only tree that has escaped, and the Crocuses and Colchicums have been laid low as impartially as the Tritomas, Sunflowers, and Dahlias. Sad havoc there has been, and such as cannot be repaired this season.

F. J. HOPE.

Wardie Lodge, Edinburgh.

A Pretty Combination in the Flower Garden.—On a long border at Hutton Hall a pretty effect was secured by making a front line next the edging to the path of *Polemonium cornutum variegatum*, alternated with white *Violas*, the two varieties used

being White Swan and Lady Gertrude, the former very pure in colour, the latter much in the way of Vestal, and both well adapted for the cool, moist Cleveland district. At the back of this was the trailing *Tropæolum Cooperi*, a variety of medium growth, bearing bright scarlet flowers. Behind this came *Viola cornuta*, growing and flowering gloriously, and as yet without a rival for its peculiar hue of colour. Then came a line of dwarf Roses, with *Gladioli* growing among them; and in the rear a line of standard Roses, having as a background a light iron fence covered with *Clematises* and similar plants. On the other side of the walk was a broad sloping bank of *Lanrals*, kept cut low, with a few ornamental trees dotted about it. This arrangement, as seen at the end of August, is a very pretty one, and by no means formal. The walk, too, was in sight of the mansion, affording a pleasant vista from that point, and the materials out of which this effective border was formed bore examination, being in excellent condition, despite the wet weather.—D.

LILIUM AURATUM IN LANCASHIRE.

It is only four years since I managed to summon up courage to plant *Lilium auratum* out-of-doors, *L. candidum* and *L. tigrinum* being the only sorts previously tried in this part of Lancashire. We purchased a quantity of *L. auratum* annually, and we treat them as follows: When the bulbs arrive they are examined, and arranged according to their sizes, the largest being set aside for pot work, and marked for that purpose; they are potted in from 5-in. to 7-in. pots, according to the size of the bulb. The pots are clean washed, carefully crocked, and a layer of Moss, with the green side downwards, is placed over the potsherds. The material used for potting is a really good turfy loam, in a mellow state, without any further mixture, except it be a dash of yellow sand. In potting, the soil is made firm under the base of the bulb, and a thin layer of sand is laid under and around it to prevent rotting. The pots are then filled with soil to the required depth, and the operation is complete. The bulbs intended for planting out are treated in exactly the same way, except that the pots used are a size smaller. All are then taken to a cold pit or frame, and laid on a thoroughly porous bottom of cinders, and covered over with sand to about 2 in. or so above the crown of the bulb; no further notice is taken of them till the young shoots push through the sand in spring. I ought to have mentioned that in potting the bulbs intended to be grown on, it would be better to leave space for 1 in. or so of top-dressing, to be laid over the young roots as they are produced at the junction of the stem with the crown of the bulb. This precaution will not be necessary in the case of bulbs for planting out, as they may remain covered with the sand till planting time, when they should be planted efficiently deep to admit of the surface roots being covered to 1 in. in depth with rich soil, and afterwards surface-mulched with rough leaf mould or some similar material. Having thus far described our mode of treatment, it would be well to point out the importance of aspect, rich soil, and thorough drainage, where the rainfall in winter and early spring is heavy, as it is in Lancashire. I am of opinion that the day is not far distant when we shall see preparation made for planting whole beds of *L. auratum*. Why should we not expend the same labour and expense on the cultivation of some of those choice Lilies as we do in the case of *Gladioli*, for instance?

As to position, it would be well to impress on intending planters the desirability of choosing warm situations, sheltered from biting winds and from the fierce rays of the sun, which soon denudes the stems of half their foliage. I have planted bulbs in shrubby borders under various conditions and circumstances, and I have been struck with the comparative results in each case. Where the conditions are more or less favourable to the general development of the bulbs, extremes either of drought or of wet will blight even the brightest prospects. I have counted from twelve to nineteen flowers on a single spike from bulbs planted three years ago, and in each case, where the best results are observable, the bulbs are situated in borders facing the south, with the sun's rays broken up into gentle beams by intervening trees and shrubs. The borders, too, are always in good condition, from the fact of their formation being such that they will not retain stagnant moisture, and the shade referred to shields them from excessive heat. I have noticed during the hottest part of the past summer how the stems of *Lilium auratum* shed their leaves even on a north aspect, and how they seemed to recover themselves after the intense heat abated. All these facts are suggestive, and serve to indicate to us certain standard rules, which seem to be of paramount importance in Lily culture. W. H.

Tropæolum Hunteri.—This is a dwarf *Tropæolum* of the compact type, sent out some time ago by Messrs. Downie and Laird. It is singularly dwarf in growth, has leaves scarcely larger than a

shilling, and bears numbers of small bright scarlet flowers. It is well adapted for small beds and moist districts, as in the wettest weather it does not make a very profuse growth. Like all dwarf bedding *Tropæolums*, it should be raised from cuttings to keep it true and dwarf, as all the compactum section have a tendency to run out when raised from seed.—D.

Salvia patens in Mixed Beds and in Pots.—I agree with all "J. G." says (p. 239) in praise of this plant; but the statement that it is quite hardy is apt to mislead. I have never found it so, nor does it appear from the context that it is so. It is simply unequalled in colour, and a striking plant anywhere. Years ago, we used to bed out this *Salvia*, and the greatest opponents of the massing system were never known to find fault with the fine style and matchless beauty of this fine plant. The roots were taken up every winter and stored like *Marvel* of Peru or *Dahlias*, and did remarkably well treated in this way. The first shoots were pegged down regularly over the beds. These, as the season advanced, broke up into a dense thicket of secondary spikes, and the effect was all that could be desired. The plant is also all "J. G." or any one else can say of it in the mixed border. It is likewise most useful in pots, and may be had in flower at any time from June to November. It looks well in the greenhouse, conservatory, or window garden, and heightens the beauty of almost any other flower by its contrast of habit and of colour. But perhaps it is most useful as a contrast with the *Chrysanthemum* in November. So many of the latter are white, orange, or buff in colour that the beautiful blue of this fine old *Salvia* forms a rich setting for such colours. To have plants of *Salvia patens* so late it is well to keep them from starting till as late as possible in spring. They may then be stopped several times till the beginning of September, after which they may be allowed to run up and flower, placing them under glass early in October. Treated thus and wintered in a temperature of from 45° to 50°, *Salvia patens* may be preserved in beauty till Christmas, a season when blue flowers are absent, or nearly so.—D. T. FISH.

—As a grower of *Salvia patens*, I can confirm all that Mr. Baines has written (p. 265) as to the desirability of lifting its tuberous roots in autumn and storing them away during the winter, but I never allow them to become dry; in fact, I treat them as though they were still in the ground by planting them thickly in a soil bed and keeping them moist. Thus treated, they do not shrivel, a state from which they never recover. Of late years the roots have not been injured by frosts when left in the open ground, but in the spring when the young succulent shoots are bursting through the soil, they are either nipped by frost or eaten off by vermin. Plants treated like mine commence to throw up abundance of strong growth during March, and this yields a profusion of stout cuttings if needed. I grow a good quantity of this *Salvia* every year for the production of seed; I have a bed of it just now very beautiful, and it would be more so if I removed the old flower stalks which are producing the pods of seed.—A. D.

Select Larkspurs.—In addition to *Victory*, a fine double kind noticed in THE GARDEN (p. 235), the following are, I think, well worthy of culture, viz., *Agamemnon*, a double variety, light blue with a white centre. *Pompon Brilliant*, a very dark double blue variety, in every way excellent both as regards flowers and spikes. *Beatsoni*, double dark blue with a fine branching habit. *General Ulrich*, a double light blue with a white centre somewhat in the way of *Victory*. *Madame E. Genry*, a single blue with a fine spike. *Globe*, very light single blue. *Prince of Wales*, a single dark blue, really a fine variety; and *Grandiflorum*, a single light porcelain blue with a fine spike. These I saw in bloom the other day at the Pink-hill Nurseries, Corstorphine.—ANDREW ANNAN, *Ravelston, near Edinburgh*.

Transplanting Lilies.—I agree with "Dunedin" (p. 264) that when the flowers of Lilies become small, and the stems weakly, it is quite time to lift and replant them in fresh quarters; but, unlike him, I do not find them to be strongest the first year after planting, but the second and third years; the last I think the best. I have had some very large clumps this year where two bulbs were planted six years ago; some of them have grown 6 ft. in height, but have only had from eight to twelve blooms on a stem, whereas the third year after planting they bore from fifteen to twenty; the flowers are also smaller than those of bulbs more recently planted. I intend lifting them all this year. Some I lifted last year and replanted immediately, and they have had much larger flowers, but they have only grown from 3 ft. to 4 ft. in height, and have borne from four to eight flowers on a stem; next year, however, they will be much stronger (their successors, I mean). I have just counted the number of flowers which one clump has borne where three bulbs were planted three years ago. It consisted of twelve stems, on which there were 168 flowers. These remarks only apply to *L. speciosum*.—D. UPHILL, *Moreton, Dorchester*.

GARDEN DESTROYERS.

THE MOLE CRICKET.

(GRYLLOALPA VULGARIS.)

THIS curious insect, though fortunately not very common in this country, at times is very troublesome to the cultivator; it seems to devour the roots of almost any plant that comes in its way, and is particularly fond of those grown in the kitchen garden. Boisduval, in a paper on this insect (speaking of its ravages on the Continent), says, "It is one of the insects most injurious to agriculture and the cultivation of kitchen gardens; there are even places where it is impossible to cultivate pot herbs." Another author writes, "Happy are the places where this pest is unknown." Mole crickets seem particularly fond of damp places, such as the banks of streams and near ponds. They live almost entirely underground, burrowing and making horizontal galleries like a mole. They do not, however, like that animal, throw up heaps of earth, but may be traced by the ridges they raise in the soil; they are seldom seen above the ground during the day, but come out in the evening occasionally. Various methods have been proposed and tried for destroying

Mole Cricket, one month old and full grown.

Mole Cricket, half grown.

them; perhaps the most certain is that of digging out their nests, which are always formed near their burrows in June or July, and destroying the eggs. Some persons in September dig holes 2 ft. or 3 ft. deep, 1 ft. or so square, and 45 ft. or 60 ft. apart in ground infested by them; these holes are filled with horse manure and covered over with earth. The insects are attracted by the heat into these holes when the first frosts set in, and can easily be dug out and killed. Fresh turves placed on the ground where they abound at night and well watered have been found a very simple and effectual trap, as the mole crickets hide underneath them and may be easily caught in the morning; this plan succeeds best in April, May, and June, particularly if the weather be dry. Boiling water poured over their burrows will kill them. Their natural enemies are few; the mole, no doubt, is their greatest foe, and probably bats and night-feeding birds kill numbers of them. Their parasites are not known. The mole cricket is a formidable-looking insect, but may be handled with perfect impunity, as it will neither bite nor sting. When fully grown it is about 2 in. long, without the antennæ and tail; the wings, when expanded, measure nearly 3 in. across. The general colour of the insect is a dark, rich brown, but its underside is somewhat paler. The head is small, and can easily be withdrawn into the

thorax or front part of the body. It is furnished with a pair of stout, tapering antennæ about $\frac{3}{4}$ in. long, consisting of a great number of small joints. The thorax is $\frac{1}{2}$ in. long, oval, much rounded, and very strong and hard. The body is wide, thick, and soft, composed of nine or ten joints on either side; near its termination are two tapering organs covered with fine, short hairs; these are supposed to act as antennæ or feelers when the insect runs backwards in its burrow, which it does as easily as forwards. The wings are four in number, and of a yellowish-white colour; the upper pair are short, leathery, and much veined, and form wing covers for the lower pair, of which, however, they only cover the base; the lower wings are large and delicate, opening like a fan, and lying closed down the middle of the body when not in use. The three pairs of legs are very strong, the front pair being very peculiarly formed. They are admirably adapted for digging, being wonderfully strong, short, very much flattened and deeply toothed; the hindmost pair are formed for jumping, and are about three times the length of the fore legs. There is very little external difference between the males and females. The female in June or early in summer constructs near her burrows a smooth, bottle-shaped nest or chamber about 2 in. long and 6 in. below the ground, with a curved passage communicating with the surface, which she afterwards closes, in which she lays her eggs, some 300 or 400 in number. They are yellowish-brown, and about the size of a Mustard seed. The larvæ, or young mole crickets, are hatched in about a month, and are about one-eighth of an inch long, and whitish brown in colour. They much resemble their parents, except that they have no wings. They at once begin to feed on the roots of the neighbouring plants, and keep together for the first month, at the end of which they change their skins, and soon afterwards separate. They continue to grow and change their skins occasionally, until they are about $1\frac{1}{2}$ in. in length, when rudiments of the wing cases appear, and they may be called pupæ (what would be the chrysalis state in most insects). They, however, continue to feed and grow, and when they shed their skins for the fifth and last time the perfect insects appear. This change generally takes place at the end of spring. During the summer these insects may be traced by the ridges raised by their burrowing, and by the plants withering whose roots they have attacked. In winter, as the cold increases, they bury themselves deeper in the earth, returning nearer the surface when the weather becomes warmer. The strength of one of these insects is surprising. According to Rösel, it can move a weight of 6 lb. on a smooth surface. The male, in April and May, often makes a peculiar sound in the evening by rubbing the wing covers together; the sound, unlike the chirp of the house cricket or grasshopper, is a dull, jarring noise, much like the note of the night jar or goatsucker. The female makes no sound.

GARDENING UNDER DIFFICULTIES IN INDIA.

"Out of the frying-pan into the fire," as a friend observed the other day when I invited him to walk into my conservatory from the verandah of my house, where a maximum and minimum thermometer marked 125° and 88° . He was, however, rather surprised to find flourishing in my glass house several fine plants of *Eucharis amazonica*, *Antigonon leptopus*, *Lagerstrœmia indica*, *Pelargonium capense*, *Clematis rubella*, and that beautiful climber *Lapageria rosea*. Mine is the only conservatory in Scinde, though by no means the only hot-house, and is an experiment in which failure has as yet been greater than success. I lived for many years in the Deccan, the tableland in the Bombay Presidency, where, with a little trouble and skill, one can raise the most beautiful flowers, and on nearly any day in the year I was able to cut a vaseful of good Roses from the 150 varieties which I possessed; but in Scinde, though from November to March the climate is well suited for most hardy and half-hardy annuals, hardly anything can stand the fierce, dry, hot winds that set in with April, and blow until checked and moistened by the tail of the monsoon winds from the south-west. I thought that if I could temper this wind by building a greenhouse, the air of which should be cooled and made moist by being admitted through Grass mats kept constantly wet, I should be able to grow almost any kinds of stove or greenhouse plants. I therefore, in April last, set up my little hot-house, and gave dignity to it by calling it a conservatory. I then applied to Mr. J. Morse, of Dursley, for a few of the best

zonal Pelargoniums, including doubles, tricolors, bicolors, and bronzes, a couple of Clematises, and one *Lilium auratum*, intending Fuchsias to follow as a second course if these succeeded—

For though on pleasure I was bent,
I had a frugal mind.

These plants, packed firmly (without any earth on their roots) in plenty of green Moss in a deal box large enough to allow of a firm bed of Moss 3 in. thick all round them, arrived in fair condition after being forty days *en route* per Indian Parcel Post. Out of thirty Pelargoniums and two Clematises, twenty-six of the former and one of the latter sprouted strongly a few days after arrival, the failures being confined to gold and silver tricolors, of which the plants sent were too small. For some time, during which the thermometer ranged between 80° and 105°, with wet-mat-ventilation and the glass roof whitewashed, with a sheet awning drawn over it from 10 a.m. to 4 p.m., the plants did well; but, unfortunately, there comes a time, in June, just before the monsoon bursts in Bombay, when the hot wind ceases and a still, damp atmosphere sends up the quicksilver and prevents evaporation from the mats, which no longer cool the air. So for six weeks the range of the thermometer was from 85° at night to 125° for several hours in the daytime. My Pelargoniums then one by one went over to the great majority, Madame A. Baltat proving the toughest of the lot. Now I cannot help thinking that if these plants had been received in November last, when I requested they might be sent, instead of at the commencement of the hot weather in April, they would have become well established, and would have stood even the heat I have mentioned. Strong in this belief, I have requested Mr. Morse and Messrs. Daniel Brothers to send me a fresh supply, to arrive in October next. I should be very glad if any of your readers would tell me what plants will probably stand such heat as I have described. The *Lilium auratum* and Clematis I received grew through it all; the former at 1 ft. high threw out one large flower, which never coloured or opened, and has now dropped; the latter is still growing, and, now rain has fallen, it stands the sun out-of-doors. Petunias, Portulacas, various Passifloras, and *Ixora indica* flower during all the hot weather. Gesneras, Gloxinias, and Achimenes, the corms of which I brought out with me, started well, but (before the erection of the greenhouse) could not stand the hot wind, and when brought into the half-darkened house damped off and died. Messrs. Sutton & Sons are sending me a new supply and some tuberous-rooted Begonias, which I hope will fare better. Many people have pretty gardens in Scinde, and are even now preparing borders for their seeds; but they contain only annuals and a few Roses; and though a garden of annuals which bloom from October to March is very pretty, "there are chords in the human heart," as Mr. Toots says, that vibrate more freely to a higher class of named florists' flowers; and if any of your readers can give me a list of such plants likely to stand the heat of a Scinde summer, and in winter sudden variations (out-of-doors) from 80° in the daytime to 27° at night, with such protection as I can afford them in my greenhouse, I should be very much obliged, more especially if the most suitable time for sowing or planting, and a few hints as to treatment in such a climate were added. If any one, too, feels inclined to back his opinion in a practical way, he has only to pack up a few spare bulbs, corms, or cuttings of hard, ripe wood in a thick bed of green, but not damp, Moss; put the package into an old cigar, or if liberally disposed, into a candle or soap, box, and address it to me, "Per Indian Parcel Post, Hyderabad, Scinde."

F. R. GRIFFITH.

Ivy on Rockeries and Rootwork.—The small-leaved variegated kinds of Ivy have a pretty effect when introduced here and there amongst rock and rootwork. Being of comparatively slow growth, and of smaller dimensions than the green kinds, they are easily kept in bounds, and do not encroach upon the other occupants of such places. If trained along the lower part of rockwork they form a neat and pretty edging, affording a charming contrast to Ferns and other dark-foliaged plants. I have remarked that in a north or shady aspect the variegation is much purer and better defined than when they grow in full sunshine.—JOHN CORNHILL, *Byfleet*.

Antirrhinums in Poor Soils.—On a piece of extremely poor sandy soil, lying so high that most plants seemed to perish from want of moisture, I have noticed a fine display of Antirrhinums. They seem, indeed, to revel in a situation which is fatal to almost everything else. If the value of this plant for such situations as that just described were better known, it would be more extensively grown. There are places which tax the skill of the cultivator to furnish satisfactorily. On poor, stony, parched spots the Antirrhinum may be planted, and will give good results with but little trouble.—J. CORNHILL, *Byfleet*.

PLATE CXLVII.

THE PUSCHKINIAS.

(WITH A COLOURED FIGURE OF *P. SCILLOIDES*.)

THE species belonging to this small but beautiful genus of Lilyworts much resemble some of the Squills in habit and aspect, but differ from them, and, indeed, from all other hardy members of the Lily family, in having a small, six-lobed corona springing from the inner base of the divisions of the flower, and united into a short tube, whilst in *Scilla* the divisions are cleft to the base. Only three species of Puschkinias are known to us, two of which, with one variety, are now in cultivation. Though introduced many years ago, they are still rarities in many gardens, a fact to be regretted, as they are amongst the earliest as well as the most beautiful of spring flowering bulbs, and the fine effect which they produce in the open garden can scarcely be over estimated when seen in combination with the host of fine plants now in cultivation which flower about the same time. All the Puschkinias are perfectly hardy, and of the simplest culture. The soil best suited to them is a good sandy loam, and when once established they should not be disturbed, except for taking off small bulbs for purposes of propagation, which may be done whilst the bulbs are at rest. In some seasons seeds are produced, which should be sown as soon as they are ripe; flowering bulbs may be obtained in this way in three or four years. Even in such a small genus as this some misapprehension apparently exists in regard to the nomenclature, a circumstance, doubtless, owing to published figures of the species having been wrongly named. The following are the names now applied to them, viz. :—

Scilla-like Puschkinia (*P. scilloides*).—The bulbs of this exquisite little gem are about the size of Hazel nuts, each producing a pair of leaves from 3 in. to 6 in. long, $\frac{1}{2}$ in. wide, and concave. The flower stems, which are slender, bear from four to ten blossoms that measure about $\frac{1}{2}$ in. across. The colour is white, delicately tinged with pale blue, especially on the tube, and the membranous corona is white. It flowers either in March or April, according to the season. It comes from the hilly woods of the Caucasus, Armenia, and also from Mount Lebanon; hence its synonymous specific name *P. libanotica*.

Puschkinia sicula of Van Houtte.—It is to be regretted that a term more expressive of its beauty has not been applied to this plant. It is larger in every part, and even more beautiful than the preceding, and much resembles in habit *Scilla sibirica*. The bulbs, which are about 1 in. in diameter, produce two leaves from 6 in. to 9 in. long, 1 in. wide, and concave, as in the last. They are green, tinged at the base with a reddish colour. The flower stalk is about one-third longer than the leaves, and bears from five to twenty blossoms, $\frac{3}{4}$ in. across, with six pointed divisions. They are bluish-white, with a delicate pencilling of a deeper blue along the centre of each division. The corona is white, and each lobe is finely toothed. In the type the flowers are arranged in a rather lax manner on slender stalks, whilst in the variety called *compacta* they are arranged in a pyramidal form, and appear crowded. It is not a native of Sicily, as its specific name might lead one to infer, but, like the preceding, is of Oriental origin. It is known in some gardens as *P. libanotica*, and the variety as *P. libanotica compacta*. An excellent figure of the type is given in the "Flore des Serres," tab. 2220, and the variety *compacta* is well figured in an early number of Regel's "Gartenflora" under the name of *P. scilloides*.

Hyacinth-like Puschkinia (*P. hyacinthoides*).—This is a small, white-flowered kind inhabiting Kurdistan and the neighbouring districts, but not as yet in cultivation. W.

Sunflowers.—These are generally regarded as suitable only for cottagers or for gardens to which little attention is given. As ornamental plants they are, however, not to be despised, their robust growth and commanding aspect rendering them suitable for many situations where plants of smaller growth would be quite lost. If placed where protection is afforded from high winds, and allowed sufficient space, they assume a somewhat dense, branching habit; and when covered with bloom present a very distinct, and by no means unattractive appearance. On no account should more than one plant be put in a place. Crowding Sunflowers destroys their distinctive characteristics.—J. CORNHILL, *Byfleet*.

PUSCHKINIA SCILLOIDES

PROPAGATING.

HOLLIES.—These may be increased by means of cuttings almost at any time of the year; they take, however, nearly twelve months to get well rooted; therefore it is best to put them in about the end of March. The sap is then beginning to move, and twelve months hence is a good time for potting or transplanting. For all the newest and choicest sorts the best way is to select a border in the garden in a south-east aspect; dig out the soil 18 in. deep and put about 8 in. or 9 in. of clinkers or broken brick rubbish at the bottom for drainage; then fill in the soil, on the top of which it is best to place 3 in. of sandy material; press the whole down firmly, and have hand-glasses in readiness to put over the cuttings, those with portable or movable tops being the best. The cuttings may now be inserted, making a hole with a small dibber and fastening the cuttings well in. They will require water only about once a month after the first application. Keep the glass tops off all

Cutting of Holly.

day, when the weather is favourable, till evening, when they must be replaced. Remove occasionally any leaves that may have fallen off; but if properly managed, they seldom lose any. This applies more particularly to the variegated and slow-growing forms than to the common varieties, which will do almost anywhere with a little attention. H. H.

Cineraria maritima from Seed.—This beautiful silvery plant may be raised in abundance from seed, but, as a rule, the produce is not so good as that obtained from cuttings, as by selecting the best for purposes of propagation, the stock in time becomes improved. Being of a woody character, the hard wood is slow to root; a good plan is to take up the best old roots in autumn and store them in boxes or pots. If the old tops be cut off in spring and introduced into gentle heat, they will produce plenty of soft growths from the base that will strike freely in the propagating pit with other soft-wooded plants.—J. GROOM.

Rudbeckia hirta.—This is one of our best autumnal border plants, its rich, deep orange-yellow flowers rendering it very conspicuous. It is now beautifully in bloom in Messrs. Rollison's nursery at Tooting.—G.

Colchicum speciosum.—This large-flowered autumn Crocus-like plant is now blooming freely in pots in the Tooting Nursery. Out-of-doors such plants do best on Grass or growing through some other green carpeting plant, which keeps the blooms clean and sets them off to better advantage than when growing on bare borders.—G.

GARDENING FOR THE WEEK.

Indoor Plant Department.

Dendrobium nobile.—This *Dendrobium*, independent of its merits as one of the family of Orchids, has few equals for the production of cut flowers, where these are required continuously. The length of time that any given flower will keep fresh on the plant, and also when cut, is a matter of the first importance to those who grow plants for general decorative purposes; in both these respects there are very few plants that equal *Dendrobium nobile*, as the flowers will remain in good condition on the plants for three weeks or a month, and will stand in water when cut for a week or more; added to this the fact that it may be had in bloom by the use of a sufficient number of plants for half the year—say, from Christmas up to midsummer—tends to enhance its value. The length of time required in forming the season's growth, so as to admit of bulb extension to the full limits the strength of the individual plants are capable of, with the attaining of the plump, mature condition of the buds destined to flower from the upper portion of the nodes or joints formed on the pseudo-bulbs, will, to a considerable extent, depend upon the strength the plants have arrived at, as the more vigor existing in the specimens, the larger size the individual growths may be expected to attain; consequently, this will, to a certain extent, determine the length of time required to complete the growth. Plants that bloomed last Christmas, and were afterwards at once placed under conditions favourable to growth, with their wants attended to since, will by this time have their growth so far completed as to admit of water being gradually withheld; but this should not be done too suddenly, or before the pseudo-bulbs, when treated as from time to time advised, have attained that thick, stout character, with prominence of bud indicative of a disposition to flower freely, for it must be borne in mind that upon the proper treatment during the growing season is, to a greater extent, dependent their power to produce plenty of flowers than on mere size in the individual plants; and if the water were cut off too quickly, or before the growth had arrived at the condition above described, the quantity of bloom produced by plants so treated would be very much reduced. On the other hand, if the plants were allowed to remain too long under the exciting conditions of combined heat and moisture, they would again commence growth, the eyes at the base of the current season's-formed bulbs pushing shoots which would necessitate either these being sacrificed, or the plants kept on growing until such growth was completed, which, as a matter of course, would prevent the possibility of the plants blooming at the season required. It is from want of attending to the necessity of checking the plants at the right time that beginners in the cultivation of this most useful Orchid fail in flowering it freely. After growth has been completely stopped, through the withholding of water, the plants may be removed to any ordinary greenhouse, there to remain for a rest, when they may be brought into heat with a view to their blooming. Specimens of this *Dendrobe* that have been treated with the object of successional flowering later on must be kept growing until it is completed, for this, in common with most other Chinese Orchids, requires more air and a drier atmosphere for the development of its growth in a way to produce the full possible complement of flowers than Orchids generally.

Dendrobium moniliforme.—The nearly allied *D. moniliforme*, which will flower even still earlier than the foregoing, will now have completed its growth. It succeeds with similar management to *D. nobile*, but is not so disposed to make second growth from the base of the current season's pseudo-bulbs. It will bear keeping quite cool when dry and at rest, after which, with a comparatively little increase in temperature, it will produce most freely its beautiful pink-shaded blossoms. These *Dendrobiums* are of very much more use for those who cultivate flowers for their beauty and for the different purposes for which they can be used than the generality of the scarce, expensive Orchids. Their non-liability to disease, their natural free disposition to grow, and the little difficulty experienced in their increase, render them deserving of cultivation by every one possessing even a Vinery, on the front of which they may be grown, or a house in which Cucumbers are grown during the summer, in the lightest position of which the *Dendrobiums* may be placed whilst making their growth, or, in fact, anywhere where an intermediate temperature is kept up during the summer will grow them satisfactorily, as in such they will usually do better than when confined to the—for them—too moist atmosphere of an ordinary Orchid house.

Dendrobium pulchellum.—Another cool species is one of the smallest growers, but very beautiful, and one of the best basket plants that can be grown, in which position its semi-transparent flowers are seen to the best advantage. It will, by this time, in most cases have finished its growth. This plant, although, like the pre-

ceding, liable to be urged into second growth if kept too long moist and warm after its season's growth is complete, yet the latter condition must be fully reached before water is ceased to be given it, otherwise it will flower sparingly or not at all. When grown under the most favourable conditions, and fully matured, the pseudo-bulbs will assume a yellowish-green colour, so plump in appearance that the skin seems almost ready to burst, and the future flowering eyes quite perceptible. As soon as this stage is arrived at water should at once be entirely withheld, the plant placed in a temperature of from 40° to 45° during the night, with a moderate amount of air in the daytime, kept completely dry until the winter is far advanced, under which conditions it is one of the most satisfactory subjects to grow, producing hundreds of its lovely, though somewhat short-enduring, flowers.

Dendrobium chrysanthum.—This useful, free-growing Orchid, like the foregoing, has no particular season of flowering, but will, according as it is treated, bloom during the summer or autumn. In most cases the blooming will now be over and growth commenced, during which time it must have plenty of moisture at the roots.

Dendrobium Devonianum, Falconeri, &c.—These, with *D. Cambridgeanum*, *D. Wardianum*, the different varieties of *D. densiflorum*, *D. Farmeri*, and *D. heterocarpum*, the forms of *D. Pierardi*, *D. transparens*, and *D. chryseotum*, although they do frequently under hot treatment, yet they will generally succeed better in a somewhat lower temperature than the plants experience in the hot plains and valleys of India, and they will almost invariably be found to flower freer when not grown so hot as there. There is a very considerable difference in the length of time required by these to complete their growth, both as regards the different species and the strong or weaker condition of each individual plant. The observing cultivator will see at a glance when each plant has quite finished its growth, that is, when the terminal leaf to each young bulb is fully developed, and has acquired its full solidity, with the accompanying plump state of the pseudo-bulb that always exists under such conditions as are naturally required by the plant. When this state is arrived at, then is the proper time for withholding water, gradually drying off and putting them to rest, for though most of these are not so easily excited into a second growth as the species first treated of, still, if kept too long in a growing house, the buds at the base of the young bulbs may be induced to push, the result of which would be their destruction, to the serious injury of the progress which the plants should make the ensuing year.

Warmer Dendrobies.—Such species as *D. Bensoniæ*, *D. chrysolis*, *D. cucullatum*, *D. Dalhousianum*, *D. macrophyllum*, *D. lasioglossum*, *D. lituiflorum*, *D. Gibsoni*, and *D. crassinode* are generally found to succeed better with more heat, making stronger growth. Most of these will not yet have fully completed their bulbs, and should be duly supplied with heat and moisture until their pseudo-bulbs show from appearance, such as described amongst the species previously mentioned, that their growth is so far matured that they may be gradually dried off.

Cypripedium insigne.—This very useful, free, autumn-flowering plant may be grown by any one having a Vinery, where, during the growth of the Grape, it is kept a little closer than an ordinary greenhouse; but in such neither the completion of the summer's growth nor the blooming will be so early as when cultivated in something more of an intermediate temperature. Under the latter conditions its latest-formed leaves will be approaching maturity, and a little less root moisture may be given it, but it must not be dried up in the manner necessary with plants that form pseudo-bulbs. If it has been grown in an intermediate-house temperature, and now kept on with proportionately similar heat, it will flower comparatively early. Where sufficient plants exist to give a succession, a portion may now be kept cooler, by which means they will come into bloom later, enceding the earliest flowered.—T. BAINES.

Housing Tender Plants.—The time is now approaching when there is usually the greatest scarcity of flowers, as the outdoor beds and borders from which, during the summer and autumn, so many were furnished to mix with those grown under glass, may be destroyed by a single night's frost; consequently, everything in pots that has been out-of-doors, and which by removal to the greenhouse can be induced to flower longer than it otherwise would do, should be at once taken under cover. For this purpose pink or scarlet Pelargoniums that have done duty through the summer with their pots plunged in vases should be taken indoors, where, with a little attention, they will bloom freely for a considerable time. Such of these plants as have received especial preparation by growing them on in 6-in. or 7-in. pots fully exposed to the sun, so as to induce that ripened condition which is necessary to insure the freest disposition to flower with the least leaf growth, should be moved to the lightest

position in the greenhouse, or a pit where they can be kept a few degrees warmer than in an ordinary greenhouse, will be still better. Elevate them as near to the roof as possible, and if the pots be very full of roots manure water once a week will assist them. Thus managed they will keep on blooming a good portion of the winter.

Tropeoliums.—Any of the free-blooming, climbing varieties of *Tropeolum* are very serviceable for the production of flowers through the winter, and for this purpose they are often trained up pillars or rafters; so managed they bloom profusely, and produce a cheerful effect, but they are not so useful as when trained to a few sticks inserted in the pot, as in this way they can be moved about to whatever place is most conducive to their blooming. If they can be accommodated with a temperature of about 50° at night, with plenty of light in the day, they will keep on flowering for months. The length of stalk possessed by each bloom, and their enduring capabilities when cut in water or wet sand make them very useful for small vase decoration; where employed in limited quantities mixed with white *Camellias*, *Azaleas*, and similar light-coloured flowers, they are very effective. Those with limited glass accommodation for growing winter flowers will find that, by employing free-growing, continuous-blooming plants such as the above, they can have a much more plentiful supply than by attempting the growth of subjects that are rarer and more difficult to cultivate.

Gladioli that were kept long out of the ground in spring, with the view of their being potted for flowering in the greenhouse in autumn, should now be taken up and potted. If the ground be at all dry, give them a good watering previous to their being got up, otherwise the roots are certain to get broken. Do not use larger pots than will hold the roots without undue pressure, say 6 in. or 7 in. in diameter. Any ordinary garden soil will do for them. The usual advice, not to give water for some days after potting, must not be adhered to in the case of these and anything of a similar character, otherwise the foliage would be certain to suffer. As soon as they are potted give as much water as will moisten the soil, and put to each a neat stake to support it. Place them in a cold frame, Vinery, Peach house, or wherever room can be found where there is no fire-heat. Thus treated, they will come into flower in succession for some weeks, and are very useful for greenhouse or room decoration. Expensive sorts are unnecessary, but such should be selected as naturally flower late.

Calla æthiopica.—Those that were divided and planted as recommended in the open ground in the spring will now be good, sturdy plants with short leaves, much superior to those kept in pots. They should at once be taken up and potted. As they are all but aquatic in habit they need a liberal supply of water continuously, on which account they must have the pots well drained, for although requiring so much moisture, they will not do well if the soil become sour. If a portion of the plants be wanted in flower early, that can be accomplished by putting them in a little warmth. Plants of all kinds in frames and pits that are in any way susceptible of cold, and that are fully exposed during the day by the lights being drawn off, should have them replaced every evening, particularly on clear, bright nights, which are more likely to be the precursors of a low temperature than when the sky is clouded. This for some weeks will be sufficient protection without having recourse to covering with mats, the presence of which when not needed has simply the effect of restricting the full amount of light.

Flower Garden.

Bedding Plants.—In cases in which it may have been difficult, or even impossible, to obtain at an earlier period a sufficiency of cuttings of any variety of bedding plants, this deficiency may now be made good, and the propagation of all such plants should be brought to a close as speedily as possible. Even bedding *Calceolarias*, which are always found to succeed best when the cuttings are inserted somewhat late, may soon, or even now, be commenced with. These plants are most successfully propagated in cold pits or frames, either in pots or otherwise. If pots are used they may be some 3 in. in diameter, and should be well drained, and the soil may be composed of one-half leaf mould finely sifted, while the other half may be sharp river or pit sand, which will answer the purpose quite as well as the best silver sand. They may be wintered in the pits or frames in which they have been struck, and will of course require the protection of mats, &c., when the weather is severe. Treated thus, they will generally be found by the end of March to be in good order for transplanting into temporary pits or trenches, where they can have the necessary protection which they may require during very severe weather; and from such quarters they may be safely transferred to the flower beds early in May. It will still be necessary to keep lawns constantly mown and rolled, although mowing will be less frequently necessary than it has hitherto been. Leaves have this season commenced to fall sooner than is generally the case; gravel walks

must, therefore, be frequently swept and afterwards well rolled in order to secure solidity and smoothness of surface.

Indoor Fruit Department.

Vines in pots, which were thoroughly ripened a month ago, may now be placed in a gentle heat, *i.e.*, if Grapes are wanted in March and April; select those showing plump prominent eyes and well ripened canes for the first batch, using Black Hamburgh in the dark section, and Royal Muscadine in the white division. Wash the canes with a hard brush, employing soft-soapy water, and clear the surface-soil away well down about the roots; then fill up to within 1 in. of the rim of the pot with a compost consisting of cow and horse manure mixed with a little fresh loam. The roots run freely and feed greedily in a compost of this kind, and at every application of water much valuable matter is washed down to the lower roots. Early growth is much facilitated by the pots being plunging in some fermenting material in which a bottom-heat of 70° can be maintained—say, here and there in a Pine bed where there is room. Where such means are unavailable set the pots on the top of hot-water pipes. A temperature of 60° by day, and 50° at night will be found to be sufficient for the first fortnight. Dew the canes overhead both morning and afternoon. The object and advantage of forcing pot Vines is to be able to cut new Grapes at Easter, or at any other special time, when only a few are required, and when a large Vinery-ful would be too many. Vine culture, in pots, also eaves Vines permanently planted out, which often suffer much if forced very early. Permanent Vines, if started into growth for a succession of years, in October or November, soon succumb to such unnatural treatment. The roots, on which so much depends, fail to act in company with the top, and failure is the inevitable result. Pot Vines may be conveniently accommodated in an old corner of any stove, and when eight, ten, and twelve good bunches can be obtained from them, the original cost and after attention are fully repaid.

Melons.—The season for frame Melons is now all but over. In pits, however, the plants for late fruiting should be vigorous, and previously prevented from setting their fruits till now, when, with great care, a night temperature of 70°, judicious applications of tepid water, and eight syringings on fine days only, they will ripen a good late crop. Mulch the beds with leaf-mould or old Mushroom manure to prevent them from drying too quickly. Do not give much water to fruits that are fully swollen, or that are ripening, as such would be apt to cause the fruit to crack, and deteriorate its flavour.

Cucumbers.—Winter fruiting plants of these should now be establishing themselves in the beds, and must not be too much syringed. The soil for late Cucumbers should not be quite so rich as for summer fruiting ones. Maintain a night temperature of 70° to 75°, and pick off any leaves affected by thrips, and use sulphur to counteract mildew. All fruits for seed should have been secured earlier in the season than this, for by keeping them thus late the plants are considerably weakened. Avoid, too, overcropping, and give some weak manure water to fruiting plants.

Hardy Fruit.

Most kinds of Apples and Pears will soon be ready to gather, and the moment they seem ripe enough let it be done, as we may still expect high winds, and ungathered ripe fruit will be either destroyed or fit for use only as windfalls; on the other hand, none should be gathered until really fit to house. Pears, especially late kinds, if gathered too soon are rendered worthless, as they never ripen to be fit either for cooking or dessert, but shrivel and become hard and dry. A good criterion by which to decide whether a Pear is fit to gather or not is to gently raise the fruit, and if it parts readily from the tree, it is ready to gather. Another plan is to cut open a fruit, and if the pips be brown, the crop may be gathered. The same rule applies to Apples, though none but the very late kinds suffer from early gathering to the same extent as Pears. After housing the fruit the room will require to be freely ventilated for a week or two until the fruit is dry and inured to the temperature of the house; sudden fluctuations more than anything else induce damp and decay. Fruit showing the slightest signs of decay should be instantly removed, for if left an atmosphere is thereby engendered inimical to the good keeping of the remainder. If space permit let the fruit be placed on the shelves in single layers; any extra labour involved in so placing it will be more than repaid by the dispatch with which it can be examined in order to detect bad fruit. Peaches and Nectarines, and also late Plums, should be gathered a day or two before they are fully ripe and placed in the fruit room. I cannot account for it, but such is the fact, that fruit so gathered is much more highly flavoured than when used direct from the trees. As soon as the latter are cleared of fruit wash well any that are affected with red spider or mildew. Plenty of clear water applied with force for the former, and soapuds for the latter, are two simple and effectual remedies. Raspberries may now have all their old

fruiting canes removed and the new ones finally thinned out in order that those for next season's fruiting may derive the fullest benefit from what sunshine we may yet be favoured with. After thinning let the ground about them be "pointed" (not dug deeply), then mulch thickly with well-decayed stable manure. The fruit tree planting season is at hand, and preparation should therefore be made for new plantations, and for lifting, root-pruning, and renovating any trees requiring such operations.

Kitchen Garden.

No cultivator who aims at producing first-class vegetables in all seasons ought to be satisfied with less than from 2 ft. to 3 ft. in depth of good soil. It may not be possible to secure this in some gardens all at once, but if this object be kept steadily in view, and as far as possible acted upon, a steady and progressive improvement will certainly take place, which will soon show itself in the improvement of the crops. The two principal ways of increasing the depth of the soil available for the roots of plants are, firstly, deep trenching in autumn; and, to this end, every spare moment that can be abstracted from ordinary routine work should be occupied in turning up deeply every vacant piece of land, and throwing it up roughly, to expose as large a surface as possible to the action of the atmosphere. Where the sub-soil is decidedly bad, be content with bringing up only 1 in. or so to the surface, but stir the bottom up well with a strong steel fork; even this will let in the air and allow the water to percolate more freely through it than before, and will make it more suitable for bringing to the surface at the next trenching. In this way a vast improvement might be gradually made in many gardens, and I am confident that if the practice was generally carried out, the result in improved crops in all seasons would be patent to even a casual observer. "Where there's a will there's a way," and any cultivator once impressed with the necessity of deep culture will find a way to accomplish his object—gradually and slowly it may probably be, but none the less surely on that account. The second mode of deepening and improving a poor soil is by adding to the surface everything that can be obtained that has any value either as a manorial or mechanical agent; and there are so many substances (often looked upon as valueless) about gardens, especially at this season, which, if properly utilised, would be of the greatest value in any persistent scheme of improvement. All refuse vegetable matter, whether living or dead, should be carefully treasured up, as it contains within itself the nucleus of future crops. There is such a number of substances usually called rubbish, such as the cleanings of ditches, trimmings of banks, roads, and hedges, all so easily obtained as to render the improvement of even a bad soil not so difficult a matter as at first sight it might appear. Amongst the most useful of mechanical agents for ameliorating a heavy soil may be mentioned all kinds of ashes and charred earth or clay, lime and mortar rubbish, and the *débris* from old buildings when taken down; whilst light sandy soil cannot have anything so beneficially applied to it for improving its staple as a good dressing of clay spread over the surface in autumn after trenching, and, after exposure to the action of the weather all winter, lightly forking it in in the spring before cropping. Where French Beans are in demand all the winter, two or three dozen pots may be planted to succeed those planted in frames; by making successional plantings every three weeks or so, the supply will be kept up. A position near the glass will be requisite, as also a moist atmosphere and a night temperature of not less than 60°. 8½-in. pots are a handy size; they should be half filled with good rich soil, and about five Beans planted in each pot. Cover the Beans about 1 in. deep, and earth up when the plants are up and have made some growth. The Newington Wonder, although small, is a very useful Bean for early forcing; if well fed with liquid manure, and if all Beans are picked off when fit for use, it will continue bearing for a long time. Cut clusters of Tomatoes, and hang them in a dry, airy house—this will give them an opportunity of maturing later-set fruit.

Earthing-up Celery.—The general crop of Celery for winter use should now be examined; all suckers should be removed, as well as a few of the smallest outside leaves, and then the foliage should be tied together loosely in the manner recommended in the case of the earliest crops; after that a thorough soaking with manure water should be given, and then about 6 in. of soil from the ridges should be drawn to the plants, an operation which not only keeps the leaves from being broken down by wind, but tends to promote growth, and, where too much soil is not applied, it has no bad effects in preventing rain from reaching the roots. The Celery maggot is now, in some places, more than usually active; it may easily be detected by the brown patches which it produces on the leaves. The only remedy is crushing it between the thumb and fingers. The Cabbage caterpillar is also now attacking late Cauliflowers; they get into their hearts as soon as they begin to form, and for these no

dressing can be applied that would not spoil the heads, consequently hand-picking must be resorted to, otherwise the larvæ will continue their work of destruction until the occurrence of sharp frost.

Extracts from my Diary.

September 30.—Potting old plants of Cloth of Gold, Golden Chain, and Flower of Spring Pelargoniums to provide cuttings in spring should they be wanted. Potting in cuttings of Blue Perfection and Golden Gem Viols in sharp sandy soil, under hand-lights, in a shady border. Putting Fraser's Broad-leaved and Green-curl'd Endive in cold pits as they become vacant; also Black-seeded Brown Cos Lettuce. Giving Strawberry beds a good coat of manure, and forking it in. Getting border under a north wall ready for Calceolaria cuttings. Taking up one portion of Beet-root, and storing it away for use in case of frosty weather. Gathering Coe's Golden Drop and Reine Claude de Bavy Plums. Watering Pine-apples throughout, and tying up the fruit where necessary.

October 1.—Putting in Calceolaria cuttings under hand-lights against a north wall. Getting Camellias, Myrtles, and other plants under cover. Earthing up Celery when the ground is dry and in workable condition. Cutting off what Grapes are left in late Black Hamburg house, and putting their stalks in bottles of water in which have been placed a few pieces of charcoal. Gathering Louise Bonne of Jersey, Jersey Gratioli, and Marie Louise Pears; also Cellini, Cox's Pomons, and Stirling Castle Apples, and laying them singly on clean Wheat straw in fruit room. Weeding Box edging, and cleaning garden walks to make them fresh for the winter.

Oct. 2.—Potting rooted cuttings of Tomatoes for succession; and putting in another batch of Hathaway's Excelsior. Clearing off old Peas, and getting the ground ready for manuring and trenching. Hoeing and weeding amongst the autumn-sown Onions whilst the ground is dry and the weather fine. Turning Gravel walks, and laying down new gravel where required. Tying up Lettuces, and covering up Endive to blanch. Clearing off all decayed vegetables, and carrying them to the rubbish heap to burn. Gathering Passe Colmar, Doyenné du Comice, Forelle, and Flemish Beauty Pears.

Oct. 3.—Potting Flower of Spring and Dr. Lindley Pelargoniums; also Hyacinths, Tulips, and Narcissus. Moving Primulas and Cinerarias to warmer quarters. Thinning Spinach, and weeding and hoeing between the rows. Making a new Mushroom bed, and turning more manure for another. Looking over all Cauliflowers and turning down the leaves over such as have formed heads, to protect them from frost. Gathering all dwarf and Scarlet Runner Beans and putting them in 4-in. pots set in pans of water with a little charcoal added for keeping till they are wanted; also treating all Vegetable Marrows in the same way.

Oct. 4.—Potting Christine and Jean Sisley Pelargoniums; also a quantity of Echeveria glauca. Planting all spare borders with Wheeler's Imperial Cabbage plants 8 in. apart. Preparing temporary frames in which to prick out Cauliflowers; also a quantity of black-seeded Brown Cos Lettuce. Giving late Peach house inside border a good soaking with water.

Oct. 5.—Sowing Mustard and Cress in boxes indoors. Potting a few Lobelia pumila and dwarf Ageratum. Putting in more Calceolaria cuttings under hand-lights. Getting up a large quantity of the most forward Cauliflowers, and laying them in an open shed. Clearing leaves from the pleasure grounds and walks and rolling the same. Gathering all unripe Tomatoes, and placing them in a sunny position indoors to ripen. Fruits in use for dessert consist of Pine-apples, Grapes, Pears, Plums, and Apples.—W. G. P., Dorset.

Sowing in Drills v. Broadcast.—Although the sowing of seed in drills has well-nigh superseded broadcast sowing with all crops in kitchen gardens, yet one occasionally finds broadcast sowing practised under the plea that it saves labour, and that more produce will result from a given area by sowing broadcast than by the drill system. Experience, however, tells me that the balance is undoubtedly in favour of drills, for, although the actual labour of sowing any crop may be reduced by the broadcast plan, yet the labour involved in keeping the crop free from weeds is altogether in favour of drills, for as soon as the young plants are up sufficiently for the rows to be visible, the intervening spaces may be lightly hoed; whereas in broadcast sowing the crop and weeds must grow together until it is possible to set the hoes in motion with anything like accuracy, and if showery weather set in a tangled mass is the result, that well-nigh defies the efforts of the cultivator to get rid of without damage to the crop. Besides, there can be no question as to which mode of cropping has the best appearance, and even in the kitchen garden this ought not to be a secondary consideration.—JAMES GROOM.

GARDEN BOTANY.

(Concluded from p. 272.)

COLLECTIVE FRUITS.—As already explained, these result from more than one flower, and the simplest form is offered by some species of Honeysuckle, in which the ovaries of two flowers unite, forming one fruit (fig. 603). The fruit of the Sweet Chestnut is also in one sense collective, inasmuch as the

Fig. 603.—Collective or aggregate fruit of *Lonicera Xylosteum*, the result of two coherent pistils.

Fig. 604.—Collective fruit of Sweet Chestnut. Several inferior fruits contained within a prickly involucre (cupule).

prickly involucre, which seems at first sight to be the counterpart of the prickly capsule of the Horse Chestnut, encloses the fruits of several flowers (figs. 604 and 605). See what is said respecting this in the paragraph treating of the involucre. The Globe Artichoke is a collective fruit, and the flower-heads of all other Compositæ become such (see fig. 606), though there

Fig. 605.—One of the single fruits of Sweet Chestnut removed from the cupule.

Fig. 606.—Collective fruit of Marigold.

is no absolute union of the fruits of each separate flower constituting the head. In external appearance, the Mulberry (fig. 607) closely resembles the Raspberry, &c.; but, as has already been explained, it is an inflorescence, consisting of numerous flowers crowded together. As it matures, the per-

Fig. 608.—Section of collective fruit of Fig.

sistent perianths become fleshy, and eventually cover the relatively small seed-vessels or true fruits. The famous Bread Fruit belongs to this category, and the Fig also; but in the latter the floral receptacle is a hollow body enclosing the

flowers. Figures 608 to 610 illustrate the nature of this fruit in the young state. The nature of the fruit of the Pine-apple and of some other Bromeliaceæ is more easily understood, as the separate flowers are large enough to be seen by the unaided

Fig. 609.—A male flower of Fig removed from the receptacle. Much enlarged.

Fig. 610.—A female flower of Fig removed from the receptacle. Much enlarged.

eye. We have only one more kind of collective fruit to mention, and that is of the Coniferæ, which presents various modifications, Cupressus (fig. 611) and Pinus (fig. 612) for examples.

This brings us to the end of our review of the external morphology of plants to the seed, to that part of the subject with which we started; and to the student who has not been able to follow us at all times we would say recommence, because what was unintelligible the first time of reading may appear clear the second. Another observation we would make. It is this: that in botany, as in all other subjects, we must

Fig. 611.—Collective fruit of Cupressus.

Fig. 612.—Collective fruit of Pinus sylvestris.

know the alphabet before we can read. Learning the alphabet may be a tiresome task, but the pleasure of reading is inexhaustible, for the book of Nature is endless.

W. B. HEMSLEY.

THE INFLUENCE OF AGE ON SEEDS.

At a recent meeting of the French Société Centrale d'Horticulture, M. P. Duchartre gave an account of some very curious observations on the influence of age in a seed on the flower and fruit-bearing powers of the future plant made by Signor Ferdinando Cazzuola, of Pisa, and embodied by him in a paper entitled "The Latent Life of Plants in the State of Embryo in Old Seeds," published in the April number of the "Bulletino della Reale Società Toscana di Orticultura." These observations are the result of many years' experience on the part of Signor Cazzuola, who seems to have commenced his experiments at a very early period. For years past he has been in the habit of sowing Cucumber and Water Melon seeds, one half of which had been recently gathered from the plant while the rest had been kept for some time. The plants produced from the fresh seed each bore only one, and very rarely two, fruits; whilst those grown from the old seed gave three or four, and at a much earlier period. In the case of some Colocynth plants (*Cucumis Colocynthis*) produced from very old seed, the flowers were all females; whereas, when grown

from fresh seed, they were all males. Last year Signor Cazzuola repeated this latter experiment, but he did not obtain a single fruit. A Gourd plant (*Cucurbita Pepo*), produced from a very fresh seed, which was trained over the roof of a portico, grew to the length of between 60 ft. and 70 ft. in thirteen weeks. On this enormous length of stalk were produced forty-seven male flowers, and, lastly, a single female flower, which was developed so late in the season that the fruit which succeeded it had not sufficient time to ripen fully. On the other hand, a plant grown from an old seed of the same variety only reached a length of 26 ft., and produced four large fruits early in the season. The results of similar experiments made with other monococious species of the Cucurbitaceæ ended in the same manner. As for the dioecious Cucurbitaceæ, Signor Cazzuola states that he has proved that the *Begonia dioica* produces only 5 per cent. of female plants if recently-gathered seeds are used; whereas, if we sow old seeds, the proportion of female plants amounts to 50 per cent., and even beyond that figure. The same observer states that having sown fresh seeds of the *Thladiantha dubia*, out of 100 plants he only found a single female, and that was so weak that it very soon withered up and died. Besides the family of the Cucurbitaceæ, Signor Cazzuola asserts that with woody dioecious plants he obtains nothing but males when fresh seeds only are sown, but that if old seeds are used he gets 40 and 50 per cent. and even more of females. He gives several examples of this phenomenon as observed by him in experimenting on the Ginkgo, the Alaternus, the Holly, the Pestachio, the Mastic tree, &c., and Signor Cazzuola thinks that there is only one conclusion to be drawn from his experiments, and that is, that the age of the seeds sown has a great influence on plants bearing hermaphrodite flowers, which are much more vigorous but less fruitful when they are grown from fresh seeds. His experiments in this direction have been made on Haricot Beans, Broad Beans, Peas, Lupins, Chick Peas, and other leguminous plants, as well as on several of the Solanaceæ. In order to explain these facts, Signor Cazzuola, as the title of his paper would lead us to suppose, seeks for a reason in the hypothesis of the existence of a latent vitality in the embryo, which, by becoming prolonged, weakens the embryo and makes it more fruitful. M. P. Duchartre, in conclusion, said that it seemed to him that Signor Cazzuola's hypothesis only partially explained the facts as stated by him, besides which he could see many objections to it. At the following meeting M. Arneuld-Bulland stated that M. Laizier had made several experiments on Melon seeds, the results of which did not seem calculated to confirm the hypothesis put forward by Signor Cazzuola. Having procured a number of Melon seeds which had been gathered yearly during the preceding ten years, he sowed the seeds produced in each year separately. The seeds gathered in the years 1868, 1869, 1870, and 1871 did not germinate. The proportion of germinating seeds became larger as the sowings were made with the more recently-gathered seeds, but the plants that they produced did not present any very remarkable differences as far as the proportion of flowers of the male and female sex was concerned. M. A. Malet at the same meeting said that, basing his opinion upon long practice, he always looked on fresh seed as the best for sowing. He had never remarked the slightest difference in the number of male or female flowers in the monococious species, no matter whether they were produced from fresh or old seed, and he maintained that they showed no difference in this respect. As for the ordinary kitchen garden species, the plants grown from recently-collected seed were often much more vigorous and showed a greater tendency to increase in length than those produced from old seed. If they are Cucurbitaceæ they must, for this reason, be allowed to grow as long as possible, and the female flowers should be fertilised by artificial means. To sum up, he advised that in every case recently-gathered seed should be sown instead of that which had become stale.

C. W. QUIN.

Paphinia cristata.—We saw the other day, in Messrs. Rolison's nursery at Tooting, a remarkably fine variety of this Orchid—one which, when better known, will be appreciated by those even who care little about the type.—G.

THE KITCHEN GARDEN.

ASPARAGUS CULTURE AT ARGENTEUIL.

YOUR offer of prizes for the best Asparagus grown in England on the Argenteuil model and other causes induced me to pay a visit to the head-centre of Asparagus culture in France. Argenteuil may be said to owe its wealth and fame to this special industry. There, too, other vegetables and some fruits are grown well. Among the latter, Fig culture holds a prominent place, most of the plants being grown as low bushes, and the tops being buried under ground in winter. But Asparagus growing is the main pursuit; and doubtless this is one, perhaps the chief, reason why it has reached such perfection. The concentration of skill and force tells on Asparagus culture as in other matters. Be that, however, as it may, Argenteuil Asparagus has a special and exceptional value in the Parisian and other markets of France and other countries, including England. It is not the first in the French markets, but its advent is hailed by a sort of ovation. The horses and vans are sometimes dressed up as for a festival that bring the first gatherings to the Halles Centrale or other markets, and gentlemen take off their hats and cheer as they see the first fruits or gatherings of the Argenteuil Asparagus arrive in Paris. And the "Grass" is worthy of this or any amount of honour. It is useless to characterise it as splendid, magnificent, &c.; neither of these adjectives give any idea of its wonderful size and general excellence of quality. To add that it is fresh, crisp, and sweet when newly gathered is only to write the merest truisms. It is also uniformly good. The entire district seems to have reached to the highest level in this special culture; and the quantity grown is also enormous. I saw on one morning at the Halles Centrale alone ten times more Asparagus than I had ever seen before in my life in all the markets or gardens I had ever been in. The stalls, streets, and squares were blocked with Asparagus, each stick averaging from 3 in. to 6 in. in circumference, and some of the hundreds ranging in price from 4s. to 12s., the latter being quite a formidable affair to lift. It is not necessary to describe further the quality of the Asparagus, as you have promised full descriptions and drawings of it; and the fact of its being all blanched but the tips of the shoots has frequently been adverted to in THE GARDEN. Neither is this the time nor place to discuss the relative merits of blanched or green "Grass." Our object now is simply to point out, if possible, how the Argenteuil Asparagus is grown to such an enormous size. Four things struck us on the spot as contributing most powerfully to this result—the selection of sorts, the preparation and careful culture of the soil, the distance between the plants, and the practice of earthing up in the spring and unearthing, to put the matter pithily, in the autumn.

The question of varieties is rather a puzzling one, it being generally held by most authorities that all varieties of edible Asparagus are but forms of one species—the *Asparagus officinalis*. Be that as it may, the French growers recognise several different varieties, and attribute great importance to the selection of the best. I called at the Jardin des Plantes the day before my visit to Argenteuil, and was much interested in the collection of Asparagus. Several were climbers, and several dwarf sorts, but the following looked superior in strength and seemed likely to be as useful for culinary purposes as *A. officinalis*. The following were growing there in the same bed, namely: *A. verticillatus*, tall and strong, with a slight tendency to a creeping habit; and *A. albus*, white. This was marked Algerian Asparagus, and varied little from the common, except in the fact that its stems were almost white. This was much stronger and more robust than the common Asparagus beside it; and on enquiring afterwards of a gentleman who had been much in Algiers about the size and quality of this Asparagus, he said it was not nearly so large there, in his opinion, nor so good as the French, though it was plentiful enough; neither could he give any particulars about the modes of culture in that climate. *A. amarus* and *davuricus* were very dwarf, though not differing much in other respects from the edible *A. officinalis*. As, however, as many as thirty or more distinct species or varieties have been introduced at different times, it is quite possible that some of these may have intercrossed to some extent with *A. officinalis*, or originated types

or forms better or worse than the species. For example, I have seen Asparagus plants—notably among Connover's Colossal—in England, and also at Argenteuil, that have much of the style, character, and height of the *A. verticillatus* of the Jardin des Plantes in Paris. Returning to the species, giant and major varieties have always been recognised. Localities have also stamped their names and characters on strains; hence we have Ely, Battersea, Colchester, Dutch, French, English, Argenteuil, and other well-known sorts. The so-called common and large varieties of the common *A. officinalis* have also originated families of Asparagus varying considerably in their earliness and lateness, the large kind being considered the parent of the later sorts. There is also an intermediate sort grown about Argenteuil. The differences between the so-called varieties are, in fact, more pronounced and decided in France than in England. Hence such sorts as *Hative d'Argenteuil*, *Hative Rose d'Ulm*, *Intermediate d'Argenteuil*, and *Tardive d'Argenteuil* may almost be distinguished at sight, while the more choice strains are named after their raisers or growers, as *A. Hative Louis Lherault*, *A. Hative M. G. Lebeuf*, &c. And yet, with all this careful selection, plants here and there in the best beds revert to common and inferior types, or refuse to come up to the high standard of others. The chief point with the best growers is to save seeds only from the strongest and most vertical-growing plants. These produce fewer shoots, and, consequently, other conditions being equal, the strongest numbers are thus freely sacrificed to size, the results averaging about 4 in. in circumference about 6 in. from the crowns of the shoots. Such facts are more eloquent than words as to the complete success of the French in growing Asparagus, and no doubt a very large share of that success arises from the extreme care in the selection of seeds, the weeding out of inferior plants as soon as they can be detected, and a constant watchfulness, that the fittest, that is, the strongest, alone should survive.

A great amount of labour and skill is also devoted to the preparation and cultivation of the soil. The cultivators make light of its original character. As a forcible means of showing this one of them assured me that he could grow good Asparagus on the public road if required. Neither do they attribute the importance to depth nor richness that we do in England. There seemed no excess of manure in it, and from 18 in. to 20 in. seemed about the average depth of the tilth. Their great point is its friability and fineness. A year's crop is often sacrificed previous to the planting of the Asparagus, so as to work or force the earth into sweetness, mellowness, and fineness; in other cases only such crops as salading or very short-topped Potatoes are taken. Even then the earth devoted to the Asparagus is ridged or mounded up from 4 in. to 12 in. high, so as to have the fullest possible benefit of sun and air. The earth, in fact, is as fine as an ash-heap, to use a hackneyed expression familiar to cultivators. Starting with such finely-comminuted soil, and planting at average distances of 4 ft. by 2 ft. between the plants, and the surface free from weeds, of course the ground continues well pulverised, loose, and friable. The plants having such copious space naturally grow strong. Each plant becomes a giant rather than degenerates into a colony of dwarfs, and the chief mystery regarding the size and quality of the Argenteuil Asparagus is solved. For the mode of planting or the time does not differ from that of the best English cultivators, but the subsequent treatment does. The French growers do less in the way of top-dressing than the English. Comparatively little salt, artificial, or other liquid manure, or solid dressings are given. What manure is applied is given mostly in the dead season, and that seldom more frequently than at intervals of two or even three years. In dry weather water is also given at times during the growing season. The ground is kept free from weeds, and special care is taken not to allow the tops to be broken or injured by winds or rains. Where specially fine "Grass" is desiderated the seeds are also picked, and worms, snails, grubs, and beetles are hunted for and destroyed.

In the autumn, when the Asparagus dies down, the earth is removed to within 1 in. of the crown and main roots, and a mulching of manure, if available, is applied; if not, an inch or so of soil is left instead, and this covering is found sufficient protection against frost. It also seems as if

the close proximity of the crowns to the atmosphere during winter invigorated and strengthened them, while the removal of the 6 in. or 12 in. of superincumbent earth no doubt protects the plants from crown and root rot, so common in some gardens in England. Few things are more likely to further this than a mass of inert, wet earth pressing heavily on them, while, perhaps, the soil around the roots or crowns has become waterlogged or impervious to moisture. The earth removed from the plants is ridged up between the rows, and, of course, immediately begins a fresh process of enrichment and amelioration as it presents fresh and raw surfaces to all the atmospheric influences of winter. Next March or April the beds are slightly forked over and the soil from the ridges heaped up over the Asparagus to a height of from 6 in. to 9 in. This at once nourishes and strengthens the roots, and forms the best possible blanching medium for the French Asparagus. As soon as the stems push about 1 in. through this fine soil, the Asparagus is gathered rather than cut, the mounds or ridges are levelled down, the shoots wrenched off with the hand, and the soil is at once replaced. Perhaps the mode of gathering should be considered a factor in the superiority of French Asparagus. No doubt much Asparagus is sacrificed, many fine roots crippled and ruined, by the hackings and hewings of saw-like knives—veritable instruments of Asparagus torture in the dark. But many English growers either cut above ground, or are careful to see where and how they cut under it. So too much importance must not be attributed to this superior mode of taking the "Grass," which is, moreover, by no means universal in France, as the regiment of Asparagus knives in the Paris Exposition proves. In the careful selection of seeds and plants, the proper preparation and culture of the soil, the furnishing each plant with sufficient room to do justice to its strength, and the annual mounding and dismounding over the crown will possibly be found all the secrets of French success; and, possibly, we could hardly do better than imitate their practice in these respects if we would match—it seems hopeless to endeavour to excel—their Asparagus. One thing more, however, is needed to do this, and that is enthusiasm. The enthusiasm of each grower about Argenteuil is at white-heat, and their courtesy and kindness are as warm as their enthusiasm. D. T. FISH.

NOTES AND QUESTIONS ON THE KITCHEN GARDEN.

Carrots for Main Crops.—I greatly prefer James's Scarlet Carrot to the longer but coarser varieties so much grown, such as Altringham and Long Surrey. These frequently grow a good way out of the ground, whereby the crown gets discoloured and useless for cooking purposes; James's Scarlet, on the contrary, is usually of fair size, and good in colour and quality.—J. G.

Late-sown Endive.—This is a good time to sow the latest crop of Endive, which should be done on a border with a good slope so as to ensure drainage. If sown in drills 1 ft. apart and thinned just sufficient to keep the plants clear of each other, they will not get large, but will be more likely to withstand severe weather than large transplanted crops from early sowings. As they keep growing slowly in the winter, they prove serviceable during the earliest months of the year, when materials for mixed salads are in great request; the Green-carled and Batavian stand the winter better than the Moss-curl'd varieties.—J. Groom.

Curled Chervil.—This useful herb is usually in pretty constant request for culinary purposes, and for mixing with salads, &c. It is of very easy culture, and a small bed of it will supply a large household. During the greater part of the year it may be obtained from the open air by sowing a few rows across a border at intervals of a month. To meet the demand, however, in exceptionally severe weather, a few boxes of it should be sown now, and when well established out-of-doors they may be removed to pits or houses for a midwinter and early spring supply; for, in addition to other uses to which it may be put, it is preferred to Parsley for garnishing.—J. G.

Pricking out Cauliflowers.—As soon as the young plants are large enough to handle they should be pricked out in cold pits or frames about 3 in. apart each way in good soil. They should be kept as fully exposed as possible during genial weather, but covered during severe frosts, for although hardy enough to stand several degrees, checks to the growth, either from excessive drought or cold, are the conditions most likely to induce premature hearting; therefore avoid all extremes.—J. G.

IMPROVEMENT IN COVENT GARDEN.

It may be presumed, without much presumption, that when Englishmen are half through the Positive Age—an age that must follow at no distant period the present age of revival and sham—they will tell funny stories of the way in which house-building was generally conducted during the latter years of Victoria; of the many important functionaries that had a finger or a hand in the design of the said house; of the preliminaries that were necessary, and often conducted with a solemnity of mystery, if not secrecy, for the acquisition of the borrowed land which was to bear the said house. Take, for instance, the Covent Garden that, since the old wooden house of the Bedford, facing the Strand, was pulled down to make way eventually for Southampton Street, has seen such striking changes. Once the abode of wealth and fashion, then of third-rate vice, then the resort of travellers, and a great hotel centre, now a market more famous than any other in England, and impassable to all carriages, except those that pay toll to the noble landowner, a market that has trebled and quadrupled in the course of this century—that has doubled within a lifetime. Well, of course, Covent Garden is to be inclosed with bran-new houses. The time has at length arrived for rebuilding the square. The first thing, therefore, to do was to make it half as big again, to allow not only space for the transaction of that business which brings an enormous income to the Duke of Bedford, but to make the thoroughfares round the market buildings eligible for public use. In any other country but England, and in far less important cities than London, a municipality would have taken care to see that such a square as Covent Garden was enlarged when the time came for rebuilding the houses enclosing it. But here in England nothing of the kind interferes with the rights that grow out of possession. Every house in Covent Garden may before long be rebuilt, but not a square inch will be added to the width of the roadway, or even to that of the pavement. True, for a short time we imagined that the southern side was being enlarged, and that some 12 ft. were likely to be added to the width of the roadway parallel with the Strand and next Southampton Street, where we risk a smash every day of our lives. But such a hope is destroyed by the fact that the alignment of Henrietta Street is being maintained by a stone coping, which has just been placed in front of the new Covent Garden Hotel, the first new building yet finished in the square; while on the other side exactly the same bit of an arcade that before existed is being rebuilt, as if the famous square belonged to two landowners, one of whom employed an architect who fashioned houses *à la mode de Turin* and the Rue de Rivoli, in defiance to the other's professional adviser, who believed that a London sun was to be courted, not barricaded off. Suffice it that Covent Garden is being rebuilt, and that for the next hundred years at least the almost perpetual block of market carts across the northern thoroughfare can neither be remedied nor reduced, except by an unlikely diminution in the market trade.

The houses, some recently erected, and others in course of erection, upon this part of the Duke's land, constitute a vast improvement over the sort of tenement that for so many years was thought worthy of the Bedford Estate. Less than twenty years ago if a leaseholder wished to obtain a renewal, for a short period, of his lease, it was necessary for him to smother the good brickwork of his old house with the dingiest cement—of a hue even more dirty than the bricks it covered. Then came a period of brick and cement dressings, followed by a few variegated fronts of red and yellow. At present, building on the Bedford estate is, in the architectural parlance, "Henri deux," approaching "Henri quatre;" and this is how the oceanumination is reached. First take the bit of land and then prepare to build upon it. You, the lessee, have your own agent, an architect, and he proceeds to do his duty. He applies to the Duke's agent for an elevation of the building his client (the lessee) desires to erect. It may be a shop, a dry-goods warehouse, a school, an hotel, a public house, or a chapel. An elevation is supplied by the Duke's architect (Mr. Henry Clutton) to the lessee's architect, and then the latter begins to make his plans. The plans made and accepted by the lessee are sent to the Duke's surveyor (Mr. Cross), who in the interest of his employer has been known to keep such plans much more than three months, during which time the ground-rent has to be paid, and the surveyor reports thereon to the Duke's agent. There is a building in progress in Hart Street, Bloomsbury, the plans of which occupied the surveyor nearly half a year before permission was given to begin, and the ground-rent during that period was not by any means declined. In short, in new Covent Garden, the exterior is settled before hand; the interior is made to fit the external wall; and we are bound to say that though, in one or two cases, such a course may terminate successfully, it is not a wise or logical mode of building houses which are to stand in their places at least for a century.—"Builder."

HEATING GREENHOUSES.

A RECORD OF A SERIES OF COMPARATIVE EXPERIMENTS MADE IN 1877.

THE trials which were made during the past year in my horticultural establishment with the warming apparatus of MM. Berger-Barillot of Moulins, Cerbeland of Paris, and Vendœuvre of Asnières, an account of which was published in the "Revue Horti-

Fig. 1.—MM. Mathian's Heating Apparatus.

cole," 1877, p. 291, attracted a great deal of attention from both horticulturists and amateurs; I resolved, therefore, to continue them during the present year. I consequently accepted the offer made to me by MM. Mathian, heating apparatus manufacturers of Lyons, to fit up one of my greenhouses with a boiler of their own construction,

Fig. 2.—MM. Berger-Barillot's Heating Apparatus.

and to try it comparatively with the one which had given the best results in the preceding year. This boiler, which is shown in fig. 1, consists of a bell of cast iron, in which the fuel is burnt. This bell is surrounded by a double concentric casing of thin sheet iron, between the walls of which is the water to be heated. The fuel is thrown in at the upper part, which is fitted with a cast iron mouth, and the furnace is so constructed that the smoke and other products of combustion are obliged to pass completely round the external casing of the boiler before they escape up the chimney. A small door placed in front, and level with the grating, is used for lighting

the fire or withdrawing the clinkers produced by the coal or coke, either of which may be used indifferently. The experiments, of which an account is about to be given, were performed with the latter combustible. The whole of the apparatus is constructed with great care, and is of a very solid character. The apparatus, made by MM. Berger-Barillot, of Moulins (figs. 2 and 3), which gave best results in 1876, was used in the experiments. It consists of a vertical, tubular boiler, and was described and figured in the "Revue Horticole" for 1877. The two pieces of apparatus were fixed in two greenhouses of the same size, construction, and aspect, being each 28 metres long by 3 metres wide and 2 metres in height. Each of the boilers had to heat the water contained in four rows of cast iron pipes 9 centimetres in diameter, forming, with the connections and cross pieces, a total length of 115 metres of piping, containing from 550 to 600 litres of water. As in the former experiments, the houses were both kept at a temperature of about 20° Cen. (68° Fah.), the object being to see which consumed the smaller quantity of fuel in obtaining the same result. The experiments extended over the space of sixty days, noting exactly the temperature of the interior of each house six times a day, that is to say at six and nine in the morning, at noon, at two, five, and ten p.m. : also noting, at the same time, every ten

Fig. 3.—Section of MM. Barillot's Heating Apparatus.

days the amount of fuel consumed. The following table shows the results:

GREENHOUSE No. 1. MATHIAN'S APPARATUS.		
	Temperatures	Coke consumed
1st ten days	21°60	11 hect 50
2nd "	20°50	10 " 0
3rd "	20°33	6 " 50
4th "	19°60	9 " 25
5th "	18°95	10 " 50
6th "	21°23	10 " 25
Totals	123°41	57 —

Mean cost, calculating the coke at 2 fra. per hectolitre, 1 fr. 90 per day. Mean temperature 20°56.

GREENHOUSE No. 2. BERGER ET BARILLOT'S APPARATUS.		
	Temperatures	Coke consumed
1st ten days	22°46	11 hect 75
2nd "	21°30	10 " 50
3rd "	21°23	6 " 50
4th "	20°23	8 " 75
5th "	20°18	10 " 25
6th "	21°75	10 " 0
Totals	127°25	57 75

Mean cost, calculating the coke at 2 fra. per hectolitre, 1 fr. 92 per day. Mean temperature 21°20

From these experiments it results that in order to obtain a nearly equal temperature, the cost of coke is nearly the same. We may therefore come to the conclusion that the heating powers of the two machines are equal for the same amount of fuel consumed; both

give excellent results. MM. Berger-Barillot's apparatus is to be recommended for its extreme simplicity of construction, and the ease with which it is kept clean, the movable firegrate and cast iron plate allowing the fireplace to be cleared in an instant. On the other hand, it lacks solidity, and there is always danger of the corrosion of the brass tubes, through which the products of combustion pass into the chimney. In case, too, of repairs being necessary, they would require special tools, which are not always in the possession of gardeners. MM. Mathian's apparatus is superior to the other in solidity, and on account of its concentric envelope, may be easily repaired. On the other hand, the interior is very complicated and requires constant attention, but if the grate were movable, instead of being fixed as it is at present, the fireplace might be more readily cleaned.

A. TRUFFAUT, in "Revue Horticole."

[Both of these boilers are identical in principle with many in use in England. Recently we have removed some bell boilers that have been in use for many years. In these cases, however, the bell had been cast hollow, thus providing a water-way between the outside and inside of the boiler. Made thus, the objections urged against Mathian's apparatus in the last sentence of M. Truffaut's remarks would be obviated. In setting the old English bell boilers, to which the fire is placed under (as shown in fig. 1), it is likewise carried all round the outside of the boilers, so that the water-way is placed between two fires, and the water can by no possibility rest for a single moment. These boilers are at once among the most simple, durable, and efficient, there being positively no complicated parts in the old English bell boiler to get out of repair. The attempt to fit sheet iron to cast, as suggested in MM. Mathian's patent, while it may render the water more easily heated, introduces an element of great weakness into the boiler. MM. Berger-Barillot's heating apparatus is also a form of boiler familiar to the older English horticulturists. It differs little from many of the earlier tubular boilers, and is still one of the most useful for the heating of small houses especially. The same form may be had in cast iron, wrought iron, or brass, so that the objection here brought against the latter metal may be obviated by using iron instead. The furnaces of both boilers may be arranged with equal simplicity. Of course, it is, however, generally more difficult to get ready access to the fire in vertical tubular boilers than in bell, saddle, or other forms. The equality of heating power in these two boilers under similar conditions, in regard to size of boiler, consumption of fuel, and area to be heated, might also have been anticipated. So long as the heat has free access to the water, the direction of the flame or the form of the water line is of comparatively little moment. These experiments, however, are interesting and most useful, especially to those—always a numerous class at this season of the year—who are meditating the warming of one or more houses, and are anxious to count the cost as well as to know the best boiler to employ.—D. T. F.]

ANSWERS TO CORRESPONDENTS.

Apple-trees Boring Caterpillars.—I send herewith a caterpillar and a piece of Apple tree in which I found it. What is its name?—C. B. [The yellow caterpillar sent with raised black spots interspersed over the body is that of the wood leopard moth (*Zeuzera Asculi*). Besides boring into the wood of the Apple tree this caterpillar has been found injuring other trees, such as the Elm, Horse Chestnut, and Pear. It is not infrequently occurs in the London district, and has been found in other parts of the kingdom.—W. W. S.]

Striking Rose Cuttings.—If your subscriber (p. 275) has failed to strike Rose cuttings outside, I would recommend him to take them off with a heel and put them in pots, plunging the pots in a cool frame and taking care to preserve an equable state of moisture in the soil throughout the winter and early spring.—A. W. P.

Substitutes for the Potato (p. 275).—I have no faith in the discovery of any real substitutes for the Potato, but much remains to be done in improving its culture and introducing better disease-resisting varieties. Much more also might, and ought to be done in the cultivation of other vegetables to partially take its place, or to be supplementary to the Potato I have lately had a week's run through many counties and have kept an eye on the allotments and cottage gardens as I passed, and I have been horrified to see the wretched condition in which too many of them are. Potatoes still in the ground under a mass of weeds that might be mown with the scythe, is far too common an occurrence, and the attention given to other kinds of vegetables is of the most fragmentary kind. The best advice I can give is, plant more early and second early Potatoes. Lift them early and plant Brussels Sprouts, Coleworts, Broccoli, Cauliflowers, Spinach, and Turnips. Parsnips, Carrots, and Jerusalem Artichokes might also be more largely grown; Haricot Beans might be tried; and, above all, the land should be well cultivated and weeds kept down.—E. HOBDAY.

Names of Plants.—*G. R.*—Certainly *Sassafras officinale*; it is remarkable for the diversity in form and size exhibited by the leaves. *D.*—*Polypodium irregulare*. *Q.*—*Laminum maculatum aureum*. *J. D. M.*—1, doubtless *Isolepis gracilis*; 2 and 3 not *Isolepis setacea*, but a

nearly allied species, *Isolepis Savii*, which is larger, paler, and has widely different fruit. The genus *Isolepis* is considered by most botanists merely as a section of *Scirpus*. *W. H. M.*—It seems to agree with *Sophora* (*Edwardsia*) *microphylla*, which is a native of New Zealand. It is, however, impossible to name with certainty any exotic Leguminous plant from leaves alone; generally both flowers and fruit are absolutely necessary. *E. D.*—2, *Dicksonia antarctica*; 3, *Aspidium capense*. *F. H.*—1, *Aster pyrenaeus*; 2, *Helenium varium*; 3, *Helenium autumnale*; 4, *Helianthus occidentalis*; *Gypsophila paniculata* is undeterminable without lower leaves. *F. T.*—*Cupressus macrocarpa* or *Lambertiana*. *X. C.*—1, *Retinospora pisifera plumosa aurea*; 2, *Cupressus Lawsoniana*; 3, *Chamaecyparis sphaeroidea aurea variegata*; 4, *Retinospora pisifera filifera*; the rest hereafter. We cannot name more than four at one time.

Names of Fruits.—*C. G.*—We are unable to name your Apples from single specimens; 1 appears to be Emperor Alexander.

SOCIETIES AND EXHIBITIONS.

CRYSTAL PALACE FRUIT SHOW.

SEPTEMBER 24 & 25.

THIS was considered by many to be the best fruit show that has ever taken place at the Crystal Palace. In point of numbers, perhaps, it did not excel its predecessors, but, as regards quality, a decided advance was observable on the exhibits of former years. Hardy fruit was especially good, nearly all the specimens shown being clear and sound. The long lines of Grapes and miscellaneous collections of fruits, however, attracted most attention, together with some magnificent pot Vines from Berkhamsted, and the bunches of Grapes shown for weight.

Collections of Fruit.—These were not quite so numerous as usual, especially in the case of the larger classes. Mr. Colman, gardener to Lord Somers, Eastnor Castle, had the best exhibition. It consisted of fine examples of Black Alicante Grapes, shapely in bunch and fine in colour and berry; also well-ripened Queen and Smooth Cayenne Pines, Barrington Peaches, Read's Netted Scarlet-fleshed Melon, Morello Cherries, and Williams' Bon Chrétien Pears. Mr. Sage, Ashridge, had also a good collection, in which were Cos's Golden Drop Plums, Pitmsston Orange Nectarines, Walburton Admiral Peaches, Brown Turkey Figs, and good Grapes. Mr. Goodacre, The Gardens, Elvaston Castle, furnished a collection, in which were fine examples of Marie Louise Peaches, Lady Downes Grapes; also Muscat of Alexandria, Jefferson Plums, and Barrington Peaches.

Grapes.—Collections of these were numerous. The first prize for ten varieties fell to Mr. Wildsmith, gardener to Viscount Eversley, Heckfield. It consisted of Black Hamburg, Buckland Sweetwater, Alicante, Barbarossa, Trebbiano, Gros Colman, Lady Downes, Muscat of Alexandria, and Venn's Muscat, all good in bunch and berry and finely finished. Messrs. Lane & Sons, Berkhamsted, had an excellent collection, but were disqualified on account of Bowood Muscat and Muscat of Alexandria being shown as two varieties, a fact worth bearing in mind by exhibitors of Grapes. For several years Messrs. Lane have shown the two Grapes in question without dispute, but on this occasion the collection, the best in the show, was disqualified on that account. The collection contained large and handsome bunches of Muscat of Alexandria, Alicante, Trebbiano, Gros Colman, Black Prince, and other well-known kinds. Mr. Sage, Ashridge, was awarded the first prize for a collection of five kinds. They were compact in bunch and fairly well coloured. A better collection came from Mr. Tyler, gardener to R. Gosling, Esq., Bishop Stortford, but this also contained Muscat of Alexandria and Bowood Muscat, and was in consequence disqualified. Muscat of Alexandria was well shown. The best three bunches came from Messrs. Lane, who had wonderfully fine bunches, symmetrical in shape, large in the berry, and beautifully ripened. Three fine bunches, to which an extra prize was awarded, were also shown by Mr. Jarman, Westwood Lodge, Isle of Thanet. Madresfield Court was, in a few cases, shown as well, and even better, than we ever remember to have seen it before, but, as a rule, the majority of the bunches were badly coloured. The best three bunches of Buckland Sweetwater came from Mr. Bungay, gardener to W. Smith, Esq., Hill House, Herne Hill. Mr. Coleman had three splendid bunches of Lady Downes. Three fine bunches of Alnwick Seedling were shown by Mr. D. P. Bell; the berries were large and finely coloured, and altogether it appears to be a Grape which will henceforward find a place on our exhibition tables. For heavy bunches of Grapes the first prize on this occasion was awarded to Mr. Kirk, gardener to Mrs. MacKie, Castle Douglas, Kirkcubrightshire. It was an enormous cluster, weighing 16 lb., the kind being apparently White Niece. Mr. Gosling, Bishop's Stortford, showed a bunch of Barbarossa, which weighed 9 lb. 2 oz., and the best bunch of Black Hamburg weighed 7 lb. 2 oz. The best three bunches of Grapes, consisting of any black kind except Hamburgs, came from Messrs. Lane, and consisted of Alicante—large, well-shaped bunches, fine in colour and large in berry. Messrs. Lane also showed some well-fruited pot Vines, some of the bunches being almost equal to those on first prize stands.

Pines.—Of these only fifteen fruits were shown, all of which were of fair size and quality. The best Queen came from Mr. Sage, and the best Smooth Cayenne from Mr. Ross, gardener to C. Eyre, Esq., Welford Park, Newbury. Mr. Miles, Wycombe Abbey, had a very fine fruit of Baroness Rothschild, and a good Smooth Cayenne was shown by Mr. Pragnell, Sherborne, Dorset.

Peaches and Nectarines.—These were not so numerous as in former years. The Peach to which the first prize was awarded was Lord Palmerston, a variety which was shown in unusually good condition; Princess of Wales, Walburton Admiral, and Lady Palmerston were also very fine. As regards quality, Peaches perhaps were never shown better than on the present occasion. Nectarines, on the contrary, were poor, being either unripe or shrivelled; the best kind was the Pine-apple.

Melons were shown in good numbers, the smaller or medium-sized fruits being the best. Heckfield Hybrid and Dickson's Exquists were the best green-fleshed kinds, and a seedling from Mr. Atkins, Wantage, and Read's Scarlet-flesh the best scarlet-fleshed.

Plums, both black and light-coloured, were numerous and excellent in quality. The best three dishes came from Mr. Sage, and consisted of Jefferson, White Magnum Bonum, and Coe's Golden Drop. Cox's Emperor, a fine dark Plum, was shown, as were also MacLanghin's Late Gage, and Gathrie's Late Green, the latter taking the place of Green Gages, which are over.

Apples and Pears.—Of these Mr. William Paul, Waltham Cross, sent a fine collection, consisting of upwards of 200 dishes. Messrs. Paul & Son, Cheshunt, also sent a smaller but excellent collection, as did also Messrs. Rivers, Sawbridgeworth. The best three dishes of dessert Apples came from Mr. Bowles, gardener to W. Skinner, Esq., Bersford House, Maidstone, and consisted of fine scarlet fruits of Duchess of Gloucester, well-coloured, clean fruits of Ribston Pippin, and Cox's Orange Pippin. The next collection in point of merit came from Mr. Goldsmith, gardener to H. T. Lambert, Esq., Sandhills, Bletchingly, and consisted of finely-coloured, even examples of King of the Pippins, Ribston Pippin, and a handsome-looking dessert Apple, the name of which was unknown. Mr. Haycock, gardener to R. Leigh, Esq., Barham Court, Maidstone, had well-coloured, even-sized fruits of Reins des Reinettes, Ribston, and Mother Apple. Among other collections, the best looking was King of the Pippins, an Apple shown on this occasion more extensively than any other kind, and, in some cases, in better condition than we have ever before seen it. Duchess of Oldenburgh, one of the best striped dessert Apples, was also worthy of notice, as was likewise scarlet Pearmain and Lord Lennox. Kitchen Apples were very large, and none of them appeared to be affected with maggot, which was the case last year. The best examples in this class came from Mr. Bowler, and consisted of the largest fruit of Winter Hawthornden perhaps ever shown, Warner's King, and Stone's Seedling. Mr. J. Pluck, New Street, Jersey, had the next best collection, in which were noble fruits of Alfriston, ReINETTE d'Angleterre, and Grosse Menagere; the same exhibitor had also marvellous fruits of Pott's Seedling and Mère de Ménage. Several extra prizes were awarded in this class, owing to the excellence of the exhibits. Amongst the best looking kinds in the whole collections were Lane's Prince Albert, Emperor Alexander, Blenheim Orange, Lord Suffield, Kentish Filbasket, and Cox's Pomona. The best dish of dessert Pears came from Barham Court; they were large, even, and of fine form; the kinds shown were Louise Bonne of Jersey, Fondants de Cherno, and Doyenné Bouscotte. The second prize exhibition consisted of ripe and finely-coloured fruits of Louise Bonne of Jersey, Williams' Bon Chrétien, and Gansel's Bergamot. Other kinds most noticeable for good quality were Beurré Superfin, Bon Louise, Duchesse de Angoulême, and Marie Louise. Kitchen Pears were shown fairly well, the best examples coming from Jersey. The sorts to which the first prize was awarded were Belle Angevine, Catillac, and Grosse Callabasse. Of Uvodale's St. Germain, King Edward, and Sarrazin very fine fruit were also shown.

Mr. Muir, gardener to C. R. M. Talbot, Esq., Margam Park, Taibach, South Wales, sent an interesting collection of fruit of the Orange tribe, consisting of thirteen varieties; and Mr. Miles, Wycombe Abbey Gardens, showed very fine Morello Cherries. Mr. Wilson, gardener to Earl Fortescue, exhibited a triple Pine-apple, each fruit weighing from 2 lb. to 3 lb.; and Mr. Thomson exhibited male and female cones of Eucepharlatos villosus, the former being nearly 2 ft. in length and the latter 9 in., which had been grown in the Crystal Palace.

Vegetables.—These were not so numerous as we have seen them on former occasions, but they were excellent in quality. The best collection came from Mr. W. G. Pragnell, Sherborne Castle, Dorset. It contained sixteen varieties, all of which were in every way excellent. They consisted of No Plus Ultra Peas, Schoolmaster Potatoes, clean and handsome Snowball Turnips, Jackson's Mammoth Tomatoes, Veitch's Autumn Giant Cauliflower (large, firm, and white), Carcanton Leeks, and four handsome and even fruits of Tender and True Cucumber. In other collections we noted very handsome and well-ripened bulbs of Sutton's Improved Reading Onions, and very fine examples of Criterion and Carter's Green Gage Tomatoes. Mr. Goodacre, gardener to the Earl of Harrington, had very fine Dwarf Mammoth Cauliflowers and well-blanchéd Cardoons. Celery throughout was generally of unusually good quality, and some very good Brussels Sprouts were shown in several collections.

Cut Flowers.—Messrs. Wm. Paul & Sons showed some beautiful Roses for this time of the year. They consisted of both Teas and Hybrid Perpetuals, among which were especially noteworthy large stands of Sofrano, Celina Forestier, Souvenir de la Malmaison, and beautiful blooms of the white Niphetos. Duchess of Bedford and Charles Darwin, two excellent new Roses, were also shown in fairly good condition, and Captain Christy and La France were likewise represented by good blooms. Messrs. Rawlings Bros., Romford, sent several stands of Dahlias, which attracted much attention. Among the most noticeable kinds were Clara, a beautiful lively pink; Baroness Burdett Coutts, white edged with violet; John Bennett, golden-yellow edged with fiery scarlet, very showy;

Perfection of Primroses, delicate primrose and fine in form; and J. E. Quennell, golden-yellow. Mr. Harris, Orpington, sent a dozen blooms of a fine yellow Dahlia named President, which promises to be a good kind for exhibition purposes. Mr. Morgan, gardener to Major Scott, Wray Park, Reigate, was awarded an extra prize for cut blooms of Quilled and German Asters, as was also Mr. Robert Brown, gardener to F. J. Brown, Esq., Windsor. Messrs. Laing & Co., Forest Hill, sent cut blooms of Begonias, which attracted much attention on account of their large size and diversity of colour.

THE INTERNATIONAL POTATO SHOW.

This was held this year in conjunction with the Crystal Palace Company's fruit show, the two combined making one of the most interesting shows of the year. The samples shown, notwithstanding the fact that this has been a bad Potato year, were much superior to those shown on any former occasion, and the competition was very keen in most classes. Mr. McKinlay, Woodbine Cottage, Beckenham, carried off the prize for twenty-four varieties, offered by the Crystal Palace Company, with probably one of the finest collections ever brought together; it consisted of medium-sized tubers, handsome in shape, and excellent in quality. The following are the varieties: Grampian, Snowflake, Trophy, Schoolmaster, Lady Webster, Porter's Excelsior, Blanchard, Woodstock Kidney, Ash-top Fluke, Shelburne, Beauty of Hebron, Early King, Late Rose, Rector of Woodstock, Beckenham Beauty, International, Red Emperor, New Cambridge Kidney, Extra Early Vermont, Onwards, Edgcott Seedling, King of Potatoes, Superior, and Breadfruit. In competition for Messrs. Sutton's Prizes offered for eighteen varieties of Potatoes there were twenty-four competitors. Mr. Croswell was first with Sutton's Magnum Bonum, one of the best new Potatoes in cultivation and an enormous cropper; International Kidney, fine in form and quality; Covent Garden Perfection, Brawnell's Superior (Red Kidney), Snowflake, and Schoolmaster, all of which were of good size and handsome in shape. In other collections in the same class, the best were International, Covent Garden Perfection, Snowflake, Myatt's Prolific, Royal Ashleaf, Ash-top Fluke, Waterloo Kidney, Magnum Bonum, and Wonderful (Red). Edgcott Seedling and International were perhaps the handsomest Kidneys in the show. Lady Paget, Fenn's Bountiful (Red), Webb's Imperial, and Red Garibaldi are also fine exhibition kinds. Among Rounds, the best were Radstock Beauty, Model, Bedford Prolific, Schoolmaster, Porter's Excelsior, White Emperor, Red Emperor, and Lye's Favourite. The best twelve dishes of English-raised Potatoes came from Mr. W. Finlay, and consisted of Lapstone Kidney, Royal Ashleaf, Salmon Kidney, Princess of Wales, Schoolmaster, Red Fluke, and Rector of Woodstock. Other collections in the same class contained fine examples of McKinlay's Pride, Waterloo Kidney, Early Rose, Fenn's Perfection Kidney, Porter's Seedling, and Berkshire Kidney. Messrs. Lott & Hart, Whitehill, Faversham, had the best nine dishes of American Potatoes, including Superior Red, Snowflake, and Bresse's Prolific. Mr. J. Pink showed, in the same class, Snowflake, American Breadfruit, and Early Oneida. The best six dishes of Potatoes came from Mr. Finlay, Banbury, Oxon, who had small but white and smooth samples of Edgcott Kidney, a seedling, very handsome in shape; also Schoolmaster, one of the best Potatoes grown; Porter's Excelsior, and Lye's Favourite, a yellow-skinned kind tinted with pink. Mr. J. Miller, Hamstead Park, Newbury, showed Rector of Woodstock, Porter's Excelsior, and Magnum Bonum in fine condition. In the class of four varieties of Potatoes Mr. W. Finlay had excellent examples of Lapstone Kidney, Sutton's Magnum Bonum, Blanchard, and Scotch Blue; and Mr. F. Miller had Model, Yorkshire Hero, Blanchard, and Red Garibaldi in good condition. In other collections the best were Snowflake, Porter's Excelsior, International Kidney, Red Garibaldi, and Breadfruit. In competition for six dishes, new kinds not in commerce, Mr. J. Pink, Lees Court, Faversham, showed large and smooth tubers of Early King and Beauty of Hebron, the latter a salmon-coloured Kidney; and Triumph, large, with few eyes. In the same class Mr. Peter McKinlay had fine, even, medium-sized tubers of Woodstock Kidney, Shelbourne, Red Kidney Trophy, Red Round Triumph, and McKinlay's Pride, a white Kidney. Other exhibitors in the same class had American Ice Cream, a round Potato with a rough skin, but evidently of good quality; and Bedford Prolific, round, white, and smooth. Mr. Porter sent seedlings and selected kinds, many of which were of a promising description; also selected garden Turnips, handsome in shape and in every way excellent. Mr. R. Fenn also sent several dishes of new seedling Potatoes. The best single dishes of Kidney Potatoes consisted of the old Ashleaf, Ashleaf Kidney, Lapstone, Fenn's Early White Kidney, and Yorkshire Hero. The best coloured Kidneys were Purple Ashleaf, Garibaldi, and Fenn's Bountiful. The best round coloured Potatoes were Red Emperor, Blanchard, and Main Crop; and the best round white Potatoes were Handsworth Early, Porter's Excelsior, and Schoolmaster. Extensive miscellaneous collections were shown by some of the principal trade growers. Messrs. Sutton & Sons exhibited fifty dishes of selected show varieties, including the new Woodstock Kidney, a beautifully shaped round-skinned variety of great promise; also fine examples of Magnum Bonum, Rector of Woodstock, Yorkshire Hero, Early Oxford, and Sutton's King of Potatoes. Messrs. Carter & Co. exhibited little mounds of Improved Magnum Bonum grown at Sandringham, Snowflake, Bresse's Prolific, Schoolmaster, Carter's Excelsior, and other varieties of superior merit; and Messrs. Hooper & Co. sent twenty-two baskets, principally of American varieties.

A complete list of the prizes awarded at both the above shows will be found in our advertising columns.

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

DIVERSITY OF FORM AND COLOUR IN PLANTS

WHEN we consider the wealth of plants both flowering and fine-foliaged which are adapted for general culture in our gardens we may not unreasonably expect to find a great amount of variety therein. It would appear, however, that adherence to fashion which Alphonse Karr has so admirably satirised still so far affects the gardening world as to produce a certain amount of sameness and uniformity in our pleasure grounds. Many plants undeniably useful and highly decorative are but sparingly met with, and their merits receive but partial recognition. So long as the rage for bright, glaring colours and strong effects exists, so long will this state of affairs continue. Whilst plants are only valued for the effect which they produce in crowded masses we shall not see much alteration in our present system, and many of our best plants will remain in unmerited oblivion. I should be sorry to see our Pelargoniums, Verbenas, and Calceolarias banished from our gardens, but I should like to see them oftener than they are in contrast with other plants. Let us take, for instance, the Pentstemon. How seldom do we see a well-cared-for collection, and yet here is a plant distinct enough in growth and inflorescence to render its presence desirable in any garden. Then there is the Antirrhinum, possessing distinctive features of its own; *Lobelia fulgens*, too, a noble plant, but seldom seen in good condition. Annuals, again, are too sparingly employed in a general way. What can surpass *Phlox Drummondii* and its varieties for delicacy and brilliancy of colour? The *Zinnia*, too, the *Aster*, and the *Stock* are not to be surpassed for effect; and yet for one bed or patch of such subjects as these one may count twenty of the so-called bedding plants. These, too, are but a few of the great numbers which deserve mention, but my object is not so much to give a list of desirable subjects as to show how very easily uniformity and sameness may be made to yield to that diversity of form and colour, which is the delight of the true plant lover. It is to be regretted that there is not a more general attempt, at least in small gardens, to stamp each one with a character and individuality wholly its own. We sometimes see a garden where the owner, disregarding the prejudices of fashion, has accumulated the plants which he loves best, and placed them in such situations as are most congenial to them. Such a garden to whoever cherishes plants for their individual worth, and who finds a charm in each and every kind, is a never ending source of pleasure. Many conceive that when they have succeeded in introducing all the colours of the rainbow into their parterres they have done pretty well all that is needful to secure a good effect. This is, however, far from being the case, as I hold that diversity of form rather than variety of colour is the main feature to be kept in view, either in planting permanently or merely for the summer season. It has probably fallen to the lot of some to have casually come across a garden which, although not more favoured in extent and situation than many others, possessed an indescribable charm; yet when this same garden was, as it were, analysed, it may have been found that the charm really consisted in the use of subjects which contrasted and yet harmonised with each other. As an instance, I will take the *Pampas Grass*. Where does it produce the best effect? Not isolated upon an open expanse of Grass, but where it is in proximity with rigid, close-growing trees and shrubs. Or take, again, a large *Fuchsia* standing in the midst of a carpet of variegated *Periwinkle*; here we get diversity of form combined with variety of colour. In what does the interest belonging to the Fernery, the Alpine rockwork, the rustic rootwork, reside? Simply in its not only affording a complete contrast to everything else, but in producing in itself innumerable variations. It is noticeable, too, that these effects may be easily obtained

by employing plants of easy culture and of a comparatively hardy character; we have no need to ransack our stores for this purpose. The hardy Ferns are as beautiful as exotic ones, and variation in foliage and general growth may be found amongst those plants which require but little protection and need but little care. Variety is to be obtained not only by means of the introduction of plants, trees, or shrubs possessing distinctive characteristics, but also by happy and tasteful combinations. An isolated tree, around the trunk and amongst the branches of which rambles some hardy climbing plant, and at the foot of which a tuft of some graceful Grass, a *Fuchsia*, or hardy Fern springs up irregularly from amidst a carpet of Ivy, will impart an air of freedom and natural grace to a place, and will tone down the formality which more or less exists in all well-kept gardens. In the case of tree and shrub planting, more might be done than is generally attempted with the view of giving variety. We have evergreens of many tints, and varying immensely in habit of growth; monotony in this direction is, therefore, inexcusable. It is really not more difficult to obtain variety in small gardens than in those of greater extent, the only difference being that suitable subjects must be chosen. There must also be a resolute determination to avoid repetition; never retain a quantity of any one plant because it is exceptionally attractive, as in the end it will, by excluding others, become uninteresting. My advice would be to select judiciously plants of each kind sparingly, and above all make a study of the various habits and tints of vegetable forms, in order to produce tasteful effects and harmonious combinations. If instead of emulating the blaze of large establishments and public gardens, amateurs would allow more scope to their individual tastes and inclinations, choosing the plants they like instead of adhering strictly to those which happen to be most in vogue, they would find more true enjoyment in their gardens than they now do, and we should have the pleasure of occasionally seeing plants at their highest stage of development which are but rarely seen or are consigned to some out-of-the-way spot where they get but little chance of developing their true character.

Byfleet.

J. CORNHILL.

SWEET-SCENTED STOVE PLANTS.

QUISQUALIS INDICA.

How seldom does one meet with this old-fashioned, sweet-scented, free-flowering plant! We have a fine specimen of it in a stove, in which there is also a large plant of *Stephanotis floribunda*. Either alone are among the sweetest of all plants; but the two together are superb, and a puzzle to most visitors. After a few sniffs, "Stephanotis? Yes; but how peculiar! What a sweet, spicy fragrance! different from any I have ever smelt before." And not one in a hundred ever saw the *Quisqualis* before, with its pretty green leaves and graceful, pendent bunches of rose-coloured flowers. To do the plant justice, it should be planted out in the stove and a few main branches trained along the roof just under the glass. The usual mixture of peat and loam suits it well. It may be spurred closely in during winter, something in the way of a Grape Vine, to give light to the other plants in the house. It will break away freely in the spring, and must not be pruned any more, as it flowers on the ends of the current year's wood. It does best, too, wholly untrained, allowing the spray to droop down gracefully from the glass. Numbers of shoots are often produced. The weakest should in such cases be cut clean out. Strong shoots often also break out and run great distances. One or more of these should be trained up to the roof in all cases where room can be found or made for them. These will break out into laterals, and continue flowering right up into the winter. As the first shoots will begin to flower in May or June, a long succession of bloom may thus be gathered from the same plant. The flowers are not unlike a pink *Bouvardia* in form and appearance. Their colour is also almost unique among flowers varying with their age and position in regard to the light from almost white to a decided rose or red. The fragrance is also unique—say *Stephanotis* with a dash of Vanilla in it, or rather *Quisqualis*, for there is no odour known to me so distinct, while nothing could be more pleasant. The plant has a drawback which may have helped to limit its cultiva-

tion. Hardly is a branch of it cut when its flowers drop off one by one, their long tubes falling from the stems. But for this failing, few flowers would be more useful for drooping over the sides of small vases and baskets than the *Quisqualis indica*. By cutting the bunches as the flowers begin to open, and handling them carefully, it may still be used for these purposes; but this peculiar failing of the *Quisqualis* only renders the blossoms more useful for other purposes. The flowers should be picked singly, and used for the furnishing of small glasses, baskets, pans, &c., or for bouquets. This prevents the large sacrifice of advancing buds incident to the cutting off branchlets of the *Quisqualis*, and preserves the flowers much longer sweet and fresh. Garnished with Moss or small Ferns, few flowers are more effective in small glasses than those of the *Quisqualis*; they also look well with *Stephanotis*, white *Bourvardias*, *Jasmines*, white *Primroses*, *Cyclamens*, or *Snowdrops*—almost the only flowers they go well with. For bouquet or wreath work blooms of *Quisqualis* are most effective in threes; used thus for the fringe of a bouquet, the flowers give a unique effect and fragrance, and are generally much admired by all lovers of chaste colours and choice perfumes. A spray of damp Moss twisted round the trio of blossoms preserves them fresh and sweet. The single flowers, placed in water, also last several days. Finally, the *Quisqualis* is an exceptionally clean plant; aphides, nor scale, nor thrips will have none of it, and, although growing side by side with the *Stephanotis*, a mealy bug seldom or never touches it. D. T. FISU.

DWARF NASTURTIIUMS.

THE exceedingly brilliant colours seen just now in these gay, but tender, garden plants resemble in one respect the leaves of the Virginian Creeper, which are never so beautiful as just before death. A sharp white frost may come at any moment, and destroy not only the beauty of the flowers, but also the life of the plant. Few annuals come into flower more quickly than these *Nasturtiums*; few bloom more constantly or longer. Modern styles of bedding have hardly dealt with the *Nasturtium*, especially the dwarf kinds. Such rich, bold colours as are found in the compactum strains—sorts that must not be confounded with the Tom Thumb kinds—are marvellously effective when seen in masses, and if the soil be somewhat poor so much the greater the mass of bloom. *Bedfont Rival*, a deep, brilliant orange-scarlet, has large flowers of fine form, and it is a robust grower. Beauty of *Malvern* is very floriferous, but the flowers are smaller and have less depth of colour. *Hunteri*, noticed in THE GARDEN (p. 236), flowers exceedingly freely, but the growth is small and dwarf; this is better fitted for moist situations, whilst a robust kind, such as *Bedfont Rival*, does remarkably well under drier conditions. The most effective yellow, the flowers of which are profusely produced, is *compactum anreum*, a good companion to the scarlet kind. *Lustrous* is an especially rich-coloured kind, having deep crimson-scarlet flowers and leaves of a dark hue; though a little less floriferous than the other sorts, it is more brilliant and effective as a bedder because of the deep rich tints of its flowers. A very pleasing and altogether unusual colour is found in *carminatum*, a rich carmine-red variety of the large-flowered scarlet kind; this is very beautiful, and produces a most striking mass of colour. The forms of compactum are so constant, that they are never without flowers from first to last. In this respect these outshine the Tom Thumb kinds, which have a short season of flower and then collapse. They can be had good from seed, and generally true, but it must be understood that actual truthfulness as regards varieties can only be ensured by means of propagation by cuttings. Fortunately, cuttings are furnished by the plants in great abundance, and these will strike freely anywhere under glass if put in about the middle of September. A few dozens put into store pots will yield a large number of cuttings in spring, and these spring-struck plants make the best for summer bedding. Plants from cuttings also make less leafage, furnish more bloom, and, curiously enough, produce little seed, but what is so produced may be relied upon to fairly reproduce the parents if no other kinds of *Nasturtium* are growing near. In growing these for seed it is the practice to weed out everything from the stock that is not true. With such care,

the truthfulness of the seed produce may be fairly maintained. As the plants cover the ground rapidly, it is found advisable to rake the surface of the soil smooth and fine, so that when the seed is dropped, as it doubtless will be largely during the summer, it can be gathered up by hand without much difficulty. The plants are uprooted early in October, the seed shed is cleared up, and the plants are placed in it. These live for some time, and soon perfect the seed which is still upon them. The late seed takes some time to fully mature, and it is needful to keep it spread out thinly on cloths under glass for several weeks before it is fit for storing. The Tom Thumb kinds are sown in large breadths in the open ground in spring, but the compactum race grow too freely when so raised, and are best produced under glass and then planted out. Treated thus, they bloom earlier, are more compact, and can be planted out to succeed spring bedding plants. All who love rich masses of colour will find these dwarf *Nasturtiums* or *Tropaeolums* worth cultivation. A. D.

Fine Willow Trees.—I have lately seen some astonishingly large and picturesque Willows in Germany, and should say the nobler Willows deserve more attention at the hands of planters, even from the point of view of their appearance when well grown and old. Perhaps Mr. Berry, or Mr. Syme, or some of the correspondents of THE GARDEN will tell us what kinds (among the very large number of Willows known and described) are most remarkable for their size and picturesque effects. Of course such questions as size, colour at various seasons, and habit are quite beneath the notice of a large number of botanists, and cannot be found alluded to in their works. These, for the present, must be left to what the "Journal of Botany," advancing half a step across the imaginary boundary which Herbert Spencer and the philosophers tell us does not exist, terms "semi-scientific" people.—J. H.

The Wild Honeysuckle.—I never remember to have seen this Honeysuckle flower in such profusion as it has done this season. The hedges in most places in this neighbourhood have been crowded with its beautiful flowers, the heads of which have been unusually large in size; this I attribute to the moist season. Its beauty, however, is shown off to the best advantage when it climbs high up amongst the Oak, Hazel, and other trees, forming here and there masses of bloom which contrast in the most charming manner with the dark coloured foliage which enrounds them. Nothing can be more pleasing than this combination of flower and verdure, and it seems to illustrate in the most perfect manner how many of our climbing plants might be utilised.—J. CORNILL, *Byfleet*.

Distribution of Bedding Plants.—Mr. Lindsey Wood, of South Hill, near Chester-le-Street, has requested his gardener to distribute the whole of his bedding plants among each of the working classes in the neighbourhood as like to apply at South Hill for them. Many, it is hoped, will embrace the opportunity of securing such plants as they require, and it will be hard indeed if, out of half-a-dozen *Pelargoniums* and *Calceolarias*, the average intelligent cottager cannot save at least one half.—TYNEDALE.

— We are requested to announce that the Commissioners of Her Majesty's Works and Public Buildings intend to distribute this autumn among the working classes and the poor inhabitants of London the surplus bedding-out plants in Battersea, Hyde, the Regent's, and Victoria Parks, and in the Royal Gardens, Kew, and Pleasure Gardens, Hampton Court. If the clergy, school committees, and others interested will make application to the superintendent of the park nearest to their respective parishes, or to the director of the Royal Gardens, Kew, or the superintendent of Hampton Court Gardens, in the case of persons residing in those neighbourhoods, they will receive early intimation of the number of plants that can be allotted to each applicant and of the time and manner of their distribution.

Carters' Improved Magnum Bonum Potato.—Last spring I purchased from Messrs. Carter & Co. 14 lb. of this Potato. The produce of the seed has in the last few weeks been taken up and carefully weighed, and the result was 332 lb. of good fit-for-table Potatoes, almost entirely free from disease, and when I say almost entirely free from disease, I mean that ninety-nine in every hundred would make a good show in a vegetable dish, and this in a wet season and in damp Lincolnshire.—THOMAS WHITE, *Scamblesby Vicarage, Horncastle*.

NOTES OF THE WEEK.

Helianthus orgyalis in Flower.—This plant, so often recommended for its foliage, is beautiful when in flower, the blooms being numerous and without that coarseness which is characteristic of a good many of the Composites. In fact, I like them well enough to cut them for large vases, cutting off for this purpose about 1½ ft. of the shoot. The effect of large plants is now (September 29) very fine.—J. H.

Catalpa Fruit.—Among the specialties of this season may be mentioned the fruiting of the Catalpa. I have never before seen the fruit in England, but my tree is now covered with it. The pods are not so fine as I have seen them in France, being only about 6 in. in length, but some may yet get longer. In France I have seen them over 1 ft. in length.—HENRY N. ELLACOMBE, *Bitton Vicarage, near Bristol*.

Corydalis lutea.—I have still some very large tufts of this old and graceful plant that are to-day (Sept. 27) as full of flower as they are often seen in midsummer. It seems to me a plant of the highest merit and one partially neglected, perhaps owing to its easy culture and its being common in some localities. On ruins, on walls, even on high and dry walls in perfect repair, on the rough and dry rock garden, or on borders dry or moist, it seems equally at home and equally useful.—J. H.

Gigantic Rhododendron.—A specimen of Rhododendron ponticum growing in the beautiful grounds of Earl Annesley, at Castlewellan, Co. Down, measures 252 ft. in circumference and 23 ft. high. It is in vigorous health, and is by far the largest Rhododendron I have seen. Is any one acquainted with a larger?—T. SMITH.

The White Lapageria.—We have received from Mr. Calley, gardener to Edward Salt, Esq., Fernisburst, Shipley, near Leeds, a cluster of this Lapageria consisting of eleven open flowers and one bud. The blooms are individually very large in size, of great substance, and of a pure waxy white. On the red kind in the same establishment there are also just now several hundred blooms open.

New White Glove Carnation.—I noticed a paragraph in THE GARDEN the other day (p. 234) referring to my white Glove Carnation Susan Askey. It comes into bloom early in July, and continues to produce blooms until frosty weather sets in, each flower being large in size, pure white, and delicately fragrant.—WILLIAM CULVERWELL, *Thorpe Perrow*.

Pontederia crassipes.—This is unusually luxuriant in the Victoria tank in the Royal Botanic Gardens, Regent's Park. The stalk of one of the leaves which we measured was 30 in. in length, and the leaf itself measured 11 in. one way and 11½ in. the other. This Pontederia is one of the most interesting of water plants for growing in ordinary sitting rooms. A woodcut illustration of it will be found in THE GARDEN, Vol. VI., p. 171.

Bananas in Covent Garden.—These are just now very plentiful, and the clusters are larger than we ever remember to have previously seen them. The pipe, too, are individually very large and plump, and as many as 120 may be counted in a cluster. They are suspended in the shops, where, with a little warmth and plenty of air, they ripen perfectly.

Choice Orchids in Bloom at Chelsea.—The Orchid houses in Messrs. Veitch's nursery are just beginning to be attractive. In addition to many of the well-known kinds of Lady's-slippers, Phalæ-nopsis, and Odontoglossums, there are also now in flower several Orchids of a new description. Among these we may mention Dendrobium Guibberti, a kind in the way of D. densiflorum, but shorter in habit of growth, and having larger bulbs and much larger trusses of blossoms, some of them measuring upwards of 12 in. in length. The flowers, which have a golden-yellow lip and cream-coloured petals and sepals, are very showy, rendering this one of the most attractive of Dendrobiums. D. bigibbum superbum is also finely in bloom, and, contrasted with the type, the superiority in size and colour of its flowers can at once be seen. A new Cattleya, the result of a cross between C. labiata and C. Loddigesii, raised ten years ago, and now flowering for the first time, is a good addition to hybrid Cattleyas; the petals are of a rich violet colour, and the lip is broadly tipped with purple. A very fine variety of Miltonia Moreliana is also in flower, as are likewise good specimens of the sweet-scented Ptilanma fragrans. Plants of Oncidium Forbesi, growing on blocks of wood suspended from the roof, are very attractive, bearing, as they do, numerous graceful spikes of rich chocolate-gold-edged blossoms. Phalæ-nopsis rosea may here be found in better condition than one usually sees it, and recently-imported varieties of P. grandiflora show a great improvement as regards the size of their flowers on those hitherto in cultivation. Odontoglossum crispum and O.

vexillarium are furnished with strong spikes of flowers, which will soon be open. In addition to those already named, there are finely in bloom Dendrobium giganteum, Indian Crocuss (Peionis), Odontoglossum Andersonianum, Cælogyne Cummingi, Masdevallia Veitchi, and a host of other well-known Orchids.

The Pampas Grass at Torquay.—There is a plant of Pampas Grass here which is truly worthy of a passing notice. It is furnished with from fifty to sixty flowering spikes, rising to a height of 10½ ft. The foliage or Grass is very abundant and about 9 ft. high, and its girth, on the green sward beneath, is some 30 ft. It is growing on a grassy slope facing S.S.W.—AN OLD SAILOR.

Alnwick Seedling Grape.—Really good new fruits are comparatively scarce, and especially so in the case of Grapes. This new variety, however, which has been awarded a first-class certificate at South Kensington and at the Crystal Palace, is likely to prove more valuable than many of the new kinds which have been sent out during the last few years. It is a noble-looking Grape, and on this account, as well as on account of its good flavour, it is likely to prove a valuable kind for market purposes.

Torenia Bailloni.—This pretty greenhouse annual, introduced by Messrs. Veitch & Sons, of Chelsea, may now be seen in flower in quantity in their nursery. Its blossoms at present are not produced in such numbers at one time as are those of T. Fournieri, but they open more successively. It is a good plant and associates well with the blue-flowered T. Fournieri and asiatica.

Daphne rupestris.—For some weeks past this charming diminutive Alpine shrub has been and is still beautifully in flower on the rockwork in the York Nurseries. The flowers are large, bright, rosy-pink in colour, and agreeably fragrant. It usually expands its blossoms in the spring, so that those now open are out of season, but none the less welcome. The plant is only of slow growth, taking some years to form a moderate-sized tuft, but then it is a gem well worth waiting for. It seems to thrive in very stony and peaty earth with abundance of white sand, and should be planted in a well-drained position, but not a dry one.—R. P.

New Crossbred Race of Nerines.—Messrs. E. G. Henderson have been trying some experiments with the view of improving the varieties of this useful bulbous plant. The aim, so far, has been to produce kinds which are not naked flowered, but which have leaves as well as flowers. This has been secured by crossing an evergreen variety, the flowers of which are almost useless, with N. coruscans major. The seedlings resulting from this cross now in flower are well supplied with foliage, whilst the flowers are good, well varied in colour, and distinct from those of any other kinds of Nerines. By further attention to hybridisation there can be no doubt that some important kinds will be forthcoming. Being easily grown and very attractive when in bloom, attention may be paid to their improvement with advantage.

Vallota purpurea in Covent Garden.—The flowers of this useful plant are now amongst the showiest and most prized in Covent Garden for use in large bouquets and other floral devices. They last for a considerable time in water, and if the whole spike be cut the unexpanded blooms open perfectly afterwards. In this market may also be observed Vallotas in the shape of small plants in 5-in. and 6-in. pots, each furnished with a strong flower spike surmounted by from six to seven brilliant blossoms and buds. Though generally in flower in autumn, the Vallota, by careful judgment, may be induced to bloom in succession far into the winter. This can be effected by growing the plants on liberally after flowering instead of allowing them to take care of themselves and go to rest shortly afterwards, as is usually done.

Tree Carnations at St. John's Wood.—There is just now a fine display of perpetual-flowering Carnations in the Pine-apple Nursery. The plants, which consist of some 4000, are the produce of cuttings put in last March in pots placed in a warm house near the glass. When well rooted they were potted on and gradually hardened off, and in August they were potted in 5-in. pots in good, friable, yellow loam. The plants are furnished with strong shoots, which bear from five to eight large buds and blossoms. At this season of the year few flowers are more useful or more highly prized, either in a cut state or on the plants, than are those of these Carnations, and considering how very easily they can be grown, and in what a short time good flowering plants may be produced, even in the smallest gardens, there is no reason why abundance of Carnations in full bloom could not be had for the window or the small conservatory during the greater part of the winter months.

Ceanothus azureus.—One of the most conspicuous plants now in flower on walls is this lovely Ceanothus, the spikes of azure blue blossoms on which are produced in great abundance.—J. G.

NOTES FROM KEW.

Hardy Herbaceous Plants.—With the exception of many Asters and other Composites, the best of which have already been noted, there are at present few hardy flowers of interest. One of the best of autumnal-flowering plants for the mixed border is *Pyrethrum nigrinum*—a native of Hungary—a very floriferous kind about 4 ft. high; the large flower heads, which look like an enlarged Ox-eye Daisy, last a long time in full beauty, the cold and wet not seeming to affect them to any extent. On one of the walls is a plant named *Eupatoria fragrantissima*; it has glossy, green leaves and large flat-topped panicles of white blossoms. *Zauschneria californica*, with its deep red flowers and neat habit, is also worthy of mention on account of the length of time it keeps producing its handsome blossoms. *Brickellia grandiflora*, a North American plant rarely seen in cultivation, has panicles of drooping, pale, straw-coloured flower heads; it is an elegant plant growing from 18 in. to 2 ft. high. *Francoa ramosa*, a Chilian herb, has tall flower stems, bearing at their extremities racemes of pale, rose-tinted flowers, each of the four petals bearing a deeper rose-coloured blotch in its centre.

Greenhouse Plants.—*Oxalis odorata* and *rigida* are charming little plants; the first has umbels of sweet-scented, mauve-coloured flowers; the other has large, rosy-red blossoms. A golden variegated form of *Ophiopogon spicatus* is flowering freely in the winter garden; the beautifully-variegated foliage and spikes of pleasing blue flowers afford an agreeable contrast. Another plant, a native of Japan, *Polygonum filiforme variegatum*, growing about 1 ft. high, is sure to be a great favourite with all who have any leaning towards plants with variegated leaves, the colouring being very constant and most effective. *Anigostanthus rufus*, from Australia, has grassy leaves and a tall flower stem bearing long, curved, deep-red flowers; it is very distinct and peculiar in appearance, decidedly ornamental, and of the easiest culture. *Begonia octopetala*, from Natal, is a handsome kind, having large leaves with red stalks, and a stout scape, also red, bearing large white blossoms.

Stove Plants.—*Plumieria lutea*, a Peruvian member of the Dogbane family, is now in flower; it is a small branching tree with its leaves, which are more than 1 ft. long—deep glossy green on the upper surface and paler below—crowded at the ends of the branches. The very sweet-scented flowers measure about 4 in. across, and are pale pink in colour with a broad, pale golden-yellow base. *Coffea travancorensis*, an East Indian shrub, has a neat hushy habit, pretty dark green leaves and a profusion of pure white, deliciously-scented blossoms; as a stove shrub it is equal to many *Gardenias*. *Episcia erythropus*, a charming plant introduced a few years ago from New Grenada by Messrs. Veitch, has tufted leaves with clusters of very shortly-stalked flowers springing from their axils; the leaves are about 1 ft. long, are bright green above, pale and suffused with red beneath, the midrib, nerves, and stout leaf-stalk being blood-red; the flowers, nearly 1 in. in diameter, are pale flesh-coloured, dotted with orange-purple spots within the yellow throat. *Dichorisandra thyrsiflora*, a native of Brazil, has panicles of splendid dark blue blossoms; this desirable plant lasts a long time in bloom, and also succeeds well under greenhouse treatment.—†.

A FEW GOOD KINDS OF OXALIS.

The following hardy kinds of *Oxalis*, which are now flowering very freely, include some of the most beautiful, as well as the rarest, of this very numerous family:—

Nine-leaved Oxalis (*O. enneaphylla*) is a charming species inhabiting the Falkland Islands. It is one of the stemless section of the genus, with a creeping, scaly, underground stem, and a tuft of leaves from 3 in. to 4 in. long, with from nine to twenty leaflets, reversed heart-shaped, and very glaucous. The flowers are freely produced, and rise just above the leaves; they are funnel-shaped, from 1 in. to 1½ in. across, and of snowy whiteness, rendering it one of the most beautiful and attractive amongst plants that bloom at this season. It is yet very rare in gardens.

Lobed Oxalis (*O. lobata*).—This, which is a native of Chili, is a better-known kind, and a veritable little gem. It is also a stemless species with slender leaf stalks, and three deeply-lobed bright green leaflets, so arranged that two pairs of lobes form a horizontal square, the two others being in a more or less vertical position. The blossoms, which are produced considerably beyond the leaves, are borne singly on slender stalks, and are about ½ in. across, and of a rich yellow colour, the centre being delicately pencilled with chocolate. It is very free flowering, and is a bright little plant during sunshine.

Smith's Oxalis (*O. Smithi*).—This rather rare kind grows about 6 in. high; it has slender leafstalks, and three leaflets cleft almost to

the base nearly 2 in. long and very narrow. The flowers, which are borne singly, are 1 in. across and of a bright rose colour.

O. Bowisana, from the Cape, is also one of the finest in the genus; it has long leaves, and broad, deep green leaflets. The flowers are borne in an umbel-like manner, on stalks nearly 1 ft. high. They open in quick succession, are over 1 in. across, and of a deep rose colour, with a greenish-yellow centre.

There are also several others of less interest and beauty, such as the pink *O. floribunda* and *purpurata*, the fine yellow *O. Valdiviana*, and the white variety of *O. floribunda*, all of which are, however, worth attention. *O. enneaphylla*, and *O. lobata* require to be grown on well-drained portions of rock-work in company with other choice Alpines. The rest will take care of themselves if planted in a border consisting of light soil. A.

Rubus cratægifolius.—This is a distinct and vigorous species of *Rubus*, not scrambling, like our native kinds, but erect or arched, and quite strong enough to support itself without stakes, and grow to a height of from 6 ft. to 8 ft. The foliage is large, and turns a fine red late in autumn. It bears a great number of fruit of good flavour. It is one of Dr. Regel's introductions from the Amoor River, and, if we mistake not, was "sent out" by Messrs. Fröbel, of Zurich.

Hibiscus palustris in Flower.—We notice this remarkable hardy plant in flower in the Botanic Garden at Munich, but as yet only the first buds are opened. It is probable these hardy American *Hibiscuses* require a higher temperature than that of Western or Central Europe to flower well. Some of the finer kinds would be worth a trial in pots in orchard houses or winter gardens. Flowering late they might prove useful.—G.

Macleaya cordata Well Grown.—It is quite surprising to notice the fine proportions this plant presents in good deep soil. I have a plant of which many of the leaves measure 15 in. in length; a more striking object at all times is rarely seen in the garden. It is now as fine, bearing its numerous erect panicles of seed-pods, as it was when in flower. The plant differs from a great number of herbaceous ones in the fine picturesque effect it affords, at all seasons, coming up, half-grown, in flower, or, as now in autumn, in seed. Therefore, it is most valuable for planting by itself (in a group of two or three plants) on the Grass in deep, rich, and not wet soil, where it may attain such proportions as those to which I allude.—H.

Potentilla speciosa.—This is a silvery-leaved species which promises to prove an interesting rock plant, and will also be attractive to those interested in silvery-leaved or variegated plants. It is in the collection of M. Fröbel at Zurich.

Malva crispa as a Fine-foliaged Plant.—This free-growing plant has attained fine proportions in my garden from self-sown seeds that, of course, came up by chance. They reached 9 ft. and 10 ft. in height, and are of a handsome pyramidal habit.—H.

Arnuncus sylvestris.—I received our now well-known *Spiraea Arnuncus* under this name, from a Continental nursery, and the hint may be useful. As to the question of names, it matters little so long as they represent distinct plants, but it is desirable to avoid duplicates in some cases, especially when, as in this case, we can procure them at home. The best varieties (for there are green-flowered poor ones) of this plant are extremely valuable for the mixed border, the margins of shrubberies, the wild garden, or for groups of hardy, fine-foliaged plants, for the leaves, as well as the white plumes of flowers, are handsome.—J. H.

A Good Border Plant.—This may truly be said of Messrs. Veitch's *Begonia Queen of the Whites* now profusely in bloom in their Chelsea nursery, where it is planted at the corner of a piece of rockwork. In this position it grows well, and its flower spikes, which are still being abundantly produced, are remarkably strong, and yield a profusion of pure white, sweet-scented blossoms. Several large frames filled with plants of this *Begonia* are just now a sheet of blossom, a condition in which they would keep till Christmas, provided they were subjected to a dry, airy atmosphere; and where white flowers are in demand during the winter months, this *Begonia*, if grown under favourable conditions, will supply large quantities.—S.

Loasa volcanica.—This was discovered in 1876 at the foot of the volcano Curazon, in the Republic of Ecuador, by M. André, who named and introduced it into Europe. It flowered for the first time with M. André in May, 1877, from the seed obtained by him in 1876. The following year, the same plant was sent to M. Huber at Hyères by Mr. Wallis, and introduced by him into commerce under the name of *Loasa Wallisi*.—A.

THE FLOWER GARDEN.

THE WILD BALSAM APPLE OR CUCUMBER.

IN "Home Topics" mention has been made of the wild Cucumber, more generally known as the wild Balsam Apple, as a desirable climber. Of late years many exotic ornamental climbers have been introduced, and while some of them may be more showy, none are more interesting than this native. Though often called the wild Cucumber, it is not much like the Cucumber; it belongs, however, to the same family, but differs in its manner of flowering and in its fruit from the Squash, Melon, Cucumber, and other common plants of the family. The botanical name is *Echinocystis lobata*, the generic name being from the Greek for hedgehog, and bladder, as its fruit is bladdery and prickly, and the specific name has reference to the lobes of the leaves. It is found from the western part of New England to Missouri, mostly in the Northern States. It

The Wild Balsam Apple or Cucumber.

is an annual, climbing 10 ft. or 15 ft. high, by means of its long and abundant three-forked tendrils. The nearly smooth leaves measure from 3 in. to 5 in. across, and have five sharp lobes. The flowers are of two kinds in the same plant; the sterile, or staminate flowers are in compound clusters, often 12 in. long, from the axils of the leaves; the individual flowers small and white, consisting of six narrow petals united at the base, and three united stamens. The pistillate or fertile flowers are solitary, or two or three together from the same axil. The accompanying wood-cut represents a small portion of the plant, though much reduced in size. The fruit is oval, or nearly globular, about 2 in. long, and has on its surface numerous weak prickles. When ripe, it bursts at the top, the rind breaking open irregularly, to liberate the seeds, of which there are four large, blackish ones about the size of Water Melon seeds, though thicker. They are contained in pairs in two oblong cells formed of fibres woven into a handsome net-work. Like the sponge Cucumber, the fruit of this in ripening becomes

very fibrous within, and makes a fine object when skeletonised. This is a capital plant wherever a quick growing climber is needed; we know an instance in which an unsightly wood-pile was converted into a bank of verdure; and last autumn we were at a charming residence near Lake Michigan where the dining-room windows were draped with this plant. It is almost constantly in flower, and its fragrance is very agreeable; the great abundance of tendrils and the curious way in which they dispose themselves, add to its gracefulness, while the fruit is ornamental when green, and exhibits an interesting structure when ripe.—"American Agriculturist."

HINTS TO IMPORTERS OF LILY BULBS.

"THE time to collect Lilies is after the flowering season is over, when the leaves turn yellow and fall off, and the stems die down." This is the advice which we are told is generally given to Lily collectors. Were I to advise, I would say: "Do not wait until after the flowering season is over, nor even until the plants are in full bloom, but collect them just when the earliest flower buds are beginning to open, or even somewhat earlier, so that the bulbs may arrive in England six weeks or two months earlier than we generally see them." I admit that this advice is so contrary to all established rule, that it will require the fullest explanation if it is to have the desired effect. All that we want is that the new bulbs should arrive in this country as early as possible in the fittest state for growing and thriving, if properly planted in the ground. When I say the new bulbs, it is necessary that it should be distinctly understood that I do not mean the lumps of decaying matter that are usually offered for sale as Lily bulbs, as these are in reality nothing more than the temporary envelopes of the new, but true living bulbs. During this last season I have lifted and replanted all my collection as the different kinds went out of bloom; and as I purpose now to communicate the result of my past and present experiments on the points in question, offering nothing for consideration but substantial facts, I trust I may be favoured with the best attention of those who are interested in the matter.

Beginning with my communication at page 237, Sept. 14, I would first direct attention to the fact that, on looking at the photographic representation and my explanation, we have there placed before our eyes in *L. candidum*, as nearly as possible, the condition of all Lily bulbs, early or late flowering, when lifted out of the ground, "after the flowering season is over," for exportation to this country. As the roots of the new bulb, it will be seen, have progressed too far (from 5 in. to 7 in.) to be lifted without sustaining injury, let us go back a few weeks and try if we can find them in a better state. If we turn to page 60, July 20, we there see that during the first fortnight in May I lifted out of the ground thirty-three specimens, small and great, one of which, No. 33, was *L. candidum*, taken from the same clump as that at p. 237. The roots of the new bulb were then nearly 2 in. long, and this, it is important to notice, was six weeks before the parent bulbs of the same clump began to bloom. As a practical proof that cutting down the stems and lifting the bulbs so early do not affect the growth of the new bulbs, I may here repeat that some of the bulbs which I lifted with No. 33, but which were not required for dissection, I replanted, and they are now sending up their radical leaves 6 in. and 7 in. above the ground, strong, fresh, and green. I may also here repeat, that for every day the stems are allowed to remain after flowering they are, in like proportion, robbing the new bulbs of their legitimate sap, the new bulbs, remember, not the old ones. Passing over the intermediate bloomers—for a description of them would be nearly a repetition of what I have already said—I now come to *L. speciosum*. On Sept. 17 I cut down all the stems to within 3 in. or 4 in. of the ground, and then, assisted by a very intelligent cultivator, who can speak as to the facts, we lifted the bulbs very carefully so as to injure the new roots as little as possible. We saw at a glance that the new roots had extended from 4 in. to 6 in. into the ground, and were, in appearance, quite in accordance with what has already been described at p. 60 in connection with *L. candidum*, the old roots being dead and dying. So far back as the middle of July I had also lifted some bulbs of *L. specio-*

sum, and found that the new roots were then about $\frac{1}{2}$ in. long, the roots when they first begin to protrude being white and plump, with rounded ends, not fibrous. My clumps of *L. auratum* continuing later in bloom, I did not lift and replant until September 25, when I found the new roots in every respect similar to those of *L. speciosum*. These are facts worthy of consideration, but there is another fact of no less importance. If the bulbs in their native habitats be not lifted till after the leaves turn yellow and the stems die down, the germ (or origin of the next new bulb) will have been liberated, and, in thousands of cases, will have been destroyed before they can reach this country, and, consequently, though the new bulb may bloom one year, the successional seed bud being destroyed, there will be no more successional bloom; whereas, if lifted just as they are beginning to open their flower buds, the germ cannot be liberated until after the arrival and planting of the bulbs in this country; after that there can be nothing to check them or the growth of the new roots, for, remember, if the bulbs be lifted late in the season new roots (in place of those that will inevitably die) must be formed at the expense of the sap in the cells of the new bulbs, which would otherwise have been expended in nourishing and developing the new flower stem, causing, besides, much loss of time and a later bloom, as well as the chance of not blooming at all.

In the adoption of a new system the greatest difficulty will be to overcome preconceived notions. Up to the present time, it has been generally believed, both by Lily growers and collectors, that the parts which we handle and look at outwardly are the true bulbs. This opinion is so universal that the Japanese practice is as follows: "In autumn, soon after the stalk has withered, the bulb is taken out of the ground and all the roots (old and new) are removed. It is then exposed to the air about ten or fifteen days, and then replanted sideways, in order that the water may not lodge between the scales, which might be the case if the bulb were placed upright." A worse practice could scarcely be imagined. In the first place, the exposure of the new bulb within the old one to the searching effects of the air is ruinous, as it dries up the sap in the cells which Nature has stored up there for the support and growth of the plant, and the bulb itself shrinks up considerably in less than ten days. In the second place, there is not the slightest necessity for planting the bulb sideways; quite the reverse, for we may water the scales of the old bulb as much as we please without ever touching the interior parts of the new bulb, the scales of which are so firmly packed one upon the other, that it requires some degree of art to separate them without injury. To be convinced of this we have only to look at the illustration on p. 237, where there is not a single loose scale to be seen, except those belonging to the old bulb. But even Dr. Kellogg, of Californian celebrity, appears to have recognised some advantage in the preservation of the gaping scales of the old bulb, for he says, in his cautions to Lily growers: "May not the cultivator, in his undue solicitude, be to blame, and by some shortcoming fail, or from excess, undo by overdoing? Suppose he flood too continuously between loose scales, &c." From this it appears that the old bulb was the only bulb that Dr. Kellogg acknowledged; and from this it is clear that he had never looked deeper into the matter. Yet he says, "Consider the Lilies, how they grow." This is what I have been endeavouring, for many months past, to induce some of your readers to do; but it cannot be done by merely looking at the scales, or outside, of the old bulb. We must go deeper into the matter. To talk of Lily bulbs requiring to be acclimatised in this country is simply the expression of a mistaken fancy, for those who talk so cannot be aware that the same identical bulb that blooms one year never bloomed before, and will never bloom again. To talk also of Lily bulbs not being fit for sale until they have been properly and fully matured, is simply deluding ourselves and others, as Lily bulbs are never fully matured until they are actually in full bloom. A Lily bulb is never dormant, though many believe that at times it is so. In some of its parts it is always growing with less or more activity. When the parent plant is beginning to bloom is the time when there is the least motion in the new bulb for the new roots alone may be said to be moving; and until they move with greater activity, they cannot draw from the soil the nourish-

ment necessary to fill up the cells and swell out the bulk of the new bulb.

This is the time, then, when I recommend importers to have their bulbs taken up and sent to this country without delay after being taken up. If at this time they were taken up, we might have the bulbs in October, instead of seeing them advertised as having just arrived in December. At this time (October) we would have an opportunity of planting them properly, instead of groping about in the midst of frost and snow. Besides this, the old bulb would be in a much fresher condition, and, therefore, calculated to form a better protection to the new bulb during its transit. As to the germ or seed-bud, from the time the old bulb has bloomed until the beginning of the next year the germ goes on growing, but at so infinitesimally slow a rate, that in the first five months it does not grow larger than a canary seed. During the next six months previous to the parent bulb coming into bloom, the rapidity of growth is, however, astonishing. Look at the seed bud on p. 143, February 16, and then at that seed-bud grown up to be a fully-developed bulb, at p. 237, September 14. It will be found, if the height and diameter of both be taken, that during these six months the bulb has grown more than 4000 times what it was as a seed-bud, a rapidity incalculably greater than what Nature assigns to bulblets, offsets, or adventitious buds, for, as Mr. Baker truly remarks, these take not less than three years under the most favourable circumstances before they can develop a flower-bearing stem. It is thus that Nature provides for the reproduction of the plant, or there could be no regular annual bloom. Every Lily bulb may be said to be a double bulb—not a twin bulb, for that is a very different thing, but a double bulb—always growing in a double state, but always keeping twelve months' growth between each bulb. The germ, when liberated by the parent bulb, takes two years from its birth to become a flowering plant, after which it dies. At the end of the first year the appearance of the germ (which we shall call No. 1) is shown grown up by the woodcut at p. 237, minus the radical leaves marked F. In this state, and at this time, it also liberates a germ (to be called No. 2). No. 1 now goes on growing in bulk, until at the end of another year it becomes, as I have said, a flowering plant, and then it dies. No. 2 at this time will also have grown one year, and will be the same size as at p. 237, and will also, like its predecessor, liberate a germ (to be called No. 3). No. 2 now goes on for another year, when it becomes a flowering plant, and then, in its turn, decays and dies. At this time No. 3 is twelve months old, and also becomes a parent bulb, liberating a germ. This is exactly how we stand at the present time, the autumn of 1878. With such a marvellous organisation as Nature here presents to us, it would, therefore, be inconsistent with facts were we to call the Lily either a perennial or an annual, and yet there are many Lily growers who know not that such wonderful action is going on within the old decaying bulbs which they are in the habit of handling, and which they say, and no doubt believe, send up every year a flower-bearing stem from their "precise" centre. What have "Amateur" (p. 198) and M. Max Leichtlin (p. 252) to say to this? In March last the former promised to institute some experiments in reference to this matter, and I am waiting, with some degree of curiosity, to know the result.

DUNEDIN.

TRANSPLANTING AND TOP-DRESSING LILIES.

"R. C. R." (p. 238) was of course right in replanting his *L. speciosum* when the growth showed the soil to be exhausted; the only alternative would have been top-dressing, as practised by Mrs. Newall (p. 200). In our experience here, where Lilies are grown in good soil, manure (liquid or solid) seems undesirable; but as some Lilies have as much, though shorter and finer, root growth above the bulb as below, it is possible that encouraging this growth of the surface roots may be good practice. In pot Lilies in the orchard house we find it well to repot in fresh soil every year. In some beds at the entrance of a carriage drive, where large bulbs of *L. tigrinum* Fortunei were planted very thickly for the sake of the immediate effect of close-growing large clumps, last year these were grand and much admired; this year, though very beautiful, the plants were hardly as strong as last, showing that their bed, though made with deep, good soil, was becoming exhausted. In one of these beds I

propose to change the soil, in another to top-dress for the sake of experiment. We see every year the effect of top-dressing in the case of our orchard house trees, which are in perfect health, although they have lived in pots for more than twenty-three years. For some years they have been past turning out of their pots, so the earth is grubbed up for some distance down, and fresh soil and afterwards manure are applied, much as Mrs. Newall treats her Lilies. The finest plants of *L. auratum* I know of at home or abroad are Mr. McIntosh's. These were originally planted singly in good soil, in which they have remained undisturbed for many years. The instance quoted by Mrs. Newall of great clumps of *L. candidum* flowering perfectly without removal may be due to these Lilies liking a rather strong soil, which takes long to exhaust.

Heatherbank, Weybridge Heath.

G. F. WILSON.

NOTES AND QUESTIONS ON THE FLOWER GARDEN:

Transplanting Lilies.—It may be desirable if Mr. D. Uphill (p. 286) would be kind enough to say at what time he lifted and replanted his Lilies; that is, if he waited, as many do, "until after the flowering season is over, when the leaves turn yellow and fall off and the stems die down?" I have known in many cases, when lifting and replanting were deferred so long, that the bloom was, indeed, anything but good the first year. I have, in fact, found late planting to destroy the very existence of the successional bulbs; and in some of my former papers I have explained the cause. But I have never known another to be the case when the bulbs were lifted and replanted immediately after the bloom was over, or even before the last of the fading flowers had fallen, or I should never have recommended early and annual lifting and replanting to those who have time to spare. I am glad to see that Mr. Uphill recognises the fact that Lily bulbs are every year new and successional bulbs. There are others among your readers who also now recognise this principle, and I trust many more may be induced to follow their example; for it seems to me to be the very acme of inconsistency to profess to know how to cultivate the Lily, and to teach others, while we ourselves are totally unacquainted with the constitution, the organic structure, and the true nature of the bulbs with which we have to deal.—DUNEDIN.

Alpine Euphorbias.—There are many species, or so-called species, of tall herbaceous Euphorbias in our botanic and other gardens, but few dwarf and neat in habit. *E. ospitata* and *E. triflora* are two true Alpine species, very dwarf and neat in habit, natives of the Tyrol. They are desirable for rock garden culture, and may be seen in the collection of Alpine flowers belonging to Messrs. Fröbel, of Zurich.

Saxifraga cæspitosa.—Among the multitude of plants that crop up from time to time it requires some degree of boldness to bring a new one into notice; but this Mr. Westland has done, and I can say from my own experience that it will equal any and surpass many of those now in cultivation. *Saxifraga cæspitosa*, or *grœnlandica* of some, is very dwarf in habit, and of such an emerald green colour as must at once recommend it. I have long recognised its adaptability for green masses, and have been working up a stock of it, feeling sure that, when better known, it would be a favourite.—THOS. WILLIAMS, Ormskirk.

Agapanthus minor Mooreanus.—The plant I grow under this name proves a very hardy and truly herbaceous form that flowers freely, and is very pretty. We may, I think, expect much from the various distinct forms of the favourite old *Agapanthus*, now beginning to be known in gardens.—V.

Bignonia capreolata Hardy.—This plant, usually grown under glass in the United Kingdom, is treated as a hardy climbing shrub in gardens in Central Europe colder than ours in winter. It grows and flowers freely, and trained up a pillar or column is most graceful in habit and in foliage. It is also furnished with little sucker-pointed tendrils, which enable it to climb up a wall like Ivy.—J. H.

Wintering Salvia patens.—My remarks on this *Salvia* (p. 239) must have been misunderstood, for if I had thought it was perfectly hardy I should not have suggested putting any covering over its roots in winter. I can only say that on the East Suffolk coast it withstood the winters of the past ten years with me under a covering of coal ashes, and that plenty of plants of it may be seen in cottage gardens there that have never been covered for years. I shall also feel equally certain about wintering it safely here in the manner described. Lifting and storing have done more towards exterminating the roots of this plant than ever frost has done. I see so

many plants flourishing in the open air now-a-days that used at one time to be kept under glass in winter, as, for instance, Palms of the hardier kinds and Camellias, that I feel more pleasure in trying experiments in testing hardiness than in going back to the old style of making tender plants still more tender by coddling them indoors.—J. GROOM, Linton Park, Maidstone.

Hardiness of Physianthus albens.—I can assure "W. E. G." of the perfect hardiness of this plant. I have known a plant of it for many years that covers a large space of wall on a Rectory near here, and that every year produces abundance of flowers and fruit.—H. N. ELLACOMBE, Bilton Vicarage, near Bristol.

Nothochlæna Marantæ.—This interesting hardy Fern is grown by M. Fröbel, of Zurich, as an edging to one of his beds of American shrubs; and, on the sunny side of the bed where it thrives very freely as edgings to these beds, *Ramondia pyrenaïca* also grows "like a weed," and is a mass of flower in its season.—V.

Hemerocallis Mittendorfiana.—This uncommon species has been flowering very freely with me of late, the plant being somewhat dwarf, though vigorous, and the flowers large and distinct in appearance from the other species. The flowers also seem later than those of most of the other kinds.—J. H.

Double Buttercups.—All lovers of flowers must feel obliged to the Rev. Mr. Harpur Crewe for the remarks which he has made (p. 285) on these charming flowers. One thing I would wish to ask, Why do we so seldom or ever see the single form of *R. aconitifolius*? *R. speciosus* where it does well is a very distinct plant. I believe specimens to be only a trade or garden name; the true name is *R. bullatus*. I have a handsome and with it a very hardy double *Buttercup*, which I have grown for years as *R. Steveni* fl. pl. It is twice the size of *R. acris* fl. pl., and I am under the impression that it will prove the plant which Mr. Harpur Crewe mentions, viz., *R. lanuginosus*, as the flowers are very soft, silky, or woolly. There is also a double variety of *R. graminifolius*.—THOS. WILLIAMS, Ormskirk.

Autumn Crocuses and Ivy.—At this season, when these beautiful flowers are in perfection, it is well to note the positions in which they are seen to the best advantage; flowering, as they do, when destitute of foliage, they require some addition in that way. I lately saw some producing a good effect growing in masses in Ivy edgings. The blossoms showed well above the Ivy leaves and were protected against being soiled and splashed by heavy rains.—J. GROOM, Linton Park.

Fuchsias Out-of-doors.—Mr. Groom (p. 281) has done good service in recommending the *Fuchsia* for autumn blooming out-of-doors, and has, in fact, anticipated some remarks which I had intended to have made respecting it. I believe that there is scarcely one of the cultivated pot *Fuchsias* that will not survive our ordinary winters with very little care. Although they die down, they spring up in summer and bloom in autumn with a beauty and a vigour never seen in the case of a pot plant. They should be turned out by the hundred in shrubberies and among herbaceous plants. One of the most beautiful for this purpose is a variety called *Wave of Life*, in my opinion one of the best *Fuchsias* in existence.—THOS. WILLIAMS, Ormskirk.

Substitute for Turf.—Lately, while walking through a suburb of a large town, I came upon a front garden so bright and fresh in comparison with others that it appeared like an oasis in the desert. The materials employed were inexpensive; indeed, much less so than those commonly used. I can understand and appreciate the love which the town dweller feels for a bit of green turf, but where the houses are crowded together it is difficult to keep turf in good condition. The substitute for it which I saw in this case, and which I can strongly recommend was the well-known *Creeping Jenny* (*Lysimachia Numularia*). This grows wild almost all over the country. It thrives in Grass fields, creeping along close to the ground, and only making its presence known by its bright yellow flowers when the Grass is short or thin. It is equally at home on dry, sandy banks, or by the side of watercourses, with its creeping stems at times under the stream. It makes a close-growing carpet with but little attention, even in the smoky, murky atmosphere of large towns, and in such places for this purpose it is well worth more attention that it receives. In the case to which I am now referring it formed a green, circular plant in front of the dwelling. In the centre of it was placed a good, bold mass of the old red *Fuchsia gracilis*, and the effect was quite unique. The other plants in the garden were in keeping therewith, as was also the house, which was draped with Veitch's *Virginian Creeper*, an exceedingly handsome kind, which clings to the wall with a tenacity that scarcely anything short of actual violence can disturb.—E. HOBDAY.

THE FRUIT GARDEN.

FRUIT STORING.

THE numerous cares and anxieties of the cultivator do not cease until the fruit is gathered and stored in the manner most suitable to bring out its best qualities and render it fit for use. I will enumerate a few of the points which are essential to success—the choice of trees suitable to certain soils and situations—the proper preparation of the soil—the care to be exercised in planting—stopping the summer shoots—and winter pruning. All these should be sedulously attended to, whether the trees are to be planted in houses, or in gardens and orchards, if the fruit is to be abundant. It is, however, no less the orchardist's duty (if he wish for healthy trees and fine produce), to thin the blossoms, if practicable, but certainly the fruit—this is imperative. Remove all worm-eaten, specked, and deformed fruit, as well as all that grows upon weak or twiggy branches, leaving only that growing on strong and healthy wood. The injury done to trees by over-cropping is incalculable. In Vines, when we hear of Grapes shanking and not properly colouring; when trees become mildeyed and present a sickly appearance, we may, in a great measure, fairly attribute these disasters to over-cropping. When Peaches and Nectarines (whether on walls or under glass) cast their fruit at the stoning period; when those pests of the cultivator, red spider and aphid, attack the trees; when the branches become cankered; when small, ill-shapen, and tasteless fruit is produced, we may conclude that the unhealthy state which has invited these attacks and paved the way for these disorders, has been brought about by non-attention to thinning; the vital powers of the trees have been exhausted; they are, therefore, an easy prey to disease. I have often passed by cottage gardens, and seen Apple trees bending beneath loads of small, ill-formed fruit really only fit for pigs. Perhaps Nature has a tendency to over-fecundity, but it is the business of art to restrain this luxuriance (so hurtful in its consequences) within proper bounds. A young tree transplanted into rich soil will, in its early stages of growth, produce an enormous quantity of fruit, but it is absolute cruelty not to check its energies and husband its strength for the demands which will be made upon both in years to come. Legislators are slowly becoming aware that if we wish our working classes to be vigorous in mind and body, it is necessary to prevent young children being put to work until their frames have acquired strength. Why not apply the same principles to trees? Why allow their youthful powers to be so overtaxed as to prevent their ever coming to a ripe maturity? Overcropping in some cases is the result of ignorance or greediness on the part of the grower. He is anxious for an abundant crop, not looking beyond the passing hour, or foreseeing that this over-luxuriance in early youth entails sterility and disappointment in the future. Some few years ago, a friend of mine, who lives in a midland county, built a house and planted a garden in a very favourable situation. Though he could not exactly have a south wall all round, he built a good wall and planted some fine kinds of Peaches, Nectarines, and Apricots. I visited him one autumn two or three years afterwards, and I never saw such splendid crops of all the three fruits; the wall literally glowed with crimson and gold. But amid these glories I could not help uttering words of warning—"You will suffer for this in future years. Why did you not have them thinned?" I spoke to deaf ears. My friend, more at home in his library than in his garden, and being rather of the *Carpe diem* sort of philosophers, treated my remonstrances with provoking indifference. But it is six years since that autumn, and he has never had another crop of Peaches. He has often consulted me about his poor trees, and he and his gardener have tried all sorts of nostrums advertised for their relief, but in vain; the mischief done in infancy and youth can never be repaired. While on the subject of remedies and insect destroyers, I cannot forbear quoting a card which I received some time ago from an anonymous friend through the French post: "*Apropos de Roses. Les pucerons. De barbouiller les pousses avec du marc de Café encore frais. Cette substance tue les pucerons et les empêche de reparaitre.*" I have never tried washing shoots attacked by aphid with fr

here, but I give the recipe, in order that any of your readers may do so if they think fit.

To return to fruit thinning. This demands as much care and science as any other gardening operation. Let the orchardist make up his mind resolutely to sacrifice part of his crop to ensure the perfection of the part he retains; the loss in quantity will be amply made up to him by the gain in quality and weight. I once witnessed an interesting experiment. Two Vines of the same kind were planted side by side near a wall, and treated precisely alike; but one was allowed to bear as many bunches as it would, the other was carefully thinned both in bunch and berry. When the fruit was gathered it was discovered that the unthinned Vine had borne four times as many bunches of Grapes as the other; but the crop of the thinned tree weighed heavier and was of far superior quality. Let any one try this experiment for himself with any kind of fruit, dividing his wall or growing space into square yards, and he will be convinced that by properly thinning (and this had better be over than underdone) the weight of fruit per yard will be greater than if he had suffered his trees to be overcropped; he will besides enjoy the satisfaction of producing fine and perfect fruit, and of preserving the health and vigour of his trees. If we look at the matter from a mercantile and economical point of view, it must surely be the grower's interest to produce the best fruit, as it commands the highest price in the market, and obtains the readiest sale. Let any one walk through a fruit market, and he will observe that the best fruit is, as a rule, eagerly bought up at a good price, while that of a poor and inferior quality often remains on hand, or is disposed of for any price it will fetch. I am surprised that growers do not offer to the public more frequently picked specimens of the best fruits. Carefully arranged, these might replace advantageously, in some cases, the untidy heaps carelessly massed on the stalls or in the shops. I am here speaking of country shops. Of course, in London and other large towns things of this kind are better done; but even here there is great room for improvement. Our neighbours across the channel show their superiority to us in this as well as other similar matters. Contrast the fruit and flower shops and markets in London with those of Paris.

The next care of the grower is the gathering and storing of the fruit, so as to bring out its best qualities. All wall and indoor trees should have any leaves which may cover the fruit carefully removed a few days before the time of gathering. This allows the rays of the sun to penetrate, and impart to it a fine colour. Any moisture clinging to it is thus evaporated, and the sugar or saccharine matter becomes properly diffused. The period for gathering depends in a great measure on the season; no precise rule can, of course, be given. With regard to Apples and Pears (and this holds good with other fruits) they acquire, as they approach maturity, a fine colour and a somewhat powerful scent; they are also soft to the touch, particularly the latter, near the stalk. Autumn Pears should be gathered from ten to fifteen days before they become perfectly ripe. Winter ones may be allowed to remain on the trees as long as they can do so without injury from frost, but must be removed when vegetation ceases. "In some seasons," says a French writer, "winter Pears may be gathered during the second or third week of October." This is, if the year has been hot and dry. If, in such a case, they are allowed to remain too long on the trees they become woolly, soft, and doughy. A fine, dry day should be chosen for the purpose. The fruit should be very carefully gathered, taking care to secure the stalks. It should be placed in a basket and carried to the fruit house. All Pears, even summer ones, are best when allowed to ripen in the house rather than on the tree. I must not forget to remark that it is quite unnecessary to strip a tree of its fruit, whether mature or not. The careful orchardist will watch his trees, and daily, if needful, remove such fruits only as are fit to gather, *i.e.*, which part readily from the tree, leaving the others until they also are ready. This prolongs the duration of the crop. The fruit now stored in the house exudes for several days a greasy moisture, which should be carefully removed, to prevent decay, and the wiping repeated until all the moisture is discharged.

I will now add a few words, which may not be out of place here, as to the mode of arranging a fruit or store house, and

the necessary conditions to be observed in its construction. The conditions for keeping fruit well are a dry atmosphere, a cool, steady temperature, and darkness. To insure these as far as possible, the house should be placed in a dry, airy situation, and its outer walls contrived so that the air freely circulates round them; this will render the temperature cool and equable. A free circulation of air is also indispensable under the floor; or the floor should be made impervious to moisture. While ventilation is attended to, the doors and

Portion of Pear stand at Ferrières.

windows should fit closely so as to exclude frost; double doors are a great advantage in preventing a too great ingress of air. The walls should always be double, the outer wall being the thickest, especially on the north side; the ceiling should likewise be double. In case, however, of a fruit house being constructed out of some other building, it is advisable to line the walls with wood, leaving a small space between the wall and the lining, which may be filled with sawdust. The light should be excluded by means of blinds or shutters, as it is an established fact that fruit keeps best in darkness. It

End view of Pear stand.

has been observed that fine specimens of Apples and Pears, when placed opposite a window, deteriorate both in colour and quality. Various methods have been recommended to absorb the superfluous moisture generated in fruit rooms. M. du Breuil proposes to place a layer of chloride of lime in a wooden trough lined with lead. This substance will absorb double its own weight of moisture from the atmosphere, and as it liquifies it may be received into a jar placed below the trough, then removed, and the water evaporated, so as to leave the chloride of lime

again fit for use. Great care must, however, be exercised in the use of this substance, as the fruit might acquire an unpleasant taste. A safer material would be gypsum, or some other absorbent and non-effluent agent. As regards the internal arrangement of a fruit room, shelves should be placed all round or on stands in the centre, the shelves or stands being arranged so that each fruit can occupy a separate space and be easily examined without being touched, the damaged fruit being capable of removal without disturbing any that are sound. Tablets should be hung near each variety, to contain written observations as to the time of gathering, and to indicate when maturity may be expected, together with any other particulars interesting to the pomologist. Perhaps the most simple is a small white slate tablet; this is easily written upon and easily read. The most perfect fruit house (says André Leroy in his "Pomological Dictionary") is that of the Baron James de Rothschild, at Ferrières (Seine-et-Marne); and in the new edition of the "Parks and Gardens of Paris" the illustrations of the fruit stands and Pear rails in use in that house are given. Some prefer to place fruit in shallow drawers or boxes, covering them with clean bran or dry sand; either of these answer well, as they fill up the interstices and absorb any moisture which may be given out, or a piece of flannel forms a cheap and clean covering. It is an advantage that this can be so easily raised and the fruit examined without being disturbed. Many Pears which are considered decidedly inferior become delicious when ripened in a gently warmed room, particularly the varieties which are dry and tough when left to themselves. I would

Section of Pear rail in the fruit room at Ferrières.

recommend placing these in drawers or on shelves in a warm cupboard; this treatment seems almost to change the character of the fruit.

Before I close I cannot forbear alluding to various ancient methods employed for the conservation of winter fruits. Some of them may not be without interest to the modern grower. The Greeks and Romans had various plans of their own, some of which seem to have succeeded, while others appear fanciful and impracticable. Their authors recommend "hanging up Pears by their stalks," "placing the fruit in earthen vessels and covering them with wine which had been boiled." More rational, I think, is the receipt for laying them in sawdust or shavings. Others advise storing Apples and Pears which have been gathered in fine dry weather in vessels, and covering them with lids coated with gypsum. The vessels are then to be buried in a place where the rays of the sun cannot reach them. Another writer advocates laying Pears as they begin to ripen in honey, but so that they do not touch each other. This rather reminds me of an old clergyman of my acquaintance, who was a most indefatigable reader of romances, but he preferred them pure and simple, and much objected to the introduction of religious discourse into his favourite stories. "Sermons," said he (as I ought to know), "are very good things in their way; so are novels. But why mix them when they are so excellent taken separately?" This applies to honey and Pears; they are too good to be mixed. The old French authors have written a great deal about the gathering and storing of fruits. "Take care," says Merlet, in his "Abrégé des Bons Fruits" (1690), "not to defer gathering your autumn Pears after the beginning of October, or your winter varieties beyond the end of that month, according to the season; but above everything gather them at the wane, not at the increase, of the moon, or when she is at full, for at those times fruits derive much nourish-

ment from the planet." La Quintinye, Director of Orchards to Louis XIV., in his elaborate and scholarly work, entitled "Instructions pour les Jardins Fruitiers et Potagers," describes a fruit house which might well serve for a pattern now. My space will not allow me to quote the passage, but I commend the book to the careful perusal of amateur as well as professional pomologists.

W. NEWTON.

Hillside, Newark.

PLUMS UNDER GLASS.

PERHAPS no other hardy fruit is so much improved in appearance and quality by being grown under glass as Plums. This has long been demonstrated, but in comparatively few gardens. Those of our readers who have been in the habit of visiting such places as the Royal Gardens at Windsor, Trentham, and Chataworth for the last quarter of a century must have been struck with the immense crops of Plums under glass, and particularly with their improved colour and quality. And the wonder is that Plum houses are not more numerous than they are, seeing that the finer varieties are so much appreciated in tarts and for dessert. If they required any expensive preparations for their culture, or were at all a precarious crop, under glass, their not being more cultivated in this way would not be so much to be wondered at or regretted. They will succeed in any ordinary soil, and under glass are one of the most certain of crops. Moreover, they stand forgoing to bring them in considerably before they can be had from walls or cool houses; and by growing some of the delicious late varieties, rendered still more so by being grown under glass, the season of Plums can be prolonged far into the autumn, or even into the winter, when other stone fruits are past. Last February we planted a very considerable extent of orchard house with Plums, and many of them bore heavy crops of splendid fruit, while the crops on previous companions on the open wall were all but *nil*; and so superior in size, appearance, and quality were those under glass, that they would scarcely pass for the same varieties. Probably the most profitable and best cooking Plum under glass, as it also is out of doors, is the Victoria. Washington, Magnum Bonum (white and red), and Hulling's Superb are excellent cooking varieties for orchard-house culture. For dessert, the best are, perhaps, Green Gage, Reine Claude de Bavay, Jefferson's, Transparent Gage, Kirk's Seedling, Coe's Golden Drop, and Ickworth Imperatrice. The two latter named varieties are invaluable for late dessert, and their quality is vastly improved by being grown under glass. By lifting trees from the open walls that are in a bearing condition, but not very old, a good crop can be had the same season; so that quick returns can be had from any glass that may be devoted to Plums.—"The Gardener."

Doyenne Boussock Pear.—This excellent variety should not be overlooked by any one who possesses a dozen Pear trees, and who intends now to add to their number. It has to recommend it four very desirable peculiarities—size, appearance, flavour, and productivity. With regard to the first and last I may mention that I have just taken from one stalk three, the combined weight of which amounted to 1½ lbs., and all three were nearly of equal weight; and as to the second, not only is the fruit handsome, but the foliage often becomes a deep red before the leaves fall. My tree, for I have only one of this variety, is on Quince roots, and is trained on a wall facing due west. I have never known it fail even in bad seasons. Orders for fruit trees should be sent without delay if they are to be planted to the greatest advantage.—B. S.

Protecting Vine Borders.—That I may not appear to have wronged Messrs. Hinds & Smith in this matter, will you allow me to say once and for all that Mr. Hinds came forward voluntarily to "collect evidence on the points at issue" between myself and others, which "points" he clearly understood and acknowledged to relate to the practicability of producing early Grapes from Vines with their roots all outside and unprotected by fermenting materials; and to prove that a job had been done successfully, he cited, with Mr. Smith's entire concurrence, the case of an early Vinery at Waterdale, with the roots outside, that was carrying its sixteenth crop of early fruit (also an error), specifying that in the case of other Vineries there the roots were inside as well. Now this Vinery is one of those where the roots are "comfortably inside," and receive regular supplies of warm water, as Mr. Smith has told us. The latter may not have written to enquire my opponents, but he has been a consenting party by his silence, while Mr. Hinds declared he had his entire concurrence in the statements which he made. Thus the last case of evidence against me is demolished as satisfactorily as I could wish.—J. SIMPSON, Wortley. [Here we think this discussion must end.—Ed.]

TREES AND SHRUBS.

DECAY OF OAK WOODS IN SOUTH YORKSHIRE.

This is a subject which ought to command our earnest attention. Hereabouts the trees, and principally the Oaks, in not a few woods are dying off prematurely and rapidly. In one Oak wood, nearly 2000 acres in extent, on this estate the trees are going off at an alarming rate; thousands are in an advanced state of decay, and there are few which are not more or less affected. To the public, as well as to the proprietor, this is a matter of concern, as the wood is entirely free to the former three days in the week, and is, in fact, the principal resort of holiday seekers, who look forward with dismay to the destruction of about the only bit of semi-natural forest in this part of the country. The decay has been going on for many years among young and old trees alike, and has not attracted attention now only, but the subject has been revived lately in the local papers, and I think might be adverted to in THE GARDEN perhaps more usefully than anywhere else, as some of your readers may have suggestions to offer in reference to the matter. Two theories have been put forward as to the cause of the decay. The latest is that propounded by some of the members of the Geological Section of the Yorkshire Field Naturalists, who lately made an excursion to the wood in question, when the premature decay of the Oak trees formed a chief topic of discussion. They came to the conclusion that the decay was attributable to the exhaustion of potash in the soil, and that the best remedy would be a change of successive plants; a conclusion and suggestion which, I imagine, will appear rather extraordinary when taken together, seeing it is hardly possible to find any suitable "successive plants" that would require so little potash as the Oak; where it cannot find the small quantity which it requires, it cannot be expected that a useful timber tree like the Larch, for example, which requires a great deal more potash, would long thrive. Besides, the potash is to a great extent restored to the soil by the decaying leaves and vegetation generally. Further, plenty of plants thrive in the woods that require more potash than the Oak, and I know from long experience that the soil suits Vines and vegetables requiring the same in large quantities. This, however, is the "Naturalists'" opinion, and I give it here. The next hypothesis is put forward by a forester of extensive experience, and who is probably better acquainted with the woods in this locality than any one else, having, in a practical capacity, been connected with them for a long period. His opinion, as stated in a provincial daily paper, is that the trees were injured by the severe frost of 1860-61. The frost, he states, lasted a considerable while here, as it did elsewhere, and during the time a heavy fall of sleet occurred which froze upon the trees, making them look "as if crystallised" from top to bottom. From that date, he adds, the decay has been observed. Now this is the problem I wish to put to those of your correspondents who are versed in woodcraft—was it the frost that did the injury under the conditions described, for I fear the potash theory is hardly tenable? My own opinion is that the frost had nothing to do with it. In the first place I have witnessed the phenomenon of trees coated with ice in the manner above described more than once in different parts of Scotland without the least injury to the trees being the result, and in the second place one would expect that a frost severe enough to injure native species seriously would first cut down all the more tender exotics, which the frost of 1860-61 did not do in this district. It did so in many other places both in England and Scotland. Near Edinburgh the frost killed not a few Araucarias down to the ground; also Aucubas, Laurustinus, Rhododendrons, great quantities of Roses, and even Laurels, but it did not injure any of the native trees. But when I came here in 1864 I was surprised to find that the above trees and shrubs and even Camellias in the open air had passed through the winter in question without injury, and they are growing on the same formation and in the centre of the affected district. These facts led me to conclude that our high-lying and well-drained district did not suffer from severe frosts, a conclusion which subsequent experience has confirmed, as during the last fourteen years we have never had such severe frosts as have been

experienced frequently both north and south of us. It is seldom we have 15°, very rarely 20°, which has not been exceeded more than once or twice, and only for one night or so. Another fact which disproves the freezing hypothesis is that the decay among the Oaks has been gradual. There are many trees whose decay, I fear, dates back beyond 1860, while there are many that are just beginning to show signs of it. Is it reasonable to suppose that a frost which injured the trees seriously nearly twenty years ago is only beginning to show its effects now? Lastly, is there any record of the Oak or other native trees being injured by frost under ordinary circumstances? My belief is that decay is not attributable to the cause assigned by the naturalists, nor to the frost of 1860, but to the presence of the numerous iron and coal works that dot the country in every direction as far as the eye can reach, and which are continually sending forth volumes of soot, which settles upon the trees and chokes up the pores of the leaves. One can hardly pick a leaf out of the woods anywhere that is not black with soot, especially in dry seasons, when it accumulates to quite a thick coat. This alone would be sufficient to produce decay in the end, but in the wood in question there is another cause at work, and that is the caterpillar, which has for years back stripped all the earlier foliage off the trees as completely as ever the caterpillar did a Gooseberry bush. In July thousands of trees may be seen as bare as they were in December. Later in the season the caterpillars go into the chrysalis state. The trees then make a feeble growth, and these causes having been in operation year after year, the results are, as has been stated, premature decay. I should be glad, however, to hear the opinions of your correspondents on the subject.

J. S. W.

FOREST WORK FOR OCTOBER.

Other work being well in hand, undivided attention should be paid early this month to the subject of planting, for though there are some soils which, from their excessive wetness, may require to be planted in the spring, yet the greater part of the land which can be profitably cultivated as woodland ought to be filled up before the end of November. It will be found that there is much truth in the old aphorism—"Plant before Martinmas and command success, plant after Candlemas and entreat success." With regard to the preparation of the soil, it may be observed that the majority of high-lying districts, the soil of which is generally of a silicious character, admit of but little previous cultivation, as any stirring or loosening of such land would deprive it of its power of retaining sufficient moisture to nourish the young plants. Here, therefore, the system of notching-in will be found the best; and two years' transplanted Larch or Scotch Fir which has stood one year longer in the lines will generally be found suitable. The small proportion of the alkalies which such soils contain suits them in most cases for the growth of anything besides the Pine and Fir. But upon richer soils and in low-lying districts, where alkalies abound in the deep loams, marls, and clays, almost any kind of hard wood may be planted after a good preparation of the land. The clays and iron-bound gravels in particular should, previously to planting, receive a deep trenching and thorough drainage; and if the holes be dug some months previous to their being used, so much the better for the trees. The advantages of a home nursery in which the plants required for filling up woodlands may either be reared from seed or grown from young stocks purchased of nurserymen are very great. The planter who has such a nursery to fall back upon can select his own time and weather for transplanting, and is thus exposed to none of the risks which attend the long carriage and damage often sustained from close packing of nursery stocks. In dry weather it will be a great advantage to immerse the roots of the young plants in a thick puddle of adhesive soil and water as a protection during their removal. Where the land selected for planting has previously been occupied by trees, all remains of the former crops should be carefully removed or burnt upon the spot. The condition of the soil will depend much upon the previous crop; for while Larch improves the land, and Oak during the latter years of its growth adds to the saline matter of the soil, the Norway Spruce, the Sycamore, Ash, and Elm are very exhausting. After such crops, a few years' cultivation under corn and roots will prove highly beneficial to the land before replanting it with trees. Such a system will also enable the planter to thoroughly incorporate with the soil those manures which are required and which are much better applied to the intermediate crop than to the trees themselves, unless in the form of compost.

October should be a busy month in the nursery, where the preparation of seed beds and the sowing of such seeds as are already ripened will require attention. Independently of the ravages committed by birds and the smaller rodents, this is decidedly the best time of year for putting in Acorns, Walnuts, Hazel Nuts, Spanish and Horse Chestnuts, and if these autumn planted seeds entail a little more trouble, the cultivator is amply compensated by the start which his plants get in the spring. A good loam is well adapted for the seeds just named, but where the land is of a heavy character, it is a good plan to lay the seeds in rows upon the surface of the beds, and to cover them up to a depth of 3 in. or 4 in. with the soil shovelled from between the beds, thus enabling them to lie high and dry during the winter. Early in the month put in cuttings of Ribes, Dogwood, Portugal and common Laurels, Elders, Alders, Limes, Poplars, Planes, &c.; also layer Limes, Elms, Maples, and such other trees as are propagated by that method. The Norway Maple ripens its seeds early in the month, and these may be sown as soon as collected. A bushel of this seed of average quality, in a favourable season and with proper care, will produce about 12,000 plants. A bushel of Acorns under similar circumstances will produce from 6000 to 8000 trees; Walnut, 4000 to 5000; Horse Chestnut, 2000; and Sweet Chestnut, about 3000. October is a good time for planting out young Hawthorns or Quicks to form permanent hedgerows. If two-years' transplanted stock be used, it may be inserted at distances of from 6 in. to 8 in. apart. A double row, with the plants placed triangularly, is preferable to a single one. The plants may be cut over within a few inches of the ground, which will generally ensure for them a good start in the following spring. Upon light sandy land, where the Hawthorn does not generally flourish, it will be well to use a compost consisting largely of clay, with the addition of a little lime. I have also found a small quantity of genuine bone superphosphate very beneficial to young Quicks. Upon these light soils an admixture of Beech, in the proportion of two or three to every Quickest, will ensure a thick, good fence; but the Beech must not be cut over at the time of planting. The beginning of this month is a good time for cutting over near the ground two-years' transplanted Oak, Ash, and Sweet Chestnut, as well as for undercutting strong nursery stocks of the hardwood kinds, which are not intended to be removed for another year. Layers of Lime, Elm, &c., in the nursery may also be severed from the parent stool and replanted, and other shoots may be layered to fill up vacancies. Coppice layers may also be similarly treated where it is not considered necessary to extend them farther.

A. J. BURROWS.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

Populus suaveolens.—This is one of Dr. Regel's introductions from Central Asia, and promises to be a valuable tree. It possesses a very agreeable aromatic odour, and hence the specific name. This is very evident when the buds, now well filled, are rubbed with the finger. I fancy it is not yet in our nurseries, though it is in some Continental ones.—J. H.

Xanthoxeres sorbifolia.—This fine-flowering tree, of which a coloured portrait was given in THE GARDEN (Vol. VIII., p. 524), has proved quite hardy in Switzerland. Its foliage is distinct and ornamental at this season. In the Garden of Plants the first specimen of it flowered against a wall. In Switzerland it grows well in the open ground, as it no doubt will do with us.—R.

The Erect-growing Wych Elm.—A pyramidal, or rather columnar, tree, of which the above appears to be the relationship, is a striking object in some south German gardens. It is well deserving the attention of planters, and would form a very striking contrast to the far more common and invaluable Weeping Wych Elm, of which there is a good old specimen in the Royal Botanic Gardens, Regent's Park.—V.

Paulownia imperialis.—As an instance of the great growth of trees this summer I have measured a shoot of *Paulownia imperialis* of this year's growth. It is 9 ft. long, and 5 in. in girth at its base. I suppose it has now stopped growing.—H. N. ELLACOMBE, *Bitton Vicarage, near Bristol.*

The Lime Tree in Towns.—We have so often condemned the common Lime tree for towns that we make haste to do justice to the American Lime as a street tree. It retains its leaves quite fresh long after those of the European Lime have perished. There is a very fine variety of this Lime raised a good many years ago by M. Froebel, of Zurich, of which there is one specimen tree planted in a street in Zurich, where it may be seen and compared with *Tilia alba*, from which it was raised, and the European Lime. Judging by what is seen there, it would seem to be a very valuable variety. It is called *specabilis* by the raisers.

PLANTS ROUND SAN FRANCISCO BAY.

WE have now rounded the point, and reached the valley beyond. There is the usual sandbar, backed by a small lagoon, from which a rilllet flows across the beach. Here we leave the shore and ascend the hill, gathering the wild flowers as we go. Patches of *Lupinus micranthus* and *Orthocarpus erianthus* fleck the hillside with blue and white, but the show of the flowers is not on this southern side, exposed to the rough westerly blast of the Pacific as they sweep through the valley, but on the moister and comparatively sheltered north-eastern slope. One of the most abundant of flowers, here and in the whole vicinity of San Francisco, is the *Enothera primuloides*, a stemless plant with yellow blossoms, each on its own peduncle, reminding us of the Primrose. Another flower, plentiful on this hill, but very local in its distribution, is the purple and white *Collinsia bicolor*, belonging to the same order with the Mimuli, two kinds of which (*Mimulus luteus* and *M. glutinosus*) may be found near by, the former by the water-courses and in the wet places which abound after the heavy rains, the latter on the dry hillsides. The great yellow, Daisy-like *Layia platyglossa*, with its ray florets tipped with cream colour, from which it has earned the name of Tidy-tips, is to be seen here and there, but does not abound as it does across the bay, at Oakland, where whole fields are golden with its blossoms. The *Escheholtzia californica* is here, of course; there is not a month in the year when it cannot be found, but now it is in its glory, its gorgeous orange petals inducing every neebsin that comes along to gather the "Lilies," as he calls them. Another of the Poppy tribe, the little Cream-cup (*Platystemon californicum*), may be found if looked for, for it is modest—unlike Poppies in general. *Orthocarpus* is a very conspicuous genus in California generally; on this hill-side we gather, besides the white one already mentioned, the purple and yellow *O. castillejoideus* and the tiny-flowered *O. pauciflorus*. *Nemophila insignis* is almost out of blossom, yet we find a few, and among the loose stones higher up the hill we find one of its rarer relations, the rough, almost prickly, *Phacelia lasiofolia* of Torrey. The more common *Phacelia*, *P. circinata*, with its coarse foliage and cat's-tail-like curled flower-spikes, and the more delicate *P. tanacetifolia*, we do not meet with in this ramble. The Rose Order is represented only by one plant, the humble *Acron trifida*, a near relation of the *Sanguisorba* or Burnet. Almost the only shrubs to be found are a dwarf Oak and the Poison Oak (*Rhus diversiloba*), the latter unfortunately only too common, as we find to our cost next day, when our wrists inflame and become covered with the pustules produced by its juice. It lurks in every bunch of tall herbage, its glossy, green leaves and greenish racemes of flowers mingled with the Vetches, *Phacelia*, and other harmless plants in so intricate a way that it is almost impossible to collect them without contact with it. On the hill-sides it is low and straggling, its roots running to great distances under the surface, and throwing up stems and leaves in unexpected places; in the copses it forms large bushes, alone or mingled with other shrubs; but in the forests it is a huge climber, mounting the tall Pines and Firs and strangling them. When a climber, its leaves are much larger and lighter in colour, and it is usually believed to be a different plant from its humbler brethren of the meadows, being distinguished as Poison Ivy.—"American Naturalist."

Vitis Thunbergi is a very robust species of Vine from Japan with large and handsome leaves (some nearly 1 ft. across) which turn a fine red colour late in autumn. There is a vigorous plant of it growing against a house in the botanic garden at Zurich.

Yucca baccata.—This remarkable species has proved hardy with me, as has also *Y. angustifolia*. Of both I have but small plants, but they have stood two winters out-of-doors without injury.—J. H.

Rheum palmatum tanguticum.—This is the name of a very fine, recently-introduced kind of Rhubarb, which, as regards vigour of growth and size, seems distinct from the old *Rheum palmatum*, which is a smaller plant, and generally a very slow-growing one. Indeed, it often "pines away," to use an expression frequently used in a recent book on floriculture. *R. tanguticum*, on the contrary, increases rapidly. The fine and boldly-incised foliage will be welcome to those who grow the other hardy species now in our gardens. There are some fine plants in the botanic garden at Zurich. It is one of Dr. Regel's introductions.

Astragalus adsurgens (Pall).—Of the very numerous species of *Astragalus* but few have come into cultivation, and, truth to say, many of them have few charms to make them worthy of a place in gardens, but this species from the Baikal region is one of the exceptions. It is a dwarf species, producing numbers of violet-carmine flowers, and is well worthy of a place in the rock garden. It has been introduced by Messrs. Fröbel, of Zurich.

PLATE CXLVIII.

THE LARGE-FLOWERED MOUNTAIN SAXIFRAGE.

(SAXIFRAGA OPPOSITIFOLIA PYRENAICA MAXIMA.)

THIS is, as its name implies, the largest-flowered variety of the Pyrenean form of the purple mountain Saxifrage. Its colour is light pink, or flesh colour, and much paler than that of the ordinary type found on the mountains of Great Britain. In habit, the Pyrenean plant differs considerably from the British one. It is much more robust, less densely matted, and the rosettes terminating the shoots are erect. The individual flowers are as large as a shilling. This Saxifrage should be planted in rich loam, in deep, well-drained fissures exposed to the sun, or overhanging ledges where the main roots can penetrate deeply into fissures behind. For the specimen from which our plate was prepared we are indebted to Messrs. Backhouse & Sons, of York.

THE INFLUENCE OF AGE ON SEEDS.

OPINIONS, like fashions, revolve in circles. In my boyhood most cultivators believed in the age of seeds as a potent factor in the production of abundance of good Melons and Cucumbers. Not only were old seeds believed to produce the most fruitful plants, but the quality of the fruit was thought to be improved by the age of the seeds. So general was the belief in these facts that artificial means were adopted to give similar effects to that attributed to age. Amongst these the best modes were storing seeds in warm kitchen drawers or seed rooms with stoves, and also carrying the seeds constantly in the waistcoat pocket, the latter being by far the most popular mode of giving artificial age to Cucumber and Melon seeds. I think, as far as that family of plants are concerned, Signor Cazzola is right. There must be some mistake about the seeds that refused to grow in the experiments of M. Laizier, referred to in Mr. Quin's article (p. 293), for Melon and Cucumber seeds ten or even twenty years old vegetate freely enough if they have been properly harvested and kept. Many years' experience leads me to the conclusion that there is some hidden law of correlation between old seeds and fertility. Vitality might become weakened by age, and so a stronger tendency to reproduction of seed to perpetuate the species be developed. In the case of some seeds, such as Cucumbers and Melons, the growth has often been observed to be as vigorous as plants produced from old seeds. Of course in regard to other seeds the terms new and old must be interpreted in relation to each species of plant. Comparatively few seeds retain their vitality so long as Melons or such plants. The subject is worthy of re-investigation. Probably not a few of the apparently inscrutable changes of plants and flowers under identical conditions might be explained by a reference to the different ages of the seeds that produced them; and possibly not a few of our crops might be improved did we know the best aged seeds to sow to produce the special results which we have in view. For example, if it be true, as M. A. Malet asserts in the same article to which I am referring, that the newer the seeds the more vigorous the crop, and the greater length it will run, new seeds would be best for Celery, and old probably for Tomatoes. These two plants—the one grown for blanched stems and the other for its fruit—would form admirable subjects for experiment. Seed-bearing ruins the one, and an excess of growth is almost the worst thing that can happen to the other in the open air in our climate. D. T. FISH.

New Zealand Bramble (*Rubus australis*).—Rarely do we see plants, which in point of structure are curious or abnormal, possess sufficient merit to render them desirable objects of general culture, but this little New Zealand Bramble admirably combines these qualities. It is singular on account of the leaflets being reduced to small white prickles; a small portion of the leaf only is sometimes seen growing from the points of the leaflets. The profusion of these abortive leaves, beset with numerous white prickles, with which the stems and branches are also covered, renders it an entangled mass, which, however, presents a very graceful appearance, even in the absence of flowers, which I believe have not been produced in this country. It is a somewhat scarce plant, but should be sought after by every lover of the curious and beautiful in plants. It should be planted in good soil on the rougher parts of the rockery.—W.

Veronics in a Cut State.—Veronics should be grown more extensively than they are, for they yield an abundance of flower spikes fit for cutting until late in the year when out-door plants become somewhat scarce, and, being of many shades of blue, they intermix well with flowers possessing brighter colours.—J. G.

THE LIGHT FLORENTINE MOUNTAIN

GARDENING FOR THE WEEK.

Indoor Plant Department.

Early-flowering Tea Roses in Pots.—Those required to open their flowers under glass through the last months of the year, with little more warmth than that afforded by the protection they thus receive, will, after having been treated as advised, during the spring and summer, especially as to the flowers being removed from the growth they made early in summer, now be furnished with numbers of buds in different stages of development. The plants should at once be taken indoors and placed in a house as light as is available. If there is convenience, one portion may be subjected to a little warmth, say as much as will keep the temperature up to 50° in the night, with a corresponding temperature on dull, cold days; when the weather is bright and fine no artificial heat will be required in the daytime. These will come in quickly, affording a gradual succession of flowers for some weeks, to assist the development of which I should not recommend much side air to be given, opening the top lights when rendered necessary by the sun raising the heat too high. By these means whatever soft, tender, young growth the plants are making will go on, and form buds that will expand in succession; whereas if they were subjected to cold draughts the young leaves are almost certain to become affected with mildew. The flowers of the plants in question will precede the portion put in cooler quarters. Previous to taking them indoors it will be advisable to wash the whole with Tobacco water. This should be done even if no trace of insects be discoverable, as there may exist the larvæ of green fly or red spider, which, if present, will at once come to life, and entail very much more labour in their destruction.

Pot Roses for Later Blooming.—The pot Roses, both Teas and Hybrid Perpetuals, intended to succeed the foregoing, now plunged out-of-doors, should not be allowed to get saturated with rain if the weather should become wet. To those not much experienced in pot Rose culture the knowledge that Roses are hardy, or in the case of the tenderest varieties, all but so, often leads them to forego the attention given to other plants equally or better able to bear the influences of our changeable climate; consequently, they are left out and get the soil reduced to an unhealthy, soddened condition with the heavy autumn rains, the result being that their roots become stagnant and injured, and when placed in warmth for forcing they are not in a condition to act, the effect of which is that the flowering is meagre and unsatisfactory. Where they can be placed under the protection of frames, pits, or even loose lights, open, airy, unoccupied Vineries, Peach houses, or any similar places, they ought to be transferred thereto; these failing, if the weather be very wet, the plants should, during the time, be laid on their sides.

Propagating Roses by Autumn-inserted Cuttings.—The desirability for general garden purposes of growing all but a comparatively few varieties of Roses on their own roots begins to be generally acknowledged. With such varieties as are new and scarce, the plea of expediency for increasing them by budding is correct, the reason being that every bud can almost be reckoned on to form a plant; whereas in propagating from cuttings it is usual to not make them of less than two eyes in the way ordinarily adopted where the rooting process is effected in heat; and, even in this case, it takes very much more time to grow them up to a useful blooming size than when large, stout pieces of the shoots, necessarily having several eyes, are used, from 8 in. to 10 in. long, and these are more certain to root. There is no better time than the present for putting them in, for, although no roots are likely to be formed previous to spring, still the base becomes callused over, and in such condition the cuttings are better able to stand through the winter and form roots early in the spring than if taken off later on when the leaves had fallen, and, consequently, the wood was in a harder state, in which condition there is a less disposition to make roots. Pieces of the shoots, such as above mentioned, should be taken off now and severed at a joint, selecting good stout growths for the purpose, as these will make double the growth next summer that weaker cuttings will. The most suitable place for them through the winter will be a cold frame, placed facing the south; in this position the warmth of the sun in spring will have its influence earlier on the production of roots. If the soil naturally is not of a free, open nature, enough sand should be added to make it sufficiently light, more so considerably than that which Roses succeed best in when planted permanently; the advantage of this is that when the plants have become well rooted they can be taken up for removal with very little loss or mutilation of the roots, as compared with that which is inevitable out of soil that is heavy and adhesive. With a view to still further adapting it for the purpose, it should be thoroughly broken and pulverised, so as to reduce all the hard lumps and fully incorporate the sand with the whole. The cuttings may then be inserted in

a somewhat slanting position in rows about 6 in. apart, placing them about 2 in. asunder in the rows; they must be put in deeply, only leaving one or two eyes above the surface, treading the soil firm about them. In this way a large number of Roses may be raised in a good-sized one or two-light frame that, with proper attention, at the end of a couple of years will form large bushes producing quantities of flowers, and even towards the close of next summer will furnish some. If the best free-growing, free-flowering varieties be chosen, there are few soils and situations in the country, away from the smoky influences of large towns, where Roses may not be grown with the addition of, where necessary, preparing the soil in the manner recommended in a recent calendar. In such situations even those who have attempted to grow them worked on the Brier and Manetti stocks and have failed with these need not be discouraged, as the way in which they grow and flower struck from cuttings is very different from the results obtainable from budded plants. Where frame room is not available they will succeed in the open ground, but, as a matter of course, will not commence to make either root or top-growth so early in the spring. Where put in the open ground as here described it will be well to prepare a slight frame 8 in. or 10 in. in depth with a few laths nailed across it that will bear a mat in very severe frost, which, with the addition of a little Fern, a few leaves, or litter, will keep them safe. This protection may not be required, but the late very mild winters which we have experienced I find are leading to a general laxity in making provision to resist the effects of severe and protracted ones, when the ground becomes congealed deeply, in which case the pressure from the frozen earth, when it undergoes expansion, crushes the bark of the established plants and still more rootless cuttings, and in this way effects their destruction to a far greater extent than occurs through the direct action of the low temperature upon them.

Tea Roses.—Even those who think they have already Roses sufficient would do well to annually raise some from cuttings, especially of the tender Tea varieties, as a hard winter frequently destroys a quantity of these, and through which the young plants might escape, and would be found very useful. Besides this in most gardens space can be found occupied by worthless, unattractive shrubs that might be replaced by Roses, than which there are few plants so acceptable. With the somewhat tender Tea varieties not near so much has been done to grow them successfully as might be. Over a considerable portion of the kingdom, where the soil is tolerably light and dry, by choosing the most suitable positions, Tea Roses on their own roots will be found to answer satisfactorily by simply giving them, through the winter months, the protection afforded by 6 in. of dry Furze (Gorse), Fern, litter, or some Oak or Beech leaves, with a little litter on the top to keep them from blowing about. After a severe protracted frost, wherein the tops are killed down to the protecting material, the collar and roots of the plants will be found uninjured, and will push up stout growth which will flower during the season—a very different condition from that in which the budded standard and half-standard plants of these tender varieties of Roses will be after a hard winter, when, except in the most favoured localities, probably not one in a dozen will be left alive. Established Tea and Noisette Roses, in most places where they succeed well, are this autumn more than usually furnished with quantities of newly-formed buds; the profusion of these so late is no doubt consequent upon the late spring. If the blooms arrive at maturity, they will come in at a time when more appreciable than at any other season of the year, through the scarcity of flowers. Their opening depends, in a great measure, not alone upon an absence of frost sufficient to kill them, but also upon dry weather, as, when much wet occurs, the outside petals rot. Where flowers from these late-blooming kinds are appreciated, the best plan that I have found is to plant a bed in a warm, sheltered position, and place over it some stout Hazel sticks, firmly inserted in the ground at each side, bent over, and tied in the middle so as to form an arch, on which throw a piece of canvas or some mats when there is an appearance of frost. The labour involved is very little as compared with the pleasure of having a handful of half-expanded buds to gather when required.—T. BAINES.

Conservatories.—The absence of stove plants in these structures through removal to warmer quarters, on account of the lateness of the season, has divested them of their principal ornaments. Substitutes for them must be found in striking foliage and flowering plants of a more hardy character. Among the former the old *Miranda zebrina* still stands pre-eminent, and is one of the most useful decorative plants which it is possible to have for conservatory work at this season. Although fond of a little more warmth than is usually kept in such places at this time of year, it will stand very well for the next two months to come if the plants have not been recently subjected to strong heat, and are properly hardened off before being used. All that is necessary to insure their safety is to keep them somewhat drier at the root than they have been accustomed to while

growing in a warmer temperature, and to set them in positions away from cold draughts or where air is admitted. A little ventilation will, however, now be required beyond what is just sufficient to keep young growths from damping off, or the thermometer from running unduly high should bright sunny days occur. At such times the ventilators should be closed early, so as to shut in a good amount of solar heat, and obviate the necessity of having to use fires to keep up a genial temperature. By so doing, such plants as Achimenes, Colons, Balsams, and others may be rendered useful for some time longer, and even zonal Pelargoniums, Salvias, and most flowering plants of that class will be all the better for the extra warmth. In cases, however, where Camellias are planted out or occupy positions in the conservatory, the temperature must be kept as cool as possible, or they will most likely shed their buds. Although they will bear a great amount of heat when making their growth, they are particularly impatient of it at this season of the year, and nine-tenths of the failures that occur in the case of early Camellias are caused by attempts to force them, which they resent by casting their buds. The only way to get them to bloom in mid-winter is to start them early into growth, and keep them in moist heat till they set their flower buds. Thus treated they bloom naturally at a time of year when they are most valued, and last longest in perfection. The flower buds will now be showing themselves very prominently, and should at once be partially thinned by removing all the smallest and such as are badly situated for being seen when fully expanded. Where it is desired to keep plants to a limited size it is a good plan to take out the wood buds at the extreme points of all the strong shoots so as to induce the plants to break further back, which they would not do were these strong buds allowed to remain. By disbudding early, those in a dormant, undeveloped state lower down the shoot are forced to swell, and, as a result, start readily when the time comes for them to do so. It will now be necessary to admit all the light possible by reducing roof climbers to moderate limits, and which at no time should be allowed to get interlaced and entangled, whereby much of their natural grace and beauty is lost. As growth has now almost ceased in the case of most of these for this season, little water at the roots will now be requisite, for a moderately dry state of the border during winter will have a beneficial effect on the health of the plants. This applies more particularly to Passifloras, Tacsonias, Bignonias, and that class of summer-blooming plants, but Lapagerias will still require liberal supplies, as the flowers they bear in such abundance are now making active demands on the roots.

Chrysanthemums are generally late in setting their flowers this season. As soon as the buds are sufficiently large to handle, the whole of the plants should be gone over and thinned, reducing the number more in the large varieties than in the case of small-flowered kinds, as the latter can mature a proportionately greater quantity of blooms. In all cases it is better to thin out considerably more than is generally the practice; not only are the individual flowers finer when so treated, but they last much longer. From this time they should be fed with liquid manure alternately with clean water when they require moisture, and they will bear it as strong as any plant in existence. The majority of those who grow Chrysanthemums never obtain fine flowers, nor leaves that keep the dark green colour they are capable of assuming, simply because they do not give the plants sufficient liquid manures. If there is a deficiency of Chrysanthemums that have been grown in pots, any that were planted out in the spring may, now that the flowers are set, be lifted and placed in pots, abundance of water being given until they have taken hold of the new soil. The inexperienced may not, in the case of these plants, be able to understand the reason of advocating the use of so much water immediately after potting, which is quite contrary to the advice generally given in the management of most subjects when newly potted, viz., to withhold water as long as possible without allowing the soil to become over dry. The reason is, that they are remarkably vigorous and free-rooting, otherwise they could not bear to have their roots disturbed in the manner indicated; and, at the same time, they naturally require a great deal of water. If the majority of plants usually grown in pots were subjected to such usage, especially in the quantity of water given, they would assuredly die. This is simply a proof of the wholly different treatment required to ensure success in the cultivation of pot plants.

Veronicas, such as Andersoni, salicifolia, and their numerous hybrids, are particularly adapted for those who have not had much experience in plant culture; they are easily propagated, easily-grown, and not impatient of a few degrees of cold or of extremes in the way of getting over-wet or a little too dry, such as would kill many plants. Their habit of flowering continuously through the autumn up to the end of the year in either a greenhouse or living room makes them additionally attractive at this season. Plants that were struck in spring and planted out-of-doors, as was then recommended, will

by this time have made moderate-sized specimens, furnished with flower spikes at every joint from the points of the shoots for some distance downwards; they should at once be taken up and potted, lifting them with a fork, so as to preserve, if possible, all the roots intact; they will require pots from 8 in. to 12 in. in diameter, according to the variety grown and the size of the plants; give them more drainage than would be required for subjects that do not want so much water as these Veronicas; they will succeed in any ordinary, moderately light, porous soil. As soon as potted, give water enough to moisten the whole, as Veronicas are amongst the limited number of plants that must be watered immediately they are potted. If this be not done, the leaves will flag, an occurrence which would most likely have the effect of causing the unopened flowers to drop. If well attended to and kept in a frame, pit, or in a room, with the air a little confined for a week after they are potted, so as to give their roots a chance of beginning to act, they will continue blooming for many weeks. These and numbers of other plants that are handsome, free-flowering, and easily managed, are quite equal in every respect to many subjects that are much more difficult to grow.

Agapanthus umbellatus.—This, though old-fashioned, is an excellent plant; by some, however, it is held in little estimation, simply because it is easily managed. It will succeed in any kind of soil, and will bear neglect through inattention to watering better than most plants; it will also do with less pot-room than many plants. The excellent habit of its curved, drooping leaves, which, when well grown, almost cover the pots in which it is placed, constitute it one of the best for standing about door porches, on terraces, or by the side of walks, where the large umbels of blue flowers it forms are seen to advantage. They are likewise very useful for cutting, lasting well in that state, and affording a colour not over plentiful. It is also equally at home in the greenhouse. As soon as the flowering is over, when it is required to be increased, the plants should be turned out of the pots, the roots (which are usually very much interlaced) disentangled, and the crowns divided; if the roots be much matted they can be separated with the least injury by plunging the ball in a vessel of water and working the whole of the soil out with the fingers; a common edging iron will sever the crowns with as little damage to the roots as any implement that can be used. If two or more crowns be retained to each piece divided they may be put in 8-in. or 9-in. pots. Grow them in ordinary loam, to which add enough sand, and ram the soil firmly in the pots, which should be well drained, as they will do with less shifting than most plants.

Flower Garden.

Bedding Plants.—Such of these as are required to be taken up and potted must not be allowed to remain out so long as to suffer from frost, as, after they have been injured in that way, they will do little good. The tricolor Pelargoniums should be first secured; in taking them up, do not break any more roots than can be avoided, but do not attempt to lift them with halls; remove about one-half of the leaves, leaving such as are nearest the points of the shoots; let the soil be open, with a good proportion of sand in it; do not use pots larger than the roots can be got into by coiling them closely inside; make the soil quite firm, but give no water for a week or ten days. Gazanias, Lobelia speciosa, and any others that are required for stock should be also taken up and potted. Respecting this Lobelia it is not advisable to trust to seedlings, as these generally vary so much in both habit and colour as to make them much inferior to those propagated by cuttings from selected plants. Where an inefficiency of the earlier-struck cuttings of bedding Pelargoniums exists, more should at once be put in, although these cannot be expected to get so well established before winter as such as were rooted sooner; yet the harder condition of the shoots now will ensure their striking freely, provided they are fairly treated. Six or eight may be put in a 6-in. pot, removing all the leaves except two or three at the top; ram the soil quite hard in the pots, and do not give any water until it gets so dry as to absolutely require moisture; they will do well in a cold frame for a time with a little air during the day; the additional warmth which they will get here through sun-heat will accelerate the formation of roots. Rooted cuttings of all kinds of bedding plants will still be benefited by being fully exposed to the open air during the daytime, whenever the weather is favourable, but it will be advisable, in order to ensure their safety, to place lights over them at night, or, in some other way, to protect them from the effects of any unfavourable change which may suddenly take place in the weather.

Herbaceous Borders will still be gay with Asters and other late-flowering plants, and should be kept free from weeds or other littery matter, such as dead leaves or decaying flower stalks; annual plants should be cleared off as soon as their beauty is over, except in cases in which seeds are required.

Indoor Fruit Department.

Vines.—Those to be started into growth early in November must now be pruned. Except where young canes are being taken up, cut off all the wood of this season's growth, leaving only two buds on each spur. The operation of pruning should be effected with a sharp knife, and the wood should be cut nearly straight through. When all the canes are pruned remove the loose bark from the rods, but avoid scraping into the wood. Where mealy bug exists the cleansing must be performed with much care. This pest is always harboured underneath the loose bark, especially in the crevices about the spurs. When the bark is removed the whole Vine should be firmly scrubbed with a stiff brush and plenty of soft soap and lukewarm water. The brushing must be carefully accomplished about the eyes or they are liable to be rubbed off. The washing of the Vines completed, the glass and woodwork of the house should be scrubbed in the same way, and the whole should be finally drenched with clean water by means of the garden engine or hand syringe. When the Vines are dry, dress the wounds with Thomson's styptic, working it well into the pores with a small hard brush, and no bleeding will occur when the sap begins to rise. Remove all the loose surface soil down to the roots, and fill up to the required height with a mixture of loam, bones, and half-rotten cow manure. Do not leave a particle of the old soil in the house, as it generally contains the insects or their larvæ which have been cleaned from the Vines. After top-dressing, clean the pathways and the pipes, and give the border a thorough soaking with water, so as to moisten the entire body of soil, and render the roots fresh for starting into growth, keeping all the ventilators open day and night until forcing begins.

Pines.—Every favourable opportunity must be taken during this month to admit air to well-rooted suckers and other half-grown plants, so as to keep them dwarf and hardy for the winter. The bottom-heat for the earliest potted suckers need not exceed 70°, or 75° at the most after this time. The atmospheric temperature may range from 65° to 70° at night and 10° more throughout the hottest part of the day. Houses in which there are plants in fruit should be closed early in the afternoon, the fire being started in time to prevent the temperature falling below 70° at night.

Kitchen Garden.

Herbs.—If sufficient herbs were not cut for drying earlier in the season more should be secured before the approach of cold autumn weather; this more particularly refers to such subjects as Sage and Thyme. Lay them loosely where they will be fully exposed to light and air until quite dry. A quantity of Parsley should also now be gathered and similarly treated; it ought to be dried quickly or it will spoil. If it can be placed near a warm fire this will answer well. A good supply should always be thus provided, as, for many purposes, it can be used in place of fresh material in severe winters.

Tomatoes.—Any fruit of Tomatoes in the open air that has begun to colour should now be gathered and placed on a dry shelf near the glass in a greenhouse or similar situation, where it will be exposed to the full influence of the sun, and will soon ripen and be fit for use; the quality of Tomatoes is better when they are fully ripened on the plant; but after this time it is not safe to leave them out on account of danger from frost. The plants may be allowed to remain longer if they have yet a considerable quantity of growing fruit upon them; for, although they do not grow so fast after this time, yet, if the weather keeps fine, they will get to a useful size. A mat may be hung over them at night if danger from a low temperature is apprehended. When they have ceased to make further progress pull the plants up by the roots and hang them up, the heads downwards, in a greenhouse or empty Vinery, where the fruit will ripen. When so treated they should not be tied up in large bunches, or the leaves will turn damp and mouldy, which will prevent the fruit becoming fit for use.

Mushroom Beds.—Beds recently made should now be examined in order to ascertain whether or not they are fit for spawning. Manure for successional beds should be prepared, as, from this time to the end of the year, Mushrooms can be grown more successfully than at any other season, especially by those who may not have a regular house for them.

Extracts from my Diary.

October 7.—Sowing Canadian Wonder French Beans in pots for forcing, using good fibry loam and leaf-mould and rotted manure; also Mustard and Cress in heat. Potting herbaceous Calceolarias; also a small batch of late Cinerarias. Getting pits and frames ready for Endive and Lettuce. Renovating linings round pits and frames in which Cucumbers, Radishes, French Beans &c., are grown. Lifting Beetroot and storing it away in dry mould in an open shed. Looking over all Cauliflowers, and doubling down leaves, where heads are

formed, to preserve them from frost, and removing all those fit for use to a cool shed, heeling them in in dry soil. Covering up Endive and Lettuce to blanch with inverted flower-pots. Gathering Easter Burreé, Josephine de Malines, and Winter Nelis Pears, and laying them singly on clean straw in fruit room. Watering the Pines all through, and tying up the fruit where required.

Oct. 8.—Potting Pelargoniums from flower borders; also a batch of Hyacinths, plunging the latter 2 in. or 3 in. deep in coal ashes in cold pits. Clearing off Cauliflower stumps and Peas which are done with, and preparing the ground for manuring and trenching. Transplanting a large border of Carter's Early Heartwell Marrow Cabbage. Turning a large heap of Mushroom manure. Moving Plum trees from nursery wall to other parts of garden where required to fill up vacancies. Planting Lettuce and Endive in pits and frames previously prepared by being filled with good soil.

Oct. 9.—Potting Lobelias and Tom Thumb and Flower of Spring Pelargoniums. Getting Chrysanthemums under cover. Weeding and thinning out autumn-sown Carrots. Hoeing amongst all the autumn-planted Cabbages. Gathering Blenheim Orange, Gooseberry Pippin, and Royal Somerset Apples.

Oct. 10.—Sowing Mustard and Cress in shallow boxes placed in heat for succession. Potting Centaureas and Carnations. Looking over Pelargonium cuttings, and removing all dead leaves and weeds. Earthing up late Celery when the soil is dry and in workable condition. Lifting Peach and Nectarine trees, and root-pruning them where required to check rank growth and bring them into a bearing condition. Clearing out all water-spouts and drains before the rainy season sets in. Gathering Burreé de Capiamont, Burreé Clairgean, and Duchesse de Angoulême Pears. Clearing up leaves, and stacking them away for use hereafter.

Oct. 11.—Potting Pelargonium cuttings which have been struck in a frame. Planting a border of spring-flowering plants, consisting of Wallflowers, *Silene pendula compacta*, Forget-me-nots, Red and White Daisies, &c. Gathering all Scarlet Runners that are of usable size, and putting their stalks in water to keep them fresh until required for use. Earthing up Cardoons when the soil is dry and friable. Erecting staging over Strawberries in pots, on which to place spare lights to throw off heavy rains and protect the plants from frost. Clearing flower borders, and digging them. Top-dressing Cucumbers with chopped turf and rotted manure.

Oct. 12.—Roping Onions during wet weather; also looking over seed Potatoes, and placing them on their ends in shallow boxes to sprout. Cleaning paint in Vineries, &c., to destroy insects. Cutting shreds, pointing nails, making labels, pegs, &c., ready for use in dry weather. Fruit in use for dessert—Pines, Grapes, Pears, Plums, Apples, Nuts, &c.—W. G. P., Dorset.

New Potatoes in Autumn.—There is nothing new in having young Potatoes in autumn; but who cares to eat such watery tubers when all the finest kinds may be had ripe and mealy and of first-rate quality in every respect? Those, however, who desire such novelties may easily have them by retarding sets of any kind in a cool, dry, airy place till the end of June or July, and then planting them in any light, rich piece of ground exposed to the sun. It is a common practice with cottagers hereabouts to get two crops of Potatoes off the same piece of land by planting, after the first is dug, the second, which comes in for seed, as they sell the entire produce of the first as soon as they are large enough to be marketable. The sort treated in this way is Myatt's, the best of all Potatoes for early cropping, either out-of-doors or in frames, the old Ashleaf being too tender and uncertain to be relied on. An easy way, although a very old one, of getting young Potatoes during winter is to save sets of any large, strong-growing kind, and as the shoots form to rub them out till autumn or as long as they continue to appear, and then bury the tubers in dry sand or sifted soil where they will get a little warmth. After a few weeks they will emit young tubers around them, which if left will attain an ordinary size. These, it must be admitted, are not what any one would pronounce really good, but they come in by way of a surprise and take up very little room, time, or labour to grow them, and it is a way of utilising any spare sets or surplus stock that may be left over after the winter. This supertuberating of Potatoes has been a common affair of late, owing to the check received through dry weather when growing, and it often occurs in pits or where many are stored together and get a little warm.—S. D.

Tomatoes under Glass.—Indoors Tomatoes keep free from disease, and when grown in pots and trained in a light, airy position where a little artificial heat can be given after this period of the year, they are exceedingly prolific, and in this way may be had all the year round.—J. GROOM.

ROSES.

ROSE GROWING IN FRANCE.

[The culture of the ever popular Rose is understood perhaps better in England than anywhere else, and the climate seems to aid the efforts of the cultivator with that amount of heat and moisture which produces the largest and finest blooms. But other nations also love the Rose, and its culture in France is both very ancient and very extensive. France makes the Rose a speciality in various districts, such as at Brie Comte Robert and Lyons, where it is grown on an extensive scale. Large numbers of our most beautiful Roses have been raised in France; it has, therefore, occurred to us that some of the Rose-lore of the country in which Maréchal Niel and La France were raised would be of some interest to English Rose growers, and for this reason we have translated some of the chapters of a French book on Roses, which will show the culture of the Rose from a point of view different from our own, and yet applicable to a country having almost the same climatal conditions.]

SOIL FOR ROSES.—The Rose tree adapts itself to every kind of soil; it does not, however, grow equally well in all. Heavy, clayey ground, with an impermeable sub-soil, is that which suits it least; the roots are too delicate to force their way through it, and they rot in the damp which they find beneath the surface. Light, calcareous, or siliceous soils, about 14 in. or 16 in. in depth, with a permeable sub-soil, are the most suitable, above all when they are stimulated with a little manure. We must not always judge of the suitability of the soil by the good condition of the plants growing upon it. In strong, rich lands the Rose tree may grow only too well; it may continue in leaf until very late in the season, in which case the young shoots will be exposed to the first frosts before they are perfectly matured. In a soil which is lighter and less rich the growth stops sooner, and the new shoots become properly ripened before they encounter the first cold. It may be remarked, also, that Roses grafted on the Brier are much stronger than those of the same varieties which have not been grafted.

PREPARATION OF THE SOIL.—The ground intended for Rose growing ought to be dug to the depth of from 14 in. to 16 in. This part of the work ought, if possible, to be done in the autumn for spring planting. There is no need to enter into details with respect to this part of the work, as it is the same in the case of all kinds of plants. Great care, however, must be taken to clear the ground of all kinds of weeds and to extirpate the cockchafer grub. It is a good thing to stimulate the zeal of the labourers in their search after these pests to put a price on their heads. At Vitry, for digging the ground to the regulation depth of 14 in., the labourers are paid at the rate of about £4 16s. per acre, with an additional 10s. for the cockchafer grubs.

THE PROPAGATING HOUSE.—In the course of this article we shall frequently have to speak of the propagating house; we think it, therefore, just as well to describe thus early the plan upon which it should be constructed, so that it may give the best results. As the propagating house is not intended for show, its construction ought to be made subservient to proper conditions, that is to say, we must have as much light and heat as we require, and at the cheapest possible rate. The propagating house is a lean-to, and has but a single sloping roof, the slope being one in two. The principal is formed of a thick beam, which rests on an upright post, which again rests on a low wall, rising about 8 in. above the surface of the ground. The upright post has a piece cut out of its lower end, into which fits a light 4 ft. 8 in. in length. A second light of the same length is placed above the first, which it overlaps about $1\frac{1}{2}$ in., while a board of about 16 in. in breadth shuts all in snugly. The vertical portion between the supporting posts, which measures 1 ft. 8 in. wide in the inside, is fitted with a light which opens outwards. The width of the inside is 10 ft. 10 in., and is thus divided:—Against the lights is a frame 3 ft. 8 in. in width, and capable of holding three rows of bell-glasses. The inner wall which supports the frame is built of bricks 2 in. thick. The passage is 2 ft. 8 in.

wide, and the other wall, which carries a second frame, 3 ft. 8 in. wide, is also 2 in. thick. The floor of the passage is 2 ft. below the level of the soil outside, the front frame being 2 ft. 8 in., and the back frame 3 ft. above the floor. The back wall which supports the roof rises more than 6 ft. above the back frame. There is, therefore, plenty of room for a couple of shelves. We shall not speak of artificial warming here, as everyone can choose the plan which he thinks the fittest to

Fig. 1.—Sécateur.

Fig. 2.—Handsaw.

carry out his purpose. In many cases, however, there is no need for artificial heat; a heap of stable manure against the lower wall, a good supply of tan in the frames, and some thick straw mats being all that is necessary. The number of the frames will depend on the length of the house itself, which in this respect should be made large enough to satisfy every requirement. If a kind of inner porch can be built with a second door it will be found very convenient to work in, besides which the house will be all the warmer for the double doors. As the article proceeds we shall have frequent occasion to speak of bell-glasses for the cuttings. The following method of protecting them, which has been introduced for some time, is to be recommended: The bell-glasses are replaced by little boxes made of deal, the top being covered with a couple of sheets of glass, which may be removed at will. The front of these boxes measures 8 in. in height, the back 12 in.; as for their length and breadth, that is determined by the size of the sheets of glass at command. In this case the back and front of the boxes should be connected by two rods dovetailed in to support the glass. We merely indicate rather than describe the construction of these boxes, for everyone can make them in accordance with his own idea. We must recommend them for Rose

growing, in preference to bell-glasses, for several reasons. They take up less room, the cuttings are closer to the glass, the heat is more fully concentrated, and they are worked much more easily. For instance, while the plants are being attended to the sheets of glass are placed upright against the wall of the passage between the frames, so that any dew which may have collected on them will run off of its own accord without any necessity for wiping them, as is done in the case of bell-glasses.

Tools for Pruning and Grafting Rose Trees.

The *Sécateur* (fig. 1) is a kind of shears with springs, consisting of a blade and a hook, which holds and steadies the branch while the blade cuts it. This tool is very destructive, for the pressure of the hook crushes the fibres of the bark, and sometimes those of the tender young wood, leaving a contused wound, which prevents the cut portion of the branch from becoming covered with fresh bark. To diminish the effects of this serious defect, the hook must always be placed under the branch to be cut, so that the principal effect of the pressure may be exercised on the upper portion, that is to say, on the part which is cut off. The *sécateur*, as shown in fig. 1, is 8 in. long. The blade forms part of the handle, as well as the hook. These parts ought to be too long rather than too short, and, above all, should be made of highly tempered steel.

THE HAND-SAW.—The hand-saw, as shown in fig. 2, is about 5 in. in length in the blade, and is provided with a wooden

Fig. 3.—Pruning Knife.

Fig. 4.—Grafting Knife.

handle, into which it shuts. It is used for cutting off useless branches and dead wood. After the cut has been made it must be pared down with the pruning knife (fig. 3) and covered with grafting wax, so as to favour its recovery by keeping it out of contact with the air.

PRUNING KNIFE.—The pruning knife, shown in fig. 3, has a handle of buckhorn, about $3\frac{1}{2}$ in. long and $\frac{3}{4}$ in. in diameter at the base. It is provided with steel caps at each end, which greatly add to its solidity. The blade is made of cast steel, and is in the English form. It is $2\frac{1}{2}$ in. long and $\frac{1}{2}$ in. thick at the back. It generally costs from 3s. to 3s. 6d. There is another kind of pruning knife with a wooden handle, which is greatly used in France, which costs only from 1s. to 1s. 3d. when taken by the dozen. It forms a very useful tool when the blade has been made by a good cutler. One or other of these pruning knives is indispensable to the Rose grower.

GRAFTING KNIFE.—This implement varies greatly both in form and length. It may be provided with a movable or fixed spatula. In the grafting knife shown in fig. 4 the spatula is movable. The handle, which is of buck-horn, measures $4\frac{1}{2}$ in. in length, and $5\text{-}8\text{ths}$ of an inch broad. The blade is $3\frac{1}{2}$ in. long, and $\frac{1}{2}$ in. to $5\text{-}8\text{ths}$ of an inch in width at the narrowest and broadest parts respectively. The blade should be of fine steel, and should have a very keen edge. The spatula is $5\text{-}8\text{ths}$ of an inch in length by $2\text{-}5\text{ths}$ of an inch in width.

LABELS.—It adds much to the enjoyment of Rose growing if every subject bears its proper name inscribed on a zinc or wood label. These labels may be easily cut from zinc clippings with a pair of shears. They are generally cut of the size and shape of a gentleman's visiting card with the corners cut off. A hole is pierced through them with a bradawl, so that they may be tied on the trees. They may be written on with the ink described below with a quill pen. Before writing on the zinc the surface must be thoroughly cleaned by washing in a solution of one part of common oil of vitriol to four parts of water. When dry, it must be sprinkled lightly with powdered gum sandarac to prevent the ink from running. As soon as the writing is dry it may be fixed by passing over it a soft brush dipped in white hard varnish. After this treatment the label will last for years, and may be washed as often as necessary.

INDELIBLE INK.—Powdered verdigris, $\frac{1}{2}$ oz.; sal ammoniac in powder, $\frac{1}{2}$ oz.; ivory or lampblack, 1 drachm; water, 8 oz. Blend the lampblack with a little water with the blade of a knife, then add it to the rest of the water, shaking the bottle until the whole is mixed. The verdigris and sal ammoniac are added next, and the whole is shaken until everything is dissolved. The bottle must be kept closely corked, and should be well shaken before the ink is used.

WOODEN LABELS.—These labels, although not so neat or so lasting as those made of zinc, are nevertheless greatly used where Roses are grown on a commercial scale. They are generally made of deal, and are 4 in. long, $5\text{-}8\text{ths}$ of an inch wide, and $1\text{-}8\text{th}$ of an inch thick. They are covered on one side with a layer of yellow ochre mixed with half its bulk of starch and enough water to make it into a thin cream. It may be applied with a brush or plug of tow. These labels may be written on with an ordinary pencil. At one end are two side cuts, through which passes the lead or zinc wire by which they are fixed to the tree. These labels can be made in France at 4s. per 1000, lead wire included.

GRAFTING WAX.—Yellow wax, 1 lb. 9 oz.; black pitch, 3 lb. 2 oz.; white pitch, 3 lb. 2 oz.; tallow, 5 oz. Place the whole in an earthen pipkin over a gentle fire, stirring it with a spatula as it melts, taking care to incorporate the ingredients thoroughly. This kind of grafting wax will remain solid at ordinary temperatures. In order to use it in the Rose garden we must provide ourselves with a charcoal or coke stove, or if only a small quantity is to be used a spirit lamp will serve the purpose, more especially when the spot is at a distance from the house.

COMPOSITION TO BE USED IN THE COLD FOR GRAFTING ROSES AND COVERING CUT SURFACES.—Yellow wax, $12\frac{1}{2}$ oz.; black pitch, 1 lb. $2\frac{1}{2}$ oz.; white pitch, 1 lb. $2\frac{1}{2}$ oz.; linseed oil, 5 oz. Melt the whole together in an earthen pipkin over a gentle fire, and incorporate thoroughly with a wooden spatula. When mixed pour out on a flat piece of slate or porcelain moistened with water. Allow it to become cold enough to handle; and having first well moistened the hands mould it into rolls about $\frac{3}{4}$ in. thick, and 3 in. or $\frac{1}{2}$ in. long. They should be wrapped up in

oiled paper and kept in a cold place. For use, a small quantity of the wax is cut off and softened by the heat of the hands just before it is applied to the tree. This grafting wax contains no corrosive matter, adheres closely to the tree, and will keep good for several years.

PANS FOR SEEDLINGS.—Fig. 5 represents the pan that is used for sowing. The dimensions vary from 6½ in. to 1 ft. in diameter, and from 4 in. to 6 in. in depth. These pans ought to be made of good porous clay, and should be pierced with holes at the bottom.

DRAINAGE.—It is of the greatest importance that the water used for watering plants grown in pots should not remain in them, for if it does the roots will infallibly rot. Drainage, therefore, must be provided for by placing at the bottom of the pots some coarsely-broken material, such as pebbles, broken brick, &c., so as to prevent the hole in the bottom being filled

Fig. 5.—Pan for Seedlings.

up with the mould. In growing Roses we need only cover the hole over with a piece of broken flower-pot.

Rhododendrons and Roses Mixed.—At Hutton Hall, Gnisborough, what in the distance appeared to be a bed of Rhododendrons in flower at the end of August was in reality a bed of Rhododendrons with standard and half-standard Roses dotted amongst them. The heads of the Roses were just the height of the Rhododendrons, which, when looked at a little way off, seemed to be in flower. This is a mixture which might be extended to many places with great advantage.—D.

Pruning Marechal Niel Rose.—I agree with Mr. Hind's remarks (p. 284), with the exception of one or two points. I must consider the Brier to be the best stock for this Rose, both for open-air planting and under glass. I have long since abandoned its cultivation out-of-doors; and as to pruning, the plan pursued by us in common, I believe with many of the leading growers, is to cut back the laterals after blooming to a single eye.—WINDHORE.

Rosa fulgens as a Standard.—I have not lately seen this in Rose catalogues, and cannot understand why it should have been discarded. Worked high, and trained over an umbrella trellis, it forms one of the finest summer ornaments of the flower garden. Being brilliant in colour, very free-flowering, sweet-scented, and so vigorous in growth, that when my last standard of it became superannated, I had its remains handsomely carved, or rather turned, and converted into the tall stem of a candlestick table.—E. H.

Beauty of Glazenwood Rose.—Allow me to make a statement about a Rose which I see in catalogues under this name. Its history is as follows: In 1870 I saw it in bloom in a garden at Meran, in the Tyrol. I sent home two buds, one of which "took," and in 1871 the Rose bloomed on a south wall in the garden at Hedingham Castle, Essex. I showed it to Messrs. Paul, who told me that it appeared to be a beautiful variety of Fortner's Brier. I called the Rose Meran, and gave plants of it to my friends, by whom since 1871 it has been known as the Meran Rose. It is now, however, going the round of the Rose catalogues as a new Tea Rose. I am very glad that it is brought into notice, for it has great merit as a beautiful Brier Rose of remarkable colour and fragrance, but as it has no right to be named from Glazenwood, I will ask those who grow it to call it by its older and right name of Meran.—SEVERNE MAJENDIE, Chaplain to the Duke of Buccleuch at Drumlanrig Castle.

NOTES FROM RANGEMORE HALL.

(THE RESIDENCE OF M. T. BASS, ESQ., BURTON-ON-TRENT.)

VINES AND PEACHES UNDER GLASS.—Some fourteen or fifteen houses are devoted to the cultivation of Grapes and Peaches, and everywhere marks of successful culture are represented. The two late Vineries—large span-roofed structures—are finishing off very fine crops of Muscats, Lady Downes, and Alicante Grapes. The Muscats especially were fine both in bunch and berry. Any young fruit grower whose lot is cast in a difficult situation might learn more than one useful lesson from Mr. Bennett's practice. The staple soil of the kitchen garden and neighbourhood is a poor, heavy, cold clay; even the top spit turf is of the same heavy, cold nature, and when its fibre decays it becomes too close and cold for healthy, active root action. Mr. Bennett meets and overcomes this difficulty by adopting Bacon's advice; and works in freely and often fresh turfy soil about the roots of his Vines and Peach trees. I believe a season never passes without some alteration or addition being made to some of the Vine borders. It involves a good deal of work, but the standard of excellence is maintained. Of course, in addition to this the houses are roomy, with a good length of rafter, and they possess all the latest improvements as to ventilating machinery. But, after all, healthy root action is the most important thing, and must be secured at any cost. Many of the Peach trees in both the early and late houses are trained horizontally, the main branches being about 6 in. apart. Mr. Bennett speaks highly of the plan, and the trees were remarkably healthy, and well and regularly furnished with branches. It is a simple plan enough when once the foundation of the tree is laid. The long main branches are furnished their whole length with young bearing shoots, which are annually replaced by others, in the same way as Vines are managed on the short rod system. It has a tendency to equalise the flow of the sap; and I think there is not the same danger of overcrowding the young wood and foliage as by the common method of fan training. The whole thing is plain and straightforward; any ordinary mind can soon acquire the details. You have a number of horizontal branches, say 8 ft. or 10 ft. long; along the upper sides of these branches are ranged a certain number of young bearing shoots, which, when the crop is gathered, will be cut out and replaced by others that have sprung from their base; and so on, year after year. Peaches out-of-doors do not bear well in Staffordshire, even when protected by wood copings and canvas blinds; but in a long Peach case, built on the model of the one at Keele Hall, some fine fruits when I was there were still ungathered.

CORDON PEARS.—In front of the Peach case just alluded to is a long border, about 90 yds. or 100 yds. long, and 4 yds. or 5 yds. wide, planted with a collection of low cordon Pears. The border accommodates three rows of trees. They are trained over a flat table trellis about 15 in. or 16 in. from the ground. The two outside rows are planted near the edge of the border, 12 ft. apart each way, and three branches are taken from each tree at right angles. The centre row of trees is planted so as to range with the outside rows, thus—* * * ; four branches are taken from each tree. Altogether, the collection is an interesting one, and some of the trees are bearing good crops of fruit. I have no doubt, after a little experience of this kind of culture, when one had discovered the most prolific kinds to plant in each district, that a plantation of such trees would be profitable, as it would be a very easy matter to shelter them in cold seasons.

THE WATER LILY POND.—This has been constructed artificially, mainly for the purpose of obtaining a supply of the beautiful flowers of the White Water Lily (*Nymphaea alba*) for indoor decoration. Cultivation improves this plant; for the flowers and foliage are never so fine in natural ponds as they are when proper preparation has been made for them. Water Lily culture is a simple matter; any one may have a Lily pond without incurring much expense. Dig a hole 4 ft. or so deep, as large as is necessary, and any shape required. Well puddle the bottom and sides with tempered clay; on the clay lay 18 in. in depth of turfy loam and manure, and in this plant the Lily roots. The depth of water when all is completed should be about 2 ft. A pipe should be laid to the pond from

a good water supply, to keep the pond full in dry weather, and if it be too large for a plank to reach across, some resting place, not too conspicuous, should be fixed in the centre of the pond to give a bearing for one end of a plank, to enable a person to gather the flowers. A pond of this character would be an interesting feature in any garden, and might be placed in some retired spot.

CAMELLIAS AND ROSES.—The Camellia house is a large lofty structure with a ridge and furrow roof. The plants are in vigorous health, showing plenty of bloom buds. But I notice it principally to direct attention to the happy and useful effect produced by the Tea and Noisette Roses which are planted in borders round the walls, and which have covered the upright sides of the house and are rapidly extending under the roof, furnishing a light, grateful shade to the Camellias, and yielding at nearly all seasons an abundant supply of beautiful blossoms for cutting. The strong, vigorous growth of *Maréchal Niel* was especially noticeable. Flowers for cutting are in great demand, and amongst other subjects *Allamanda Hendersoni* and *nobilis*, trained on the roof of one of the stoves, are now a grand sight; I do not remember having seen before these plants so well flowered. *Cissus discolor* and *C. porphyrophyllus*, trained up the supporting columns in the same house and festooned about, are very effective; the latter kind is not nearly so much grown as it deserves to be. It is a vigorous grower with large, handsome, bronzy-looking foliage. A very good collection of Orchids is being got together. I noticed amongst others a fine plant of *Phalænopsis Schilleriana* showing two fine spikes, *Saccolabium guttatum*, several specimens finely in flower, and large numbers of those useful winter-flowering kinds *Calanthe vestita* and *Veitchi*, *Cypripediums*, *Lælia*, *Dendrobiums*, *Coclogynes*, *Odontoglossums*, &c. Very large quantities of Ferns are grown for supplying fronds for cutting, and the old Maiden-hair (*Adiantum cuneatum*) remains here, as elsewhere, the favourite. The back and end walls of the Fernery are most effectively draped with a mixture of ornamental-leaved *Begonias*, *Fittonias*, and *Gymnostachys*. I have seen the same idea worked out in other places, but never better done than at Rangemore. A framework of galvanised wire netting is stretched over the face of the wall and about 3 in. from it. The cavity thus formed is filled full of turfy peat by pushing it through the meshes of the netting, and then small plants of the kinds named are inserted all over the surface. The effect in contrast with the green foliage of the Ferns is rich in the extreme. I got another useful idea for table decoration that may, perhaps, be new to some of your readers. Thin pieces and strips of deal board that will work into ornamental designs are covered 2 in. or so thick with peat; small bits of *Lycopodium densum* are dibbled in thickly, and soon form a dense mass, covering the wood effectually. At certain points the *Lycopodium*-covered peat is raised into low broad mounds which for the present contain small flower-pots to keep the sides up. When required for use, the flower-pots can be lifted out and the circular cavities which they occupied be filled with cut flowers, or some contrasting plant may be dropped in for a change. E. HOBDAY.

SUGAR IN THE NECTAR OF FLOWERS.*

NECTAR is the term applied by botanists to the sweet-tasted fluid which is secreted within the cups of insect-fertilised flowers, and the object gained to the plant by its presence is that insects, induced to visit flowers for its sake, are useful to the plants by effecting a cross-fertilisation. Mr. Darwin has shown what an amount of additional vigour is thus conferred on the seeds which subsequently result in contrast with the evil effects produced by continuous inbreeding. In many instances this sweet liquid is exuded from special glands, but in other cases from portions of the flower that do not seem to have been specially adapted for this purpose. Morphologically, nectaries may represent very different structures, but not unfrequently they are of the nature of an aborted organ—such as a petal or stamen. It is a point in dispute among biologists whether this saccharine matter is a true secretion or simply an excretion of effete matter from the vegetable cells, a by-product of the chemical changes taking

place within these cells. The latter view seems to be favoured by the fact that a similar sweet-tasted fluid, much sought after by insects, is exuded on different parts of some plants quite unconnected with the flower, as in the Laurel, Brake, Fern, Lime tree, Acacia, &c. As to the use of such exudation of sweet fluid, various suggestions have been made by those who are disposed to regard it as a true secretion, as, for instance, that it serves as an attraction to certain insects to frequent the plant, these insects rendering service by keeping off animals to whose attacks the plant may be subject. Probably this is, to some extent, true, but it cannot be said to hold universally. Nectar is, of course, the source whence the bee derives honey, but it also affords food to many kinds of insects which do not possess the habit of storing up. A division of the humming birds is named *Meliphagi* on account of living on this substance; but it is probable that in some cases the small insects seeking the nectar, and not the nectar itself, may be the object of the visits of these birds to nectar-producing flowers. The bright colours, as shown by Sir John Lubbock's experiments, serve to guide insects to the flowers, and the odours which they emit fulfil the same end. The markings on a flower's petals, it is to be noted, always converge towards the nectar, as in the Violet. The importance of these guides to insects will be apparent from the following estimations, which show how indispensable it is that as little time as possible should be lost by an insect collecting honey. It must also be remembered that the nectar is usually contained in the most secure and best covered part of the flower, the object being to prevent the access of rain, which, owing to the extreme solubility and diffusibility of sugar, would speedily cause it to be transferred to parts of the plants where insects could reach it without being of any service in the way of cross-fertilisation. The chief purpose of the flower would in this way be frustrated. The formation of nectar is observed to take place most freely in hot weather, and to be prevented by cold or wet. So great economy is exercised by the plant that it is only formed at the time when insects' visits would be beneficial, i.e., when the anthers are ripe and shedding their pollen, or when the stigma is mature and ready to receive pollen. By biologists the visits of bees, butterflies, and other insects are believed to have exercised in past times an important influence in modifying the size, shape, colour, &c., of flowers, and the following experiments, in spite of their incompleteness, are of interest, as showing to what an extent this action takes place in Nature, and as helping to determine the value of this factor. These estimations are only the first of a series, and the writer regrets that he has been unable to give them the desirable completeness, but hopes to continue them.

The nectar was extracted with water, and the sugar determined before and after inversion by means of Fehling's copper solution. Many of the estimations were done in duplicate, and gave results that agreed perfectly. In the case of *Fuchsia*—which is not deprived of its nectar by any insects in this country, the nectary being inaccessible to native species—we have probably the whole amount formed, but in other cases the visits of bees, &c., may have reduced the amounts considerably. In this case it is a clear, colourless liquid, having an acid reaction and intensely sweet taste; that of many others has the strong characteristic odour of honey:—

SUGAR IN FLOWERS.

	Total.	Fruit.	Cane? (as Fruit.)
	M.m.g.		
1. <i>Fuchsia</i> , per flower . . .	7.59	1.69	5.9
2. <i>Claytonia alsinoides</i> , ditto . . .	0.413	0.175	0.238
3. Everlasting Pea, ditto . . .	9.93	8.33	1.60
4. Vetch (<i>Vicia cracca</i>), per raceme . . .	3.16	3.15	0.01
5. Ditto, per single flower . . .	0.158	0.158	—
6. Red Clover, per head . . .	7.93	5.95	1.98
7. Ditto, per floret . . .	0.132	0.099	0.033
8. Monkshead, per flower . . .	6.41	4.63	1.78

Approximately, then, 100 heads of Clover yield 0.8 gm. sugar, or 125 give 1 gm., or 125,000 1 kilo. of sugar; and as each head contains about sixty florets (125,000 x 60), that is, 7,500,000 distinct flower-tubes must be sucked in order to obtain 1 kilo. of sugar. Now as honey, roughly, may be said to contain 75 per cent. of sugar, we have 1 kilo. gm. equivalent to 5,600,000 flowers in round numbers, or, say, 2,500,000 visits for 1 lb. of honey. This shows what an amazing amount of labour the bees must perform, for their industry would thus appear to be indispensable to their very existence. Another point worth notice in these results is the occurrence of what appears to be cane-sugar, and that in the case of *Fuchsia* in the proportion of nearly three-fourths of the whole. This is remarkable, as honey is usually supposed to contain no cane-sugar, its presence being usually regarded as certain evidence of adulteration. The question therefore arises whether this change which takes place

* Read before the Chemical Section of the British Association, Dublin, 1878, by Alex. S. Wilson, M.A., B.Sc., Fellow in Natural Science, Glasgow University.

while the sugar is in the possession of the bee, is due to the action of juices with which it comes in contact while in the honey-bag or expanded œsophagus of the insect, or whether the process of inversion goes on spontaneously, as may perhaps be the case.

PROPAGATING.

SHRUBBY CALCEOLARIAS.—These are best increased in autumn. If strong plants are wanted for early planting out, take a 2-light or 3-light box, or more, according to the quantity required, and place it in some part of the garden; put at the

Cutting of Shrubby Calceolaria.

bottom about 3½ in. of rough soil and then 3 in. of finer soil, with a little sand mixed with it on the top, and press down rather firmly and level; select the side shoots for cuttings, avoiding all that show any signs of flower buds, and make them as represented in the accompanying illustration; take a small dibber, or peg, and make the holes 3 in. apart, insert the cuttings and press them in firmly; then give a sprinkling of water, and shut up closely. As soon as they begin to show signs of growth, take the lights off for an hour every morning, and give a little air at the back during the daytime. They may be wintered in the same box in which they are struck, protected from frost, and potted up or replanted in February. For the spring propagation of new and scarce sorts, a close box or hand-glass may be put on a cold bottom in the propagating house. The plants should have 55° of heat to draw out the cuttings, which are best cut and put in the same way as Verbenas; give air every morning, and a slight sprinkling overhead with water. As soon as they are rooted, gradually harden them off. H. H.

Wasp and Fly Trap.—The accompanying illustration represents an admirable fly and wasp catcher. I have tried it this summer with

Wasp and Fly Trap.

the greatest success both for flies and wasps, and by placing it over a wasp's nest in a few days I caught 1500. I also placed one in a Vinery, and hundreds of flies and wasps were caught by it. It differs but little from that published in THE GARDEN (p. 259).—P. C. B.

GARDEN DESTROYERS.

THE NUT WEEVIL.

(BALANINUS NUCUM.)

ALMOST every one who has gathered and eaten fresh nuts has found some that contain grubs or maggots. These grubs are the larvæ of the nut weevil, a very common insect and one that in some years destroys a great number of Filberts and other nuts. It is, however, a very difficult one to keep in check, for while in the egg and grub states it passes its existence within the nut, after which it buries itself in the ground and assumes the chrysalis state. The perfect insects are by no means conspicuous, and picking them off the nut bushes would hardly be worth the trouble. There is one way, however, by which their numbers may considerably be reduced. The nuts containing grubs generally fall to the ground before the others are quite ripe; these should be at once picked up and burnt or crushed; by this means many of the next generation will be destroyed. The nut weevil is ⅝ in. long and of a rich brown colour, thickly covered with very fine reddish-yellow velvety hairs. The head is produced in front into a very long slender nose or beak which is almost of the same length as its body. The antennæ are composed of several joints, that at the base being nearly as long as all the others together; they are set into the long joint at an angle, making quite an elbow. The antennæ are placed on either side of the beak about half-way between the eyes, which are quite towards the back of the head and the mouth

The Nut Weevil (*Balaninus nucum*).

which is at the extremity of the beak. The thorax or fore part of the body is coneshaped, the widest part being where the wing-cases join it; they are rather wider than the thorax, and taper to a point at the extreme end of the body, which they completely cover. The legs are short and strong. When the nuts are still young and soft, the female makes small, round holes in them with the help of her long beak, depositing an egg, which is dark brown, at the bottom of each when a hole is finished. She seems to take care only to bore one hole in each nut, and to avoid those which have already been bored by another weevil, as two grubs are never found in one nut. The grubs are hatched in a week or ten days, and at once begin to eat the kernel of the nut, avoiding, however, any vital part until they are nearly full grown. They are of a white colour, fat, fleshy, and legless, with large tubercles on their sides. They attain their full size in September or October, and then bore holes in the nut-shells, through which they make their exit and drop to the ground (unless the nut has already fallen) and work their way some distance below the surface, where they form a little cell, in which they remain in a torpid state during the winter and until May or June, when they change into the chrysalis state. In about a month or six weeks the perfect insect is developed and leaves the chrysalis case or skin; it does not, however, make its appearance above ground for another week. The amount of mischief one nut weevil may do is very considerable, for though it may not lay so many eggs as insects often do, they are laid in very secure places, and each grub that is hatched destroys a nut.

S. G. S.

ANSWERS TO CORRESPONDENTS.

Propagating Briers.—I have found a beautiful variegated Brier. How can I propagate it? It is growing far from my house; therefore I cannot layer it. Will cuttings grow? If so, how are they to be treated?—M. D. [Cuttings of your variegated Brier will probably grow. They should be from 4 in. to 6 in. in length, taken off, if possible, with a heel, and planted in a north border to the depth of 3 in.—A. W. P.]

Cutting Down the Marechal Niel Rose.—I have got a Marechal Niel Rose which has grown very tall and run very much to stalk. Will it be wise to cut it down to within about 3 ft. of the ground? It is at present about 12 ft. high, and somewhat straggling although very healthy. What time of the year should it be cut?—M. Q. [If the wood of your Marechal Niel be well ripened I would cut it down to about 7 ft. from the ground, and either tie up the branches to a stake, to form a pillar Rose, or bend them over in a weeping form. If the wood be not well ripened, cut it down to the ripened point, not now but in April.—A. W. P.]

Maize as a Vegetable (p. 275).—The proper stage of growth at which the ears of Maize may be gathered for use in a green state is just as the milk commences to thicken in the seed. To gather the cobs younger than this is wasteful, and when allowed to get much older they get somewhat dry, and lose that pleasant sweetness so much prized in ears picked at the right moment. As to dressing, the general way is simply to unhusk it, clean all the "silk" from it, and to boil it for twenty minutes in clean water. It should be served hot and eaten off the cob with butter. Used thus, no vegetable is more delicious.—J. KNIGHT, *Shinfield, Reading.*

Preserving Filberts.—How can I preserve Filberts and Walnuts until Christmas?—Z. P. A. [Place them when dry in dry sand or salt in stone jars, tied down with some impervious material, and bury them in the ground or place them in a cool cellar.]

Diseased Shallots.—If "E.'s" Shallots (p. 275) are merely shrivelling, the cause may be early pulling, but if, as I suspect, the bulbs are decaying at the base, it is probably due to a disease of a fungoid character, to which the Shallot is sometimes subject. The best remedy is to obtain a change of stock, and plant on fresh, well-worked land in some open, airy position. Dress the ground with soot and lime and a sprinkling of salt, and plant in February.—E. HOBDAY.

Spiced Rose Leaves.—The following receipt for spiced Rose leaves may perhaps be of use to your "Subscriber" (p. 165). This receipt is used in South Carolina, where there are so many sweet Roses.—M. S. A. [Gather the Roses while fresh (a dry day is best) and place them in a chins jar with a cover. First let there be a layer of leaves, and then sprinkle them with powdered cloves, mace, nutmeg, &c., mixed with fine salt, in greater or less quantity, according to the moisture contained in the Rose leaves (less salt if the leaves be very moist), as the salt is intended to keep up the moisture, which will cause the spices to penetrate. Each day add a layer of leaves and spice mixed with salt. Examine the contents of the jar from time to time. If mouldy stir them up and let them dry a little; they will be more apt to mould if too many be done at once. By uncovering the jar the perfume in a room is very pleasant, and the Rose leaves will keep and be sweet for years.]

Trees Difficult to Move.—I am very doubtful if "Exempt" (p. 275) will succeed in transplanting an evergreen Oak so high and large as the one of which he speaks, as they are, of all shrubs and trees, the most difficult to deal with. This is owing to the very little fibre they make, sending out as they do long, clean roots that penetrate deep in the soil, and when these are severed, it is so long before others are formed that the plants perish from want of sap. Even small plants, such as are generally sent out from the nurseries, are always kept in pots plunged to render their removal a matter of safety and certainty, which shows what bad subjects they are to treat at that stage, unless their roots are confined. If I were desirous of transplanting a large specimen, I should open a wide trench around it, at about 4 ft. distant from the stem, and work well under the ball, cutting all roots that come in the way; in doing this, I should take care not to bruise or mutilate them in any way, but leave each clean and smooth at the end by trimming them up with a sharp knife. This done, the next proceeding would be to fill in the trench again with some leaf soil and sand added to that thrown out, so as to induce the formation of fresh feeders, to give time for which it will be necessary for the plant to stand for at least twelve months, when it should be lifted with as large a ball of earth as possible. The best time for this work is about the middle of April, as then they are just about forming their young growth, and a corresponding root action takes place at the same time, besides which, just at that season, genial showers and a soft balmy air usually prevail, and these are great aids in keeping the foliage fresh till the sap gets into proper circulation again. As evergreen Oaks bear cutting back well, I should advise the head being pruned in a hit, which, by lessening the amount of leafage, strikes a closer balance between the top and the bottom. A large area of foliage is so much more surface for evaporation, which goes on at a greater rate than most plants have any idea of, and it frequently occurs that losses of valuable plants are sustained through not reducing the branches. Much that has been said with regard to the evergreen Oak applies equally to the Hemlock Spruce, so far as the preparatory process for removal is concerned, but I have never looked on the Abies canadensis as a difficult tree to transplant, and I should have no hesitation in taking in hand one of the size your correspondent mentions. I should do this, however, at

the time recommended for the Evergreen Oak, a season which, I am convinced from experience, is by far the safest and best for removing all evergreens, many of which, in some localities, are much cut about by the severe frosts and searching winds of winter, even when undisturbed, and how much less chance have they of withstanding the trying ordeal after being fresh transplanted? The principal thing to ensure success is to well wash in the soil among the roots as the filling in proceeds, and then to finish off with dry earth and a good thick mulching, by doing which there is no cracking of the earth, and loss of moisture by evaporation is reduced to a minimum. For trees and shrubs of large size a good drenching overhead, by means of a garden engine, for the first week or two after their removal is a fine thing for them, and does much towards giving them a start. Late at night is the best time to syringe them, as then it is not so quickly lost in the atmosphere.—S. D.

Cutting Down Evergreens.—I would be glad to know the proper time for cutting down Portugal Laurels which are growing too tall; also Laurustinus.—M. Q. [Cut them down in winter, say January or February.—S.]

Names of Fruits.—M.—101, Golden Pippin; 102, Yellow Ingestrie; 103, 104, Cockle Pippin; 106, Forelle or Trout Pear.

Names of Plants.—Correspondents wishing plants to be named will oblige by complying with the following rules: To send the specimens as complete as possible, i.e., both stem, leaves, and flowers, and fruit, when possible. To carefully pack them in gutta-percha tissue, or other impervious material which will prevent evaporation. Not to send varieties of popular flowers, such as Fuchsias or Pansies, which are best named by experienced growers of such plants, who have the means of comparison at hand. Not to send more than four plants or flowers at a time. Always to send, in addition to whatever pseudonyms or initials they may desire to use in the paper, their full name and address. To pre-pay all packages containing plants or flowers.—C. M. O.—*Begonia Evansiana* (syn., *discolor*), *Retinospora ericoides*, *Sedum carneum variegatum*, and *Fuchsia Dominicana*. X. C.—5, *Retinospora obtusa anrea*; 6, *Cupressus macrocarpa*; 7, *Pinus strobus*; 8, *Abies Douglasi*. The rest hereafter (see notices). O., *Gorey*.—*Aster dumosus*, as far as we can judge from the specimen sent; *Valloia purpurea*; *Sedum anglicum*; some *Diosma* not in flower. G. W.—1, Buckwheat, excellent for pheasants; 2, apparently *Hypericum oblongifolium*. J. H., *Lewes*.—Not *Genista triquistra*, which has a more southern distribution, but *G. sagittalis*. H.—*Bomarea Carderi*. Colonel P.—*Heubane*, a Solanaceous plant.

Questions.

Winter-blooming Greenhouse Climber.—I intend cutting away some Vines which overrun the roof of a small lean-to greenhouse. What may I plant in the border which is outside to run up the roof in the place of the Vines? I shall be able to keep the house in winter up to 45° or 50°. Would any of the Passifloras or Tacconias be suitable? In fact, any plant from which I could cut bloom in winter would be suitable.—J. W.

Woodsia alpina.—In the course of my rambles in Switzerland this summer I possessed myself of a good many plants of *Woodsia alpina* (or *hyperborea*), the management of which I hardly feel myself up to, taught, as I am, by former failures. I shall, therefore, be very grateful for hints from any who have succeeded in growing this interesting Fern either out-of-doors or in a cool conservatory. With two other valuable Ferns which I was fortunate enough to find in considerable abundance, *Cystopteris montana* and *alpina*, I expect no difficulty, from the sort of habitat in which they flourished.—CANONICUS.

Forming Lawns.—Will some of the readers of THE GARDEN kindly enlighten me as to the best mode of making a good lawn for lawn tennis by sowing seed, and the sort best adapted? We cannot get good turf here. There are a great many tress about my place, and the wet weather has made my lawn, which lies very low and flat, very like a swamp, and the Grass in some places is nearly all gone. The soil is gravel and sand, but doubtless it has never been properly drained. How should that be done?—SUBSCRIBER.

Propagating Clematisses.—Can Clematisses be increased by means of cuttings? and are they easily raised from seed?—I mean such kinds as *C. lanuginosa* or *Jackmanii*.—D. V.

Scottish Horticultural Association, Oct. 1.—Mr. Charles Taylor read a paper on this occasion on "Fern Spores," illustrating his remarks by diagrams. He described the views generally held on this subject, and, after tracing the development of spores, concluded by urging the members of the Association to give more attention to this question than they had hitherto done, as it opened up a large field for fresh and important inquiry. Mr. Andrew Kerr continued the subject by another paper, in which he gave his experience as regards the treatment and culture of Ferns. In the discussion which followed it was stated that *Adiantum gracillimum* was a sport from *Adiantum cuneatum*. This was borne out by the personal observation of several of the members present. A number of plants and flowers were exhibited.

THOMAS ROWLANDS, foreman in Mr. Bass's garden at Rangemore, has been appointed gardener to Viscountess Downe, Baldersby Park, Yorkshire; and Mr. James Groom, late gardener at Henham Hall, has gone to Linton Park, Maidstone.

HYACINTHS IN POTS, BEDS, AND GLASSES.

BULB catalogues, which are now making their appearance, remind one that the season for obtaining the supply of Hyacinths has again come round, and those who would desire to have these much-esteemed favourites in flower early should lose no time in sending their orders. It is generally supposed with these, as with most other things supplied by nurseries, that those who come first are best served, which is not to be wondered at, as otherwise the heaviest and most valuable bulbs might be left on hand, when they would, if sent out, have brought credit to those who supplied them, and have given increased satisfaction to the buyer. Whether or not first-comers have the preference, certain it is that to get Hyacinths in bloom by Christmas, or soon after, they must be potted or put into glasses at once; but, unless particularly required for that early season, it is best to wait a month or so later before starting them, as then they will come considerably stronger and finer. There is one kind, however, that is naturally of an early-flowering character, and well suited for forcing—the white Roman, so sweet and easily managed that no one should be without a few pots, to come in before the others; but, as these are considerably smaller, it is necessary to grow several together to produce much effect. A 6-in. pot is quite large enough to contain as many bulbs, and if these be placed at equal distances apart they form a good mass to stand in a vase in a room; or if for outing, a quantity of bloom may thus be had in a small space. Single pipes of these, mounted, answer admirably for bouquet making, and they are therefore valuable for that purpose, coming in as they do when other white flowers are scarce. The soil best suited to grow them in is a light fibry loam, made rich by the admixture of any kind of mild, thoroughly decomposed manure; and in placing the bulbs in this a pinch of sand should be put under the base of each, so as to prevent any contact between them and the soil, otherwise they are apt to rot at that particular part. The after treatment of these Roman Hyacinths, in preparing them for forcing, &c., does not differ materially from that requisite for the others; and, as these will be touched on in due order, that part of the subject may be passed over.

Those I have principally to deal with now are the Dutch, and in ordering these it is generally best to leave the selection of varieties to those supplying them, as it often occurs that the stock of some particular kind is scarce, and the bulbs inferior to others which are grown more largely, and from which selections of the best may therefore be made. It is not the largest bulbs, however, that are always the most preferable, as much depends on their weight and ripeness; besides which, they differ much in size according to the sorts, some being altogether closer and more compact than others that would readily take the eye of a purchaser. In regard to beauty and general asymmetry of flowers, the single varieties are best, the double kinds frequently coming with crowded pipes and deformed spikes, which is seldom the case with the former. The time for potting will in a great measure depend on the time they are required in bloom; but, as a rule, it is best to allow them to come slowly on instead of putting late, as then they often have to be hurried to make up for the delay. Those who have to keep up a prolonged display generally pot at intervals of a couple of months or so, beginning with the first as soon as the bulbs can be obtained, and continuing on as late as March or April; but it is a question if anything is gained by keeping them so long out of the soil, as they must perforce lose strength; whereas, if potted and kept cool, masses of roots would form to support the spikes as soon as it emerges. For making a fine display there is nothing like growing three bulbs in a pot, a 7-in. size being quite large enough to contain sufficient rich soil to support that number. Those who have once had them in this way are not likely to be satisfied with single plants, as there is no comparison in the effect which they produce, and when grown three together they may be all of one colour, or arranged for contrast according to taste.

In draining the pots one crock is quite sufficient, and it is a good plan to scatter over this a little soot to exclude worms, which otherwise are apt to be a source of trouble. As to soil, nothing suits better than good friable loam, rotten cow manure, and leaf-mould—of the latter two, in the proportion of about one-fifth of the former—and this mixture should be used moderately dry, and pressed in the pots somewhat firmly, so that when finished the crown of the bulb shows just above the soil. The next thing is to place the pots level and give a gentle watering through a fine rose, and allow them to stand for a day to drain and dry a little before being covered up with half-rotten leaves, Cocoa-nut fibre, or anything of that kind, to exclude the light from them till they have formed roots and the tops begin to grow. As soon as this takes place, the covering must be gradually removed, so that the young blanched leaves do not suffer from sudden exposure; and when they will bear this, they cannot well be placed too close to the glass, or receive too much air whenever the weather is favourable. So treated, the spikes and foliage come

sturdy and strong, and will then bear forcing without becoming unduly elongated, as they otherwise would be. Although Hyacinths will grow in bottles of water and require plenty of moisture, they will not succeed in a wet stagnant soil, and therefore, till the pots are well filled with roots and the plants are making active progress, watering should be done with care and judgment; but after they get fairly forward it is absorbed too quickly to do any harm.

Bulbs intended for glasses should be examined to see if they are sound at the base, and have any loose part removed, as when placed in water this is apt to lead to decay. Clear soft water is best for these, and this may be kept sweet by putting into it a few small pieces of charcoal, which is a powerful deodoriser, and highly congenial to the roots of all plants. The point with Hyacinths in glasses is to see that they are kept perfectly dark at starting, and have only just sufficient water to touch the bottom of the bulb, and to keep this replenished from time to time as occasion requires. A close cupboard answers admirably to place them in till they get a start, from whence they should be removed by degrees to the window, and set as close to the glass as possible, that they may have the full benefit of all the light which such a situation affords.

As regards those to be planted in beds, November is quite early enough for getting them in; but the thing now to be done is to prepare the soil by trenching it well up, that it may have time to subside and be ready when the right season arrives. If this be not done early, it settles irregularly after the bulbs are in, and in making the surface uniform some are buried much deeper than others, which retards their progress in the spring and makes their flowering later, thus giving the beds a somewhat gappy appearance, instead of having them in full beauty all at one time. In situations where the soil is naturally cold and wet, a little drainage is necessary, for which purpose nothing answers better than broken bricks, put in at a depth of from 18 in. to 24 in. or so. If on these some half-rotten manure be scattered, the interstices will be kept open for years, and the percolation of water be so regular that the bulbs will lie snug and safe for the winter, instead of rotting away, as they sometimes do when less favourably circumstanced. A handful of sharp sand put in around each when planting is a great help in warding off decay, as it prevents the soil from coming in immediate contact with them, and keeps them altogether in a more uniform condition as to moisture than they otherwise would be. In planting, the best effect is produced by having the rows about 9 in. or 10 in. apart, and the bulbs the same distance from each other in the rows, but placed quincunx fashion, so far at least as the shape of the bed will allow. The planting complete, the neatest way, and the best as regards the safety of the plants, is to finish off the surface with sifted leaf-soil, which is a capital non-conductor, as is also Cocoa-nut fibre, which may be used instead where the former is not readily attainable. Good Hyacinths for beds are now sold at a very cheap rate; and if taken care of, and allowed to stand and ripen off their foliage naturally after blooming, instead of being thrust aside, they will not deteriorate, but rather improve under good cultivation, and be available for the same purpose for an indefinite period.—“Field.”

The Iron Tree (*Parrotia persica*).—This member of the *Witch Hazel* family is a native of Northern Persia and the Caucasus, and is one of the rarest trees in cultivation. Its beauty consists in the magnificent colouration of the foliage very late in autumn, when, except in unfavourable seasons, the leaves turn various bright colours, the principal being brilliant orange, golden-yellow, and scarlet. Sometimes, however, as is the case with many of the American trees which usually put on such lovely autumnal tints, they content themselves with dull yellow, purple, or brown. The small flowers are rendered conspicuous by their long, spreading stamens, with scarlet anthers. The leaves, about 3 in. long by $1\frac{1}{2}$ in. or 2 in. broad, are coarsely-toothed, and when young are more or less clothed with silky hairs. The position which the tree likes best, and one which, on account of its rarity and beauty, it is well worth, is a wall with an eastern or western aspect. Here its foliage remains attached to the branches much longer than when in the open ground, and, moreover, under such conditions it grows more freely. It is called “Iron Tree” by the Persians on account of its excessively hard wood. The genus, which only contains another species—a small Himalayan tree which has not yet found its way into cultivation—was named in honour of Prof. Parrot, who made the first ascent of Mount Ararat in 1829. From the “Botanical Magazine” we learn that the two specimens at Kew—one of which is trained against a wall, and the other planted on a lawn near the principal entrance—were received as pot plants from St. Petersburg some thirty-five to forty years ago. In a wild state 10 ft. to 15 ft. are the heights attained; one of the Kew plants is about 10 ft. high. Layering would probably prove the easiest and most expeditious mode of propagating this very slow-growing tree.—N.

No. 360.] SATURDAY, OCTOBER 12, 1878. [Vol. XIV.]

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—Shakespeare.

PICTURESQUE GROUPING OF TREES.

IN the large and, in many respects, very fine English park at Munich we were lately very much struck with the naturally picturesque details of various groups of trees. Fine specimens often grew from almost the same root, or in any case from the same spot of earth, the result being frequently a wide divergence from the perpendicular in at least one individual of the group. This was a gain so far as beauty was concerned, though, no doubt, it would form a blemish in the eyes of planters generally. But this irregular natural and varied way is the right one, nevertheless, if the production of beautiful effects be the object. Timber is another question. Few, we hope, would attempt to form a picturesque group of trees by adopting in the beginning any kind of geometrical plan as to the spacing of the plants, but even those who would carefully avoid any such disposition would probably end by allowing each plant room for future development. We have ourselves, indeed, often recommended this, but now think otherwise. While generally it is well to allow each species room for full growth, it will in many cases be desirable to deviate from this rule for the sake of contrast as well as for that of the finer effects which may be thereby produced. Great size and dignity are all the more impressive if contrasted with evidences of the effects of the struggle for life, as shown in the distortion of some trees and even in the starvation of others. But as to "distortion" (or we, perhaps, had better say deviation from the perpendicular), many of the loveliest trees existing are of this character as regards the stem and main branches. The most beautiful forms assumed by the stems of trees will result from early attempts to grow towards the light from beneath the shade of some greater tree, or from the diverging growth assumed by two trees of nearly the same age and the same species growing very closely together. In pointing out the need for deviating from the usual prim and mathematical way of encouraging trees to grow, we are by no means insensible to the charms of perfectly-grown, clean timber, and can see beauty in a straight stem as well as in a crooked one. We, however, think that much beauty may be added to our ornamental planting by securing striking deviations from the usual form as regards the stem, and even deliberately overcrowding here and there. Abnormal growths such as those alluded to would, by contrast, relieve and heighten the fine size and symmetry to which we are now accustomed.

PLANTING FOREST TREES.

THOUGH, as a general rule, the principal aim of every planter on a large scale is profit, yet by a judicious selection and distribution of his trees he may at the same time afford the necessary shelter to the homestead, the pasture, and stock, as well as to his crops, and the ultimate benefits of such planting are nowhere more perceptible than in the woods themselves, where the vigorous growth of the trees in the interior often presents a striking contrast to the stunted and weather-beaten forms upon the windward margins of the plantations. Many attempts to clothe with wood the summits and sides of hills have failed, from the planter having been confined to the most exposed parts. In assigning his lower limits the proprietor has not unfrequently been guided more by his map and his rule and compass than by considerations of soil and situation, and the adaptability of the land to the operations of the spade and mattock. By allowing the planter to obtain a footing upon the more fertile soil below, he would, by degrees, have been able to push upwards until he had reached the limits of profitable cultivation, and this in situations where the planting of the higher grounds first would have failed, for in most cases where a few inches of soil can be found a combination of planting and layering will enable him to grow re-

munerative coppicing even where standards of large size cannot be reared. Almost every selected site of any considerable extent will present great varieties of soil and surface, and it will be the duty of the planter so to distribute his species that each may occupy the spot best adapted to its habits and requirements. In order, too, that they may present no harsh outlines, the various kinds of trees in the same plantation should so gradually approach and intermix with each other as to make it appear that each species was gaining ground and taking possession of the soil.

As a barrier against the prevalent winds of the district, the Mountain Ash, Wych Elm, Sycamore, Beech, and Hornbeam may be planted; and to ensure a compact and dense front, a belt of Norway Spruce, which may afterwards be kept headed down to any required height, should be formed. In rearing plantations upon very exposed sites, an admixture of scrub or underwood with the standard trees is of the greatest importance. This checks evaporation, and at the same time fixes the fallen leaves, so that they decay *in situ* instead of drifting. Upon the higher ground and upon chalk ridges the Larch and Scotch Pine may be mixed with Birch and Beech. The Alder, also, though best adapted to moist and even wet situations, grows freely at a great height. The serrated outlines of spiral-topped trees, such as the Larch, are so harsh when they meet the horizon that these trees require to be planted in large masses. In mountain districts they harmonise with the peaks. The lower rocky slopes and the sides of dells are generally suitable for the Ash, the Silver and Spruce Firs, and various kinds of Pine; thin and sandy soils suit the Stone Pine, the Scotch Pine, and the Spanish Chestnut. Where rabbits abound, plant the Corsican Pine (*Pinus Laricio*), as they will seldom touch this while other food can be found. The plains and valleys with a moderately dry soil will be found well adapted to the Elm, Lime, Plane, Horse Chestnut, and Durmast Oak (*Quercus sessiliflora*), while moist situations suit the common British Oak (*Q. pedunculata*), the Spruce, Willow, Poplar, and Alder. To obtain the maximum of profit from his woods, the planter must exercise great judgment in selecting his trees and in preparing the land.

A. J. BURROWS.

FUCHSIAS AMONGST IVY.

AS the cultivation of the Fuchsia involves little or no trouble there is really no reason why sorts that are of robust habit, free blooming, and fairly hardy might not be found not only in ordinary shrubberies, but also under the shelter of trees in the wild garden. Fuchsias make in the open pleasure grounds grand summer beds, and permanent ones; but when the plants are cut down for the winter, and the stools sheltered, as is customary, with a heap of ashes, the effect is the reverse of pleasing; whilst the birds persistently refuse to allow the ashes to remain undisturbed. The obvious cure for this would be found in associating Ivy with the Fuchsia, *i.e.*, covering the surface of the bed with plants of Ivy, which would soon become permanently established, and which in winter would afford to the Fuchsia stools all the protection from frost that would probably be required. The danger, perhaps, would be that fast-growing Ivy might choke up the Fuchsia plants, but the stools might be cleared and freed from the too close embrace of the Ivy every spring, and even some well rotted manure might be dug in about the roots at the same time. The result of this arrangement would be that the plants would produce branches richly laden with flowers from a setting or groundwork of green Ivy, whilst in winter the beds would still be a mass of green leafage. Who can doubt that this would present a more charming spectacle than a mass of Cannas, Solanums, or even scarlet Pelargoniums? There are not wanting an abundance of Fuchsias suitable for outdoor planting that would give variety of growth and of colour, the most robust kinds, of course, having the central position. Double sorts should be avoided. Any plantman would easily furnish a selection that would be most fitted from habit and strength for the purpose. Plants that had been once before cut back hard, and which had thrown up a bushy growth, would be better than single stem plants, as the latter do not break so freely in the open ground the first year. The cutting back should always be such as to encourage fresh growth from near the roots.

A. D.

Conifers in Towns.—We often blame London so vigorously for causing the destruction of so many evergreen trees that, by comparison with it, one might suppose they would in other towns have a

chance of succeeding. From what I have lately seen in various towns and cities happy enough to possess as pure an air as falls to the lot of any town, I should say that Conifers are not fitted for planting anywhere in cities, where they are exposed to street dust. It is most difficult to find them really growing well in any city, and, though there may be a few exceptions named, yet it will always be found that they grow in spots not liable to the objection spoken of, or to smoke.—H.

Cotoneasters in Masses.—Although Cotoneasters look well on walls or on pillars, there is no way in which they look so well as in masses on hilly or broken ground. In such situations, if planted so as to form irregular clumps, they are most effective at all seasons, whether in flower or fruit.—J. GROOM.

Magnolia Lenne.—This fine variety seems to have a habit of flowering somewhat freely in the autumn; at least, my specimen, now a strong one, bore a good many flowers and buds at the end of September, the colour of the outside of the buds being very fine.—J. H.

Cercis japonica.—This species of Judas tree is remarkable for its large, leathery leaves, which might almost entitle it to the term "fine-foliaged." It seems a dwarfier kind than the others, but I only judge from young and cut-down specimens.—V.

Magnolia grandiflora.—Few plants are better adapted than this for clothing the principal columns of a mansion, which it will do to a height of 40 ft. It is one of the grandest subjects imaginable for such a position, in which it flowers freely. Perhaps the sunny situation, a full south exposure, and ample room for extension, increase its floriferous character, as on lower walls I never saw it flower so abundantly. Even now (October 7) there are many perfect flowers expanded on it.—J. GROOM, *Linton*.

Pterocarya caucasica.—This handsome tree with its rich green and large compound leaves is a little more frequent in Continental gardens than in England. From its hardness and great beauty of foliage it is, however, worth the attention of all who care for a distinct tree for the shrubbery or pleasure ground. It no more than any other tree can be expected to prosper if subjected to the muddling and crowding that so often passes muster as 'garden tree and shrub culture.—R.

Thujaopsis dolabrata variegata.—We have in the Pinetum here a beautiful young specimen of this variegated form of *Thujaopsis*, about 15 ft. high, the appearance of which fully bears out Mr. Syme's description of this variety (p. 232). My own experience of this Conifer is that it is somewhat slow in forming a good leader, and, consequently, wants a little attention in stopping shoots that are competing for that position, but that, when once fairly started, few trees maintain more symmetrical proportions. This may be said to be one of the numerous trees and shrubs that on their first introduction are rendered tender by being grown under glass, and when turned out in the open air suffer in consequence, and not from their natural inability to withstand the vicissitudes of our English climate.—J. GROOM, *Linton*.

Grouping Shrubs in Woods.—We have often recommended this for the lawn or pleasure garden instead of the usual way of massing them in shrubberies. We have lately seen excellent effects from doing this on a larger scale in woods. For example, out from a stately wood (and yet near it, and part of it, so to say) were wide and irregular groups, mostly of one kind of deciduous shrub, which, thus thrown out from its usual position as undergrowth, could attain its full size and character. As the foliage died off, it assumed its bright hues in the sun—as several of the masses showed at the time of our seeing them. Numerous flowering shrubs offer themselves for this purpose, and of these and others, of course, many gentlemen would prefer the most useful for covert. Such groups would tend to modify agreeably the severity of the monotonous areas of Laurel and common *Rhododendron* in so many country places.

Rocks in Shrub Culture.—In carrying out a frequently repeated recommendation of THE GARDEN, now often done, that the choicer and dwarfier shrubs be grown into fair specimens in the open sun on the Grass, I have made use of small groups and single small outcroppings of rock to assist in the work. Choice dwarf shrubs planted against or between these have obviously advantages in being partly protected from destruction through accidents, such as those of the mowing machine, or from being trodden on; they may also in many cases be a protection to the roots from drought. The association of choice mountain or Alpine shrubs with such rocks is also agreeable, and the effect is much better than that of the ordinary piled-up rock garden.—V.

BEST WAY OF WINTERING TUBERS AND BULBS.

THE discussion as to the hardness of *Salvia patens* and other tubers and bulbs when left in the ground through the winter is full of interest, especially to amateur gardeners. My object in writing is to ask for the experience of others, particularly in the culture of *Gladioli*. I am assured that it is unwise to risk the finer kinds in the ground during the winter for fear of frost. The only sorts of which I have had experience are *G. Colvillei albus* and roses and a strong-growing scarlet and yellow variety, the name of which I do not know, and which has become without any care almost a weed in the garden. About five years ago I bought a pot of *Colvillei albus*, with, perhaps, three bulbs in it, from the late Mr. Wheeler, of Warminster. Since then the clump has been lifted only once, to remove it to another position, and each season it becomes stronger. This year I counted fourteen spikes open and opening at one time, and nothing could have been in greater perfection as regards beauty. *Tigridias* also, for several years past, have been left unmolested, and reward me throughout August and September with a daily and abundant supply of their splendid blossoms. *Commelyna ocellata* takes care of itself in the same way. In a neighbouring garden *Dahlia*s have been left alone for ten years past with the same good results.

On the other hand, my experience goes to prove that the storing of bulbs and tubers is full of risk. The difficulties seem to be threefold: 1. To choose the exact time to take them up when they are completely at rest and before new growth has commenced. In the case of bulbs, I believe this time to be an exceedingly short one. With tubers I greatly doubt whether, strictly speaking, there is such a period at all; and the most careful lifting is, besides, apt to cause more or less injury. Consequently, to take them up gives a serious shock to the root action, even though it may be partially suspended. 2. To regulate the hygrometric condition of the bulbs when stored so as to ensure their keeping plump and good, yet without danger of damping off. Shrivelled bulbs must surely have parted with some of their vitality, yet how difficult is it to attain to the proper degree of moisture at which to keep them. 3. Stored bulbs, being in a weakened and unnatural state, require, as a general rule, the stimulus of heat to start them early, otherwise, they do not complete their growth soon enough in our climate to bring their flowers to perfection. This tends to further enervation and the gradual decline too often of valuable plants. These theories, I must confess, do not altogether meet with approval amongst my gardening friends, who insist that *Gladioli*, at any rate, and *Dahlia*s must be taken up or lost by frost. Would any successful growers of the more delicate kinds of these beautiful plants give their experience on this point? It is quite true that the late mild winters may have made us less cautious, but would not deep planting—say 6 in. below the surface—ensure safety? And may not the whole matter rest upon a question of soil? Given a light soil, well drained, and the bulbs may be allowed to take care of themselves, or require a mere covering of coal ashes to carry them through an ordinary winter; but a heavy, cold clay, retentive of wet, may plainly show the necessity of choosing the least of two evils and storing them. K. L. D.

Ashtmore.

Wintering Pelargoniums.—As *Pelargonium*s still occupy a prominent place in the flower garden in summer, the question of how to store the requisite number during winter is an important one. There are still many who continue the old-fashioned custom of striking the cuttings in the open border, lifting them when well-rooted and potting them in single pots, a plan which answers well where labour is abundant and space equally so, but I find that putting the cuttings into boxes about 4 in. deep, 2 ft. long by 1 ft. 3 in. wide, being space enough for about seventy-five cuttings, reduces the space required for wintering such material considerably compared with what is possible when the plants are potted off singly. There is, however, no question as to each plant in a single pot being the best for producing good-shaped plants, but when the stock amounts to many thousands this cannot be done.—J. G.

Cypripedium insigne in a Cold Pit.—This is seldom so well grown as it ought to be. Most people keep it in an intermediate house or a stove, which is too warm for it. If cooler treatment were tried greater success would attend its cultivation. Mr. O'Brien, when at Bromley Hill, in Kent, used to grow it in a cold pit, and I do the same myself, and with good results. I place my plants in a frame under a north wall until they come into bloom, when I transfer them to a cold show house, and after blooming they are removed to the cold pit. Under this treatment, I have often from six to a dozen blooms on a plant in a 5-in. pot, which I find to be [the most useful size for this *Lady's-slipper*. So hardy, indeed, is this *Orchid*, that I have on several occasions even had its foliage frozen without its sustaining any injury.—JOHN CLEWS, *Kells, Co. Meath*.

NOTES OF THE WEEK.

A New Masdevallia.—Under the name of *M. velifera*, Mr. Bull has a plant in flower which is wholly distinct from any other variety yet in cultivation. Its blossoms are of large size, hood-shaped, and furnished with long tails. They are of a waxy substance and of a golden-yellow colour. Its chief value will probably consist in its being made available for crossing with some of the more showy kinds.

Vriisia brachystachys in Pane.—This showy stove plant is rendered much more attractive than it otherwise would be by being grown in the form of several plants together in pans. In this way we find it in Messrs. Veitch's nursery at Chelsea. Six or seven good plants are placed in a pan of convenient size, and each being now furnished with a strong spike of orange-scarlet blossoms, one of the most attractive features now to be found in the stove is the result. The longevity of the flowers, too, is very considerable, a point of some importance.

Meadow Saffrons.—The meadows of Germany and Switzerland, and, indeed, of the greater part of Central and Southern Europe, have lately been dotted with *Colchicum*, beautiful enough, but not so much so as the various double kinds now happily beginning to be looked up by various growers. We are often disposed to regret the multiplication of varieties and the preservation of double varieties of some flowers that are more beautiful in the single state, but there can be no doubt that the double *Colchicum* are a great gain in point of colour and endurance. Such new kinds, too, as *Colchicum speciosum* are most important gains, and it is to be hoped we shall one day see double varieties of this. These plants are most valuable for naturalisation in our cold, wet climate, where they grow so freely in any soil.—W. G.

Camellias and Euryas.—At this time of the year, when Camellias have just been placed in their winter quarters, and before they are well in bloom, they may be rendered more effective than they otherwise would be by having plants of *Eurya latifolia variegata* mixed with them. At Messrs. Veitch's nursery, Chelsea, where the Camellias are in better condition this year than we ever remember to have seen them, they are edged with dwarf plants of this *Eurya* with excellent effect. Many of the Camellias are already opening their blossoms, and the plants, both in pots and planted out, are literally studded with flower buds.

Scutellaria macrantha.—This showy hardy border plant is now flowering freely in Messrs. Veitch's nursery. It was figured many years ago in the "Botanical Magazine," but since then has received but little attention. Its free growth and bright blue flowers ought, however, to render it worthy of a place among the choicest of outdoor autumn-blooming plants. It is a native of Northern China.

Sarracenia Drummondii and alba.—Medium-sized plants of these *Sarracenas*, arranged in masses, are much more effective than large specimens; their trumpet-shaped, radiate leaves are of finer quality than those of large plants, and the two kinds combined make a very interesting group in the greenhouse. Masses of them may now be found in the principal London nurseries.

Pilea nana.—This is a compact-growing little plant, largely cultivated in the Pine-apple Nursery for furnishing material for indoor decoration. It is easier to grow than Club Mosses, it can be readily propagated, and will stand a fair share of rough usage. As a carpet plant in the conservatory, or for any purpose where a close-growing plant is required, this *Pilea* will be found useful.

A Prolific Bullace.—Mr. Harwood, of Colchester, grows a kind of Bullace which ought to be better known than it is. Its fruiting properties are remarkable, shoots 6 in. or a little more in length, being so crowded with fruit as to represent clusters of Black Grapes—indeed, a little way off to be undistinguishable from a bunch of Black Hamburg with berries a little larger than usual. Being so fruitful the trees make little wood, and on that account seldom get beyond the size of small bushy pyramids. When fully ripe the fruit is of good flavour, and excellent for culinary purposes long after Damsons are over; indeed, Mr. Harwood states that it will hang on the trees till Christmas.

Roses on Grass.—We have lately seen carried out what has often been recommended in THE GARDEN, the planting of Roses on the Grass, that is to say, Roses on their own roots planted in groups of a dozen or so in the Grass irregularly, so that one could walk between them and cut the flowers or otherwise attend to the plants. Of course the necessary good and deep soil may be given in this way as well as in a bed. When freshly planted the small circle of bare earth is sown with a *Lobelia* or some fragile annual. The effect is

very good, inasmuch as the formality and bareness of the bed is got rid of, and those interested in the flowers can go more freely among them at all seasons. The preparation ought to be first-rate to begin with, as opportunities for refreshing the soil do not often occur.—H.

Dahlias on Grass.—In like manner we have recently been pleased to see in a German garden a group of tall Dahlias planted on the turf in an irregular group, each plant so far apart as allowed of easy movement on the Grass between them. They were as well grown as they could be in beds of the ordinary type, and we never saw Dahlias looking to better advantage.

Acacia dealbata.—I saw this *Acacia* (the White Wattle of Australia) the other day covered with recently-developed flower buds. The plant, which is thirty years old, was killed down to the ground in the winter of 1860-1, but is now vigorous and about 25 ft. in height.—J. J. ROGERS, Penrose, Cornwall.

Annual Balsams.—We notice two annual species of Balsam in the Munich garden which are worth a place in botanical collections—*Impatiens scabrida* (Walp.) and *I. Roylei* (Walp.), both tall and vigorous kinds, one with yellow and the other with lilac blooms.

The Red-berried Elder.—This showy species has lately, as usual, been very conspicuous on the Alps, and, indeed, in many hilly places throughout Central Europe. It is very brilliant and also graceful as regards the drooping of its coral-laden branches. Why is it not more grown?

Prizes for New Grapes.—At the meeting of the Committee of the Royal Horticultural Society on Tuesday next, the prizes offered by Messrs. Pearson, of Chilwell, for their new Grapes Mrs. Pearson and Golden Queen will be competed for. The latter Grape was figured in THE GARDEN, Vol. XII., p. 600, and we have seen fine examples of it this season.

Giant Cockscombs.—Messrs. Carter & Co., of High Holborn, possess a strain of Cockscombs unequalled, as regards size, by any we have ever seen. The measurement of the comb of a specimen plant sent belonging to this strain is 3 ft. 2 in. lengthwise, and in the thickest part 1 ft. 4 in. across. The leaves are large and healthy, and the comb itself is of a rich velvety crimson, very double and highly ornamental. It is called the Empress Cockscomb.

Galatella cana.—I have always avoided the *Galatellas* as being somewhat too nearly allied to the *Asters* in all ways, and not quite so ornamental as the best *Asters*, but this autumn I have learnt to value highly *Galatella cana*, which has large, open, spreading heads of pretty lilac flowers, and which is of pleasing habit, and has silvery foliage.—H.

Canna iridiflora.—What a charming plant this (the true species) is. Among neglected ones few have such claims; such bold and graceful leaves that the plant would be well worth growing for their sakes, and such large, deep, rosy flowers that hang with a *Fuchsia*-like grace, but more stately. It blooms fairly enough in autumn out-of-doors in Paris gardens, and in those of Southern Germany, no doubt receiving the treatment usually given to "ornamental-leaved plants" in those places. It would, no doubt, also bloom well in our southern counties in favourable soils and positions, but the distinct charms of this plant make us ask, Why is it not grown, and well grown for the conservatory?—not always very full of beautiful fresh flowers and leaves in the autumn.

Cyclamens at Reading.—Messrs. Sutton have some beautiful varieties of the Persian *Cyclamen* now in flower, consisting of all colours, from pure white to rich crimson, the intermediate shades being delicate rose and purple. Though not what are termed Giant *Cyclamens*, the blooms are of large size and of great substance, and the petals, which are not too numerous, are well formed. They are growing in a house, the temperature of which is about 60°, a heat in which seed of the *Cyclamen* may be sown with advantage, and it may be added that this is the best time for sowing it.

Desmodium penduliflorum for the Conservatory.—There is no month of the year probably when the conservatory is so flowerless as in October, and therefore any good plant which can be grown and flowered easily at this time is acceptable. What are termed the summer-blooming plants are over, and Camellias, Azaleas, *Chrysanthemums*, and similar plants are not yet in flower, but *Desmodium penduliflorum* is now in full bloom. We saw plants of it in Mr. Bull's nursery, Chelsea, the other day furnished with long racemes of bright rosy-purple, Pea-shaped blossoms, which are remarkably attractive. The plant, of which a coloured plate appeared in THE GARDEN, Vol. X., p. 216, is easily cultivated, graceful in habit, and flowers during the greater part of October and November. Either for the greenhouse, conservatory, or window, it is well worth culture.

NOTES FROM KEW.

Hardy Climbers.—Foremost in interest, as well as in beauty, amongst hardy climbers at present in flower is *Smilax aspera*, a native of the Mediterranean region. As a wall plant or as a screen to hide unsightly objects it is most effective, its shining dark green, heart-shaped leaves and wreaths of small, pale flowers—rendered somewhat conspicuous by their deep red ovaries—forming a very attractive combination. *Aristolochia altissima* is an uncommon and handsome plant. Like the last-named climber, it has glossy dark green, heart-shaped leaves, which are, however, more pointed and very wavy in the margins; the long-stalked flowers are much curved, about the size of those of *A. Siphon*, and reddish-brown and orange-yellow in colour. *Clematis Vitiocella* (the first of all the exotic kinds of Traveller's Joy to find its way into English gardens, where it has been known for upwards of three centuries) merits mention on account of the profusion in which its purple blossoms are produced at this season either on plants grown on stakes in the open air or on those trained to walls.

Hardy Shrubs.—*Abelia rupestris* is one of the most distinct and ornamental of the genus; its flowering season seems to extend over a much longer period than that of any of the other kinds. It is of neat habit and has pretty foliage and sweetly-scented blossoms, with a conspicuous reddish calyx and a white corolla, the outside, as well as the inner surface, of the tube being tinged with purplish.

Hardy Herbaceous Plants.—One of the most beautiful, as well as one of the rarest, plants we have had the pleasure of noting is *Oxalis eucaphylla*; it is of neat, dense habit and has tufts of very glaucous leaves and snowy white blossoms. From the letter-press accompanying the figure in a recent volume of the "Botanical Magazine" we learn that this charming little plant was brought from the Falkland Islands by the "Challenger." In the "Flora Antarctica" Sir J. D. Hooker describes it as the "Pride of the Falkland Islands," where it grows in such profusion on banks overhanging the sea, at Berkeley Sound, as to cover them with a mantle of snowy white in the spring month of November, adding that it is an excellent antiscorbutic and an agreeable pot-herb. Like most plants from those dreary, inhospitable, almost sunless islands, it requires coolness and moisture to ensure success in its cultivation. *Rudbeckia subtomentosa*, a North American perennial, is one of the most desirable of a showy genus; it grows about 2 ft. high, has large flower-heads with bright golden yellow ray florets—those of the disk being purple—and possesses an additional qualification through being in full beauty when nearly all the other *Rudbeckias* are passing or are quite gone. *Salvia farinacea*, noted in these pages some time ago, is still in flower; as an autumn, as well as a summer-flowering plant, this fine Mexican sort is invaluable, the handsome deep blue and white blossoms being very conspicuous even at a considerable distance. *Aster surculosus*, 1 ft. in height, is a desirable sort with fine flower-heads of a lavender-blue colour. *A. azureus* grows about 3 ft. high and is a very floriferous kind with small blue flower-heads; it is of twiggy growth and a most distinct and useful kind. *Heliomeris multiflora*, 4 ft. high, has bright yellow flower-heads measuring 1 in. or 1½ in. across and looking like miniature Sunflowers. *Boltonia latiquama*, a North American perennial about 5 ft. high, is very free-flowering, its blossoms being of a pleasing pale purplish-pink colour. *B. decurrens*, about 1 ft. higher than the last, has flowers of nearly the same shade. *B. glastifolia* is higher by 2 ft. than *B. decurrens*. Amongst the autumnal Crocuses the most noticeable are *C. serotina* and *C. Salzmanii*, both with light blue flowers, the first being a native of Portugal, the other of Tangiers. *C. Schimperii*—or *C. oscellatus*, as it is sometimes called—is a lovely oriental kind with white blossoms. *C. pulchellus*, another oriental, and *C. speciosus*, from the Caucasus, are extremely fine; the first has handsome pale blue flowers, the other has beautifully striped blossoms somewhat darker in colour.

Greenhouse Plants.—*Oxalis pentaphylla*, a lovely species from the Cape of Good Hope, has long-stalked leaves (with five very narrow leaflets) and large blossoms of a beautiful pale rose colour, which are borne singly on long flower stalks. *O. longicaepala* is of totally different habit, the small, hairy leaves being almost or quite sessile on the branches; the fine flowers are also borne singly on somewhat long stalks, and are a beautiful deep rosy-red. *Gastrostema sanguinea flamma* is a very pretty South African bulb of easy cultivation, its large, orange-scarlet blossoms being freely produced, even from small bulbs in very small pots.

Stove Plants.—*Aechmea fasciata*, an interesting and beautiful Bromeliad, has dark green leaves—banded with interrupted lines of white—narrow, serrated, rose-coloured bracts and large flowers, white tipped with blue. *Echynanthus grandiflorus*, an East Indian epiphyte of easy culture, has thick, fleshy, dark green leaves and large flowers clustered at the tips of the branches; the lower part of the corolla is orange-yellow, the upper orange-scarlet, with deeper coloured blotches.—†.

THE HOTTENTOT FIG.

(MESEMBRYANTHEMUM EDOLE.)

I WAS surprised to observe in THE GARDEN (p. 53) that this plant has proved hardy in England, as it cannot stand the winters here (Queenstown). I should mention that we are 3500 ft. above the sea level, and 150 miles from the coast; latitude 32°. We have occasional snowstorms in the winter and frequent frosts, the thermometer often marking from 4° to 6°, and occasionally from 8° to 10°. The lowest temperature recorded was four years ago, when 16° Fahr. were reached. I have several times tried to grow *M. edule* here, having brought up the plants from Bothus Hill, near Graham's Town, some 120 miles from here, which is the nearest point where they grow naturally, but I have always had them killed by frost; there is, however, a white variety (I think it is only a variety) which I got from the same place, and which is quite hardy here. The variety is more robust than the type, having stouter leaves and stalks and growing faster. I have it planted on a bank which it covers and forms a dense mass, and it is covered for at least half the year with large, yellowish-white flowers; but, strange to say, it has never yet perfected a fruit, though that is no great loss, as the fruit of this variety is insipid and slimy. In its native habitat *M. edule* grows along the coast, from where the salt spray reaches it to about thirty miles inland, thinly scattered in tufts over the country, usually in some sheltered spot—a knoll—a bank—rocky places, or partly sheltered and protected by a *Mimosa* bush from the feet of the cattle, which, though they do not eat it, play havoc with its tender leaves when they walk on it; though occasionally it is found in dense patches on level, sandy ground, and the sides of deserts and little-used roads is a favourite place. The plant trails on the ground, rooting at the joints, and does not rise more than 1 ft. above the surface; the leaves are very succulent, triangular in shape, and of a bright, lively green colour. The juice of the leaves has a saline taste, and is said to possess considerable medicinal virtues. In spring the plants look very pretty, covered with their bright pink, starry flowers, followed by fruit, which is about the size and shape an elongated Medlar would be; it ripens in December, and when ripe is soft and of a brownish colour, full of small, dark brown seeds embedded in pulp. The flavour is exactly like that of a slightly over-ripe, somewhat dried Strawberry. The fruit is occasionally dried, but loses a good deal of its pleasant properties by that operation. It is known as the Hottentot Fig, or more commonly by the native name of Goom (pronounced with a click between the first two letters), which is certainly easier than *Mesembryanthemum pomeridianum*, as I have seen it written.

HENRY GOLDING.

Queenstown, Cape of Good Hope.

Kniphofia foliosa.—This fine species, which possesses a heavy peculiar to itself, is a native of Abyssinia. It has been grown at the Berlin and Karlsruhe Botanic Garden, from roots sent by Schimper from Adoa. It will prove, I suppose, hardy in England, but I can say nothing yet about its hardiness in this country. It dies down entirely in winter, which is not the rule with other species. The leaves are from 2 ft. to 3 ft. long and ½ in. broad, and bright green. They grow in great profusion, not upright, but rather in a flatish tuft, gracefully drooping outwards. From amidst them rises the flower stem to about from 1½ ft. to 2 ft. high. The flower spike is about 3 in. or 4 in. long and 1½ in. through, and perfectly cylindrical. The individual flowers open first at the top of the spike. Their colour is a very beautiful glaucous, brick orange, very pleasing to the observer, and it is brightened by the protruding anthers, which are ornamented by deep yellow pollen. Taken all in all, it is a plant which attracts attention at once on account of its singular habit and beauty.—MAX LEICHTLIN, *Baden-Baden*.

Zi-Goma.—The last issue of the "Revue Horticole" contains an important rectification concerning the above-named Japanese plant, described in Vol. XIII. of THE GARDEN (p. 379), which M. Maëda, the Japanese Commissioner at the Paris Exhibition, pronounces to be *Sesamum orientale*, from the seeds of which the Japanese extract the oil with which they render waterproof their paper umbrellas. The Japanese name also turns out to be Ye, not Zi, Goma, or sometimes only Goma, simply without any prefix. The plant introduced by M. Léon de Lunaret, and distributed by him as Ye-Goma, turns out not to be this plant at all, but a member of the *Perilla* family most closely resembling *P. ocymoides*, which M. Maëda says is eaten as a salad by the Japanese, for which purpose, according to M. E. A. Carrière, the editor of the "Revue Horticole," its leaves can be but ill suited, from their hard, rough, and hairy texture.—W. E. G.

Saxifraga sancta.—This is a very neat and pretty little Saxifrage with yellow flowers which I may recommend to lovers of choice Alpine plants. It is a native of Mount Athos; hence its name, owing to the convent on that mountain.—J. H.

THE FRUIT GARDEN.

STANDARD CURRANTS AND GOOSEBERRIES.

PASSING out of the rear entrance of Horticultural Hall at the Centennial Exhibition in Philadelphia in 1876, with a party of experienced horticulturists, on one of the hottest days of July, we came across a large clump or bed of Currants and Gooseberries in which the bushes presented a strange sight, the foliage and fruit being about on a level with the eye. Our friends were at first puzzled, but having heard of the plants through Dr. Chas. Siedhof, North Hohoken, N.J., we were on the outlook for them. It was a novelty to us to see Currants and Gooseberries, that we are usually obliged to look down at, growing where the fruit could be examined without stooping. This interesting exhibition came from Messrs. Kuhn & Co., Hoboken. Mr. Kuhn, in 1869, went to Germany to attend the widely known Pomological Institute of Dr. Edward Lucas, at Rentlingen, where, soon after his arrival, quantities of these standards were received from Austria. Knowing the interest which Dr. Siedhof took in such matters, Mr. Kuhn immediately wrote to him an account of these standard plants, which

Standard Gooseberry.

brought an order for a number of them. We mention this to show that they are no untried thing, but have been in cultivation in Dr. Siedhof's garden for seven years, and though he has increased his original six to fifty, those first planted are in full perfection and vigour. The stock used to graft upon is the Missouri Currant (*Ribes aureum*), well known in cultivation as an ornamental shrub with very fragrant yellow flowers. The stocks are usually propagated by what is known as stooling, or mound-layering, and are ready to be grafted when two years old; simple straight stems are used, or the stocks by proper pinching are made to produce several branches at the top, each of which may be grafted and form a large branching head sooner than when a simple graft is inserted. The stocks are taken up in autumn and potted, or wrapped in balls of Moss, and kept in a cold frame until they are brought into a cool house to be grafted. Here they are forced very gradually at a temperature of about 50°, and as soon as the stocks start well, the grafting is done; the grafts are inserted in the heavier stocks by ordinary cleft-grafting, but for others what is known as the American whip-graft—without cutting a tongue—is employed; the operation being finished by wrapping with waxed paper. All unripe, pithy stocks are rejected. The

grafted stocks are kept rather dark until they start, they are then given full light, and when the shoots are 2 in. or 3 in. long, they are placed in a cooler house, where they are gradually hardened off. When spring opens they are planted out, or those in pots plunged in a somewhat shaded place, and by the autumn the plants are fit for sale. They usually bear the year of setting out, the second year of the graft, and increase in size and productiveness from year to year. The pruning consists mainly in thinning out the weaker branches and keeping the heads well open to light and air. The advantages claimed for this treatment of the Currant and Gooseberry are: 1. Great fruitfulness, the plants bearing enormous crops. 2. Great size and excellence of the fruit. 3. Freedom from the borer, which does not attack the Missouri Currant. 4. The ability to raise the fine large English varieties of the Gooseberry without mildew; Dr. Siedhof states that in seven years he has not had a single fruit mildew upon his standards, while plants near by, cultivated in the ordinary way, were badly affected by it. 5. Cleanliness of the fruit, and the ease with which it may be gathered. 6. The highly ornamental character of the trees, a matter of no little importance to those who pride themselves upon a neat and well kept garden. The longevity of the plants seems to be well established, they having been, as already stated, imported by Dr. Siedhof seven years ago, and Mr. Kuhn informs us that the oldest he knows of, in Germany, are fourteen years old, and as healthy and as productive as ever. Messrs. Kuhn exhibited at a meeting of the Centennial Fruit Committee Gooseberries which measured 5½ in. by 3¾ in. in circumference, and weighing an ounce and a quarter and an ounce and a half each. We regard this treatment of the Currant and Gooseberry as one of the most interesting of recent horticultural developments, and are glad to find ourselves in this respect in accord with Mr. Chas. Downing, who says of the standards: "I have no hesitation in saying that they will become a valuable appendage to the garden for ornament as well as for general use, and are without doubt a novel and interesting addition to horticulture." Those who know the proverbial caution of Mr. Downing in all such matters will see that this is for him enthusiastic praise. The accompanying woodcut represents one of the bushes as shown at the Centennial, and has not by any means so large a head as older ones.—"American Agriculturist."

FRUIT GROWING AT SAWBRIDGEWORTH.

THE culture of miniature fruit trees has for many years been made a speciality in the nurseries of Mr. Rivers at Sawbridge-worth, and to this may also be added the culture of orchard-house trees in pots. Beginning with the Peach and Nectarine in orchard houses, it is here shown that in an unheated glass house, properly constructed and efficiently ventilated, well-established pyramid or standard trees in pots, or planted out permanently in the inside borders, are capable of giving a supply of excellent fruit from July to September, *i.e.*, provided kinds which ripen their fruit successively be chosen for the purpose. A light, airy, span-roofed house 100 ft. long and 24 ft. wide, filled with established trees, some of which are twenty years of age, and which have been grown in the same sized pots, *viz.*, about 22-in. ones, has yielded yearly large crops of fruit when outdoor trees on walls have been comparatively fruitless. No doubt in the culture of fruit trees in orchard houses much experience is necessary, in order to gain such results, and from the want of this, together with houses unsuitably constructed, many failures have occurred; but failures here are unknown, and the system adopted appears to be one easy of application. The trees, as before stated, are always kept in the same pots, and these constantly remain in the orchard house; the roots are not allowed to enter the border through the bottoms of the pots, but each year, when the trees are shedding their leaves, all the soil, which is full of fibrous roots, is dug out from the sides of the pots, by means of a small iron fork or the hand, to within a circle of 6 in. from the stem of the tree. The vacant space thus opened up is then filled with good maiden loam and rotten manure, and firmly rammed down. The removal of the roots in this way would to many probably appear to injure the tree, but such is

not the case, inasmuch as when the leaves fall the roots are no longer needed; and if allowed to remain, and provided with more room in which to develop, they would emit rootlets which would cause the trees to make more wood the following year than would be desirable, a great part of which would not bear fruit. By adopting the system alluded to, however, the leaf buds are kept in check to a great extent; and, whilst the new soil affords food to assist the tree to carry the next year's crop, growth, in consequence of the very small roots which are emitted, is only made to such an extent as to provide fruiting wood for the following season. Pruning is little needed on this account, the removal of a superfluous twig or the shortening back of a strong growth being all that is necessary; and yet these trees are in the best of health, and at the time of our visit (the last week in September) several of them, consisting of late kinds, such as Comet and a new yellow-fleshed Peach named Golden Eagle were still laden with large and handsome fruit. The majority of the trees are from 8 ft. to 10 ft. in height and 4 ft. or 5 ft. through, and are placed at a sufficient distance apart to allow light, sunshine, and air free circulation round them. There are also in this house several old standard round-headed trees, which, on account of their being so close to the glass, necessitate their being cut hard back every year in order to keep them within bounds. Their heads measure from 6 ft. to 8 ft. through, and some of them this year have yielded upwards of fifteen dozen good fruits. Watering in winter is a very important matter; enough is given to keep the roots from shrivelling and no more, but when the trees are in full growth and bearing, copious supplies are necessary two or three times a week, and manure water is also applied freely. From this house this year have been gathered 4000 fruits, and this does not include a large quantity disposed of in other ways, of which no account was kept. Apricots are grown in much the same way as Peaches, but the top dressing does not take place till spring. Several large Mulberry trees, about sixteen years old, are also to be found in this house in pots. They are top-dressed yearly in the same way as the Peaches, and they yield a large quantity of fine fruit.

Pear trees are grown in pots, in the form of pyramids, with remarkably good results. They are lifted from the ground in autumn when two years old, potted into 10-in. pots, and then plunged up to their rims in slightly-raised beds of soil. Here they are allowed to remain until a year from the following spring, when they are coming into bloom; they are then moved into the orchard house and placed between the Peach trees close together until their fruit is fairly set, after which they are again taken outside and replunged. These are also top-dressed yearly, in the same way and at about the same time as the Peaches. Most of the Pear trees now in bearing are about 3 ft. in height and 2 ft. through, and well furnished with spurs, but there are no rank growths, and on some of these miniature trees may be counted nearly two dozen of fair-sized, well-developed fruits. Among the kinds which appeared to be bearing the best crops were Williams' Bon Chrétien, Duchesse d'Angoulême, Winter Nelis, Beurré d'Amanlis, Doyenné de Comice, Beurré Superfin, and Bergamot d'Espéren. Pear trees are also grown extensively out-of-doors on walls, and also in the form of cordons, espaliers, and pyramids with excellent results.

Among new Pears, of which there are a great number here, the best were named Fertility and Autocrat. The former receives its name on account of its fruitfulness. It is a medium-sized fruit of good shape and appearance, and of excellent flavour. It is ripe in September and October, and during the past five years this kind has always borne an abundant crop, and this in seasons when other kinds have been almost fruitless. It will, no doubt, when well known, be largely grown for market, for which purpose it appears to be well adapted also for planting in small gardens. Trees of it here are grown in the shape of tall columns, and in this way they can be planted close together, and a large amount of fruit can thus be obtained from a very limited space. Autocrat is a Pear almost as large as Pitmaston Duchess, figured in *THE GARDEN* (Vol. XI., p. 234). It ripens in October and November, and is almost equal in flavour to Marie Louise, which, in various ways, it somewhat resembles.

Plums are also grown successfully in pots, in which they are treated in the same way as Pears. Vertical, five-shoot cordons out-of-doors also do remarkably well. They are trained up light wire trellises, also up narrow walls, positions in which they bear wonderful crops. As single stem cordons Plums grow too rapidly, and make growth at the expense of fruit; they are, therefore, only grown in this way in limited numbers. Among the kinds most noticeable for their free-bearing qualities in autumn may be named Belle de Septembre, Bouquet de Evéque, Autumn Compôte, Wyedale, a very fruitful black Plum, Pond's Seedling, Jefferson, Late Grand Duke.

Apples have done remarkably well this year on upright cordons. They are trained on light wire trellises to a height of about 6 ft. In this way they have a light and elegant appearance, and succeed infinitely better than the old horizontally-trained trees. As single shoot cordons Apple trees do well on the Paradise stock, but on the Crab stock they grow too vigorously to be fruitful. Among the sorts of Apples best adapted for growing as vertical or horizontal cordons, and which, this year, are bearing heavy crops of fine fruit are Small's Admirable, Cox's Pomona, Mannington Pearmain, Wadhurst Pippin, Lord Burghley, Lord Clyde, Sykehouse Russet, Betty Geeson, Blenheim Orange, King of the Pippins, Pine Golden Pippin, Cox's Orange Pippin, Melon, and American Mother. The Bijou Apple, from the South of France, is a kind grown here, both planted out and in pots. It is a small finely-shaped fruit of a deep crimson colour, and very handsome on the dessert table.

Oranges receive considerable attention here; they are not grown, as is often the case, just for the sake of having Orange trees or Orange flowers, but they are cultivated expressly for the fruit which they produce. The plants to be found here consist of round-headed standards, from 3 ft. to 5 ft. high, with clean stems. In some cases plants with only small heads bear a dozen good fruits, which will ripen in winter. If required entirely for ornament, such fruit could of course be left on the plants, where it would hang for at least twelve months, and thus one could have ripe fruit, green fruit, and bloom all at the same time. Orange trees require more heat and more careful treatment than they generally receive in order to induce them to yield good results. Here young plants grafted on the common Lemon stock are brought into a good fruiting condition in two years from the time of grafting, and sometimes even in one year, whereas in private gardens it is common to find large specimens of great age which seldom yield anything but a few flowers. During the summer months it is usual to place large Orange trees growing in pots and tubs on terrace walks and in similar positions. This is an operation which may be carried out without much injury to the plants, provided they are not placed in such positions until the middle of June, and are taken indoors again early in September, and afterwards placed in a light, airy house, the temperature of which ranges about 50° during winter and spring, instead of being crammed into an outhouse, shed, or unheated corridor, to lose their leaves and get covered with filth and insects, as is too often the case. Few plants are more ornamental than well-shaped Orange bushes laden with fruit and blossoms, and they would no doubt be more largely grown than they are at present if the conditions of their successful culture were better understood. The best soil for Oranges is that composed of two parts good turfy loam and equal parts well-decomposed manure or leaf mould, to which may be added a little road sand. Some cultivators strongly recommend turfy loam and fresh horse manure. The soil should be made firm in the pots or tubs, good drainage should be provided, and potting of established plants will only require to be done once in five or six years. Light, air, sun, and heat are highly necessary for the perfect growth of the Orange, although established plants will exist for years under very rough treatment. The best kinds grown for dessert at Sawbridgeworth are the small-leaved Tangierine, large oval Maltese Blood, and St. Michael's. Pruning is usually performed in summer by pinching back vigorous shoots, and in winter by thinning out a little of the unfruitful wood where too much crowded. The Orange is liable to a kind of black fungus, which infests its leaves and gives them a very unhealthy appearance, but this can easily

be removed by sponging with warm water and soap, and, indeed, it seldom occurs on well-cultivated plants. Green fly is destroyed by Quassia chips boiled in water for a quarter of an hour, at the rate of 4 oz. of chips to the gallon. The shoots may be dipped in the water when cool, or they may be syringed with it. Scale may be prevented by syringing frequently with Quassia water; and it may be effectually destroyed by methylated spirits of wine applied to the shoots with a brush.

Pot Vines are grown in a very simple manner here. The pots, which are only of sufficient size to hold about a shovelful of soil, are placed on the hot-water pipes surrounding a span-roofed house. A few pieces of slate are inserted in the soil round the edges of the pot, in order to admit a top-dressing of rich compost being added at a time when the Grapes are so far advanced as to most require assistance, namely, when they have completed their stoning. On Vines thus treated may be found at the present time from eight to ten good bunches of Grapes, not over large, but well coloured, and fit for any table. After being once fruited, the Vines are, of course, thrown away. This shows how easy it is for any one having only a limited amount of glass to obtain a good supply of Grapes without having permanent Vines. A long, lean-to house of medium width planted with mixed Vines is well worthy of notice on account of the heavy crop of Grapes contained therein. The Vines, which are growing in the natural soil, have been planted about four years; their canes are remarkably stout, and each bears about twenty large, shapely bunches of perfectly-finished Grapes. Gros Morocco appears to do well in this house. It is a noble-looking black Grape of good flavour. Pearson's Golden Queen is also good.

Lovers of fruit and fruit trees will find a visit to Sawbridge-worth at all times interesting, but especially so early in autumn, when the trees are in full bearing. C. W. S.

NEW WAY OF TRAINING PYRAMID FRUIT TREES.

I saw near Paris, not long ago, a way of growing fruit trees against walls that rather struck me. It was a wall of Pear trees which had apparently been planted as cordons, but which had developed into one-sided pyramids, or something like it, the trees being broad and bushy at the base, sloping to a point about the top of the wall. It occurred to me that the plan might be very well adopted in this country by those who have not much time to train their trees in the usual way. What, for example, is to hinder any one from planting his pyramids, big or little, close up to the wall on one side? Of course he would have to cut away some of the stiffest back branches, and squeeze the trees up to the wall. They would then receive the benefit of the wall nearly as much as if they were trained close to it; and, except in keeping the leading shoot only tacked to the wall, they would need no nailing or training whatever, which is an important consideration, as in gardens of any extent the nailing and training of the trees is one of the most expensive as well as one of the coldest operations that have to be performed. I am acquainted with gardens where such work costs annually more than the value the fruit comes to, and I am afraid the same applies to not a few private gardens. The time will probably come by-and-by when fruit culture in this country will be confined to glass structures, except in the case of small fruits, and the market will supply our dessert Apples and Pears, &c., as it does now to a large extent. It is interesting to see a garden of finely trained fruit trees; but if they scarcely ever pay for the cost of labour in keeping them, they are hardly worth a place. At all events, any system which cheapens their culture and renders it more easy is worth trying, and I recommend the above plan to the attention of your readers. I remember a similar kind of proposal being made a number of years ago by a cultivator who had not time to train his trees in the orthodox fashion, particularly his Morello Cherries, which require more attention perhaps than any other tree in the garden, though the cook and confectioner in any large establishment do not, as a rule, use above a few pounds' worth during the season. This practitioner's plan was to allow his trees to grow out from the wall without any training whatever, except perhaps an occasional thinning of the branches, and it succeeded perfectly, as one can understand; for the more a Morello Cherry is allowed to grow, the better it bears, provided the branches are not too crowded. The object of training this Cherry on north walls is, of course, to have the fruit as late as possible; but it seems to me that the same end could be perfectly well accomplished by planting, say, 5 ft. standards close to the wall, and allowing them to grow naturally. The wall would

shade them just the same, and they could be netted just as usual, while the labour of tying in a profusion of small shoots during the summer, and again in winter, would be entirely obviated. How far the same mode of culture might be applied to other wall fruits I will not say; but the question is worth considering. I submit that garden walls fringed round with fruit trees in the manner I have described would look as well as if they were covered with trees trained in the usual way. S. W.

PEACHES AND NECTARINES AT WELBECK.

MR. TILLERY having had on the glass-covered wall at Welbeck a more than usually good crop of Peaches and Nectarines this year, I venture to furnish some account of them. No one ever saw such a display of these two kinds of fruit as was to be seen here some two months ago, and now the last of them, the Salwey, is just being gathered—fine fruit, each measuring some 10 in. in circumference, while Lord Palmerston, Princess of Wales, Desse Tardive, Late Admirable, Barrington, and Walburton Admirable were equally large and fine. There are altogether fifty-seven Peach and Nectarine trees growing in this glass case, and every tree this year produced from ten to twelve dozen fruit. The following is a list of the Peaches, according to their season of ripening, viz.: early sorts—Beatrice and Early Louise; the Early Rivers Mr. Tillery has discarded, as it generally splits at the stalk, and is then badly-flavoured; other early kinds are Hales' Early, Early York, and Early Grosse Mignonne. Mid-season sorts consist of Dagmar, Dr. Hogg, Royal George, Noblesse, Alexandra Noblesse, and the Malta, the latter a delicious small Peach of the Noblesse section. Amongst late varieties were Exquisite (a yellow-fleshed Peach of good flavour), Galande, Comet, Princess of Wales, Late Admirable, Golden Eagle, Lord Palmerston, Barrington, Desse Tardive, and the Salwey. Nectarines, according to their season of ripening, consisted of Hunt's Tawny, Lord Napier, Elnage, Violette Hative, Pitmaston Orange, Rivers' Orange, Pine-apple, Albert Victor, and the Victoria, the latest and finest of all. The soil in which these Peaches and Nectarines are grown was principally taken from the top of a magnesian limestone rock in the neighbourhood, and it seems to suit the trees, for they always show fine, healthy, well-ripened wood, and are generally free from mildew. No manure of any kind was added to it when the borders were made, but liquid manure from the farmyard, with a little salt in it, is given during the growing season. One great help to these trees in always securing a full crop is that a little artificial heat can be given to the atmosphere of the case when the trees are in flower in frosty springs, and in autumn it can be applied to ripen the wood. J. M. H.

POT STRAWBERRIES WITHOUT LIQUID MANURE.

PERHAPS no fruit-bearing plant is more frequently fed with liquid manure than the Strawberry when grown in pots. It is a general practice with all Strawberry growers, and is recommended by all, both when the plants are growing and when they are fruiting, and my own practice up till within a number of years back was no exception to the rule; but the danger of using such manures in the hands of inexperienced assistants, and more particularly the injury done by the drip and spilling of the liquid upon the leaves and fruit in houses, where the plants were necessarily arranged on shelves near the glass and above one another, not to speak of the offensive smell produced in the house, led me to think of discontinuing the practice and employing a more convenient substitute. This I found in concentrated manures like Standen's, which suits the Strawberry admirably, and, if given in the right quantity and at the right time, renders liquid manure quite unnecessary. I have used this manure now for years—first, by mixing it pretty liberally in the soil in which the Strawberries are layered, again in the loamy compost in which they are potted, and finally in the soil with which the saucers are filled that are placed under the pots as soon as the plants are introduced to heat, and into which they root through the hole in the bottom. Our plants of Héricart de Thury and Black Prince, which have been thus treated, are now matured, and range from 15 in. to nearly 20 in. across, with broad leaves of the texture of leather and pots crammed with roots. They have received nothing stronger during the season than clean and wholesome water from the village reservoir, and will receive nothing stronger till they have done fruiting as heretofore, thus saving both trouble and accident from the use of liquid manure. J. S. W.

Drying Hardy Fruit.—This is a question of some importance to all who have gardens. Quantities of fruit are wasted in this country for the want of some simple system of preserving it. The Americans

have of late years made great progress in various kinds of drying machines, by which their common hardy fruits are dried very successfully, both for home use and for export. These drying machines, however, are mostly adapted for drying fruit in quantity for commercial purposes. We have lately been interested to see the extensive way in which all ordinary fruit, now so abundant (Pears, Apples, and Plums), were being dried in a Swiss house. Single layers were packed in shallow trays with sieve-like wire bottoms, and these were placed one over the other in a large oven reserved for the purpose in a cooking range, and in it thoroughly dried. Such quantities were preserved as supplied a very large family till the hardy fruits come in again. Of course fresh fruit is better than dried fruit, and in the case referred to it is used in preference as long as possible. But an immense quantity of fruit perishes before it can possibly be used fresh, and therefore other means of preserving it than are common with us are desirable. Of course the process does not supplant various excellent ways of preserving fruit in bottles and jars. It is mainly useful when the great harvest of the orchard is gathered in autumn, and by its use the products of this harvest are saved for food. Fruit dried in this way has an advantage over any other mode of preserving in the facility of carriage if it be marketed, and it would probably be more agreeable to most consumers than fruit preserved in any other manner; it is, moreover, the way by which fruit can be preserved so that it may be sold at reasonable prices to the working classes in towns.—V.

THE INDOOR GARDEN.

IMPATIENS JERDONIÆ.

THOUGH very different from the common Balsam of our gardens in general appearance, this plant is botanically nearly related to it. To those who love and grow flowers for their own sakes it is frequently a matter of surprise that plants, beautiful in themselves, very distinct in character, and, as one might suppose, possessing every property to recommend them for growing generally, should too frequently, through caprice, fashion, or some unknown cause, be allowed to go almost out of cultivation. Such has been the case with the plant in question. When first introduced, if my memory serves me rightly, some twenty-five years ago or so, it quickly became a favourite, so much so, that few people possessing a stove were without it. Its comparatively compact habit and profuse disposition to flower were such then, as now, as to place it within the means of culture by those who had little heated glass space. Another advantage possessed by it is that it does not require great heat; but there is one matter connected with its cultivation essential to its very existence, and that is, in the winter, when at rest and all but denuded of leaves, it must be kept very dry at the root, and also in a comparatively dry atmosphere, as well as near the light, otherwise its succulent stems are apt to decay. The whole texture of the stem and branches of the plant is very similar as regards their fleshy character to the ordinary annual Balsam in general cultivation; consequently, it will be seen that in propagation the cuttings will not do to be kept too close or confined, and they must have comparatively little moisture about them. It is best propagated in the spring about the beginning of March, taking for cuttings portions of the mature preceding season's growths, as in the case of a healthy plant these branch out freely, attaining, during the season, a length of from 4 in. to 10 in. The smaller size, severed at their base, will be found most suitable. They should be inserted singly, or two or three together, round the sides of small pots, well drained, and half filled with a mixture consisting of equal proportions of fine peat and sand, the upper portion being pure sand. The sand must not be made more than very slightly damp—in that condition best described as neither wet nor dry, a state in which it must be kept until the cuttings have formed roots. As before said, they must not be subjected to close confinement in a frame or under propagating glasses, or they are almost certain to become a rotten mass. They do the best on a shelf near the roof or set close to the upright front or end glass of the house or pit in a temperature of 60° at night with a proportionate rise during the day. Thus treated, they will emit roots freely in a few weeks, the presence of which will be indicated by the points of the shoots beginning to grow.

If the cultivator is anxious to get the plants on in size quickly, two or three of the newly-struck cuttings may be placed together in a 3-in. pot, or singly if deemed preferable. This Balsam succeeds best in material of a light, open nature, partaking more of the character of that in which Orchids are grown than any compost more retentive. Two parts good fibrous peat added to one of chopped Sphagnum, with which is mixed a liberal sprinkling of charcoal, broken to the size of Horse Beans, and some silver sand, will answer perfectly. The pots should be one-fourth filled with crocks or charcoal for drainage, and the material should be pressed moderately close round the roots. The temperature may be raised as solar heat increases, but the plants never require so much warmth as many stove subjects; the heat kept up in an intermediate house suits them best. They will also do with more air than is liked by the generality of stove plants. The nearer they are kept to the glass the better, using a very thin shade in the middle of the day during bright weather. Through the season of growth they will bear watering at the root freely, and will also be benefited by syringing overhead once a day, but this should be done early enough in the afternoon to allow the moisture to get dried up before nightfall.

By midsummer sufficient root progress will have been made to admit of the young plants being transferred to pots 1 in. larger; or, in the case where two or three were put together, and are intended to be grown so, they will bear a 2-in. shift. It is naturally of a bushy habit, to still further assist which the points of the shoots may be taken out, but every operation of this kind should be done with the knife, as a bruise resulting from pinching is not unlikely to cause the shoots to rot. The singular-shaped, yellow and pink-tinged flowers are produced so freely that in all probability some of the plants will bloom the first autumn. After the flowers are faded, pick them off, and dispense with shading as the sun begins to decline in power, at the same time reducing the temperature of the house; they must likewise be kept drier at the root and not syringed overhead at all. During the growing season a shelf near the roof will be the most suitable position for wintering them, in a house or pit, where the night temperature is about 55°, giving very little water from the time they cease to grow. In fact, the soil through the whole season of rest should be kept, as to moisture, much in the same condition as that of the majority of Mexican Orchids during their dormant period. Towards the end of February give a little additional warmth with more moisture in the atmosphere, and, as soon as growth commences, more water to the soil. By the beginning of April the roots will commence to fairly extend, and pots 2 in. or 3 in. larger may be given, using soil similar in character to that advised the preceding season. The plants will now begin to grow apace, and will require two or three neat sticks each to support them; little further stopping will be needed, treating in other respects, as to shade, moisture, heat, and air as during the first summer. If all goes well, they will now grow freely, and by the end of July or beginning of August will have their shoots fully clothed with flowers; as soon as these show themselves, cease syringing overhead, or it will sometimes have the effect of causing the advancing bloom-buds to fall off.

During the time of flowering they may be placed on the front stage of the stove or intermediate house, where, associated with other blooming or fine-leaved plants, they will form a very distinct feature. When the flowering is over it will be well to move them to their original quarters on a shelf near the glass, treating them through autumn and winter as before. The ensuing spring they will bear pots 3 in. or 4 in. larger, but in this it is well to be guided by the quantity and condition of the roots, as they are impatient of too much pot room. When the potting is carried out as much of the old soil may be removed as can be got away without injuring the roots. During this summer the plants will attain a size that will enable them to produce flowers as abundantly as may be expected, however long they are grown, although with treatment such as advised they will usually last for years, but being essentially what may be termed plants of small growth they have a better appearance, and are more useful cultivated in numbers of medium size than when grown larger; consequently, it is advisable to each year propagate a sufficient quantity of young ones to

take the place of such as get less shapely and not so well furnished. This *Impatiens* is an excellent subject for growing in small or medium-sized wire baskets suspended over the paths, and in no position is it seen to better advantage when in flower, but when so used, instead of being trained upright the shoots should be tied in a horizontal position over the edge of the baskets. For this purpose it is also better to use three or four of the young struck cuttings together; it is likewise better to keep them in pots, plunging these in the baskets, filling up with Sphagnum, in which a few pieces of Lycopodium are planted in the spring, which much improve the appearance of the baskets, and add to the general effect when the plants are in bloom. Their treatment in other respects when in baskets requires to be in no way different from that which is advised for pot culture. When the plants flower sufficiently early in the summer months before the cool autumn weather sets in they may be put for a few weeks in a conservatory, not exposing them during the time to currents of cold air. I have never seen this *Impatiens* attacked by any of the usual stove pests, except green fly, for the destruction of which fumigate repeatedly, but not too severely.

T. BAINES.

MAMMILLARIA LONGIMAMMA.

THIS deep green-coloured species bears large yellow flowers, and has the merit of being half-hardy. It comes from the high lands of North California. Though described as a *Mammillaria*, I believe that

it is really an *Echinocactus*, judging from the size and shape of the flowers.

Sudbury House, Hammersmith.

J. CROUCHER.

A WINTER-FLOWERING HONEYSUCKLE.

I AM glad to see attention directed to Honeysuckles for pot culture, as up to the present time they have somehow or other been almost entirely overlooked. Why this should have been so I am at a loss to conceive, as during the early summer months, when they can be had out-of-doors or gathered from the hedgerows, they are much sought after. Flowers that are so delicately perfumed have a special value in winter, and as Honeysuckles can easily be forced and had in bloom at that season, the wonder is that they are not more largely grown for the purpose. There is one variety, however, I think not generally known that flowers naturally about Christmas, the name of which is *Lonicera fragrantissima*, one of Mr. Fortune's introductions from the north of China; and although not so large and showy as some, it is of great value for working into bouquets or using for button-holes, for either of which

purposes its pale, highly-perfumed blossoms are particularly adapted. If grown in pots and kept pinched in so as to induce a lot of small, twiggy shoots, it is very floriferous, as also when trained to a wall having a sunny aspect, and treated in the same manner, as every joint or bud then emits blooms, which are produced for some time in succession. The great advantage of growing this particular kind is, that without any artificial heat whatever the sweet odours of this favourite class of plants may be enjoyed at a dull time of year, as all it requires is a little shelter from the wintry blast, and with this afforded, quantities of flowers may be gathered from it. The best way to treat it when used

Lonicera fragrantissima.

as a pot plant is to spur or prune it back a little every spring just before the young growth commences, so as to get as many fresh shoots as possible, the heads of which, nipped out well, as above mentioned, cause them to break again and form fine bushy heads. Two or three of these placed in a greenhouse would quite scent the air, and last till any of the other varieties can be got in. The best of these for forcing are the shrubby kinds, such as *Ledebouri*, *præcox*, *odoratissima*, and *Xylosteum*, but most of the climbing varieties are amenable to the same treatment, and when somewhat stunted in pots partake a good deal of the habit of the former. All the different sorts of Honeysuckle may be propagated in several different ways, and cuttings put in now of the half-ripened young wood will strike freely under glasses in sandy soil on any open border, or they may readily be increased by layers, but these take a year to root sufficiently to be severed from the parent plant. Short pieces of the tender growths taken off with a heel in the spring and placed in moist heat soon make plants, and this is the most expeditious mode of working up a stock.

S. D.

ACACIAS AND THEIR CULTURE.

ACACIAS, though numerous, and many of them very showy, are now but seldom met with in cultivation. This arises partly from the great similarity which many of the species bear to each other, and partly from the fact that they have been driven out of notice by newer subjects. Many of them should, however, find a place in every collection of flowering plants in which variety is a desideratum. A. *Drummondii*, when covered with a mass of bright yellow flowers, is one of the most telling plants we have, and is valuable either as a small plant or large specimen, flowering equally well in either state. Bushy, well-grown plants in 4-in. and 6-in. pots are very useful for decorative purposes, the habit being neat and compact, and the colour striking. When associated with such plants as *Cincarias*, *Cyclamens*, and *Azaleas* it is seen at its

best. This species is easily propagated from half-ripened shoots inserted in silver sand, and placed in a close frame or house, covering them with a bell-glass. In March they may be potted off into a compost of fibrous loam and peat, and kept growing along during the summer in a frame, stopping them occasionally to induce a bushy formation. In September they should be thoroughly hardened by full exposure to sun and air, housing them about the commencement of October. The following season shift into 4-in. pots, placing a neat stake to each, tying the stem firmly thereto at the base, and treat them as before. They will the next year flower profusely, and may then be shifted on as required. Where large specimens are necessary for conservatory decoration this *Acacia* will be found very suitable, as it is not at all of a miffy nature or liable to go off as many New Holland plants are apt to do when they arrive at specimen size. *A. pulchella* is a beautiful species, and not at all difficult to grow; it is worthy of a place in every collection. *A. armata* is an old and well-known kind, one that will bear a deal of rough usage, but it is very liable to be attacked by scale, which must be promptly exterminated if the plants are to be kept in a healthy state. *A. lophantha* is a great favourite for window decoration, its light, feathery, gracefully-disposed foliage rendering it one of the most suitable plants which we possess for that purpose. It should be grown by every one, and as it comes freely from seed, which may be obtained very cheaply, there is no reason why any one who has the smallest amount of convenience for plant growing should not possess it. The seed should be sown early in the spring, if possible in a little gentle bottom-heat, and kept growing on during the summer months, shifting so that it does not become stunted; a free, quick growth is essential to secure handsome foliage. Plants suitable for window decoration may be thus obtained the first year. Where convenience for raising the seeds easily does not exist, then they may be sown in April and placed in a cold frame, placing a piece of glass on the pan. When up pot the plants off into small pots, and keep them till the following April, when they may be shifted into 4-in. pots. By no means allow them to suffer from want of water, as they will become naked at the base, thereby much impairing their decorative value. Good fibrous loam and leaf mould suit them very well, but they are by no means fastidious as to soil. The best plants I ever grew were potted in some very old rotten manure, but if this be used it should have been thoroughly well sweetened, and should be at least three years old. This plant is most useful when from 1 ft. to 2 ft. in height, but if sufficient space can be accorded it, it will increase in beauty as it attains larger dimensions. It is not advisable, however, to retain them after they have filled the largest-sized pot; it is better to grow a few on every year, so that those that show signs of becoming bare or stunted may be made away with. Where there is sufficient space to plant it out, it naturally assumes more handsome proportions than are to be obtained by pot culture. It is well worthy of a place in a large cool house, as, by reason of the unique disposition of its foliage, it affords a fine contrast to most other plants. I once had it planted out amongst Camellias in a lofty house, and it presented at all times a charming appearance. This species does not flower in a small state; it is, consequently, to be regarded as being valuable only as an ornamental foliaged plant. The *Acacias* are essentially amateurs' plants, inasmuch as they are of easy culture, and do not require so much care in a general way as many greenhouse plants do; they grow rapidly, and are by no means fastidious with respect to winter quarters. Those who would wish to grow a few of this genus should procure their plants in the autumn, choosing young, thrifty plants, if possible, in 3 in. pots. Keep them in a cool, airy house during the winter, water only when dry, and they will be in good condition for growing on when spring arrives.

JOHN CORNHILL.

Byfleet.

Drip-proof Shelves.—M. Ortgies in the Botanic Garden at Zurich stores plants on shelves to the extent of having several of the shelves directly over each other. He prevents all drip by using a water-proof zinc tray, which is neatly fitted on a strong shelf formed of several pieces of T and angle iron. The whole forms a strong and very durable contrivance, and is withal neater in

appearance than an ordinary shelf. Each zinc tray has 1 in. of gravel in it.—V.

PROPAGATING.

SENECIO PULCHER.—This pretty hardy border Groundsel, of which a coloured plate was given in THE GARDEN (Vol. IX., p. 572), is best increased by means of cuttings made of the roots, and the best month for inserting them is November. Take up a plant, and remove a portion of its roots, which should be cut up into pieces 1 in. long, keeping all the top parts one way, as they must be put in in that manner. Well drain the pots with crocks, and fill them with soil composed of loam, leaf-mould, and sand in equal parts, putting $\frac{1}{2}$ in. of sand on the top; water, and insert the roots $\frac{1}{2}$ in. apart in an upright position, leaving the tops just above the sand so that the light may induce them to grow. Place them on a shelf in the pro-

Root cutting of *Senecio pulcher*.

pagating house near the glass, and in three or four weeks they will begin to make growth at the top, between the pith and the rind of the root. Water must be given sparingly until they show signs of growth, when it may be increased in quantity. The soil will be full of roots and the plants ready to pot off in March. It is best to keep them in the house for two or three weeks before they are removed to cold frames, in which they should be placed until they can be planted out. H. H.

Propagation of *Daphne Blagayana*.—This fine new introduction, illustrated in THE GARDEN (p. 200), I find may be readily propagated by layering. A short time ago I pegged a few shoots of it down in some light soil, previously cutting them half through. Later on, when roots were emitted, I completely severed the shoots, and the result is several good specimens, and the old plant is again breaking freely. I think this mode of propagating is preferable to grafting, as by that process the dwarf growth of *D. Blagayana* is altered into the generally robust growth of the stock. Doubtless those who fortunately possess this plant will be pleased to learn that it may be propagated so simply.—A.

***Cineraria maritima* from Seed.**—I quite agree with Mr. Groom (p. 289) in reference to this matter, and should be glad if he can explain why young plants of this *Cineraria* are so much greener than old plants raised from cuttings. Some years ago, when using this plant extensively for ribbon purposes, some seedlings were employed to complete a line, and their green tinge completely marred the effect. It was thought to be a different and superior variety, but next year the same plants came white as the whitest, and it was found to be a matter of age only. Has any one seen a golden variety of this? We had it here once (a sport); we merely placed it in heat to force growth for propagating, neglected it one hot day, and it dried up and perished.—D. T. FISH.

Pelargoniums from Root Cuttings not True to Name.—As it is customary about this time, when shaking out and repotting old plants of what are called show Pelargoniums, to make outtings of the roots of those kinds that are new or of which the stock is small, it may be worth mentioning that many of the regal kinds, such as Queen Victoria, Reanty of Oxtou, &c., frequently do not come true from such cuttings. We had a quantity of regal Pelargoniums from root cuttings two or three seasons ago that perplexed us considerably, as they were not true to name and the propagator was certain that no mistake had been made in naming them; the flowers also were quite distinct from any kinds which we grew. The difficulty was at last solved by some of the plants putting forth branches bearing flowers resembling the plants, from which the cuttings were taken, while the rest of the branches bore wretched nondescripts. It would be interesting to know if this phenomenon has been observed elsewhere, and if any explanation can be offered regarding it.—CHAS. E. PEARSON, *Chilwell*.

***Sempervivum Reginae Amaliae*.**—This fine species of House Leek in its true form is now in Messrs. Froebel's collection at Zurich. Generally the plants going under this name belong to S. Heuffli.

THE FLOWER GARDEN.

CLEMATISES IN MIXED BEDS.

I HOLD the opinion that although our fine hardy Clematises have increased in numbers and variety and cheapened in price during the past ten years, yet cultivators have not utilised them to the extent to which they might be made serviceable. Occasionally one meets with *C. Jackmanni* trained to a wall, or used for pillar purposes, or for covering archways over walks, and sometimes plants of it are employed in beds; but only unfrequently so. In respect to the latter mode of utilising them they can be made of great service as permanent bedders, using something else in association with them to prolong the flowering season to the greatest extent. There is one great advantage about the Clematis, that is, when planted out for permanent service, if the roots be mulched in summer and manured in winter, the plants increase in strength and vigour, and this means, under good management, a greater quantity as well as heightened beauty in the flowers. The pretty and free-blooming spring-flowering varieties have not been so much used in our gardens as they deserve to be. They are characterised by free growth and a greater hardiness of habit than is generally supposed. I can particularly recommend the following varieties: *Albert Victor*, deep lavender with purple bars; *azurea graudiflora* (patens), pale mauve-lilac; *Gem*, deep lavender, a little later in blooming than some of the spring-flowering types, but very useful; *Lady Londesborough*, silver-grey with pale bars; *Lord Londesborough*, deep mauve; *Miss Bateman*, pure white with chocolate anthers, very free indeed; *Standishi*, deep lilac, very free and attractive; and *Victor Lemoine*, violet tinted with blue, very good. Here, then, are eight varieties that would make charming beds in spring; but, in order to give the beds a furnished appearance, I would also plant them with *Tulips*, *Hyacinths*, *Ranunculuses*, *Anemones*, and other early-flowering subjects that would precede the Clematis. The profuse growth of the latter spreading over the bulbous plants would do them no harm, as after they have done blooming, the *Hyacinths* and *Tulips* would be comparatively worthless. A few bulbs of *Gladiolus* dotted about the beds and some later-blooming *Lilies* would carry on the flower till late in the summer.

If it be objected that the spring-flowering Clematises are apt to be cut back by frost, it may be stated that as a rule they suffer much less from this cause than is generally supposed. For some years past Mr. Charles Noble has been growing at his Sunningdale nursery a number of spring-flowering Clematises as pillars tied up to stout poles, and it is very rarely, indeed, they are destroyed to any degree by frost. If severe weather threatened just at flowering time, a few branches of *Spruce*, *Fir*, or any evergreen laid over the beds would ward off the effects of the frost and keep the flowers from injury. It is not necessary to plant many specimens in a bed. For small beds one or two may be used, according to their size; for larger beds three or four. The longer a plant is established in the soil, the more vigorous growth does it make, and if a number of plants were introduced to a bed in the first instance, some should be taken out as the others increase in size and strength. One caution is necessary here. The spring-flowering Clematises flower from the wood made the previous summer, and the grower should be careful not to cut it back, but simply thin it out, removing only the decaying and weak shoots, and shortening back the immature growths at the points. When the old wood is spread out on the beds after planting with bulbs or any other plants, it should be so distributed as to give the beds a furnished appearance when the shoots break into leaf. Of the summer-blooming varieties, which may be said to flower from early in July till October, the following are well adapted for bedding purposes: *Alexandra*, pale reddish-violet, flowers very freely; *hybrida splendens*, velvety purple; *Jackmanni*, deep velvety purple, one of the very best; *Lady Bovill*, soft greyish-blue; *lanuginosa nivea*, fine pure white; *magnifica*, reddish-purple with bright bars; *Otto Fröbel*, greyish-white; *rubro-violacea*, maroon-purple; *Star of India*, reddish-plum with red bars; *tunbridgensis*, deep bluish-mauve; *velutina purpurea*, blackish-mul-

berry; and *Viticella rubra grandiflora*, a very fine Clematis, bright brick-red, very distinct in colour, small-flowered, but very free.

All the foregoing bloom from the young wood made the same season; so they can be cut back to any extent in the autumn or spring. The stronger the plants are the more necessary is it to cut back hard when a limited space only has to be covered. The beds in which the foregoing varieties are planted can be furnished with plants that can both precede and follow the Clematises, and also, if thought desirable, flower in combination with them. A bed of *C. Jackmanni*, for instance, studded over with *Anemone japonica alba*, would make a fine and effective combination; and there are many other plants that would readily suggest themselves as well adapted for the purpose. For any position in which some effective decorative plant is required, these Clematises will do well, provided it be open and somewhat sunny; and they do well in shaded positions, provided they be somewhat open. One of the best for this purpose is *rubella*, a variety that should be included among the summer bedders; it is most profuse of bloom, and the more shaded the position the finer the colour. I have a plant of *rubella* covering a portion of a west wall, and by pinching back some of the leading shoots two or three times a lengthened succession of bloom is obtained. One remark is necessary. In anything like confined places snails and slugs are apt to devour the young growths put up from the base of plants cut down close to the ground. I have found a few dressings of lime and soot excellent preventives, and the shoots when once started come away with great strength. At planting time let the Clematises be put into thoroughly good soil. They root freely, and are gross feeders, and need plenty of sustenance. Give them plenty of manure at planting time, and follow this treatment up with mulchings in spring and some liquid manure at flowering time; by doing so large and richly-coloured flowers will undoubtedly be the result. D.

BOUVARDIAS FOR THE FLOWER GARDEN.

THERE does not appear to be anything to hinder these beautiful plants being used in the flower garden during the summer and autumn months, when their conspicuous flowers of numerous shades of colour would be exceedingly attractive. Hitherto they have been used as winter-flowering conservatory plants, but they will do perfectly well in the open air from early summer till October or until frost comes. Whether they would actually stand a touch of frost or not I would not venture to say, but I think they would. Our *Bouvardias* have been plunged in the ground in a sheltered situation throughout the summer until now (October), and the plants would be ill to beat, though ours is one of the coldest situations in Yorkshire. The plants were disposed to flower long ago, but the buds were picked off till the beginning of September, and since then they have been coming freely into bloom, and the flowers are all that could be desired for purity of colour and brightness. As I have passed, I have often thought what a splendid addition, as well as novelty, they would be to the flower garden. Old plants cut down would, perhaps, be best for outdoor work, as they flower more freely and also earlier. Being a native of Mexico, I am afraid some erroneous notions are entertained as to the treatment required by the *Bouvardia*. In the new edition of the "Gardeners' Assistant" it is stated that "if flowers are required throughout the autumn (under glass), a portion of the plants should then be at once placed in a temperature of 65° or 70° at night with a few degrees higher in the daytime." This is simply misleading. With us they have been growing in a shallow frame with the lights off since ever danger of late frosts were over, and we are 700 ft. above the sea. Our difficulty has been to keep the plants from flowering. The shoots are exceedingly strong, and nearly as woody and stiff as a *Weigela*. The plants are in 5-in. and 6-in. pots, and many of them have from sixty to eighty flower trusses upon them, either fully expanded or coming on. Some of the plants are still in the cold frame, and are only covered in case of frost. I find it is not a good plan to prune the plants back in autumn, as they are apt to die. They should be left till they begin to sprout in

spring, and then cut back as may be desired. Loam, peat, and sand is the compost used, and a little of Standen's manure is given once or twice during the season.
J. S. W.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Mentzelia ornata.—This seems a very handsome and distinct looking plant which, however, appears to bloom too late in our climate in which the sun heat is not sufficient for its full development. Would it be worth growing in pots for the greenhouse? Perhaps Mr. Thompson, of Ipswich, or some of your readers who know the plant well may enlighten me. I was very much smitten with a plant of it I saw lately, its only drawback being that the autumn weather seemed to damp off a little the numerous flowers and buds.—V.

The Surface of the Rock Garden.—We notice in the botanic garden at Munich that the surface of this is covered with pieces of Graywacke (a conglomerate or grit rock, consisting of rounded pebbles and sand firmly united together), brought all the way from the Tyrol. This, in addition to the use of sand and grit, prevents evaporation and helps the grower, no doubt; but we did not notice any better result than is usual in Continental botanic gardens in the culture of Alpine flowers. The use of stone and grit are, of course, indispensable in the rock garden, but the best and the right covering for eight parts out of ten of its surface is Alpine plants. Till this is recognised by growers we shall never have rock gardens worth looking at.

Transplanting Lilies.—Some of your correspondents ask as to the best time for removing Lilies; I think the safest guide is the appearance of the stems. When they begin to change colour and show that the growth is checked is the time when the old roots have done their work, and the new ones just showing themselves. I had occasion last week to take up some bulbs of a few different species of Lilies, such as *L. pardalinum*, *L. californicum*, *L. Humboldtii*, *L. Szovitzianum*, *L. auratum*, and *L. superbum*, and found no difficulty in finding all but the last in a perfectly fit state to take up. While it is of course desirable that they should be moved when they are not at rest, if circumstances prevent this, late bought and late planted Lilies may do very well, as this year we have strong proof, in a couple of beds of *L. auratum*, the bulbs of which were bought and planted last April. These plants look as healthy and have had as fine flowers as any of the old and early planted ones, and, as they number some hundreds, it is not question of a chance bulb or two. Mrs. Newall speaks of her Lilies having been acclimatised; we have a curious instance of change of habit in *L. auratum*; these, of course, often seed when planted in the open air, but as a rule only strong plants do so. In a bed of seedling plants of *L. auratum*, which have bloomed for the first time this year, many of the weak young spindly stems bear seed. These almost baby Lilies bearing seed have an odd effect, and the fact seems to point to a change of habit from change of country.—G. F. WILSON, *Heatherbank, Weybridge Heath.*

Notes from Wardie Lodge, Edinburgh.—I never remember to have seen *Helleborus olympicus* in bloom in September, but it opened its flowers here on the 19th, and at the Botanic Garden I observed it in bud on the 5th Sept., while on *H. niger* there were both flowers and nearly ripe seed-pods. *Cyclamen* at the foot of our wall have done better than ever we have had them, but in spite of the fine summer *Dahlia Cervantesii* is still too late in flowering; probably it should be brought on in heat earlier than other sorts. I do not suppose that it will yield us any flowers this season. *Mimulus cardinalis* and *Borago laxiflora* are finely in flower now; by cutting them down when shrivelled up with the great heat and soaking them thoroughly, they made a second growth, and will be good all this month if the weather be favourable. A line 34 yds. long of the double lilac and lilac and white *Colchicum* is very satisfactory planted between the Grass verge and a line of Daisies (some eighteen sorts for spring flowering). Thus situated, they are kept clean and have plenty of green; the flowers just top the Grass and Daisy line, and, free from overhanging trees, they escape falling leaves which are apt to cause such thin flowers to damp off. *Papaver epicuratum* is still throwing out fresh flowers and stalks; it is a most useful Poppy, distinct in colour, which is fawn or apricot with a white spot at the base of the petals to match the white stamens, and the young tufts of yellow-green foliage have always a neat appearance; it grows and flowers for six months. The beds of *Crocus speciosus* are charming, and much affected by honey bees, which, I observe, do not care for that grand autumn bedding plant, *Sedum spectabile*, which is always covered with drones, humble bees, and flies.—F. J. HOPE.

PLATE CXLIX.

TWO NEW VARIETIES OF AMARYLLIS.

It has been asserted by good judges that notwithstanding cross breeding and the raising of new varieties of *Amaryllis* the flowers do not in reality show much improvement on old kinds. Last year, however, when the Royal Horticultural Society offered a series of prizes for new varieties of *Amaryllis*, some really distinct and improved kinds were brought forward, and if similar prizes be still continued they will, no doubt, produce good results as regards varieties of this the most useful of greenhouse bulbous plants. The two kinds shown in the annexed illustration were raised by Mr. Williams, of Holloway, and exhibited by him on several occasions at South Kensington, where first-class certificates were awarded them. The lower flower in the illustration, which is named Mrs. Rawson, belongs to one of the most distinct and beautiful of *Amaryllises* which have been raised for years. It is a seedling from *marginata* crossed with a deep crimson, and having the broad white margin extending to the base of the flower, partakes of the character of both parents. The uppermost crimson-flowered kind named Prince Teck is a garden hybrid of great excellence, the result of a cross between *A. Ackermannii pulcherrima* and *A. Mendeli*. The flowers are medium-sized, good in shape, and of great substance, a most important character in an *Amaryllis*. *Amaryllises*, on account of their showy flowers, ought to hold their own against all comers; but, like other plants, they have had their rise and fall, and the latter chiefly through bad treatment. So much is required in the way of flowers at most places, that plants, after blooming, get pushed aside to make way for others, and bulbs more especially come in for this hard usage, much to their detriment, for just at that time, of all others, they require the most care and attention to enable them to regain strength, form fresh flowers, and elaborate the requisite amount of sap to carry them through the period of rest. During the summer time there is no better or more suitable place for finishing these off than a common pit filled to within 18 in. or so of the glass with fermenting material, such as tan or leaves, that will afford a bottom-heat of from 80° to 90°, in which the pots should be plunged. This will induce them to form plenty of roots, and a corresponding amount of foliage, on which their blooming capacity depends. The ripening process later on is a very simple matter, brought about by a gradual exposure to sun and air after growth is complete.

A New Key to the Genera of *Amaryllidaceæ*.

We take the following interesting remarks on certain genera of plants popular in gardens from a paper by Mr. Baker in the "Journal of Botany":—

1. *GALANTHUS*.—Here I consider there are three species, viz., 1, *nivalis*, of which *Imperati* (Bart.), *latifolia* (Ruprecht), and *reflexus* (Herb.), are varieties; 2, *Elwesii* (Hook. fil., in *Bot. Mag.*, t. 6166); and 3, *plicatus*. *G. Reginae-Olgæ*, of Orphanides, I know by name only.

2. *LEUCOJUM*.—Including *Eriocoma* and *Acis*, as in Kunth, good as sub-genera, and under the latter *Ruminia*, of Parlatores—species eight or nine. *L. Hernandezianum* (Camb.) is evidently the same as *L. pulchellum* (Salish.), which is common in London gardens. Of the species of *Acis* in Kunth I should join *grandiflorum* with *trichophyllum*. None of those figured by Jordan and Fontana ("Icones," figs. 103 to 108) seem distinct from those given in Kunth. *L. autumnale* is autumnal, all the others vernal. *L. hyemale* is a misleading name, as the plant flowers in April (not autumn, as stated by Kunth); *Ruminia niceensis* (Jord. and Fourr.) is identical with it.

3. *STRUMARIA*.—Including *Imbofia*. Seven species, *Baueriana* being conspecific with *ligustifolia*, and *Barbelliana* and *Bergiana* with *geminata*.

4. *HAYLOCKIA*.—Monotypic.

5. *APODILIRION*.—Three species, as described *Journ. Bot.*, 1878, p. 74.

6. *GETHYLLIS*.—Four species known in flower, and one clearly distinct, and one doubtful in fruit only. *G. aculis* (Blanco) is doubtless a *Curculigo*.

7. *COOPERIA*.—Two species; *mexicana*, now known in flower, being identical with *Drammoadi*.

VARIETIES OF AMARYLLIS

8. *STERNBERGIA*.—Including *Oporanthus*; five species, Kunth's needing much reduction. *S. dalmatica*, *ætnensis*, *citrina*, and perhaps even *Clusiana* seem to be the same species as *colchiciflora*, and *Fischeriana* and probably *exigua* to belong to *lutea*. Of new discoveries we have *S. macrantha*, J. Gay (*S. latifolia*, Boiss.), the finest plant of the genus, and *S. pulchella* (Boiss. and Blanche). *S. sicula* (Tineo) is a variety of *lutea*, and *S. excapa* (Tineo) altogether doubtful.

9. *ZEPHYRANTHES*.—Two sub-genera, as in Kunth. Species about fifteen, *Grahamiana* being a form of *scasilis*; *flavescens* and *acuminata* of *mesocloa*; *Lindleyana* and *nervosa* (M. and G.) identical with *pallida*; and *texana* the same as *Habranthus Andersoni* var. *texanus*.

10. *PYROLINION*.—The three species in Kunth are doubtfully distinct; *albicans* rests still solely on the authority of Feuillé, and there are two novelties still undescribed in Mandon's "Plants of the Bolivian Andes."

11. *HEMANTHUS*.—Species about thirty, five of which are tropical African, and the rest Cape. The structure of the flower is very uniform through the genus. Of the plants in Kunth, *concolor* and *Hookerianus* are probably the same as *sanguineus*, *atrigosus*, and *brevisifolius*—mere forms of *carneus*; *tenuifolius* the same as *abyssinicus*; and *H. coccineus*, Forak. (*H. arabicus*, Roem.), of which there is a type specimen in the Smithian Herbarium, identical also with *abyssinicus*. Of published novelties since Kunth, there are *H. natalensis* (Hook.), Bot. Mag., t. 5378; *H. cinnabarinus* (Deene), Bot. Mag., t. 5314; *H. deformis* (Hook., fil.), Bot. Mag., t. 5903; *H. rotularis*, *rupestris*, and *Katharinæ* (Baker); and there are four or five novelties in the group of *H. coccineus* still undescribed.

12. *BUPHANE*.—Two distinct species, *disticha* and *toxicaria* being identical, and a third (*guttata*) doubtful; *toxicaria* has been gathered lately in Zambesiland by Dr. Meller, and on the banks of Lake Tanganyika by Lieut. Cameron.

13. *HESSEA*.—Species two to three, *Dregana* being doubtfully distinct from *stellaria*. The plant described in detail by Kunth under *H. erispa* is this same *stellaria*, and *Amaryllis crispa* (Jacq.), Hort. Schoen, t. 72, is a distinct species.

14. *CARPOLYZA*.—Monotypic.

15. *LAPIEDRA*.—Species two. *Martinezii*, imperfectly described by Kunth, is fully figured by Boissier, Voy. Hisp., t. 171; and a second very distinct species, yet undescribed, is in Schousboe's Mauritanian collection.

16. *ANOIGANTHUS*.—Two species, as described in Journ. Bot., 1878, p. 76.

17. *UNGERNIA* (Bunge), in Bull. Soc. Imp. Nat. Mosc., 1875, ii., 171. Monotypic.

18. *CLIVIA*.—Three species, the two additional to Kunth's being *C. Gardeni* (Hook.), in Bot. Mag., t. 4895, and *Imantophyllum miniatum* (Hook.), in Bot. Mag., t. 4783.

19. *PHEDRANASSA*.—Three species, *chloracea*, *obtusa*, and *multiflora*, being mere forms of one; and the two novelties, *P. Carmoli* (Baker), in Ref. Bot., t. 46, and *P. viridiflora* (Baker).

20. *CALLIPSYCHE*.—Three species, the two additions being *C. arantiacæ* (Baker), in Ref. Bot., t. 167, and *C. mirabilis* (Baker), in Ref. Bot., t. 168.

21. *GRIFFINIA*.—Seven species now known, the additions being *G. ornata* (Moore), *G. Blumenavia*, Bot. Mag., t. 5666, and *G. Liboniana* (Morren). *G. dryades* (Roem.) the finest plant in the genus, mentioned in Kunth by name only, is figured and fully described by Sir Joseph Hooker from the Sanders' collection, Bot. Mag., t. 5786.

22. *SPREKELIA*.—Only two good species; *glauca*, *ringens*, and *Karwinskii* being varieties of *formosissima*.

23. *NERINE*.—Including *Ammocharis* and *Lycoris*. Species, eighteen. I cannot make out any definite line of demarcation between these three. If we widen *Ammocharis*, as in Kunth, to take in *Nerine lucida* and *marginata*, it differs from the other two by its short, stout scape, and resembles *Brunnsvigia* in habit, but not in ovary and fruit. Additional species to those in Kunth are *Nerine japonica* (Miquel) and *Lycoris Sewerzowi* (Regel).

24. *BRUNSVIGIA*.—Eight species; *B. Cooperi* (Baker), in Ref. Bot., t. 330, being added to those in Kunth.

25. *AMARYLLIS*.—Monotypic, *A. blanda* being a variety of *Belladonna*, and *A. etaminea* (Seubert), a synonym of *Hippeastrum stylosum* (Herb).

26. *HIPPEASTRUM*.—Including *Habranthus*, *Phycella*, and *Rhodophiala*, as in Kunth; and *Rhodolirion* (Philippi), in "Linnaea," xxix., p. 65. Species about fifty, those in Kunth needing to be much

reduced, especially in *Habranthus*. Many novelties have been described by Philippi and others. For details, see Journ. Bot., 1878, p. 79.

27. *VALLOTA*.—Monotypic.

28. *CRINUM*.—Species about fifty, those in Kunth needing little change. *C. Lindleyanum*, *undulatum*, *attenuatum*, *Commelyni*, and *graciliflorum* are scarcely more than varieties of *crubescens*. The principal novelties are *C. Moorei* (Hook., fil.), in Bot. Mag., t. 6113, *C. Tinneanum* (of Kotachy and Peyritsch), *C. uniformum* (F. Muller), *C. floridanum* (Fraser), and *C. Macowani* (Baker); and there are three or four others still undescribed. *C. brachynema* (Herb.), imperfectly described by Kunth, which differs from all the rest by its short filaments, has now been introduced in a living state from Western India, and is figured in Bot. Mag., t. 5937.

29. *CHLIDANTHUS*.—Monotypic; *Ehrhenbergi* being apparently the same as *fragrans*, and *Camingi* something totally different, probably *Hippeastrum advenam*.

30. *URCEOLARIA* (Herb.).—(*Callania* (Schultes) a later name).—Monotypic, *fulva* being a mere form of *pendula*.

31. *PENTLANDIA*.—Monotypic.

32. *CYRANTHUS*.—Three sections: *Cyrtanthus* proper, *Monella*, and *Gastronema*, with the last of which *Cyphonema* is identical. Species fifteen, *pallidus*, *striatus*, and *ventricosus* being apparently varieties of *angustifolius*; and the additions *C. Mackeni* (Hook., fil.), *C. sanguineus* (Hook.), in Bot. Mag., t. 5218, and *C. Macowani* and *Tucki* (Baker).

33. *EUSTEPHIA*.—Monotypic. See Journ. Bot., 1878, p. 39.

34. *VAGARIA*.—Monotypic. *Panocratum parviflorum* (Kunth) is identical.

35. *CALLIPHURIA*.—Species three; the additions being *C. edentata* (Baker), in Bot. Mag., t. 6289, and a third, still undescribed.

36. *TAPEINANTHUS*.—*Carregnoa* (Boiss.).—Monotypic.

37. *HYLINE*.—Monotypic.

38. *HYMENOCALLIS*.—Including *Choretæ*. Species ten to fifteen, those in Kunth needing great reduction. *H. Bonplandi* is a *Eucharis*.

39. *ISMENE*.—Species five to six; *pedunculata*, *Macleanica*, and *virescens* being apparently identical. Two novelties yet undescribed. *I. deflexa* is probably a hybrid between *Ismene* and *Elisena*, such as Colonel Trevor Clarke has lately raised.

40. *PANCRATIUM*.—Species about a dozen; *carolinianum* being undistinguishable from *maritimum*; *malabathricum* (Herb.) from *triflorum* (Roxb.), and *cambayense* (Herb.) from *longiflorum*. Additions are *P. parvum* (Dalzell) and *P. collinum* (Coasson & Durieu). *P. tortifolium* (Boiss.) is *P. tortuosum* (Herb.), and *P. Chapmanni* (Harv.) and *P. tenuifolium* (Hochst.) are *P. trianthum* (Herb.).

41. *PLATEA*.—Species four; the three additions being *P. lutea*, *Germainsi*, and *Arzæ*, of Philippi.

42. *ELISENA*.—Species two to three.

43. *EUCHARIS*.—Species two. *E. candida* (Planch.), in "Flore des Serres," t. 788, and *E. grandiflora* (Planch.), in Bot. Mag., t. 4791 (*E. amazonica*, Linden).

44. *CALOSTEMMA*.—Species three. See Benth. Fl. Austral., vol. vi., p. 457.

45. *EURYCLES*.—Species two; *australis* being the same as *amboinensis*.

46. *LEPERIZA*.—Species two; a second, still undescribed, imported lately from Ecuador by Messrs. E. G. Henderson & Son.

47. *STENOMESSON*.—Including *Coburgia*. Species about ten, Kunth's needing great reduction. See Baker in Ref. Bot., sub. t. 308. *Incarinata*, *splendens*, *bichroma*, *variegata*, *chæropoyensis*, *versicolor*, *lata*, and *minuta* appear to be mere forms of one species, and *recurvata*, *diacolor*, *obragillensis*, *lutea*, and *Macleanica* of another. Additions are *S. Pearcei* (Baker), in Ref. Bot., t. 308, and *S. suspensum* (Baker), in Ref. Bot., t. 22.

48. *EUCROSTIA*.—Monotypic, the habitat being Ecuador, not Peru, as given in Kunth.

49. *CALLITHAUMA*.—Species two.

50. *NARCISSUS*.—Including *Corbularis*, *Ajax*, *Queltia*, *Ganymedes*, and *Hermione*. Species twenty-one.

51. *IXIOLIRION*.—Monotypic, *tataricum* being a mere variety of *montanum*. It extends to Beloochistan and Afghanistan.

52. *POLIANTHES*.—Monotypic.

53. *ALSTREMERIA*.—Species twenty to thirty, or more, a large number of novelties from Chili having been described from Philippi and several from Brazil by myself (Journ. Bot., 1877, p. 259).

54. BOMAREA.—Including Sphaerine and Wichuræa. Species about fifty, Kunth's needing to be greatly reduced, especially in the neighbourhood of *B. edulis*. A fine addition is *B. Carderi* (Masters), and there are many others still undescribed. Sphaerine and Wichuræa differ from Bomarea in habit alone. Both this genus and *Alstrœmeria* greatly need re-monographing from present material.

55. LEONTOCNIU (Philippi).—Desc. Nuev. Plant., p. 69. Monotypic.

ROSE GROWING IN FRANCE.

(Continued from page 316.)

The Brier.

The Wild Brier, which furnishes us with nearly the whole of the stocks for grafting Roses, fully deserves a special description in every practical treatise on the cultivation of Roses. It is, however, rarely that we find it spoken of in such works, writers of Rose manuals apparently caring but little to learn what it is and whence it comes. The price of the Brier in Paris is always rather high. Some time since Brier stocks were at from 8s. to 12s. per 100, but lately, owing to some 40 or 50 per cent. of the wild trees having died, this price has become doubled. This mortality is partly due to the negligence, and still more to the ignorance, of those who collect the stocks. We think, therefore, that it may be useful to give the results of five years' experience of Brier stock collecting in the forests of the Haute Saône.

The Wild Brier (*Rosa canina*) is indigenous to Europe. It is found in every forest and hedge, and propagates itself by seed and, above all, by suckers; in fact, it has the property in the very highest degree of throwing off underground stems which spread out a long way from the parent stem, and cause themselves, by their entanglements, to be looked on by woodmen as a perfect plague. The Brier is often confused with its near neighbour the *Rosa rubiginosa* or Sweet Brier. The leaves of this kind of Rose are rust coloured, the skin of the stem is of polished green, the thorns are small and numerous, the leaves are dark green and crinkled, and when rubbed with the fingers leave behind them an odour closely resembling that of a Reinette Apple. This Rose and its four varieties make but poor stocks, but they may, nevertheless, be used for grafting Pimpernel and Moss Roses, which have a certain amount of analogy with it. As far as yielding good stocks for Rose growing, all Briers in a wood are not alike. Those which grow in freshly-cleared parts are preferable to those found in the old underwood or under high trees; their stems, being always exposed to the light and air, are very strong, the tissues being firm and the bark hard, and they fear nothing from either the sun or the dry March winds, which are always fatal to subjects grown in the shade. In the young Brier the skin is bright green with a tendency to purple on the side exposed to the sun; the thorns, which are bent like the blade of a scythe with the point downwards, are unequally placed on the stem. In the third year the bark becomes grey and rough. Besides this, the old Briers which have been cut down close to the ground throw out vigorous young suckers, which grow faster than the trees and bushes surrounding them, and, being much taller than their neighbours, they produce perfectly straight stems. It is, therefore, in forest clearings of from three to six years old that we must look for our Brier stocks, but we must remember that, although uprooting them is a real benefit to the forest in which they occur, it is not always agreeable to the landowner, who naturally considers that he is the best judge as to what should be taken away and what should be left.

UPROOTING BRIERS.—The labourer whose work it is to pull up the Briers ought to be provided with a pickaxe, a sécateur, and a hand-saw. He ought also to be given a good pair of thick leather gaiters, rising above the knee, to protect his legs from the Blackberry bushes and the Thorns. Somewhat luckily for the owners of woods, the Brier does not grow abundantly in many parts of the same forest; there are, however, quite enough to enable a clever labourer who knows how to choose his spot to collect from 150 to 200 stocks per day. As he uproots the Briers they are laid

together in little heaps at the side of the pathway leading through the wood, the heaps being collected into larger ones of 150 each, and carried away by the labourer at the end of his day's work. When carried out of the wood the Brier stocks are, so to speak, in an unmanufactured condition; they have still to undergo the operations of trimming and sorting. These operations are not always performed on the spot; it is, therefore, advisable to wrap up the roots of the Brier stocks with the Moss found in their native habitat, and stow them in a cellar, or some other cool, dry locality. If these precautions are taken, and they are not difficult to fulfil, the Briers will stand a temperature of 9° Fahr. below freezing point, and may remain in this condition, while waiting to be trimmed and sorted, for a month or more without their ultimate healthiness being interfered with.

TRIMMING THE STOCKS AND PREPARING THE ROOTS.—The roots of the Brier stocks have to be properly trimmed before they are fit for planting. The Brier ought first to be deprived of the more or less strong portions of the old stem from which it sprung, and should have a good healthy root allowed to remain. It is at the point of junction between the stem and the root, called the collar, that the new roots will spring forth. It often happens that these roots are already developed when the Brier is pulled up, and, being very delicate, have no doubt suffered in the process of extraction, in which case they must be cut off within $\frac{1}{2}$ in. of the stem, or even close to it, according as the injury done to them is serious or not. The outermost bark of the root of the Brier is dark brown; the inner bark greenish-white, sometimes of a pinkish hue, at others purple. When the root is of an unnatural colour the skin should be lifted up; if the inner bark is found to be dark brown or black, and if in addition the fibres are very porous, we may be certain that the stock will not live. When several stems belong to the same stool, they are divided, so as to leave a good root to each stem. As many stems as possible must be kept; at the same time, if there be any need for it, weak stems must be sacrificed for the sake of growing nothing but vigorous stocks. The preceding operations are performed with the sécateur and hand-saw, taking care to pare down the rough edges of all the cuttings with the pruning-knife. The edges of the bark should also be smoothly rounded off. For trimming the roots a very strong sécateur, with long handles and without springs, is necessary. One of the handles is fixed horizontally in a heavy block of wood firmly fastened to the ground, the other being provided with a wooden handle similar to that of a chisel or screw-driver. The stock to be trimmed is held in the left hand and the free handle of the sécateur worked with the right. The dimensions of this tool are as follows: Length of the handles, 10 in.; thickness, $\frac{1}{2}$ in.; length of the cast steel blade, $2\frac{3}{4}$ in.; width, $1\frac{1}{2}$ in.; thickness, $\frac{1}{2}$ in.; length of the hook, $2\frac{1}{2}$ in.; thickness, $\frac{1}{2}$ in. The price is from 12s. to 16s. Amongst the gathering we shall no doubt find a number of seedlings and suckers which have sprung up naturally. These stocks must have their own roots, which may be trimmed down by the pruning-knife to within 1-10th in. of their point of insertion. In trimming the stocks we must invariably cut away all the underground stems, which make their appearance in the form of buds and suckers. Fig 6 shows a stock of each kind, the cross lines showing the parts of the root which should be cut off. The buds spring out of the lower part of the stem, and are of a bright red colour and of a woody texture. The sucker, on the other hand, has a smooth bark, and is of a pale rose colour, or red, and in its general character it is more like a branch than a root. Both buds and suckers must be rigorously cut down to the point from which they spring, otherwise they are almost certain to grow into useless shoots that will only exhaust the stock instead of strengthening it.

PREPARATION OF THE STEM.—The rudimentary buds which make their appearance on the stem of the Brier stock should be cut off in such a manner that the whole length of the stem should be upright and smooth without any growths upon it. The last operation is to cut the stocks to the proper height, which allows us to divide them into four classes.

SORTING THE STOCKS.—The first, which includes "full stocks," properly so called, consists of the strongest Briers, of

from 6-10th in. to $1\frac{1}{2}$ in. in diameter, and about 4 ft. 4 in. in length. The second class, or "half stocks," includes Briars of less diameter than 6-10th in. and only about 2 ft. 8 in. in height, that being the length proportionate to the vigour of the stock. The third class, called "bastard stocks," are too weak for half stocks, and are cut to a length of less than 2 ft. 8 in. The fourth class are called "dwarfs," and include those Briars which are too small to be included in either of the other classes. They are cut down to within 1 ft. of the root, and are used for grafting dwarf Roses. In order to cut the stocks to their proper lengths, gauges are used by the workman, the cutting, of course, being performed by a sécateur. They are thrown into four heaps as they are cut, and afterwards bound up into bundles of fifty stocks, and sent immediately to the

Fig. 6.—Trimmed Stocks.

nursery. With these four different sizes stocks of all descriptions can be supplied, whether for borders, circular beds, or clumps. So much for the ordinary operations of preparing the stocks; but we cannot refrain from recommending Rose growers to supplement them by covering the cut surfaces with the protecting wax before mentioned. The grafting wax will protect the stem from the effects of damp, which is apt to lead to the rotting of the upper part of the stem. When once this decomposition sets in it proceeds slowly but surely, and spreads upwards towards the graft, which it will ultimately destroy. The evil is sometimes not so great as we have represented, but in any case a dry, dead mass of wood is always found at the top of the stock, which soon becomes hollow, affording a refuge to the insects that ultimately prey on the graft. The application of grafting wax to the cut ends of the stocks is neither

an expensive nor troublesome operation. It may be performed with the spatula, or, better still, by dipping the end of the stock in the melted wax as soon as it has been cut to the proper length.

PLANTING BRIER STOCKS.—These stocks are laid in by the heels if the weather is not favourable for planting; if, on the other hand, the weather is fine, the ground pretty dry, and all fear of frost is past, the Briars may be planted out in borders or elsewhere. We will suppose that the planting out takes place in spring, according to general practice, the collection of the stocks being made in the winter. Briars, however, can be planted out in the autumn if necessary.

PLANTING IN BORDERS.—The ground is divided into borders 5 ft. 6 in. wide, the borders being separated by pathways 2 ft. 2 in. wide; the stocks are planted in rows 1 ft. 4 in. from each other, the distance between each Briar being 1 ft. 2 in. The row in the middle (the third) is planted with full stocks, the second and fourth with half-stocks, and the first and fifth with bastards or dwarfs. This plan of arranging the plants gives more light to the middle row, and greatly facilitates the operation of grafting, &c. This method of planting in borders is generally adopted in the environs of Paris, as it allows a large number of stocks to be placed in a limited space—a great advantage in localities where land is scarce and rents are high. Some growers object to this mode of planting on account of the stocks being too crowded, so that many of them will not take root for want of room, or because the grafts are liable to be broken off by careless or stupid labourers, so that in many cases there is nothing gained, and planting in the open ground is to be preferred.

PLANTING IN OPEN BEDS.—The soil of the bed having been properly prepared, the sides being, let us suppose, on the north, south, east, and west, we first of all lay down rows of pegs from the east to the west sides, the space between the rows being 1 ft. 8 in., between the pegs in each row 1 ft., and between the end pegs and the north and south sides of the bed about 6 in. The pegs are intended to show the places where the stocks are to be planted; the plantation is begun on the north side, the tallest stocks being used first. A cord is stretched between the first and last pegs, and a labourer makes the first hole with a spade at a distance of 6 in. from the edge of the bed; the hole should be from 6 in. to 8 in. deep, according as the soil is light or heavy. A second labourer, who carries the Briar stocks under his left arm, places one in the hole, leaning it lightly against the string, without, however, forcing it into the ground. The first labourer makes a second hole at 1 ft. from the first, filling up the latter with the earth he takes out, treading the soil firmly round the stock, and so on to the end of the row. The line of stocks is then made perfectly straight by treading the soil round their roots to the right or left, as the case may be. The planting out proceeds in this way, passing successively from full stocks to half-stocks, bastards, and dwarfs. The plantation, when completed, will have the heads of the stocks inclining gently from north to south, and under the best conditions for light and air. This method of planting seems to us the best, always provided that the extent of the ground and the number of the stocks do not allow us to devote a whole bed to each class. The Briars generally having but few roots at the time they are planted, we must encourage the formation of fresh rootlets by spreading over the beds a layer of deodorised night soil, or, better still, this valuable fertiliser may be placed in the holes before planting the stocks, their striking being then made almost certain by this simple precaution. The vigour of the growth of the stocks fully compensates for the extra expense of the manure.

AFTER TREATMENT.—The after-attention to be bestowed on the plantations is the same, no matter what method of planting out has been adopted. It consists in turning over the ground three times during the first year, and in pinching off all useless buds and shoots. The first digging is generally performed immediately after the first pinching off, which generally takes place in May. The second should be in July, and the third in September. The number of diggings and time at which they ought to be performed varies greatly with the condition of the ground and the state of the weather since the last time the ground was

turned over. For instance, if the turning over of a bed filled with weeds is followed by heavy rain, it will facilitate their growth, thus in part destroying the good effects of the operation. In this case it is better to wait until the weather is settled, and then give the ground a thorough forking. The weeds brought to the surface are soon burnt up by the sun. This operation should, however, be entrusted to a careful man, or the stocks will run great danger of being stripped of their bark, or otherwise injured by the prods of the fork. Pinching off the useless buds and shoots is a very important piece of work, the object of the operation being to rear a stock with a certain number of vigorous shoots growing from its head, any or all of which will be fit to receive grafts or shield buds, besides being so symmetrically placed as to form a handsome head. At the same time we must not be in too great a hurry to destroy useless or badly placed shoots, as by so doing we may injure the growth of the stock. The shoots should be allowed to reach a length of from $1\frac{1}{4}$ in. to $1\frac{1}{2}$ in. before they are pinched off. We may now choose the shoots which are to form the head of the future Rose tree. When the stock is strong and healthy we may allow three to remain, leaving only two, or even one, on those which are weaker. The shoots which are chosen should, of course, be on the upper part of the stem of the stock, and should, as far as possible, be in a circle and at equal distances from each other. Having made choice of the shoots to be preserved, the others are cut off with the pruning-knife close to the stem. The labourer whose duty it is to prune the stocks ought to precede him who turns up the ground, in order to prevent the freshly-disturbed soil from being trampled upon. He should also examine the foot of the stocks to see if they are throwing off any underground suckers, and destroy them if necessary. A sharp lookout, too, must be kept for the cockchafer grub amongst the roots of the stocks. We will now suppose that all our Brier stocks have been uprooted from their native soil and, for the most part, successfully transferred to the nursery ready for grafting or shield budding. Some of the stocks will no doubt have failed to take root, the mortality amongst them, as we have already stated, being sometimes as high as 50 per cent. If the directions given above, which are the result of thirty years' experience, are strictly followed, the loss may be diminished to one-half. Another precaution which may be taken to prevent loss is to daub the entire stock over with a mixture of clay and cow manure, an easy and cheap operation, which may be performed either immediately after the stocks have been trimmed, or just before they are planted out. Take equal parts of dry earth and dried cow manure, or one-third of earth, one-third of fresh cow manure, and one-third of clay, and mix them in a tub with sufficient water to form a thin paste. The stock should be steeped in this mixture and allowed to dry. The coating which it thus acquires remains upon it sufficiently long to protect it against the cold March winds and the heat of the sun in spring, and keeps the bark in fresh and supple condition, which is favourable to its growth. When the best shoots for grafting are not exactly at the end of the stem, they are, nevertheless, allowed to remain in company with the terminal shoot, which will help to draw up the sap and prevent that part of the stem which is above the choicer shoots from becoming dry and withered. After the grafts have taken the central shoot is cut off. When several shoots spring from the same point, the weakest are sacrificed and the strongest allowed to remain. When all the shoots on a stock are badly placed, the highest is allowed to remain to keep up the supply of sap; and at grafting time the stem is used for shield-budding, as we shall see further on. As already explained, pinching off ought to take place about the month of May, but the growth of the stocks must, nevertheless, be continually watched, in order to give the shoots which have been allowed to remain a fair chance of developing.

J. LACHAUME.

Rose de la Grifferaie as a Stock.—Mr. William Paul recommends the use of this as a stock, and certainly the growth made upon it in his nurseries, as contrasted with that on the seedling Brier or the Manetti, is very striking. This was pointed out in the account which was recently given of the Waltham Cross Nurseries in THE GARDEN (p. 255).

GARDENING FOR THE WEEK.

Flower Garden.

Auriculas.—In the south of England it is absolutely necessary to grow Auriculas in a shady position, not under trees or in a place where they can be overshadowed, but under a north wall or high, close hedge, with the back of the frames placed against them. Even in such a position, at midsummer the plants almost get too much sun and require to be shaded in the afternoon from, say, half-past one to between four and five o'clock. Early in August shading becomes unnecessary, and by the first or second week in October, or earlier if the weather should be dull and wet, the frames must be removed to an open position in which they will be exposed to the full effects of sun and air. It is difficult to keep the plants free from green fly during summer; fumigating with Tobacco smoke is injurious to the young leaves, and it requires great patience to brush the fly off with small camel's-hair brushes; by the middle of October the leaves are able to resist the effects of Tobacco smoke strong enough to kill the aphid. See that the plants are cleared from decaying leaves and weeds when they are removed, and that the ground where the frames are to stand is saturated with lime water to kill slugs and worms. Slugs are a great pest to Auricula cultivators, and at this season they are very troublesome; if there be any in the frames they must be looked for at night with a lamp.

Geraniums and Picotees.—Growers of these are now busy moving layers from their plants and potting them. This may be done any time during October, but it is not desirable that it should be done earlier, as I have found that the plants when potted very early do not succeed well during winter. It is well, too, for growers in different districts to be acquainted with one another, as a change of plants from north to south, or from south to north, is beneficial to the plants, and this change is made most advantageously now. One grower in Bradford, let us say, wishes a change of stock; he writes to his friend in Essex, and offers to send him 100 pairs, and the southern grower reciprocates this offer by sending 100 pairs of similar sorts to Bradford. No time, moreover, must now be lost in obtaining any new sorts which it may be intended to purchase. Many wait until spring before they buy their plants; but I do not think that a good plan. The plants are much more easily removed now, and they do not experience any check to growth at this season. I find that they stand the winter best if no manure is mixed with the soil at the time of potting up the layers. A good compost consists of turfy loam broken up fine four parts, leaf-mould one part, and sharp sand one part. When potted, plunge the pots in some dry, light material in cold frames. I use 3-in. pots for one plant, and 5-in. ones for two.

Polyanthuses.—The treatment which these require is nearly akin to that of the Auricula, except that it is not usual to grow Polyanthus in pots all the year round. They are turned out of their pots after they have flowered and planted in rich soil in a part of the garden not too much exposed to the sun. A good time to lift and pot them is in August or September, but many prefer not to disturb them until October. I shall not pot my plants until the middle of the month. Seedlings that were sown in July or August ought now to be pricked out from the seed pots; from twelve to eighteen plants may be potted into a 5-in. or 6-in. pot. The Polyanthus requires a rather heavier soil than the Auricula, and this is obtained by using less leaf-mould and sand in its composition. I find that there are many autumn trusses of flower showing; these, of course, are pinched out as soon as they can be handled. When potted the plants must be placed under glass lights the same as Auriculas.

Dahlias.—Where these are cut down by frost it will be necessary to dig up the roots after cutting over the stem about 1 ft. above the ground. The stems sometimes contain water, which should be allowed to drain out by turning them upside down, and they may remain in that position for a whole day out-of-doors if the weather be favourable. When the roots are dry let them be stored away in a room for the winter. I have seen Dahlia roots much injured when placed near hot-water pipes in a Mushroom house. They do best stored in dryish sand in a shed, from which frost is excluded, and while at rest they ought not to be stimulated by artificial heat.

Hollyhocks.—Choice sorts ought to be taken up and potted before severe frosts sets in; the pots should be plunged in a cold frame, in which, indeed, the general collection ought to be wintered, but it is a good plan, and saves some trouble, if the frame be filled with some good friable loam, and the plants put out in that, planting them rather closely together, but not so close as to injure the growths. The lights may be kept rather close for a few days; after-

wards in fine weather they may be removed, replacing them at night to prevent the plants being injured by a deluge of rain or cutting, frosty winds.

Gladioli.—The great difficulty with hybrids of the *Gandavensis* section is to get the roots sufficiently ripened before the ground is deluged by the autumn rains, succeeded by sharp frosts. It is desirable to lift them before the stems are quite decayed, and a dry day should be chosen for the purpose. The bulbs should be separated from the stems as they are lifted and put into clean flower pots, with the label attached to each. I then place the pots containing them in a Vinery, from which the fruit has been cut, and plenty of air ought to be admitted to dry them. When dry store them in a fruit room, or any dry place, and do not allow frost to get at them. In the operation of lifting a number of very small corms will be found attached to each root, and if it be desirable to increase the stock these ought to be preserved. Each sort should be wrapped up separately in paper in a little dry mould or sand.

Pansies and Pinks.—Beds of these may now be planted in rich soil as has been described in previous numbers. It is also desirable to plant a few of each in boxes, and to keep them in a cold frame to fill up any blanks that may be made during winter. Pansies intended to be grown in pots should now be potted into 4-in. or 5-in. pots to be potted again when the pots have been well filled with roots. The Pansy, as most of us know, likes a rich soil in which to grow, and the plants when potted should be placed in a cold frame near the glass.—J. DOUGLAS.

Spring Gardening.—Wherever it is intended to carry this out, the arrangement of the garden should now be decided upon without delay; and everything, as far as possible, should be in readiness for replanting the beds and borders as soon as their present occupants have been removed. It is necessary that Hyacinths, Tulips, and other bulbs intended for this purpose should be planted as soon as possible, as well as the various species of spring-flowering herbaceous plants used for spring bedding, such as the different species of *Aubrietia*, which are nearly all suitable for this purpose; *Arabis alpina*, *lucida*, *præcox*, and *purpurea*; double Daisies of various kinds, all of which are most effective as profuse-flowering spring plants; *Gentians*, *Hepaticas*, *Myosotis dissitiflora* and *azorica*, double and single *Primroses*, *Polyanthuses*, *Vincas*, *Violas*, bedding *Pansies*, double and single *Wallflowers*, and others. Many hardy succulent plants, such as the *Sedums*, *Sempervivums*, and other species, may also be used with good effect in spring bedding; and, by their aid, the carpet style of planting may be adopted in spring as well as in summer. In arranging the spring-flowering plants for the various beds in the flower garden it will seldom be advisable to plant any of them with bulbs alone, such as the *Hyacinth* and *Tulip*, as this would necessarily leave the surface of the beds destitute of verdure for a considerable portion of the season. But a more satisfactory arrangement may be made, and a better effect produced, by planting the bulbs somewhat thinly in most of the principal beds at least; and, as soon as this has been done, by carpeting the surface with such plants as *Aubrietias*, *Violas*, *Silenes*, *Sedums*, and other suitable plants, a finished look is given to the garden which will continue to increase in beauty as the various bulbs are developed. Lawns and Grass belts will still require to be occasionally mowed either with the scythe or the mowing machine, and, together with gravel walks, will require frequent attention as regards sweeping and rolling—in fact, the broom or the sweeping machine will, for some time to come, be in constant request.

Herbaceous Border.—While the late autumn-flowering plants still gladden the eye and give interest to the herbaceous border, the great majority of its occupants have already had their summer growth levelled with the ground, or are in a condition for that operation. A word or two, as to what may be considered by many a very simple process, will not be out of place. Be it remembered that Nature's mode of removing the haulm is a gradual one, viz., by the ordinary process of decay, extending, in most cases, through the entire winter months. Admitting at once that, where neatness and trimness is an essential point, it will not do to follow Nature's lead too closely; nevertheless, we may take a lesson from her, and that, too, with advantage. The lesson is this—never to cut down too close to the ground, but leave sufficient length of the old stems that they may readily be bent to one side. Such stems are almost invariably hollow towards the base, and not unfrequently constitute channels whereby decay, owing to the continued presence or accumulation of water therein, is conveyed beyond the ordinary stem into the very heart of the root-stock. From this cause alone many a valuable herbaceous plant has been lost; therefore, though not absolutely necessary in all cases, it is well to act up to it as a rule. Another bit of advice, bearing on the same operation, is, that the knife used

for the purpose should always have a sharp, keen blade. The supposition generally prevalent is that any old knife will do, but such is not the case. In many of the better classes of herbaceous plants the buds, upon which depends the next year's floral display, are densely arranged on a somewhat fleshy root-stock immediately below the surface of the ground, nor is this root-stock always tough; hence, when a blunt knife is carelessly applied to the old decayed stem, the jerk intended to remove the decayed part is liable to break off the crown at the same time, and thus leave a blank in your border hearty for next year. In the wild garden this operation should always be left to Nature herself; let there be no cutting until a general clearance takes place in spring.

Indoor Plant Department.

East Indian Orchid House.—The non-pseudo-bulb forming section of Orchids, such as *Phalænopsis*, *Vandas*, *Aerides*, and *Saccobulbiums*, do not require a long season of rest like most of the *Deudrobes*, *Cattleyas*, *Lælias*, *Oncidiums*, and many others. When they are treated so as to induce the necessary cessation of growth through the winter, it should not be done too suddenly by keeping the temperature up to the full height of the growing season, and a corresponding amount of moisture in the atmosphere until it is reduced all at once, or nearly so. In place of this, a gradual reduction should be made as the days shorten, especially in the night temperature, which may range some 5° to 6° lower than when the days were longer. There should also be a corresponding diminution in atmospheric moisture, which will still further assist the solidifying of whatever growth is yet made. This is essentially necessary, for such portion of leaf-growth in the above plants as is made under the shortened conditions of light existing through the autumn months will be of a much softer character than that which is formed earlier in the season, unless there be some counterbalancing effect produced, such as that consequent upon a drier state of the atmosphere. For a like purpose much less shading should now be used; in fact, after this time it may wholly be dispensed with for plants that have been grown under a regular course of moderate heat, moderate moisture, and no more shading than is absolutely necessary, except in the case of lean-to houses facing the south, where sometimes when the sun is very bright and there are any flaws in the glass, these will burn the leaves both late in the autumn as well as early in spring, when otherwise the plants would be in no way injured by the sun acting upon them; neither is it advisable to dispense with shading so early in the season with those Orchids that have been systematically treated to the heavy shading, and hot, stifling atmosphere that some growers consider necessary, as under such conditions the whole tissues of the plants are weak and watery, and little calculated to bear any extreme. As a matter of course, with Orchids, more than any other subjects cultivated under glass, it is necessary to be guided by the actual condition of individual plants, as where any particular species is duplicated to a considerable extent, which almost always occurs in large collections, there will be some plants of each kind earlier or later in their growth, as the case may be, according to the time at which they flowered. In houses that are a good length much may be done at this season to meet the requirements of the description of plants under consideration, placing those that are about completing sufficient growth at the coolest end of the house, where less moisture may be applied to the roots, reserving the warmest end for such as flowered and commenced growing later, for with these plants there is no completion of growth in the way that takes place with those that form pseudo-bulbs, the production and completion of which amounts to an ordinary season's growth; but with the plants now under treatment the growth is simply an extension of leaves, roots, and stems; consequently, there is no particular point in its formation to indicate where the treatment calculated to keep on the extension of the parts should cease; hence it becomes necessary to be guided by the season and the amount of growth that has taken place since their blooming. At the same time it is well to remind beginners in the cultivation of these plants that the thorough maturation of a moderate amount of growth is very much preferable to the extension of such as is of a weak, indifferently matured character. Where fixed shading, such as whitening or paste, is used, it is a very common occurrence to see this left on until late in the autumn, when its presence, through obstructing the light at a time when every ray available should reach the plants has a most weakening influence.

Calanthes of the vestita Section.—In most cases the pseudo-bulbs of these will be about attaining their full size, after which time I have found that they do better with considerably less water at the roots than when growth was in its most active state. The whole of the roots of these plants die annually; but upon their retaining vitality as long as possible, in a great measure depends the retention of the leaves; when these can be kept in a moderately healthy condition until the flowering is approaching completion, the plants not

only bloom much better, but their appearance is very much enhanced; by a diminution of the supply of water when the pseudo-bulbs have attained their full size, the leaves will keep fresh longer, but nothing approaching a complete drying up of the soil must be attempted.

Mexican Orchid House.—The temperature here, both day and night, may with advantage be reduced some 5°, as well as a reduction of moisture in the atmosphere, with little shading, or dispensing with it altogether where the form and position of the house and the treatment the plants have previously been subjected to has been such as to enable them to bear the comparatively little sun that we may look forward to.

Miltonias.—These plants do not find nearly so much favour with growers as they did some years ago, yet there are many very beautiful species amongst them, such, for instance, as the best variety of *M. Moreliana*, usually known under the name of *M. Moreliana atrobicolor*, producing, as it does, immense flowers in proportion to the size of the plant, of an intense deep reddish-purple colour, unequalled in its particular shade by any other Orchid. The flowers are of an enduring character, lasting good for a month, and blooming at the present season when Orchid flowers are the scarcest renders it a most desirable plant. The different forms of *M. spectabilis* are well worth more extended cultivation than they now receive. They are amongst the freest of free-flowering subjects. These *Miltonias* are plants that may be said to have comparatively little rest, for almost as soon as the blooming is over the slow development of their next growth commences. Like the majority of Orchids, they do not like disturbing oftener than necessary, but when the young growths have extended so far as to get beyond the confines of the pots they must either be divided or have larger pots, for if the roots have no soil in which to descend they will cling to the outsides of the pots, where they can receive no sustenance, except through the water given. In this way the growths are weakened. The time of potting will need to be regulated by the period at which they have bloomed and the extent of after-growth made; but when potting has to be resorted to, it should be done before the young growths have made any roots. They require considerably less water from this time through the winter season, but should not be kept too dry. In potting, keep the soil well rounded up above the rims of the pots. Small copper wire hooks I have found the best for securing them till the roots have got good hold of the new material. After flowering the plants should be subjected to a thorough cleansing, especially if there be any white scale about them, which insect is worse to eradicate on *Miltonias* than most plants, as it establishes itself under the scales with which their creeping stems are covered, and on the pseudo-bulbs inside the base of the leaves, where it is bad to get at without injuring the plants. Little brushes, such as the small ones ordinarily used by painters, made of camel's hair, in place of which they should be made of bristles, I have found the best for the removal of the scale. *Miltonia candida* is another autumn-flowering plant, now about in bloom, well worth cultivation, particularly the best variety *M. candida grandiflora*, as also one or two of the best forms of *M. Clowesi*, which likewise usually comes in about this time. The flowers of both these last long, and as they form elegant spikes are well adapted for cutting. After blooming plants of both want keeping somewhat drier than the first-named species.

Ceelogyne cristata.—Those plants of this that flowered early will now be about completing their growth and pushing up their flower spikes; the development of these takes a considerable time from their first appearance. They are rather impatient of water standing about them, consequently the syringe should not be used so as to wet the spikes, giving whatever water is needed with the ordinary pot. Plants the growth of which is so far advanced as is here indicated will now require less water, but they must not be kept so dry as many subjects. Examples of this most useful winter-flowering Orchid that bloomed, and therefore made their growth, later, must be encouraged to finish it up stout and strong, for the larger the pseudo-bulbs the greater the number of flowers they are able to produce.

Lælia Perrini.—This very beautiful autumn-blooming species will now be pushing up its flowers. The roots should be kept slightly moist, and a temperature maintained sufficient to fully develop the blooms, but as soon as they are expanded they should be stood in a position in the house where there is the least accumulation and condensation of atmospheric moisture, such as usually takes place near the end upright glass, where it often happens that the flowers soon after opening get spotted to an extent that would not occur if placed in the centre of the house.—T. BAINEs.

Conservatory.—There is no better time than the present for giving the inside of conservatories a thorough cleaning, as this can be done now before many things are brought in for the winter season. A general cleansing of this description has the double advantage of much improving the appearance of the house and also is conducive

to the health of the plants, through the maximum amount of light that it secures. As the plants are returned to their places let each be well cleaned, as well as the pots and tubs or boxes they occupy, an operation which gives an air of order and cleanliness that goes a long way to compensate for a less display of flower than earlier in the season.

Stove.—Shading may now be dispensed with, and still further reduce the moisture both in the atmosphere and at the roots, as plants generally will now be approaching the season of rest. Cut back *Ixoras* and *Dipladenias*, and keep them drier at the root until they have broken afresh. If any roof climbers are grown here, which in a stove properly so called never should be allowed, as, however beautiful they may be in themselves, they exclude light to an extent that renders it impossible to grow well the far greater number of plants which ought to be found occupying the body of the house, they should now be well cut back, keeping them dry so as to discourage growth as much as possible.

Fern Houses.—The reduction in the atmospheric moisture recommended here for last month, with the decreasing warmth of the season, will have materially checked growth, and brought the plants into a favourable condition for a thorough cleansing, more especially from insects. Thrips, even with the greatest care, usually make their appearance. The plants, in their present state, are in the best condition to bear a good application of Tobacco smoke, which ought to be repeated sufficiently often to destroy the young brood as soon as it comes to life. Remove all dead or unsightly fronds. See that the drainage of all plants in pots or tubs is in good order. Ferns are water-loving plants, and it sometimes happens that the quantity of water they receive has the effect of choking the drainage, more especially if worms have got possession of the soil. If the water when applied does not percolate freely, it is an indication that the drainage is defective. Where such is the case it must be remedied at once, or the roots will perish.

Azaleas.—Late-blooming plants should by this time have thoroughly matured their wood, and should have abundance of air night and day, only closing the house when there is danger of frost. Complete whatever tying yet remains to be done. Any plants that are suffering from want of more pot room may yet be potted, but great care must be taken to make the soil equally firm as the ball of the plant, and the watering of such plants through the winter must be done carefully, as, if the new soil gets too wet, the roots will not enter it.

Indoor Fruit Department.

Selecting and storing soil for forming new Vine borders or for putting additions to old ones must not be neglected at this season. The best surface turf attainable should be taken to the depth of about 6 in. or 8 in. The older and fuller of fibres it is the better. When cut into square pieces and laid Grassy side downwards in mounds it is preserved in good order until required in the spring. When placed in narrow ridges the frost has a beneficial influence in mellowing each parts of it as may be of a clayey character. Here the most fertile soil for Vine growing is a substantial calcareous loam, obtained from the hill tops, where it is found here and there in small patches on whinestone. These patches, which have remained unmolesated for ages, are rich in organic remains. As regards young Vines, such as were planted out during the past summer, if not already well ripened, they should be assisted to do so by means of a little fire-heat. Thin away all lateral growths from them, in order that the air may play freely about the buds; keep a vigilant eye on Grapes hanging, in order to see that none are decaying; in cutting, take them from the top of the house first, say half-way down the rod; the bunches at the bottom of the Vines always keep better than those at the top; this is owing to the moisture rising and settling at the top of the house, while the bottom is comparatively dry; when well ripened, it is surprising how perfectly Grapes will keep for months in the winter time if strict attention be paid to ventilation; see that abundance of air is given at the top of the house before sun-heat has induced moisture to rise; tardy ripening sorts of Grapes, such as Muscat of Alexandria and Gros Colman, may probably require a little fire-heat, in order to prevent the temperature from falling before 55°, and to ensure their perfect maturation.

Kitchen Garden.

If there be any doubt about the supply of Parsley being sufficient for the anticipated demand, there is yet time to transplant roots from the open ground into pots or boxes for use in January and February; and, even where there is an abundant supply well protected in the open air, it is always advisable to have some growing under glass for garnishing, as the leaves are usually fresher than can be obtained outside, especially during or after severe weather. It is generally

after Christmas that this want is felt, therefore there is yet time, if it be necessary, to add to the stock under cover.

Globe Artichokes.—Cut over old fruit-bearing stalks close to the crowns, and remove the weakest of the shoots so as to strengthen those that are left, in order to cause them to stand the winter better and be more easily protected. From plantations made last spring some heads may be obtained at this time, and, if they are required for pickling, they should be cut when they are about 2 in. in diameter. If severe or unsettled weather set in, cut over all remaining flower stalks having heads on them, plant the stalks in damp sand in a cellar or shed, and cut off the decaying portion of the stalk every three or four days.

Beet.—This should now be taken up, the operation being performed with care, as the slightest injury to the roots will cause them to bleed, after which the fine dark colour so much esteemed is lost. They, on this account, should not have the tops cut off close, as with many vegetables the leaves are better twisted off by the hand. A dry day should be chosen, and the roots allowed to remain on the ground for a few hours before taking them to the root shed, in which place they may be allowed to remain for some days previous to their being placed in dry ashes, when they should be piled up in layers in the same way as that recently recommended for Carrots. The latest crop of Carrots will now be ready for taking in.

Planting Cabbages.—Another hatch of summer Cabbages should now be planted; it is much better practice to plant twice, at intervals of about a month, than to make only one planting. If all goes well with those that were put out the earliest, they will be considerably in advance of such as are planted now, and it is desirable to try to have some ready as soon as possible in spring, otherwise there will be a blank between the late Greens and the first Cabbages. There is, besides, another contingency to guard against—the earliest-planted Cabbages take hold of the soil and commence growth whilst there is a good deal of heat in the earth and also in the air; this makes them grow freely, and in this state they are liable to suffer should a severe winter follow. The second batch put in, although they will be a fortnight later in the spring after a mild winter, are much better able to resist the effects of a severe winter of long duration, or the more trying vicissitudes of vegetable life—alternate frost and thaw. When these occur it frequently happens that few of the first crop of Cabbages escape; whereas, such as were planted somewhat later suffer comparatively little. At this time they should be put in as advised for the first batch, 2 ft. being left between the rows for both early and late kinds, the former 9 in. apart in the rows, the latter 12 in. A little soot and lime mixture should be applied to the roots of each plant at the time of putting out. The August-sown Cauliflowers will now be ready for putting into their winter quarters; for those that are to come in the earliest hand-lights are the best, as, when planted under these in the situations in which they are to remain, they do not require to be moved in the spring, as is the case when they are put in an ordinary garden frame for the winter. A hand-glass of the usual size will accommodate nine plants, five or six of which can, in the spring, be removed to the open ground. The ground should be well dug and enriched with manure, after which the lights should be put down, a space of 2 ft. being left between them, and each light should be pressed down upon the soil so as to mark the position the plants are to occupy. The latter should be put in 3 in. or 4 in. from the sides of the lights, dividing the space amongst them. Put in a little soot and lime to each, as recommended for the Cabbages, and dust the ground over if it is infested with slugs. Do not put on the lights until there is a probability of a sharp frost, as a certain amount of exposure renders the plants strong and capable of withstanding the cold of the winter. If there are no hand-lights available an ordinary one or two-light garden frame must be used. This will be all the better for being shallow, as a deep frame has a tendency to draw the plants up weakly. If the ground be heavy, dig in any light material, such as old potting soils of a sandy nature, or leaf mould, as the plants will move from it with better roots in the spring than if it was of a retentive nature; put in some manure, mixing it well with the soil. The plants should be placed 6 in. apart, and the surface dusted over with the lime and soot mixture. A narrow strip of ground should also be prepared at the foot of a south wall on which some Cauliflowers and Cos Lettuce may be pricked out. The latter may be put in at from 6 in. to 10 in. apart, according to the size of the plants. In the southern parts of the kingdom they will stand, with a little protection, in frosty weather, unless the winter be exceptionally severe. Here, also, dust well over with soot and lime. A frame should now be got ready, in which to sow Cos Lettuce for planting out in spring; an open, light situation ought to be selected for this, raising the frame at the back, so that the glass may slope considerably, to prevent drip, as success in keeping these late-

sown Lettuces through the winter depends upon the surface being quite dry, otherwise, in severe weather, when the frame has to be kept closed, sometimes for weeks together, the plants are sure to damp off. It must face the south, and be filled with soil to within 6 in. or 8 in. of the glass, with some light, moderately dry, earth on the top; in this sow the seeds broadcast, sufficiently thick to allow for failures. If the soil be too dry for the seeds to vegetate, sprinkle with water, but use no more than is necessary. The light should be put on until the plants are up, when it ought to be drawn off on fine days, and tilted when there is any likelihood of rain, so as to keep them dwarf and strong. These autumn-sown frame Lettuces require a good deal more attention than any others during the year; but, where a continuous supply is wanted, they cannot be dispensed with, as their absence would cause a void between the earlier autumn-sown crops that come in the first in the season and the earliest spring sowings.

Extracts from my Diary.

Oct. 14.—Sowing Mustard and Cress. Putting in the last of the *Calceolaria* cuttings. Tying up Lettuces, and covering up Endive to blanch. Turning manure for Mushrooms. Getting manure and leaves together for making hotbeds. Gathering the last of the Tomatoes and hanging them up in Pine stove to ripen; gathering also Glou Morceau and Knight's Monarch Pears.

Oct. 15.—Potting *Echeverias*; also old plants of Tom Thumb and Indian Yellow Pelargoniums. Thinning out Mignonette in pots. Salting out all the flint gravel walks. Looking over Cauliflowers and turning down leaves where required to protect the heads from frost. Hoeing among all late planted Cabbage, Endive, and Lettuce. Stacking away Carrots and Beetroot. Collecting leaves, cleaning walks, watering Pines, and tying them where required.

Oct. 16.—Sowing Canadian Wonder French Beans. Looking over cuttings, taking off the tops where required, removing dead leaves. Earthing up Celery when the soil is dry and in workable condition. Cutting back the heads of Yews, Laurels, and other shrubs where beginning to overhang each other. Gathering Easter Pippin and Lamb Abbey Pearmain Apples.

Oct. 17.—Putting in cuttings of *Peotstemons* and *Antirrhinum*. Clearing off flower borders, and getting them ready for spring-flowering plants. Filling up all pits and frames as they become empty with Lettuces and Endive. Making another Mushroom bed. Gathering last of Vegetable Marrows and clearing away the plants.

Oct. 18.—Potting various kinds of Pelargoniums. Planting spring-flowering plants of the following sorts, viz., Red and Yellow Wallflowers, Red and White Daisies, Iberis, Myosotis, Alyssum saxatile, Pansies, Nemophila, Saponaria, and Silenes. Fumigating Cucumbers. Clearing off late Peas, and stacking the best of the sticks for another year. Gathering Uvedale's St. Germain and Catillac Pears.

Oct. 19.—Potting Hyacinths, Narcissi, and Tulips. Getting cuttings of some of the tenderest plants into warm quarters. Looking over Grapes in bottles, and putting more water in each as require it. Putting haybands round Cardoons, and earthing them up. Cleaning up pleasure grounds and rolling walks where required. Fruit in use for dessert—Pines, Grapes, Pears, Apples, and Nuts.—W. G. P., Dorset.

The Speediest Way of Growing Leeks.—This consists simply in sowing the plantation where it is to remain instead of transplanting and earthing up the plants like Celery. This has been my plan now for some years, and I think I can show as good Leeks as anybody need desire, though they are not as thick as one's wrist, but they are half as thick, or nearly 5 in. in circumference and well blanched. One bed supplies us nearly till Leeks come in again. Not having been transplanted the plants do not run to seed so fast in spring, and they are laid in behind a north wall to keep them from pushing. I never could see the use of monstrous Leeks, and I am sure many of the large examples which I have seen at the Edinburgh shows did not pay for the pains that had been bestowed upon them, and which might with great advantage have been expended on other subjects. In a cook's estimation a small Leek is just as good as a large one. The French market gardeners, with that rare aptitude for gauging the wants of their customers, know this, and they grow several dozen plants in the space in which our Leek growers grow perhaps one, but they are well blanched and quite good enough for their purpose. I saw piles of them at the Halle Centrale, not one of them much thicker than my little finger. The Leek is an important crop in the little Paris market gardens, and one that appears to be hardly thinned out at all.—J. S. W.

FRENCH BELL BOILERS AND COPPER PIPES.

I LIKE the material of which these are made better than their design—at least, of the boilers. Bell boilers, but not known by that name, have been in use in this country for a long while, though not now manufactured extensively. We have four in use here that have been fired constantly for about twenty years, and they are yet in good condition, except one which has leaked for some time back. They are nearly the shape of those figured in THE GARDEN (p. 296), and are set and flued in the same way, but they have not the outer "water jacket," which they are better without. We do not, however, like them, because they take a long while to get up heat, and are equally long in cooling down again, and cool pipes are often desirable on bright days. The reason they do not heat so quickly is because the flame or heat can only act upon them sideways, not directly, and the reason they take so long to cool is because they cannot be damped down when required, like a saddle boiler, unless the fire is pulled quite out of the "bell," which is troublesome work, and productive of waste. It is different with the saddle boiler of any kind. No matter how big the fire may be, if you wish to cool the pipes, in the event of a bright day, you have only to push the cool-rake over the fire, then put a few spadefuls of ashes on the top, shut the bottom door and open the top one, and you at once set a cold current through the flues which cools the boiler quickly. Another fault of the bell boiler is that it does not readily burn any other fuel than coke or coke and coal mixed. Coal alone cakes in the boiler, and does not fall down as the coke does. If I am not mistaken, the three boilers referred to in THE GARDEN were exhibited in the "Heating and Lighting" department (French) of the Paris Exhibition; but I saw no boiler of French make that could be considered equal to some of our modern English ones; indeed, some of the apparatus exhibited were of an old pattern. I liked, however, their light copper pipes, which, if they could be employed in this country without greatly adding to the cost, would, in my opinion, be better than iron. They are no thicker than tin, and appear to be put together in a simple and expeditious manner. All the boilers are also of copper; no iron ones were exhibited. Could any one tell us the difference in the cost of iron and copper pipes? Copper is said to heat quicker, which means that it also cools sooner, which some say is a disadvantage, but that is an open question. It is as often desirable to cool the pipes quickly as to heat them quickly. The French copper pipes seemed to be made up of short pieces soldered together, and fitted, when set up in the hothouse, by means of light handy clips and india-rubber.

J. S. W.

Double Roofs for Glass Houses.—These are frequent abroad, and no doubt they are useful in districts where the winter is severe and where large hothouses have to be kept warm enough for tropical plants, but they are always ugly and complicated, and should be avoided at any risk. The roofs built in this way are apt to be far from clean, and there is a good deal of heavy mechanism required. Better, so far as we are concerned, fight it out with one perfectly sound roof, clear and clean.

Paraffin Oil as an Insecticide.—I believe we have at last found a cheap and perfectly effectual cure for bog and scale—the two worst enemies with which plant growers have to contend. I was recommended to try the paraffin by a well-known cultivator, who said it acted like magic, and I did try it, and found it to do so. In a very short time, almost as soon as it touches them, it seems to turn bugs into a kind of buttery substance, and scale syringes off in half-an-hour after application. I syringed about fifty large plants of *Eucharis amazonica* with it, some *Gardenias*, *Crotons*, a large *Stephanotis*, and other plants, in many cases with complete success. There is nothing like it. Add a good wine-glass full to an ordinary garden pitcher of soft water, keep stirring it up constantly and syringe the plants the while, and in five minutes or so afterwards syringe off again with clean water. I have not tried it on Vines or fruit trees, owing to the necessity of having to syringe it off the fruit soon afterwards, or there is danger of its tasting the berries. I should think it would be a safe and excellent cure for the Gooseberry caterpillar.—J. S. W.

Geographical Gardening at Munich.—We have lately seen an elaborate and painful attempt to illustrate geographical botany by living plants at Munich. It was the most painstaking of the kind we have seen—all sorts of poor, scraggy plants being brought out of the houses and arrayed in the open air to represent this country and that country, and even divisions of each country. But it was merely a ridiculous libel on the vegetation of each country that was to be seen. This is one of the things that botanic gardens would do well to leave to the books. A really truthful drawing in black and white of some well-chosen spot would do more to show what the vegetation of a district was than any amount of this kind of exposition of pot-sticks,

scraggy plants, confusion, iron, glass frames, and padoany. What the botanic gardens of the future will probably be constrained to do will be to fairly show the vegetation of their own country, not in a pedantic, but in all desirable and beautiful ways. And when they have succeeded they may attack the rest.

A TRINIDAD FOREST.

CANON KINGSLEY in his "At Last" thus describes one of these forests: "Soon you will be struck by the variety of the vegetation; and will recollect what you have often heard, that social plants are rare in the Tropic forests. Certainly they are rare in Trinidad; where the only instances of social trees are the *Moras* (which I have never seen growing wild) and the *Moriche Palms*. In Europe a forest is usually made up of one dominant plant—of Firs or of Pines, of Oaks or of Beeches, of Birch or of Heather. Here no two plants seem alike. There are more species on an acre here than in all the New Forest, Savernake, or Sherwood. Stems rough, smooth, prickly, round, fluted, stilted, upright, sloping, branched, arched, jointed, opposite-leaved, alternate-leaved, leafless, or covered with leaves of every conceivable pattern, are jumbled together, till the eye and brain are tired of continually asking, "What next?" The stems are of every colour—copper, pink, grey, green, brown,

The Ceiba tree (*Eriodendron anfractuosum*).

black as if burnt, marbled with Lichens, many of them silvery white, gleaming afar in the bush, furred with Mosses and delicate creeping Filmy Ferns, or laced with the air-roots of some parasite aloft. Up this stem scrambles a climbing *Seguine* (*Philodendron*) with entire leaves; up the next another quite different, with deeply-cut leaves (*Philodendron lacerum*); up the next the *Ceriman* (*Monstera pertusa*) spreads its huge leaves, latticed and forked again and again. So fast do they grow, that they have not time to fill up the spaces between their nerves, and are consequently full of oval holes; and so fast does its spadix of flowers expand, that (as indeed do some other Aroids) an actual genial heat, and fire of passion, which may be tested by the thermometer, or even by the hand, is given off during fructification. Beware of breaking it, or the *Seguines*. They will probably give off an evil smell, and as probably a blistering milk. Look on at the next stem. Up it, and down again, a climbing Fern (*Lygodium*) which is often seen in hothouses has tangled its finely-cut fronds. Up the next, a quite different Fern is crawling, by pressing tightly to the rough bark its creeping root-stalks, furred like a hare's leg. Up the next, the prim little *Griffe-chatte* plant has walked, by numberless clusters of small cats'-claws, which lay hold of the bark. And what is this delicious scent about the air? Vanilla? Of course it is; and up that stem zigzags the green fleshy chain of the *Vanille Orchis*. The scented pod

is far above, out of your reach; but not out of the reach of the next parrot, or monkey, or Negro hunter, who winds the treasure. And the stems themselves: to what trees do they belong? It would be absurd for one to try and tell you who cannot tell one-twentieth of them himself. Suffice it to say, that over your head are perhaps a dozen kinds of admirable timber, which might be turned to a hundred uses in Europe, were it possible to get them thither: your guide will point with pride to one column after another, straight as those of a cathedral, and 60 ft. to 80 ft. without branch or knob. That, he will say, is Fiddlewood (*Vitex*); that a Carapo (*Carapa Guianensis*), that a Cedar (*Cedrela*), that a Roble (*Machobarium*); that, larger than all you have seen yet, a Locust (*Hymenæa Courbaril*); that, a Poui (*Tecoma serratifolia*); that, a Guatecare (*Lecythis*), that an Olivier (*Bucida*), woods which, he will tell you, are all but incorruptible, defying weather and insects. He will show you, as curiosities, the smaller but intensely hard Letter wood (*Brosimum Aubletii*), *Lignum vitæ* (*Guaicum*), and Purple heart (*Copaifera*). He will pass by as useless weeds, Ceibas (*Eriodendron*) and Sand-box-trees (*Hura crepitans*), whose bulk appals you."

ANSWERS TO CORRESPONDENTS.

Woodsia alpina.—Let "Canonicus" (p. 319) take a sod of good, fibrous peat, reduce it by hand into small pieces, rejecting the very fine particles, so as to leave for use the fibrous portion only. Intermix with this a quantity of small stones, or broken pieces of potsherds; add a good proportion of white sand, and mix the three well together. In potting use smallish-sized pots, in proportion to the size of the plants; have the pots carefully drained, and pot firmly; then place the pot with the plant in a pot a size larger; this ensures permanent moisture round the roots. Set them in a small frame with a west or east aspect, and shaded from the mid-day sun; keep them close during the day, and give air at night. If for a conservatory, place a bell-glass over the plant, so as to ensure a moist temperature for the fronds.—R. P.

Chasselas Grape Vine.—Can plants of this Vine for growth on an outside southern wall, as at Fontainebleau and other places in France, be procured in England? The Chasselas is a white Grape of remarkable sweetness.—H. R., *Christchurch*. [The Chasselas de Fontainebleau Grape is grown in this country under the name of Royal Muscadine, which may be procured from any nurseryman.—B.]

Cutting Down Evergreens.—If "M. Q." (p. 319) intends cutting down his evergreens to the ground, then the months of January and February may be as suitable as any other time. But if (as I am inclined to think) he merely wishes to diminish the height or dimensions of the plants, the present would be a better time than the depth of winter to perform the operation, as this would give time for the wounds to heal before very severe frost was likely to set in. In the case of the Laurustins, which is more tender than the Portugal Laurel, the best time to cut it back would be as soon as it had flowered, and just when it was about to commence the formation of young growth, say, early in May, and this would also be the best time to cut back the Portugal Laurels.—P. G.

Transplanting Evergreen Oaks.—If "Exempt" (p. 275) will cut in his Oaks to nearly bare poles, removing all the side branches to about 6 in. in length, leaving no leaves, and also root-pruning if need be, I think he will find that he can safely transplant Evergreen Oaks of large size. I saw this plan pursued by Mr. John Bain, of the College Botanic Gardens, Dublin, many years ago, and was surprised at the success he met with; the trees broke out in healthy buds all over the main stems, and became in a few years beautiful symmetrical specimens. I have tried the same plan with Cork trees, and with perfect success, transplanting them in spring.—W. D. HEMPHILL, M.D., *Oakville, Clonmel*.

Celery Maggots.—These I find get between the tissues of the leaves and commit great havoc. They may be easily seen on holding up the leaves to the light. Is there any known remedy for this pest, which is very general in this neighbourhood this year?—A SUBSCRIBER. [What you have sent are the larvæ of the Celery fly (*Tephritis oenopordinis*), which in some seasons do much mischief to the Celery crops. When Celery is infested with the larvæ the leaves become blistered and turn yellow, and as the grubs are underneath the blisters, they may be crushed between the finger and thumb. The grubs, when full grown, descend into the earth, and remain in the chrysalis state until the following spring, when they give birth to the fly, which, in due course, deposits the eggs on the leaves. Therefore, to prevent the attack of the pest next year, leaves badly infested should be removed and burnt, to prevent the grubs attaining their full development. Mr. Rose, of Byfleet, having been for some years troubled with Celery fly, filled a 36-gallon water-barrow with sufficient water to dissolve two 1-lb. boxes of Gishurst Compound, mixing with 1 lb. of Pooley's Tobacco Powder, and filling up the whole with boiling water, stirring all well together. The mixture, after being allowed to stand for some twenty-four hours, was used to water

the affected Celery plants, a watering-pot with a very fine rose being employed for the purpose. The plants, having been well saturated with this mixture, were then examined, and the grubs which had burrowed into the leaves were all found to be dead. The crop, too, seemed to be greatly improved, the mixture having evidently acted not only as an insecticide, but as a fertiliser. About three weeks after he repeated the same treatment with another crop, with exactly the same results.]

Tropæolum speciosum.—Can you inform me how to induce seed of this *Tropæolum* to germinate? I have given sound, well-ripened seed of it to my friends, but neither they nor I have ever succeeded in raising young plants from it.—J. E. C. [Sow the seeds as soon as they are ripe in light loam, leaf-mould, and sand in a pan or box; place them in a pit or frame, and keep the soil moist, but not wet, until the plants make their appearance in spring. The careful division of the old roots is much the best and easiest method of propagating this *Tropæolum*.—W.]

Francoa ramosa.—Amongst notes from Kew (p. 302) mention is made of this plant, which is described as bearing racemes of pale, rose-tinted flowers. We have for many years grown a plant under the above name answering to the description given, excepting that the flowers are pure white. I should like to know if our plant is wrongly named, or whether its being flowered under glass would account for the difference in colour.—C. E. PEARSON. [*Francoa ramosa* has white or pink flowers, and being grown under glass may influence it in some way; it has a short stem, and in this respect differs from *F. appendiculata*, which is stemless, and has flowers deeper in colour than the others. *F. sonchifolia* has also, like *F. appendiculata*, a short stem, but its leaves are sessile and not stalked as in that species; its flowers are rose-coloured. All three are natives of Chili.—G.]

Parsley Grown for its Roots.—I notice in some Austrian towns what appears to be Parsley grown for the sake of its roots—sometimes very badly, other times well, the roots being nearly as large as fair-sized Parsnips. Has it any peculiar value? and what is the best way of preparing it for use?—E. G. [This Parsley is chiefly grown in North Germany for the sake of its roots, which attain a large size. The latter often measure from 12 in. to 15 in. long, and from 2 in. to 3 in. thick. They bear considerable resemblance to those of the Parsnip. Fine roots of it might have been seen in Covent Garden Market last season. They are cooked and prepared in various ways; like Parsnips, Celeriac, Salsify, and Carrots, they give a fine flavour to soups. Roots taken up in autumn, and stored in a mild, well-ventilated place, will afford a good supply of leaves during the winter. It should be sown in deep ground in spring, and thinned to from 5 in. to 10 in. apart, and the leaves should not be cut if large roots are required. Keep the ground clean in summer, and harvest the roots in November; if not wanted, the roots may be wintered in the open ground. This Parsley is seldom cultivated in England, where, however, it might be tried with advantage.—D. GUIHENEUF.]

Souvenir de Malmaison Carnation.—This Carnation is strongly recommended in THE GARDEN (p. 221) as being valuable both for decorative purposes and for cut flowers. I regret, however, that I am obliged to state that I have been compelled, through unfavourable results, to have the plants carefully taken to the rubbish heap after a trial of several years, during which time I devoted special attention to its culture, anxiously hoping that I should be able to find a remedy that would prevent the pods from bursting, which they have always done with me just before the flowers should open. This is an evil that has, in my case, rendered this Carnation worthless.—J. J., *Co. Cork*. [This is one of the largest Carnations in existence; the petals, indeed, are too numerous to open without bursting the calyx. If "J. J." happens to be amongst those who object to Carnation dressing, he will not be able to grow this variety well. The calyx always splits before the flower opens; to prevent this he must slit the calyx down one-third of its length from the base of each segment, and, as a further precaution, the calyx must be tied round with a strip of matting or waxed linen thread. There are always a few badly-shaped petals, which may be removed by a pair of tweezers. If "J. J." will do this before putting the tie on he will have a grand flower.—J. DOUGLAS.]

Names of Fruit.—P. S.—You will find the information you want in another column.—W. H. G.—1, Marie Louise; 2, cannot be named with certainty.

Names of Plants.—1, *Chrysanthemum fœniculaceum* (in flower), the other is probably *C. frutescens*; 2, *Asplenium cicutarium*; 3, *Aspidium coriaceum*; 4, impossible to determine. J. B. R., *Stamford*.—We cannot name your plant from leaves only; send it when in flower. J. M. *Bisanquet*.—The drooping flowers of *Meconopsis simplicifolia* measure from 2 in. to 3 in. in diameter, and are of a violet-purple colour. *Anon.*—The fungus is a button-specimen of *Agaricus rachodes*, a variety not always safe for the table. X. C.—9, *Picea balsamea*; 10, *Pinus sylvestris*; 11, *Picea cephalonica*; 12, *Pinus pinea*. G. *Beard*.—*Arum Dracunculæ*. H. J. *Ross*.—*Sarcanthus filiformis*.

Question.

Caraguata Zahni—Could any of your readers tell me how to treat this plant so as to get it coloured more or less like the specimen figured in the "Botanical Magazine"? I have grown this plant for the last three years alongside with *Caraguata musica* and *tessellata* and the two varieties of *Tillandsia Lindenii*, all of which do magnificently, whilst *C. Zahni* has proved itself nothing but an insignificant weed, growing and flowering vigorously, but scarcely showing any colour at all.—ISTAMBOL.

THE KITCHEN GARDEN.

TOMATOES UNDER GLASS.

TOMATOES out-of-doors have again in many places proved an entire failure this season. The wholesale manner in which the half-grown fruits have been attacked and rendered useless has been a serious disappointment to many, and ought to teach us to make the most of every spare corner under glass where a few plants could be accommodated. Many such places may be found where, with a little ordinary care, a crop of fine Tomatoes might be depended upon, as I have never yet seen or heard of a single fruit under glass being attacked with the disease; and, what is more, a good supply is kept up until late in the season. I could have gathered nearly a bushel in Christmas week last year from such places, and hope to do the same again this year. Tomatoes are highly esteemed here; I therefore try to make their season as long as possible. I do not grow many plants, having repeatedly proved that one good plant properly attended to is worth twenty half-starved ones. My earliest supply, from the end of May to July, I get from pots in the early Vineries. I need not describe the treatment which they receive, as it is the general crop about which I wish to speak. Now for this, I have only six plants planted out against the back wall of a late unheated Peach house; they are planted singly between the Peach trees, and occupy the vacant space that will eventually be covered with them as their growth extends. The Tomatoes were planted in May, and were carefully trained and stopped in the usual manner, each plant occupying now a space of 70 sq. ft. or 80 sq. ft. I have not kept an account of the number of fruits gathered, but the crop has been a very heavy one, and the plants promise to keep up a good supply of fruit for months to come. I may safely say that the fruit would average about thirty dozens on each plant, and fine fruit too. I have come to the conclusion that if I have only room for one plant under glass I will never again be troubled with any out-doors, and I would strongly recommend others to do the same. The sort I have grown this year is Hathaway's Excelsior. It is the handsomest and most prolific variety I have ever grown. I saw some good Tomatoes at the late Crystal Palace Show, but none to beat Excelsior.

Denne Park.

H. HARRIS.

TRANSPLANTING AUTUMN-SOWN ONIONS.

I MAKE one sowing of Onions only any time between the middle and end of August, having the ground in a proper condition to receive the seed being, I consider, of more importance than dates in regard to any kind of cropping. I select a piece of the poorest ground I can on which to sow, which I do generally after a crop of Potatoes in open quarters. In my case the Potatoes receive a very light dressing of manure in spring, and often none at all. In this way I neither coddle the plants nor encourage them to make rank and tender growth by stimulating them with manure; this, in my opinion, is a mistake in the case of young crops that have to stand the vicissitudes of winter. The less ssp they contain and the harder their fibre the better do they withstand severe weather. I sow in lines, not too thickly, 1 ft. apart. On looking over my notes I find that last year I sowed on Aug. 18, on a bit of the very poorest land in the garden, and I transplanted on March 6 this year, on a bit of heavily-manned ground, and I do not believe that a dozen "bolted" bulbs could have been found among the crop, which I considered the best that I had ever grown, and no attention whatever was given it after being planted beyond keeping it clear of weeds. From this crop I exhibited a dozen bulbs at the Oswestry District Show, held there Sept. 6. They measured from 15 in. to 18 in. in circumference, and weighed from 1½ lb. to 2 lb. each, or nearly 1½ stones imperial the 12 bulbs. For these I received the first prize. The bulbs were perfect in shape, and attracted much attention, if one may judge by the groups of visitors that gathered round them discussing their merits and demerits; they were of the Tripoli class. I do not put this forward as an extraordinary result, as doubtless many of your readers may have surpassed it, but merely as a confirmation that good Onions may be grown by following the old beaten track.

Halston, Oswestry.

J. FAIRWEATHER.

Autumn Cauliflowers.—These, with us, have not been a very satisfactory crop, so large a percentage of them coming as they do with malformed heads. The best variety we have in use is Veitch's

Autumn Giant. I have observed the same to occur before, and probably it is owing to the plants receiving a check during their early stages of growth.—J. G.

NEW V. OLD MELON AND CUCUMBER SEEDS.

In a report of the meeting of the French Central Horticultural Society, printed in THE GARDEN lately, it is stated that the subject which heads this paper was discussed, and some of the members expressed the opinion, based upon long practice, that new seed was the best, all things considered, to sow, an opinion, I have no doubt, which many English cultivators will corroborate, though it is well known that it was the practice of old horticulturists, as it is of many modern ones still, to sow old seeds of Melons and Cucumbers in preference in the belief that such produced plants that want "less to live," as they expressed it, and were more fruitful. So impressed were some cultivators with this notion, that when they could not procure old seed they used to convey the new about in their pockets for months before sowing, in the conviction that it dried it more quickly, and produced the same effect as age. I confess to having entertained the same opinion at one time, but long experience has convinced me that, as the French cultivators state, new seed is the best, particularly in the case of Melons, and I never sow seed that is more than two years old, and the previous year's seeds are preferred. I do not dispute the fact that old seeds produce less vigorous plants, but, everything considered, they are not the most fruitful. Plants from old seed are often so feeble that they can with difficulty be raised. They will not stand the hardships of early forcing like plants from fresh seeds and full of vigour, and they are the first to go off with disease, or become the prey of insects. As to their retaining sufficient strength and good foliage to produce a second or third crop of fruit, I should think very few instances are on record, but new seed will do this frequently, and the second crop is generally heavier, and it can be got in less time and with less trouble than by raising successive plants. Melons are rather an important crop with us, and this has been our experience. The effects of age upon seeds is to destroy its vitality, and old Melons, or Cucumbers, or Marrow seeds, though they may look well enough when sown, either rot in the soil or produce feeble plants; but, besides, there is no excuse for employing old seeds to produce moderately vigorous plants. The cultivator has his plants always under control, and he can prevent them making too strong growth by giving them a poorer soil and less of it. He can grow his plants in pots, for example, and treat them just as he has a mind. Fertility is, however, more a matter of sorts than of new or old seeds. There are some Melons which are fertile, and others that are not; indeed, the greatest difference exists between varieties in this respect, and it would be well if the fact had more weight with both growers and raisers of new varieties. A Melon may be good flavoured and all that, but if it be a shy bearer it is almost valueless, and that is the character of half the new sorts that are sent out. J. S. W.

Johnstone's St. Martin's Rhubarb.—This is a very fine variety, strong in growth, and excellent in flavour, not being nearly so acid as some varieties. I would strongly recommend those who contemplate planting Rhubarb during the ensuing season to include this as a standard variety—good for all purposes.—J. G.

Cabbages for very Early Use.—With spring Cabbages, earliness and tenderness, the result of rapid, unchecked growth, is preferable to mere size. In fact, few people care about a very large Cabbage at any time, as, according to my experience, size is generally obtained at the expense of delicate flavour. Now everybody has warm corners about their premises somewhere, or can easily extemporise some shelter. Into one of these warm spots dibble a quantity of Atkins' Matchless Cabbage, 6 in. or 8 in. apart each way; have as much depth of soil as possible, keep the surface freely stirred as often as it happens to be dry, and after Christmas, just when they appear to be folding up their leaves to form a heart, give one or two good soakings of liquid manure or house sewage. This crop, of course, is only intended for the first cutting, and as fast as they are cut the stalks should be pulled up, and the ground repaired for some other crop that will appreciate the warm position better than the Cabbage will when the hot days in spring arrive. A very large number of dishes of sweet early Cabbage may be obtained from a small space in this way. There is yet time to plant out a batch, although it had been better done last month.—E. HORDAY.

The Secateur, delineated in the last number of THE GARDEN (p. 314), is a very inferior tool to the one which I use, which has two cutting blades, and does not crush any branches out by it. I procured it in Geneva. I never saw one in France, not even among the collection of garden tools, &c., in the Exhibition.—J. E. C.

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

GRAPES WITHOUT FIRE-HEAT.

ALTHOUGH it is well known that good Grapes may be obtained without the aid of fire-heat, still there are, perhaps, few who fully realise to what degree of perfection they may be brought without that aid if only ordinary attention be paid to a few essential, yet simple, details. I am induced to make these remarks not only from past experience, but more especially from having, a few days ago, paid a visit to a neighbour, in whose garden I saw a house of ripe *Hamburgh Grapes* grown without fire-heat, which so pleased me, that I venture to furnish a brief description of it, and also give a few explanatory notes of the treatment which the Vines receive, hoping that those who have hitherto failed to produce good Grapes by this method may thereby be induced to make another attempt.

The house in which they are grown is a small span-roofed one, facing east and west. At the north end is a wall, the top of which reaches within 18 in. of the ridge of the house, thus allowing a triangular ventilating shutter of that size being introduced at that point. The length of the house is about 24 ft., width 11 ft., and height at ridge 9 ft. The sides are about 2 ft. high, and roughly boarded from end to end (I say roughly because no attempt has been made to plane or fit them closely, there being a continuous opening along each edge throughout their full length). The roof is a fixed one, the glass, about 15-in. squares, being glazed on to the rafters. The only door is at the south end, and this, in addition to the shutter at the opposite end, forms, with the permanent air spaces along the sides already mentioned, the only means of ventilation. The Vines (twelve in number) are planted inside; and as the house is supported on Oak posts, there is a free way for the roots to ramble outside. The inside border, which is devoted solely to the Vines, was prepared when they were planted, seven years ago, by simply forking into the ordinary garden soil a small quantity of stable manure to the depth of 2 ft. This, in short, was the only preparation the border received. Owing to the excellent natural drainage, concrete, rubble, and all similar details of preparation were dispensed with. The outside borders received no attention whatever, and are in precisely the same condition as they were before the house was erected, being annually cropped with salads and other dwarf vegetables. There is, however, on the western side a one-light frame, raised about 2 ft. 6 in. high on a manure bed, for the purpose of raising tender annuals in the spring, but this does not appear to have exercised any perceptible influence on the Vines, as those situated nearest to it are not a whit better than those on the eastern side, which are completely isolated from such apparently favourable conditions. The Grapes are uniform in size and quality, with one slight exception, and this occurs on a rod situated close to the end wall, where a few of the bunches are somewhat larger than the rest, and the berries present in a marked degree that distinctive "hammered" appearance so indicative of perfect finish. Such is the house; now for the treatment.

I have already stated that the inside border is entirely devoted to the roots of the Vines; and the same remark equally applies to the house. For the Vines it was built, and for them only is it used. The inside border receives twice during the growing season a thorough soaking with liquid manure—first, as soon as the Grapes are properly set, and again when they are about half swelled; with these two exceptions it receives no water beside what it gets from the syringing which the Vines receive early in the afternoon on fine days in warm weather up to the time the Grapes begin to colour, after which no moisture in any form is applied. This constitutes the sole root management. The ventilation is constant rather than copious, the chinks along the sides admitting sufficient air in cold weather and during the early stages of growth, the object

being at this period to keep the atmosphere dry and cool. As the season advances the wooden flap is used, and in hot weather, and as the Grapes approach maturity, the door is also opened. Strict and timely attention is paid to the proper thinning and regulation of the shoots, leaves, and fruit, the object being to distribute each thinly and regularly over the whole roof, at no time allowing an undue accumulation of either in any part of the house. The bunches are regulated according to the strength and vigour of the Vines, the average weight of fruit being about 1½ lb. to every 18 in. square. Early thinning is practised, and it is done in such a manner as to prevent, when ripe, "jamming" on the one hand, and "looseness" on the other. Having stated these few simple rules of practice which constitute the sole method of treatment, I will just say that this house cost in erection £20; and if the crop this year were valued at 2s. 6d. per lb., fully one-half more than that sum would be realised. I have seen this house each year for the last four years, when it has always presented the same satisfactory appearance. The Vines are vigorous, the foliage green and healthy, and the wood brown and perfectly ripened; there are no signs of spider, mildew, or shanking; the bunches are even and symmetrical; the berries are large, black, and luscious, covered with a beautiful bloom, and without a speck or stain upon them. Altogether, this house is most satisfactory.

To recapitulate, the following seem to be the elements of success: 1. Vines only are cultivated. 2. Dryness in the inside border and atmosphere during the early and late stages of growth. 3. Moderate, yet constant, ventilation and careful conservation of sun-heat. 4. Judicious and timely thinning and regulation of both branches and fruit. T. C. W.

PRUNING BUSH FRUITS.

THE pruning season being close at hand, a few words on the subject may not be unacceptable. The Gooseberry, though undoubtedly one of the most popular of fruits, is nevertheless seldom managed as well as it ought to be. It may often be seen in the form of a stunted, starved bush, crowded with old, Moss-grown, unfruitful wood; or as a great, overgrown, ungainly bush, with nothing in the shape of fruit-bearing wood about it. In a general way, both these incongruities arise from mismanagement. Another form of mismanagement may be found even in some well-kept gardens, where the bushes are annually pruned into some symmetrical form, regardless of their fruit-bearing properties. The Gooseberry will grow and succeed well in almost any soil, but it does best, undoubtedly, on deep, rich alluvial deposits. Grown in such soils it sometimes becomes, as regards size, a tree. Given a good suitable soil and healthy plants to begin with, there ought to be no difficulty in keeping Gooseberry bushes always in a shapely form and bristling with strong, clean, healthy fruit-bearing wood. It is no uncommon thing in many gardens to follow the pernicious practice of cutting the young wood back to two or three buds—a system decidedly wrong, because it does away with a large amount of fruit-bearing wood, and, also, because the Gooseberry, being naturally addicted to making spurs, this system induces it to make many that have eventually to be removed. To avoid this, it is necessary to remove entirely all superfluous wood and to leave the leading shoots quite two-thirds of their length. At the same time all overcrowding must be avoided. Bushes treated in this manner rarely fail to produce heavy crops of fruit of the finest quality. It will also be found that they will bear well up to the very tips of the previous year's growth, an important advantage in cases where fruit is grown for profit.

Red and White Currants, as a rule, produce fruit of finer quality when spurred close in than when the wood is left at greater length. Therefore, the most satisfactory way of pruning these is to cut the current year's growth back to two buds. In places where sparrows do not pick out the fruit buds Currant bushes may be pruned as soon as the leaf falls; but where these little depredators are plentiful it is perhaps as well to defer pruning until spring, unless, indeed, the bushes can be protected from their ravages by means of netting. Nothing is more common, particularly amongst

cottagers, than to see Black Currants spurred in the same manner in which Red or White ones are. A worse mistake could not be made. Our method of pruning these is to entirely remove all the old and worn-out wood, also any superfluous young wood, always keeping an eye to the shape of the bush. The fruiting wood left is not shortened at all, or cut in any way, the great object being to have as great a quantity of strong, short-jointed wood as possible without overcrowding.

Raspberries ought now to have all the old fruiting canes removed, in order to allow a free circulation of light and air through the plantation, without which it is useless to expect the wood to ripen or the fruit buds for the ensuing year to mature. After the leaf has fallen the young canes will have become hard and firm, and will be in a fit state to be shortened. The length will have to be determined by the operator; it should be regulated by the growth which the plants have made, as should also the number of canes to be left. Where the growth is vigorous from five to seven canes, from 5 ft. to 6 ft. high, may be left; these may be slightly twisted round each other and bound at the top with a piece of Willow. The twisting causes them to break more regularly than they otherwise would do. Of course where Raspberries are grown as espaliers this twisting is unnecessary. TYNEDALE.

AUTUMN TREATMENT OF STRAWBERRIES IN POTS.

The way in which Strawberries fruit in spring depends greatly on the kind of treatment to which they are subjected in autumn. The finer the crowns, and the better ripened they are now, the better will be the results when they come into fruit. During last month and this they cannot have too much sun and light, and should they have been previously growing in a shady place they will have all the more need of such assistances. We generally set them on an elevated spot, and we have sometimes even erected a rough deal stage on which to place them, and that with satisfactory results. Of course, no weeds, runners, or anything else that will shade the crowns in the least, are allowed to grow in or about the pots, and the latter are not packed closely together, but are set a little distance apart in order to allow the air to circulate freely about them. Manure water, in a pretty strong condition, is given two or three times a week, when watering is necessary, but for weeks sometimes in wet weather they never get or need a drop from the watering-pot. When this happens, it is a good plan to sprinkle a little guano or soot on the surface of each pot and let the rain wash them down to the roots. Such treatment about this time ensures good plants, which will always fruit well, provided they are not spoiled during winter. It is during that season that many make mistakes with reference to their Strawberry plants in pots. It is a common practice after November to stack them up so as not a drop of wet can reach the soil, and if this be not done they are put into frames or houses and protected by glass. To such an extent is this often carried, that, by the time the plants have to be brought in for forcing, the crowns, roots, and leaves are about half the size which they were in autumn, and, when shrivelled up in this way, they are not in half such good condition for producing a full crop of fine fruit as they were before they were put under cover in autumn. This covering up and protecting is the very worst thing that could be done with Strawberry plants in pots, a fact which any one who doubts this assertion can prove. The best crops of Strawberries in pots which I ever grew, and the finest which I ever saw any one else have, were produced by plants that were allowed to stand out in the open air in winter until they were placed in heat for forcing. Thus treated, the soil and leaves were kept moist, similar to plants growing in open quarters. When frost seems likely to break the pots, a little straw or dry Fern may be spread over the plants at night, but should always be removed during the daytime; and protecting from wet, snow, or anything else should never be attempted. CAMBRIAN.

Absorbents for Fruit Rooms.—In the remarks on fruit storing (p. 307) Mr. Newton states that chloride of lime is used as a desiccant, and seems to doubt the result; as there appears a strong possibility that a mistake has been made, and that chloride of calcium is the article meant, I would call the attention of those interested to the fitness of this salt for the purpose named. Being a permanent salt, it gives off no vapours of chlorine, while the unstable compound known as chloride of lime is valuable only for the facility with which it parts with its chlorine. The use of chloride of calcium for preserving the delicate balances used in laboratory work from

rust, by placing it inside their cases is proof of its harmlessness, while the facility with which its absorbed moisture can be driven off by the application of heat, thereby rendering it again fit for use, undoubtedly places it at the head of the list of absorbents fit to use in a fruit room. A dish of strong sulphuric acid would also prove efficacious, but it labours under the disadvantage that a distillation would be necessary to render it again ready for use.—LONDON STONE.

Grapes from the Open Air in Nottinghamshire.—I herewith send you two bunches of Chasselas de Fontainebleau (Royal Maccadine) cut from a Vine about seventy years of age, growing in front of a house not far from Newark. Unfortunately, before I knew of the existence of the Vine the main crop had been gathered, and the accompanying samples are, I am assured, not considered up to the average excellence. They are, however, very good, as you will see; well coloured and ripened. The present tenant has taken crops from the Vine regularly for forty years, and this season he does not consider an exceptional one as regards the crop, but he had gathered, up to a week ago, 112 lb. from the Vine, not to speak of the fruit still hanging when he sent me the bunches in question. The Vine has a stem about as thick as a man's leg.—J. SIMPSON, *Wortley*. [The bunches sent were large in size for outdoor fruit of this variety, quite ripe, and of good flavour.]

Standard Gooseberries and Currants.—I have read with interest the remarks (p. 325) on this subject. Standard Gooseberries and Currants have been cultivated here for many years, as I found them here upwards of twenty years ago when I took charge of the gardens at this place. Our system is to select good, strong, long cuttings, to pick out all eyes to within two or three at the top, and to plant the cuttings and train them to stakes. The following year we cut them back to the required height, and afterwards yearly prune the heads into good shapes. The height is usually about 3 ft., and some of the heads measure from 5 ft. to 6 ft. through. Such trees are very suitable for planting beside some of the main walks. The Red Warrington, Rough Red, and Early Yellow are some of the best sorts for standards, and the Currants should be free-growing kinds.—J. GARLAND, *Killerton, Exeter*.

Avenue of Fruit Trees.—Where, in certain parts of Bohemia, the cultivated fields are hedgeless and the trees all gathered on the hills around, it is a common practice to plant fruit trees on each side of the main roads. Lately Plum trees bordering some of these were laden with fruit, which any one passing could easily gather, but the fruit was apparently untouched, and is carefully guarded when ripe where necessary. Such fruit trees do not, of course, completely shade the road, but they make it a little more endurable during very hot weather. In some cases, but not often, two rows of fruit trees are on each side of the road, and in this case there is more shade, especially for the pedestrian walking between them. Some such plan might perhaps be carried out in some of our chalk districts where the roads are often hot and bare.

Netting Melons.—I think cultivators generally, and Melon growers particularly, will agree with me that no Melon is perfect unless it is well netted, and I find from many years' experience that the best-flavoured Melons have the least network upon them; I speak of the green-fleshed section. Victory of Bath ranks amongst the best as regards flavour, but it is often smooth-skinned. This season I have been trying, and I am happy to say that I have succeeded in putting on the surface of a Melon a very fine network, and that by a mode so simple that I am constrained to lay it before your readers. When the Melons are about half-grown, I turn up a pin's point and gently stroke the fruit, first into quarters, and then I fill in between these with a series of small strokes. I have now a house of Melons naturally nearly all plain; I have netted several of them, but I have left some for comparison; those we have netted are simply unique, while fruits of the same variety not netted look commonplace beside them.—R. GILBERT, *Burghley*.

The Apple Crop in Kent.—Although this is by no means a good season for Apples generally, they are abundant in this neighbourhood, and Apples that would be considered a luxury in many parts of the country are here not considered worth sending to market. There is such a general outcry about the scarcity of home-grown fruit that one would think our growers were not alive to their own interests in letting so valuable an industry pass into the hands of foreigners. But, if railway fares, market expenses, and labour leave but little for the grower, it is clear that we must have cheaper transit and better means of communication with consumers, for at present it is a positive fact that the only places really well supplied with fruit and vegetables are our large centres of population. In rural districts devoted to Corn growing the inhabitants seldom see an English-grown Apple offered for sale, while Oranges from distant lands are offered in every window. Reform is slow, even in our most urgent necessities of daily life.—J. GROOM.

NOTES OF THE WEEK.

Lilium neilgherrense.—A fine display of this beautiful autumn-blooming Lily has lately been on view in several of the London nurseries. It is by some considered inferior to *L. longiflorum* and *L. eximium*, and if it flowered at the same time of the year as those kinds it would not probably be thought so much of as it is at present. Its great value lies in the fact that it flowers at a season of the year when other Lilies have gone out of bloom, and by good management strong bulbs might possibly be kept back for associating with the *Chrysanthemums* in November. Its scent is delicious without being overpowering, and altogether it constitutes one of the most valuable Lilies in cultivation.

The Pterocarya in Vienna.—This fine-leaved tree is often seen here, its foliage in mid-October being still of a rich dark green and very handsome. In its foliage and habit it is wholly distinct from any other tree we grow, and it is curious that it has not been more extensively planted in England. Some vigorous young specimens have the shoots like lance-shafts seen all their length coming straight from the stem. Its somewhat low and spreading habit prevents an idea from being formed as to its use as a forest tree, but as a garden and pleasure-ground tree it is of the highest value.

A New Autumn-flowering Crocus.—In the Kew collection may now be seen an addition to the list of autumn-flowering Crocuses under the name of *C. Elwesi*, a native of Smyrna, but in its present condition it so closely resembles the ordinary *C. estivus*, that it need not be sought after, except by those who aim at making a complete collection of the cultivated species of this interesting class of plants.—A.

Aster Curtisi.—This forms another addition to the list of cultivated varieties of this very numerous family; but it is deserving of special notice, as it is a very desirable kind, being allied to the fine *A. grandiflorus*. The heads are about 1 in. in diameter, with numerous reflexed scales below them. The colour of the outer florets is pale violet, the centre being creamy-white. It grows about 3 ft. high, with ovate and toothed basal leaves, those of the stem being very small and pointed. It is very floriferous and now in full beauty; it possesses one desirable point, *i.e.*, having the majority of the blossoms expanded at the same time.—W.

White and Rose-coloured Anemone japonica.—It is worthy of note that the white-flowered *Anemone japonica* lasts in flower for a much longer period than the rose-coloured kind. Large beds of each kind planted side by side in an open position in Messrs. Rollison's nursery at Tooting began to flower at the same time, *viz.*, about two or three months ago, and whilst the rose-coloured kind has now for some weeks been completely flowerless, the white variety is still fresh and covered with blossoms.

Jacaranda mimosæfolia as a Standard.—Well-grown plants of this, having a clean stem from 18 in. to 24 in. in height, and crowned with a bushy head of deep green, finely-cut, Fern-like leaves, are amongst the most attractive objects, in the way of ornamental-leaved plants for dinner-table ornamentation, which can be cultivated. This plant is now largely grown in some of the London parks and gardens, and examples of it planted out in that way might soon be induced to assume the form just mentioned if taken up in autumn and potted.

Violets in Autumn.—Visitors to Covent Garden Market might almost be led to imagine that it was spring instead of autumn, judging by the number of baskets of blue Violets that may be seen at every turn. I observe that wherever young runners of the Czar and similar sorts have been planted or have established themselves, the blossoms are abundant and fine, but when left in old-established clumps no blossoms are visible; therefore, any one wishing for Violets early and late should take the trouble to replant young runners on good, fresh soil in May; they will afterwards be amply rewarded both by the season of bloom being lengthened and by the size of the individual blossoms.—J. G.

Plumbago capensis as a Pyramid for the Flower Garden.—We have been much struck with the appearance of open and free pyramid bushes of this favourite plant 7 ft. high in the gardens at Vienna. Every shoot has borne many flowers, of which the last were visible in mid-October. The comparative scarcity of really good blue flowers for the open-air garden in autumn ought to make these bushes all the more valuable; besides, the tall bushes, with their lovely crop of flowers, would be a novel feature in the garden. Inasmuch as this *Plumbago* has been flowered in the open air about London as an edging plant, there would probably be no difficulty as regards climate, tall, well-developed plants, like those we mention, being more likely to flower freely than young dwarf plants. This plant is never seen to advantage unless when so grown

that the flowers hang naturally and freely. Nothing can surpass it against a pillar, but as pyramids it is as beautiful. Of course, the plants should be grown indoors and prepared for flowering in the open air throughout the summer and autumn.

New Coleuses.—One would almost have imagined that this class of plants had had its day, considering the number of new and attractive kinds which have been raised from time to time. Mr. Ball has now, however, in his nursery several entirely distinct species which will, when crossed with other kinds, no doubt, be the means of bringing out an entirely new and distinct race of these useful and easily-cultivated plants.

Oncidium tigrinum.—Amongst all Orchids now in flower in the London nurseries none are more beautiful than this. It is easily grown. Its flowers are exceedingly attractive; they last for a long time if kept in a moderately dry, genial atmosphere, and their perfume is equal to that of the sweetest of Violets.

Lapageria rosea superba Out-of-doors in Cheshire.—In the gardens of Mr. Stephen Williamson, Copley House, Thornton Hough, Cheshire, there is now in bloom a magnificent specimen of *Lapageria rosea superba* covering a wall 14 ft. high and 18 ft. in length. The plant has now over 300 blooms on it, and is also beset with innumerable successional buds.

Cypk Kentia macrocarpa.—This is a truly handsome Palm at this season of the year, its gracefully arching, feather-shaped crimson and bronze-coloured fronds forming a striking contrast to those of older growth, which have assumed a deep green hue. When introduced amongst fine-leaved Crotons and similar plants it is one of the most effective of fine-foliaged plants. We lately saw fine examples of it in Messrs. Rollison's nursery at Tooting.

Lychnis coronata grandiflora.—I have had for some years a charming plant of this *Lychnis* which bloomed with me in perfection this summer. *Lychnis coronata* is figured in vol. vii. of the "Botanical Magazine," but my plant is a bright salmon-pink, not red-lead, as there represented. It is not safe to consider it hardy, as far as my experience goes, but it is an excellent window and pot plant.—K. L. D.

Dendrobium bigibbum at Chelsea.—A good display of this, one of the most beautiful of *Dendrobes*, is now to be found in Mr. Bull's nursery at Chelsea. Dozens of plants of it arranged in groups bear long graceful spikes of pretty rosy-pink blossoms and unexpanded buds. Altogether, we counted eighty-four fully expanded flowers, and there are yet quite an equal number of buds to open. It is a plant which keeps long in bloom, and it flowers not only from the ripened pseudo-bulbs, but also from young shoots. On some imported plants we counted over twenty dried flower spikes, clearly proving that it is a profuse bloomer. It is not by any means a new plant, but it had become almost unknown to cultivation until it was reintroduced, an event which happened a year or two ago.

October-blooming Border Flowers.—The collection of cut flowers of hardy border plants shown by Mr. Parker, at South Kensington on Tuesday last, served to illustrate what a fine display of blossom can be obtained in our gardens at this season of the year, after the plants generally used in flower gardens have long since gone out of bloom, by planting well-selected hardy plants. Where cut flowers are needed, and there are no glass houses in which to grow them, by planting choice hardy plants, such as those alluded to, and of which further particulars will be found in another column, not only may a large quantity be had, but such a variety as no indoor plants can supply at this season, and that without any more trouble than merely procuring the proper plants for the purpose, planting them in deep, rich, sandy soil, and keeping them clear of weeds.

New Public Park for Newcastle.—At a meeting of the Newcastle-on-Tyne town council a letter was read the other day from Sir Wm. Armstrong, in which he offered to present to the town 26 acres of land, adjoining the 22 acres recently purchased by the Corporation, for an east-end park. The land is worth about £20,000. This gift was accepted, and it is proposed to call the park the Armstrong Park.

A Gift to Sheffield.—It was announced at the meeting of the Sheffield town council the other day that the Duke of Norfolk had set apart three pieces of land as recreation grounds for the people of Sheffield. The land is situated at Parkwood Springs, Carlisle Street East, and Beighton Lane districts, where thousands of working people will be able to use these open spaces. These grounds, which are upwards of twenty-six acres in extent, have been given to the corporation on condition that they be preserved as recreation grounds for the people of Sheffield for ever.

Viola stricta alba.—Blossoms of this Violet have been sent to us by Mr. Ware. It is pure white with a yellow eye, large in size, and very desirable, especially at this season of the year.

NOTES FROM KEW.

Hardy Shrubs.—The Strawberry tree (*Arbutus Unedo*) and its varieties are now amongst the most handsome of all hardy shrubs; during the present month and November their lovely burden of blossoms and beautiful Strawberry-like fruit render them peculiarly interesting and charming. The typical plant is well known, but the following varieties are not so often seen as their merits deserve. *A. Unedo macrophylla* has larger, bolder foliage than the common Strawberry tree; its leaves are, however, quite similar in outline, and the panicles of flowers are also nearly identical. *A. quercifolia*, another white-flowering variety, has leaves with sinuated margins which almost warrant its name of Oak-leaved. *A. rubra* has the leafage and habit of the type, but panicles of beautiful red blossoms; this is a very free-flowering and valuable shrub. *A. Crooni* seems to be a stronger grower than the last, and has rather larger, much more deeply serrated leaves and large panicles of beautiful red, wax-like blossoms individually larger than those of *A. rubra*; this probably is the finest of all the varieties of *A. Unedo*. *Colletia cruciata*, a leafless Chilean shrub, has peculiarly flattened, spinous branches, the upper portion of the plant being covered with a profusion of small, shortly bell-shaped, white flowers; except in the southern counties—where, however, it will not succeed in very open, exposed situations—this singular-looking shrub will need the protection of a wall.

Hardy Herbaceous Plants.—A Mexican perennial, *Mirabilis longiflora*, is at present attractive on account of its long, tubular, viscid flowers, which are white with a deep violet-purple eye; these are not the only colours owned by this pretty plant, the blossoms of some individuals ranging from white to pink and violet. *Cheiranthus mutabilis*, a native of Madeira, is a Crucifer, which, both on account of its beauty and its prolonged flowering season, is a most desirable plant; when first the flowers open they are white, but a short time suffices to change them into a violet-purple colour. *Aster Chapmanni*, a United States perennial, is one of the most distinct and handsome of the Michaelmas Daisies; it grows about 5 ft. high and is an extremely floriferous kind, being totally covered with lavender-blue flower-heads. So pretty is this sort that a friend—an enthusiastic collector and cultivator of hardy herbaceous plants—declared that if he were restricted to six *Asters*, *A. Chapmanni* should be one of the six. *A. Drummondii*, from the Southern United States, is a very fine species about the same height as the last; its graceful sprays, covered with small, pale lavender flower-heads, being very useful for out flowers. *Neja gracilis*, from Mexico, and *N. falcata*, a South American sort, ought not to be passed over without mention; they are the most charming of all the dwarf Composites now in blossom, and their fine golden yellow flower-heads have been very freely produced at all times within the last four months. Two or three Himalayan *Polygonums* are amongst the most striking of all border plants still in full beauty. *P. amplexicaule* grows about 3 ft. or 4 ft. high, and its spikes of deep rosy-red render it a conspicuous object even at a distance. Quite similar in habit and stature is *P. oxyphyllum*, which, however, has white blossoms. *P. vacciniifolium*, a very lovely creeping sort with small neat foliage and numerous spikes of red flowers, is one of the most charming of all the species of this genus for cool, moist spots in the rockery and open border. As a pot plant, too, for cool house decoration, few plants are prettier. *P. chinense* grows about 2 ft. high, and is of interest both horticulturally and botanically; its pinkish flowers and fleshy coral red fruit are most attractive. *Tanacetum fruticosum*, with its small yellow flower-heads arranged in much-branched, lax panicles, grows about 2 ft. high, and attracts attention now that most herbaceous plants are dying or dead. *Convolvulus maritimus*, which is now covered with its blue, saucer-shaped blossoms, should not be omitted; as a border plant it seems to do even better than when cultivated in pots. *Helianthus argyria*, from the United States, grows about 8 ft. high, and forms a striking object; its tall stems—which are unbranched, except at the summit—are thickly clothed with narrow, arching, drooping leaves which impart an effect to the plant not possessed by any other kind of Sunflower; the golden-yellow flower-heads are most freely produced.

Stove Plants.—*Aphelandra cristata*, an old favourite, is at the present time the most gorgeous stove plant in flower at Kew; the foliage, which is a rather dull green, cannot compare in beauty with that of several more recently introduced kinds, but the large spikes of blossoms—glowing orange-scarlet in colour—would vie with those of any of the other *Aphelandras*. Of all the fifty species or more of the genus *Cinnam*, none are more beautiful than the West African *C. Forbesianum*; it is, indeed, one of the finest *Amaryllids* ever introduced. A recently imported specimen has been one of the most striking of Kew plants during the last week; it has an enormous bulb with a stout scape about 12 in. long, which bears an umbel of thirty blossoms 8 in. in length; each of the six segments (4 in. long) has a deep rosy-red band running down its centre.—†.

RAPID GROWTH OF CANNAS IN IRELAND.

IN May of this year I obtained from a leading London nurseryman a couple of plants under the name of *Canna iridiflora hybrida*, said to be a great improvement in size of bloom and brilliancy of colour on the fine variety known as *C. iridiflora* (of which good figures appeared in vol. xlv. of the "Botanical Magazine," t. 1963; vol. viii. of the "Botanical Register," t. 609; and vol. x. of Loddige's "Botanical Cabinet," t. 905), and imported from a Continental firm. Each plant consisted of a single stem, from 18 in. to 2 ft. in height. Early in June each plant was put out of its pot into the centre of a bed of ordinary garden soil, without any special preparation, the surface of one bed being covered with different varieties of *Lobelia Erinus*, that of the other with bedding *Pelargoniums*. They soon commenced to grow very rapidly, and to throw up additional shoots of great vigour and substance from the root, of the young leaves of which, when in a folded-up state, the slugs and snails seemed very fond of eating holes therein, which, when the leaves expanded, had all the appearance of lady's pierced embroidery work. The number and vigour of these shoots exceed anything I have ever seen of the kind, one plant having now no fewer than seventeen stout stems and the other thirteen, varying in height from a few inches to 8 ft. 5 in., the height of the tallest stem, which ends in a bloom-spike, which, I may add, as to colour and size, is an entire disappointment, being of a small size and of a dull, insignificant buff colour, instead of the brilliant deep crimson, large-sized flowers that this improved variety was announced to have. It seems evident, in fact, that the foreign firm, having more orders than it had young plants to supply, made up the number with offsets of some inferior variety, the plants sent to me being those received from the Continent, and, of course, unproved by the London firm which sent them out. The foliage is very handsome when fully developed, closely resembling that of a *Musa*. BOSCBEL.

Mentzelia ornata.—In reply to "V." (p. 332) perhaps you will permit me to state that I have not attempted to flower the above-named plant under glass, as it would require considerable space for its proper development. In the open ground success appears to depend on the seed being early sown the first season, so that the young plants have a fair chance of becoming strong and sturdy by the end of the summer. This ensures early development the second season, which is essential to an early production of its grand flowers. It must be admitted, I fear, that our climate is not so favourable to its growth, in the open ground as could be desired. The arrival of autumn generally finds the plant covered with flower buds in various stages of growth, and which, of course, are destroyed by frost or damp. I have read in the "American Agriculturist," somewhat to my astonishment, that in the State of New York, or not far from its borders, the seed of this plant is sown in the open ground and the resulting crop of seedlings left exposed the following winter. If this plan could be adopted on this side of the Atlantic, it is possible that the plant would bloom at an earlier period of the summer than it now does.—W. THOMPSON, Ipswich.

Fuchsias amongst Ivy.—"A. D.'s" bed of Fuchsias carpeted with Ivy looks well on paper, but I am afraid that when it comes to be worked out in practice it will be found to be a bed of Ivy minus the Fuchsias. The first season, perhaps, the Fuchsias might do fairly well, but after the Ivy had got established, owing to its being a gross, insatiable feeder, it would take good care that the Fuchsias got little of either the manure or water that might be applied. I know nothing more exhaustive than Ivy, and, as a rule, we never see weeds of even the grosser kind growing on Ivy-covered ground; when once it takes possession it holds it against all-comers. Even in woods we never see any but bulbous plants growing amongst it, and here, after the leaves have fallen off the trees, the autumn and winter rains prove sufficient to penetrate its leafy coat and enable the water to perfect their season of growth and no more. There are many more surface-rooting plants with which to carpet, if the beds must be treated in that way; but why carpet at all? A dense, leafy covering might, and no doubt would, do much towards protecting the collars of the Fuchsias, but why not protect the whole plant? It can be done in this way: After the first frost has denuded, or partially denuded, them of their leaves, choose a dry spot of ground in a sheltered, out-of-the-way place, excavate a shallow trench of sufficient size to hold the number of plants you have, take them up and lay them in it heads and roots until all are packed away; then cover them over with sufficient straw to keep out frost, and either thatch with the same material or cover with mats to ward off rain; or, better still, cover with wooden shutters. Let them remain here until all danger from frost is over; then take them out and gradually expose them to light. One of the advantages of this plan is that they come into flower much sooner than killed-down plants, and another is that you can have other plants in the beds during the winter and spring.—T. SMITH, Newry.

GARDEN DESTROYERS.

THE ONION FLY.

(ANTHOMYIA CEPARUM.)

THE grubs of this harmless-looking little fly are one of the Onion grower's greatest enemies, for at times whole crops of Onions, Leeks, Garlic, and Shallots are almost entirely destroyed by them. As they live singly or only a few together

Fig. 1.—Section of Onion, showing the position of the eggs (aa) and direction (c) in which the larva (d) enters the bulb (b).

within the bulb of the Onion, which they eventually destroy, it is impossible to check this insect when once the Onions are attacked, as any means taken to destroy them would kill the Onions which were not infested. Some persons advocate strewing the beds with powdered charcoal as a means of preventing the fly from depositing its eggs on the plants, leaving a portion of the bed in its ordinary condition; the fly will in preference choose the roots on this portion on which to lay its eggs; these can then be destroyed. This plan is, however, by no means always successful. The best means of reducing the

Fig. 2.—Onion-fly. Larva, chrysalis, and perfect fly; all magnified.

numbers of this insect is to at once remove and destroy by burning or deeply burying (merely throwing them on to a rubbish heap is of no use) any roots which may be attacked by them. These may be easily known by the leaves drooping, turning yellow, and emitting a tainted smell; if a few of the scales are removed the grubs will easily be seen crawling about inside. The Onion fly is a small, two-winged insect belonging to the same family (Muscidæ) as the common house fly. It makes its appearance early in the summer, and may be found throughout that season in several generations. The female lays her eggs at the base of the leaves of the Onion,

and the young grubs when hatched immediately eat their way through the outer leaves and work themselves into the bulbs, which they commence to feed upon and soon destroy when full grown. They either assume the chrysalis state within the root of the decaying Onion or descend into the earth, and there undergo their change. During warm weather the perfect insect emerges from the chrysalis in about a fortnight. Later in the season, however, the insect remains in a chrysalis state during the winter, the fly not appearing till the beginning of the next summer. It is probable that the flies from the chrysalides which are found in the Onions make their appearance in the same season, whilst those from the chrysalides buried in the earth do not appear until the next. The flies are about 3-10ths in. long and 6-10ths in. across their wings; they are of an ashy-grey colour, sparsely covered with fine hairs. On the back of the male are a few black stripes. The wings are transparent and iridescent with brownish veins. The grubs, when fully grown, are about 3-10ths in. long and are white, fleshy, smooth, and shining; they have no legs, and are of a peculiar conical form, the body terminating in a point at the head and very abruptly at the tail, just as if a portion of the grub had been cut off. Round the edge of this last joint are eight small, fleshy points. The chrysalides are oval and about the same size as the grubs, but somewhat shorter; they are reddish-brown in colour, and are composed of several joints.

S. G. S.

Indelible Ink.—The receipt (p. 315) for making ink I doubt not answers the purpose very well, but it appears to me unnecessarily troublesome. Many years ago a friend gave me a simple receipt for ink for writing on zinc, which I have constantly used since. It is 12 to 16 grains bichloride of platinum dissolved in 1 oz. distilled water. If kept corked, a small bottle will last many years. The labels (zinc) must, of course, be cleaned before using. This is readily done either by rubbing with fine emery paper or using the solution of oil of vitriol you recommend. But my ink requires no preliminary sprinkling of the labels with gum sandarach or after treatment with hard white varnish. Simply write the name and allow the ink to dry. I have used labels of this description for many years, and have never lost a name since adopting them. They are equally suitable for the house or the open air.—P. NEILL FRASER, Rockville, Murrayfield, Edinburgh.

Double-glazing on the Continent.—Allow me to state that there is another important reason for double-glazing glass houses in some parts of the Continent besides that assigned (p. 340). For all glass structures which do not admit of being easily covered with boards double roofs are absolutely necessary, on account of the frequent destructive hail-storms and heavy falls of snow which are experienced in those parts. The outer frame is generally of what is there termed double-glass, which is about the same as our 21-oz., whilst the inner one is equivalent to our 15-oz. The air vacuum thus obtained offers an efficient resistance to both hail and snow. Houses glazed in the ordinary manner would be liable to be broken in a single night by those tremendous snow-falls which are, especially in North Switzerland and South Germany, so often experienced. I would at the same time wish to enter an emphatic protest against double-glazing in this country, as, apart from the uneightly aspect which such a roof must always have, I have found that it has a weakening and debilitating effect upon everything grown under it.—J. CORNHILL.

Begonia Weltoniensis in the Flower Garden.—In my opinion this Begonia is one of the best which we have for bedding purposes. We have it bedded out here with the best results. It withstands rain, wind, and sun without injury, besides affording a change from Pelargonium, now so common. To those who have not tried this variety, I am confident that if it succeeds with them as it has done with me, after they have once grown it they would give it a second trial. This variety looks well grown in pots, but it does best out-of-doors. Small plants of it put out in the end of May or beginning of June soon make fine specimens. I have grown other kinds, but have not succeeded so well as with this one, as rain and wind damage them, and they require staking, which Weltoniensis does not.—D. GILLET, The Heath, Weybridge.

Vegetable Moth Trap from Brazil.—I have a large plant of *Physianthus albens* trailing up the porch at my front door on which it grows rapidly, and in the autumn flowers in profusion. It is one of the most deadly moth traps I know. Every day I find from two to eight humming-bird hawk moths caught by their probosces in the flowers, and they appear to die in about two minutes. I often find other insects dead in the flowers.—"Field."

TREES AND SHRUBS.

TREES AND SHRUBS FOR AUTUMN EFFECT.

Now that deciduous trees and shrubs are once more beginning to attract the attention which they so well deserve, and which was diverted from them when Conifers became such favourites, instead of the monotonous sombre green of the Pines and their allies, we may expect to see more frequently the delicate tints of early spring furnished by the swelling leaf-buds or opening blossoms, the manifold shades of green during the summer months, and the brilliant coloration assumed in autumn by many of the fine deciduous trees from North America and Eastern and North-Eastern Asia, which were much more generally known at the commencement of the present century than they are now. At present many trees at Syon and Kew form magnificent pictures in their gaudy autumn dress of scarlet, yellow, or purplish-red illuminated by the rays of an October sun. If planters would but note the wondrous autumnal changes in the foliage of many deciduous trees and plant accordingly, they could easily create such effects as would as much surpass the ordinary haphazard style as a picture by a "Turner" would be superior to another painted by a schoolgirl. With care, too, the summer tints might be made to thoroughly harmonise, so that at all times the individual beauty of a tree might be enhanced by judicious contrast. Trees with totally different habits might also be chosen, so that, even when leafless, the tracery of the branches would be a source of artistic enjoyment. My remarks, are, however, confined to autumnal tints and to trees and shrubs which are most noticeable at the present moment. Many of these are somewhat uncommon, all are strikingly handsome, and even the common ones deserve to be more generally known and appreciated. For truly gorgeous coloration now some of the American Oaks bear off the palm. Perhaps the most beautiful is the Quercitron Oak, of the Eastern United States (*Quercus tinctoria*), the fine, deeply-lobed foliage of which exhibits a lovely combination of dark glossy green, crimson, and reddish-brown, the green occupying generally the central portion of the leaf. *Quercus rubra*, the Red Oak, and its varieties, are especially noteworthy; in these the redder tints are more unalloyed with other shades, so that in the sunlight the leaves brighten up and glow as if they were on fire. *Q. alba*, the White Oak, is a noble tree with large, finely coloured leaves, brownish-red being the prevailing shade. The Chestnut Oak (*Q. Prinus*) and its varieties, with their large, Chestnut-like leaves, are hardly less beautiful than the Quercitron and Red Oaks, and assume colours in which bronze and reddish-purple predominate. Totally different in colour and habit of growth are the Hickories; two of the most showy at present being the Pig-nut Hickory (*Carya pecorina*) and the small-fruited Hickory (*C. microcarpa*) from the Eastern United States; both have Walnut-like foliage, the large leaves of the first being of a uniform rich golden-yellow, while the smaller ones of *C. microcarpa* are toned down by an admixture of green. The Yellow Wood (*Cladrastis tinctoria*), from Kentucky and Tennessee, is one of the handsomest of the flowering trees of the Locust kind; it is now clothed with large, pinnate leaves, which are of a fine orange-yellow shade. The Bird Cherry (*Prunus Padus*), particularly when planted in open ground, has leaves tinged with rosy-red, and one of the prettiest effects I have seen for some time was a group of Bird Cherries with a background—a few yards away—of dark, glossy, evergreen shrubs. The June Berry (*Amelanchier canadensis*), although not possessing the delicate tints of the last-named, wonderfully enlivens the shrubbery with its red-brown leafage. The Red Mulberry (*Morus rubra*), from the Eastern United States, is very conspicuous on account of its sulphur-coloured, prettily-lobed leaves; it is a small tree, and, with a background of dark green, such as that afforded by the Evergreen Oak (*Quercus Ilex*) is most striking. The Blue Beech (*Carpinus americana*) is a small tree from 10 ft. to 20 ft. high, and a group of it now, on different individuals and, in a few instances, on the same plant, exhibit a charming combination of green, golden-yellow, light red, and crimson. The South European *Acer Opulus* furnishes us with a mixture of purplish, orange-scarlet, and brown tints. The Cherry Birch

(*Betula lenta*) of the Northern and North-Eastern United States, makes a fine tree; it is now covered with clear golden-yellow foliage, which is especially attractive in sunlight. The Black or Sour Gum, or Pepperidge—for under all three names is *Nyssa multiflora* known in its native haunts, the Eastern United States—has fine, bold, glossy leaves, now assuming a brilliant orange-scarlet colour; an accidental combination of this with a specimen of *Ptelea trifoliata*, with its lemon-yellow, pinnate foliage, produces a very happy effect, which is much admired. The Cocksbur Thorn and its numerous varieties make striking objects during the autumn, and vary much as to the time when their leaves change colour, and also when they fall. The most handsome now are *Cratægus Crus-galli splendens*, in which the normal dark green foliage is enlivened by an admixture of crimson-scarlet and orange-yellow leaves, some being merely edged with deep red; and *C. Crus-galli ovalifolia*, which is one of the first to don its autumn garb, and, moreover, one of the most desirable; deep red and reddish-brown, tempered by a suspicion of orange-yellow, are the principal tints exhibited by this pretty little tree. *C. Downingi* has dull purple leaves, which are, however, very effective in strong light or sunshine. *Rhus radicans* is a very suitable plant for the woodland border; when allowed its own way it will climb amongst shrubs and low trees, and take perfect care of itself. In sheltered places its leaves have not yet begun to change, but more in the open they are already bright yellow. A plant which has climbed amongst the branches nearly to the top of a tall Cypress, at the edge of a wild piece of shrubbery, forms a perfect picture, its large, bold foliage being set in a framework of glaucous green. *Hamamelis virginica* is a small shrub with golden-yellow, Hazel-like leaves, which remain attached to the branches for some time after they have changed colour. *Rhus elegans*, a North American shrub or small tree, which ought to be much more generally known, has elegant pinnate leaves, from 12 in. to 18 in. long, the brilliancy of whose tints, of which the predominant ones are orange, scarlet, and lemon-yellow, nothing can well exceed. The common Guelder Rose furnishes rather dull purplish shades, which, however, form an agreeable and striking contrast to the foliage of most other deciduous and evergreen shrubs; it stands cutting well, and when so treated, retains its foliage for a longer period than when allowed to grow untouched. It is now very effective in the mixed shrubbery. The Maiden-hair tree (*Salisburia adiantifolia*) makes pretty autumnal effects, its peculiar green leaves turning to clear, soft yellow, while a blotch near the attachment of the stalk to the blade keeps for a time the normal colour. A variety of the common Vine (*Vitis vinifera rubescens*) either when trained to stakes, when grown against a wall, or as a covering to arbours, &c., assumes a deep purplish-red colour, both striking and peculiar, and under the influence of sunlight, extremely gorgeous. *Pyrus arbutifolia* is a charming shrub with glossy, pointed leaves about 3 in. long by 1½ in. broad, which have now put on magnificent shades of rich vinous red and deep orange-yellow. The purple-leaved variety of the common Sycamore (*Acer pseudo-platanus purpurascens*) has its purplish tints intensified at the present season; when grown in company with some of the American and South European Maples in which yellow is the prevailing shade, a good contrast is obtained.

G.

Cassia corymbosa Out-of-doors.—It may interest Mr. Uphill (p. 279) to know that there is quite a large shrub of *Cassia corymbosa* out-of-doors in the garden of Canon Beadon at North Stoneham, near Bishopstoke. It surprised me exceedingly when I saw it a few days ago, and it certainly is a most beautiful shrub. It was planted several years ago, and though of course it is cut down in a hard winter, it sends up strong shoots in the spring and just now it is in a most flourishing condition.—HENRY EWBANK, Ryde.

A Birch Wood.—In passing through a wood wholly composed of Birch trees the other day I saw beauties in the crowded trees distinct from those that we all admire in the isolated ones. The numerous white pillars, tall and slender from overcrowding, and the arched effect over a narrow roadway were beautiful. The whole thing was very suggestive to me of the drawbacks of the usual mixed system of our shrubberies and groves—a system by which one sees the same effects almost everywhere.—H.

BUDDLEIA INSIGNIS.

This is a very remarkable *Buddleia*, raised, it is stated, from seed of the old *B. curviflora*, from which it differs in almost all

Buddleia curviflora.

its characters. It is a dwarf, compact, erect shrub, not unlike a large *Veronica* with ternate leaves. The flowers are of a

Buddleia insignis (one-twentieth of natural size).

lilac-purple tinged with red, and they are produced in great profusion. Of its value as an ornamental shrub in the climate of this country we can say nothing at present, but it is much praised in the "*Revue Horticole*." W. B. HEMSLEY.

AUTUMN LEAVES.

THERE is no department of ornamental gardening in which more remains to be done than in that of trees and shrubs with coloured foliage, particularly and mainly those that change their usually green leaves to various bright hues. We have all heard and read much of this subject, even from a garden point of view, but we have never yet witnessed any deliberate and worthy attempt to represent in garden or in park the glory of the leaves of trees. Of course we except that shown by our native trees, which is often as remarkable as those of any other country. It is common to praise the beauty of certain North American trees, but seldom or never is allusion made to our own. Nevertheless, we did not observe (so far as one autumn in America could enable us to judge) anything more beautiful than we have now and then seen afforded by English trees in the south of England, and even in parts of Scotland. We remember one year seeing the avenue of Elms in Kensington Gardens a golden grove, and a most lovely one.

We say so much of native trees mainly to call attention to the many treasures that are within the reach of planters. For if so much leaf-beauty is displayed by the comparatively few trees and shrubs of our own island, the fact suggests the rich stores that are within our reach from the trees and shrubs of many other northern and temperate countries in both worlds. For, as before shown, it is a mistake to suppose that American trees alone possess marked beauty in this way. The habit of changing from green to various colours as the leaf prepares to fall is frequent with deciduous trees and shrubs in northern countries generally, modified considerably, no doubt, by the amount of sun at the period of their ripening, the climate, soil, and situation. If, however, America does not by any means possess all the tree-beauty in this way, there are many of her trees and shrubs that possess the charm of autumn colour in a marked degree, and these for the most part are much neglected—and neglected not only by those who know little or nothing of trees, but also by people with some knowledge of the subject, and much opportunity as to the chances of making pictures of such materials as we speak of. None possess them in such a high degree as the owners of the parks of the United Kingdom. In few other countries does one, even occasionally, see in private hands such beautifully wooded and Grass-carpeted "home landscapes" as occur in almost every part of these islands. Only in such places can ornamental tree culture be carried out as it ought to be, including the particular form of it we now allude to. The unrivalled and necessary foregrounds of turf, the variety of surface, the ample space to allow of objects being seen at various distances—these are the conditions that permit of tree culture being carried out to a far more satisfactory and far more scientific degree than ever was seen in the old pedantic botanic garden way of crowding species together, and rarely permitting any one to express its full value singly, in groups, groves, and combined with others.

It is essential to a fuller representation of the coloured arboretum, so to say, that more attention be paid to the planting of deciduous trees than has long been the case. For years the attention of planters has been almost entirely fixed on Coniferous trees, to the neglect of those we think more valuable for the parks of these islands generally. Taking these Conifers at their best in their native countries, many of them (not by any means all) have excellent qualities; but the question for us is what they are likely to do in our own country or district. There can be no doubt to any observer who looks beyond the young trees in nurseries, and watches what becomes of most Coniferous trees as soon as they get beyond the fresh, moist soil of the nursery, and above its sheltering hedges, that a great number of what we may call fashionable Conifers are wholly unfitted for planting in our lowland parks generally. Of course there are places where a genial seaside or hill climate, and favourable soil, enable some of the trees to which we allude to keep in good health, and even to grow vigorously, for many years; but we speak of the country generally, and of the many places where there is no Philip Frost to place many a load of good loam over the roots of his favourite Douglas Fir. The trees we want are the trees that take care of themselves after being fairly planted. Few deciduous trees fail to do this, while scores of Conifers do. Deciduous trees are those naturally suited for our lowland gardens, because they are the trees of the plains, and also of the hills and lower mountains, whereas Conifers are generally trees of the mountain, and often require somewhat similar conditions. But even if the Conifers were able to hold their own in growth and endurance with the deciduous trees, we should then have to claim for the latter, at the very least, an equal place from their beauty of changing dress, flowering and picturesque qualities. Those, therefore, who want their parks to display all the beauty which trees can show in our latitudes, will plant them largely in groups and groves, as well as singly, and always seek to use species that colour well in the planter's district. Some few trees of Norway Maple, which we saw this morning in a garden, make me wish for a cloud of its foliage on rising ground, with a good sweep of

Grass in the foreground. If, indeed, we only had the various Maples, fine effects of colour might be obtained in autumn; but there are many other trees equally good. How rich we are in this way, indeed, has probably never been ascertained, certainly never stated. The autumn beauty of trees and their curious changes is of course a subject far beneath the lofty contemplation of the botanist, who is more frequently found adding to the mass of technicalities with which the science is burdened, or writing a memoir on a fungus found on a stickleback, than studying such facts and effects as we speak of. On the other hand, the usual types of "bedding-out" maniacs, whether gardeners or amateurs, are deplorable creatures, whose costly efforts have only succeeded in making the gardens of Europe ridiculously alike. Splendour of colour in a tree is of course nothing to anyone who spreads out the colour of flowers as manufacturers do that of oilcloth. To those who look at the vegetable kingdom in a broader way, there is, apart from the important question (or rather need) of planting for use and profit, a great deal of delightful interest to be found in planting ornamental trees somewhat out of the common way, and not a few new paths remaining to be followed up in it.—"Field."

FOREST WORK FOR THE END OF OCTOBER.

The early part of the present month has proved most favourable to the operations of the forest planter, both in respect to the preparation of the land, the cartage of materials, and the getting up and removal of nursery stock. Wherever the transplanting of evergreens and coniferous trees is finished, he may now proceed with those of a deciduous kind, the wood of which is, in most situations, fairly ripened. The system of pit planting without trenching is not to be recommended upon very retentive soils, as the holes hold too much water throughout the winter to admit of the young trees being in a healthy state. For spring planting this system is not so objectionable, but it should be followed by a complete trenching or stirring of the intermediate spaces during the following autumn. Avoid raising, removing, or planting trees during frosty weather, from which their future growth will be certain to receive a check.

In cutting new ditches or watercourses through the plantations, those upon the higher ground should run obliquely to the fall of the land. This insures a more regular drainage, and also prevents the washing of the bottoms of the drains, which takes place where the stream is rapid. All open ditches should now be cleared of rank growths of weeds and accumulations of leaves, so as to give a free course to the water. The benefits of good open drains in plantations upon very wet soils may be seen at a glance by following the course of a main ditch, as the growths of underwood upon its margin will be much stronger and healthier than shoots of the same age springing from stools more remote from the watercourse.

Commence the thinning of plantations, leaving Oak and other trees, for the bark of which there is a local demand, to be felled in the spring. Early thinnings give great advantages to the forester by enabling him to avail himself of frosts for the removal of his timber. Where the timber is to be sold standing it should now be marked and allotted; but in most cases the interests of the proprietor are best served by the timber being felled and cleared under the directions of the forester, and the produce afterwards removed to some convenient place outside the woods for sale by auction.

Finish trimming and clearing the wood-rides, and attend to the repairs of culverts or pincocks; also look to the larger transplants, staking and tying such as require it, and treading up the soil or ramming it round the stem. Wash with a mixture of Stockholm tar, linseed oil, lime, and cow manure, the stems and lower branches of all young stocks liable to attacks from hares and rabbits. Trees fresh from the nursery are much more likely to attract them than those which have stood sometime in the woods.

In the nursery continue the planting of Acorus and Sweet Chestnuts, and gather Maple seeds of all kinds. Beech nuts, if put in now, may require protection from the frosts in April and May. Manure and trench nursery plots from which Spruce, Ash, Elm, Beech, Sycamore, Hawthorn, and some other exhausting plants have been taken. The planting of all Hawthorn hedges should be finished with as little delay as possible.

The falls of coppice or underwood may now be marked out, and allotted ready for sale, but we reserve particulars of this for next month. Collect seeds of the Ash, Alder, and Birch, preserving the former in dry sand, and the two latter in a dry and airy loft. The transplanting of young stock in the home nursery will also now demand attention. Upon heavy soils this should be carried on when the ground is damp, but not excessively wet, as the treading on the land is very detrimental to the young plants. A. J. BURROWS.

THE AZARAS.

ABOUT a dozen kinds of Azaras are known, and all are natives of Chili; although they are not by any means generally known, most of them are in cultivation, and some are strikingly handsome. As wall plants, particularly if the walls have an eastern or western aspect, they make fine objects and flower freely, while in the southern counties, at least, they do well in the open shrubbery—unless too exposed. Good, rich, well-drained loam and partial shade from taller shrubs seem to be the conditions in which they most delight. All are easily propagated by cuttings of the half-ripened wood inserted in sand under a bell-glass. The following are those best worth growing:—

Gillies' Azara (*A. Gilliesii*) is probably the handsomest of the whole genus: its toothed leaves have the colour and texture of those of the Holly, the branches being richly tinged with red. In its native country it attains a height of 10 ft. or 15 ft., and, as a cool conservatory plant, will grow quite as high in England; it, however, bears cutting well, so can easily be kept within any bounds. As a corridor plant few shrubs are more charming than this. Both in the open air and under glass it flowers in the late autumn and winter months. The blossoms are small, but are collected into oblong heads, resembling golden catkins from the enormous number of rich orange-coloured stamens. *A. caestrina* has coarsely-serrated leaves similar in outline to, but rather less than, those of *A. Gilliesii*; its yellow blossoms are arranged in lax corymbs.

Entire-leaved Azara (*A. integrifolia*) has handsome, thick, leathery, dark green leaves and drooping spikes of very fragrant, golden-yellow blossoms; it forms a dense bush a few feet in height. A variegated form of this originated, we believe, a few years ago at Kew. It is a beautiful plant of good habit, and very constant in its variegation, but as yet seems to be very little known.

Small-leaved Azara (*A. microphylla*), introduced a few years ago, and recently distributed by Messrs. Veitch, is a fast-growing and very beautiful shrub with small, deep green, glossy leaves. The flowers are somewhat inconspicuous, but the graceful and peculiar habit of the bush makes ample amends for the smallness of the blossoms; the branches, which are densely clothed with pretty foliage, are arranged in nearly horizontal tiers, and furnish a style of beauty not possessed by any other hardy shrub.

Tooth-leaved Azara (*A. dentata*) is a quick grower, and forms a fine evergreen bush in a tolerably short time; it has hairy, glaucous leaves, and flowers arranged in umbellate clusters.

Saw-leaved Azara (*A. serrata*) has prettily-serrated leaves, and long-stalked umbels of yellow blossoms. A.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

Rosemary in Masses.—Where a dense low thicket is admissible, jutting out from a taller growth behind, or to clothe the side of an overhanging bank, Rosemary may be effectively employed. The play of light and shade amongst its spikes of grey and green foliage is very charming when grown in a mass. A single plant fails to give an impression of its unique character in this respect. Cuttings put in now soon make good plants.—E. HOSDAY.

An Avenue of Mountain Ash.—A line of old and large and rugged trees of this looked well lately bordering a road entering a Bohemian village. Even the large and old branches drooped, so heavy was the crop of scarlet berries. The Mountain Ash is by no means one of the best trees that could be selected from among the deciduous groups for avenue planting, yet it struck us that it afforded a better effect than could be hoped for from some of the avenues of half-hardy Conifers, which it has long been the fashion to plant in the "best places" too often without considering the fitness of the climate for them.

Rhododendrons and Roses.—I can well understand "D." (p. 316) being pleased with the effect which these produce. We have some clumps of Rhododendrons here from 20 ft. to 30 ft. high, and here and there amongst them different kinds of monthly and China Roses have been planted which throw out clusters of flowers, and as they bloom nearly all the year round, they have a very pleasing effect at all seasons, but more especially when the Rhododendrons are out of flower. They are, of course, allowed to grow without restraint, rambling about where they like over the tops of the Rhododendrons, a circumstance which enhances considerably the effect which they produce.—CAMBRIAN.

THE FLOWER GARDEN.

THE CAPE IVY.

(*SENECIO MACROGLOSSUS*.)

MOST people are acquainted with the German or Parlour Ivy; that quick-growing, tender plant now so popular for window and basket culture, and so useful for soon covering a screen in the garden. The German Ivy is not an Ivy proper at all, but belongs to the great Composite family; it is *Senecio scandens*, and own brother to the Groundsel, a common weed, to the Tassel flower of the gardens (sometimes called *Cacalia*), and to that golden-yellow Squaw-weed, or Golden Rag-wort (*Senecio aureus*), which is everywhere so bright, especially in wet places, in spring. This new plant has received in Europe the name of Cape Ivy, and it well distinguishes it from the

The Cape Ivy (*Senecio macroglossus*).

other climber, which, though called German, comes from the same locality—South Africa. After growing the plant for a few weeks we have had an engraving made of it, which, while the leaves are not so large as they would be on a stronger plant, gives a good idea of their shape and Ivy-like appearance. While the colour of the better known German Ivy is of a light and rather yellowish green, the leaves of this have the dark and blackish green so peculiar to true Ivy, and which gives to this newer one a richness which the other lacks; besides this, the leaves have much more substance than those of the other, though they are still soft, and have not the rigidity of those of true Ivy. Some months ago we made the statement that, though we had in 1867 figured the German Ivy in flower, it rarely bloomed; since then several have informed us that it flowered with them, and one friend sent us abundant specimens. The flowers in the "German" are in large clusters of small heads which have no ray-florets, and are only about

$\frac{1}{4}$ in. across, while the Cape Ivy has but one or two heads at the ends of the flowering branches, which have showy rays, and are 2 in. or more across. THE GARDEN and other English papers say that this Cape Ivy is quite as well suited to house culture as the other; If it proves to be as manageable as the German Ivy, it must become very popular, on account of its finer colour and closer resemblance to Ivy.—"American Agriculturist."

FACTS AND FALLACIES IN LILY CULTURE.

I REGRET that other engagements have hitherto prevented me from replying to Mrs. Newall's "comments" (p. 264) on my letter (p. 216), which have been forwarded to THE GARDEN by Mr. G. F. Wilson. Mrs. Newall writes as follows: "'Duncdin' misunderstands my letter a little. I do not say that my plants degenerate, and that the flowers grow smaller and the stems dwarfer every year." Now, if Mrs. Newall will look at my letter again, she will see that I made use of no such words as those written by her. She adds: "I simply mean that, contrasted with what they were when only put out for the summer, they are smaller." This is something entirely new; for it will be seen that no such phrase appears in her first letter (p. 200), and therefore it could not have been even alluded to by me. She said in her first letter: "The flowers may be a little smaller, very little, and the plants considerably dwarfed, but I consider that they are acclimatised." And in her second letter she calls this "a great gain." As regards acclimation, Mrs. Newall is simply deceiving herself, and sacrificing the quality and beauty of her Lilies to a visionary idea, as she cannot be aware that the bulb that blooms one year never bloomed before, and will never bloom again. This is confirmed by her second letter, "comments on mine," in which she actually compares other plants, "bulbous and tuberous rooted," with the incomparable organisation of the Lily itself. That her culture is faulty in other respects there cannot be a doubt, for she says: "This summer the number of stems in a round bed $1\frac{1}{2}$ ft. in diameter was eighty-two." Now we know that, though there may be twin bulbs and triplets among so many, every stem must spring from a distinct bulb. We have, therefore, here eighty-two bulbs crowded into a space only 18 in. in diameter, besides the dead and dying crushed into a mass below, a feast for worms. Eighty-two bulbs of *L. speciosum* or *auratum* in such a confined space would not allow each bulb to grow more than one-third of its natural size without being crushed up against its neighbour. And yet Mrs. Newall complains about the plants being considerably dwarfed. How could they be otherwise? If "R. C. R." (p. 238) had treated his Lilies in the same way, where would have been "his hulbs hy the hundred, and his blooms of the greatest beauty by the thousand?"

Top-dressing Lilies.

Let us now turn to p. 304, and see what Mr. Wilson himself has to say regarding Lily culture. He says: "'R. C. R.' (p. 238) was of course right in replanting his *L. speciosum* when the growth showed the soil to be exhausted; the only alternative would have been top-dressing, as practised by Mrs. Newall" (p. 200). Does Mr. Wilson really mean to say that any kind of top-dressing would have relieved "R. C. R." of the "nest of bulbs" which "he found deep in the soil?" "R. C. R." did, in fact, what Mrs. Newall should have done, and what I recommended her to do long ago. Had "R. C. R." applied top-dressing, as practised by Mrs. Newall, he would have done a great deal of harm and no good whatever, for he would have encouraged the growth of offsets among the "root growth above the hulf," to which it will be seen Mr. Wilson himself alludes, making the bottom part of the stem a perfect colony of small bulbs to the great detriment of the main, or new bulb itself. Mr. Wilson continues: "In some beds at the entrance of a carriage drive, where large hulbs of *L. tigrinum* Fortunei were planted very thickly for the sake of the immediate effect of close-growing, large clumps, last year, these were grand and much admired; this year, though very beautiful, the plants were hardly as strong as last, showing that their bed, though made with good, deep soil, was becoming exhausted. In one of these beds I propose to change the soil

in another to top-dress for the sake of experiments." It is strange that Mr. Wilson did not recommend this plan to Mrs. Newall. The reader may recollect that at p. 217 I recommended it to Mrs. Newall, viz., one half one way, and the other half the other way. In my opinion, however, as already stated with regard to the stem roots, Mr. Wilson will gain nothing by top-dressing *L. tigrinum* Fortunei. As regards changing the soil, unless this has been done immediately after the bloom was over, the change will be too late, I fear, to ensure a good bloom the first season. It is a common complaint that transplanted Lilies do not bloom well the first season after their removal, but few seem to know that late or deferred lifting and replanting is the cause. With regard to top-dressing, Mr. Wilson says, "We see every year the effect of top-dressing in the case of our orchard-house trees which are in perfect health although they have lived in pots for more than twenty-three years." Surely Mr. Wilson cannot mean to compare the culture of fibrous-rooted perennial trees more than twenty-three years old with that of successional Lily bulbs, the interior economy of which is so clearly illustrated in THE GARDEN (p. 237), though still—as it appears to be—a dead letter in the hands of all who believe in Mr. Baker's perennial theory? Mr. Wilson says: "For some years they (the trees) have been past turning out of their pots, so the earth is grubbed up for some distance down, and fresh soil and, afterwards, manure are applied, much as Mrs. Newall treats her Lilies." I fail, however, to see the slightest resemblance between his treatment of the trees and the top-dressing as practised by Mrs. Newall. She says, "I only lay cinders and tan over the roots during the latter part of the winter, and use no protection in spring, but I water and manure freely." In another part of her letter she says, "I take as much soil off as I can every year and heap fresh soil on to them." There is not a word about "grubbing up the earth for some distance down;" in fact, she could practise nothing of the kind with eighty-two bulbs growing in so small a space as 18 in. in diameter. A top-dressing of manure applied in the autumn to *L. caudatum* and its varieties would in a great measure prevent the leaves from falling off from the lower part of the stem, which they are apt to do before the blooming season is over. But if applied to *L. speciosum*, *auratum*, *tigrinum*, or others that have a tendency to send out "root-growth above the bulb," it would do a great deal of harm, as the offsets encouraged thereby would draw nourishment from the main bulbs, which it is the function of the lower roots to supply to them. The natural and, consequently, most beneficial way is to feed the plant at the lower roots, which imbibe crude sap from congenial (not exhausted) soil, conveying it up to the bulb, where it is elaborated and stored up during the winter and early spring in a growing and enlarging new bulb, and in which it is fitted to be carried up by the growth of the stem, for the production of the flowers. I regret to see that Mr. Wilson has made so sad a mistake (see p. 332) as to say that the safest guide, as to the best time for removing Lilies, is the appearance of the stems. It will be in the recollection of some of your readers that, in May last, I undermined clumps of *L. bulbiferum*, *candidum*, *longiflorum*, *speciosum*, and some others, and separated the stems entirely from the bulbs. The stems without the bulbs continued to grow, and actually flowered at the same time with those of similar kinds that had not been disturbed. These stems, with the exception of those of *L. candidum*, which faded first, have kept their leaves green for a very long time, as it is only ten days ago that I lifted them, and some of their leaves, you will see from the stems which I send you, are not quite faded yet. But what I most particularly wish you to notice is the quantity of fine offsets at the bottom of each stem. Some of the original bulbs that were cut from these stems, and replanted at the time, were also again taken up ten days ago, and had new roots 13 in. and 14 in. long. They had also short new roots when taken up in May. These things can be verified by a cultivator who was present. Your correspondents may, of course, do as Mr. Wilson recommends; but they will do so at the expense of the early and best roots, for we cannot get over the fact that every day after the flowers have faded before the bulbs are transplanted is a day lost, to be deducted from the welfare of the new roots; for the appearance of the stems has no connection whatever with the new successional bulbs.

Large Bulbs not the Best.

As Mr. Wilson, and almost all Lily growers, seem to look upon "large" bulbs with special favour, allow me to make a few remarks on the subject for the consideration of your readers, more particularly as the time is approaching when we may expect to see imported bulbs. A writer in THE GARDEN, among other qualities, recommends the selection of "weighty" bulbs. This at once indicates that the writer is a believer in the perennial theory, namely, "that the bulb goes on living for an indefinite period, sending out each year a flower stem from its centre." But we who know that the bulb of the season is a successional bulb know also that to purchase our bulbs by weight we would be paying for the old decaying scales, as well as for the new bulb within them. What Mr. Wilson now believes I am somewhat at a loss to say; but when he supported me in 1877 (p. 183, March 10) by saying that the bulb of *L. giganteum* unmistakably dies after flowering, and that the same may be said of some of the North American Lilies, I was in hopes that he had found the perennial theory to be entirely untenable. At page 286 "W. H." says: "We purchase a quantity of *L. auratum* annually. When the bulbs arrive they are examined, and arranged according to their sizes, the largest being set aside for pot work." He does not explain on what principle he conducts his examination, or why he sets aside the largest for pot work, though it is evident that he considers them to be the best. Now, I would never think of choosing a large bulb because it was a large one. I would sooner have a medium-sized bulb of a certain character. I remember some very large bulbs, with two and three crowns or growths each, being offered for sale at a much higher price than any of the others. These I would never choose if medium single-crowned ones could be had. My reason is this: These sorts of bulbs are what are properly called twin bulbs, and triplets or three at a birth, springing from the same source, and consequently they have only one set of roots to support the whole. These wonderful phenomena in Nature lead me to think that our Lily bulbs would have more of our consideration if we could only realise the important fact that "plants, like animals, are organised and living beings." That when there are two or three at a birth, the stems are often more weakly than when only one springs from a bulb. We are indebted to Mr. J. Stewart Gathorne Hardy (see p. 238) for proving that the shilling or third-class imported bulbs of *L. auratum* bloom admirably, and flower with from five to sixteen flowers on a stem, and may be relied on, "if purchased from a respectable person." This agrees entirely with my experience. Take one of the largest or first-class bulbs and plant it in the autumn in poor or exhausted soil; then take one of the third-class, and plant it in fresh congenial soil. The new bulb within the third-class one will soon send down its roots, and will grow more and more during the winter and spring, and if taken up just before the flowering begins, it will be found to be much larger than the new or successional bulb within the first-class one, while the new bulb within the first-class one may be dwindling away from want of proper nourishment. This is indirectly confirmed by the author of "Notes on Lilies," though the cause is not given. He "found bulbs of the size of a medium Orange when in flower, though when planted they were only as large as a five-shilling-piece." He also found some that "when taken up were smaller than when planted." It is not what we plant, but what we can make of the new or successional bulb by intelligent and careful cultivation. Mr. Wilson stands deservedly high as a Lily grower, and so do many others, but no man can become a good cultivator who believes in the perennial theory, which is a pernicious fallacy.

DUNEDIN.

Valeriana Phu aurea as a Spring-bedding Plant.—This is one of the best spring-bedding plants with which I am acquainted. This golden variety, as we have it here, attains a brilliant transparent yellow, far surpassing that of the Golden Feather. It grows luxuriantly, and on good soil need not be closer planted than 1 ft. apart. Beds of it command more attention in February than those filled with any other spring plants, and they hold good till required for their summer occupants. It assumes the appearance of well-blanching Chioory, but is of a soft clear yellow colour. I am not aware

whether heavy or light soil suits its growth best, but on our soil it keeps its colour in perfection for three months. It is perfectly hardy, and was picked up, an only plant, by a cottager's door in Northumberland.—J. HUNTER, *Lambton Castle, Durham.*

THE HOLLY-LEAVED LOBELIA.

(*L. ILICIFOLIA.*)

THE annexed illustration represents a little old-fashioned Cape Lobelia in fruit. It has a trailing habit, with slender stems rising from 3 in. to 6 in. high, furnished with small oval leaves, toothed, and wavy, much in the same manner as in the common Holly. The flowers are produced about September, and are borne singly on slender stalks from the axils of the leaves. They are about $\frac{1}{2}$ in. across, have five narrow divisions, and are of a pink or flesh colour; these are succeeded by purplish, globular fruits, which remain on the plant the greater part of the winter. It is well adapted for growing in suspended pots or baskets, so that the branches

Lobelia ilicifolia in Fruit.

hang over the sides, a way in which they have a pretty effect in cool greenhouses. As regards soil, it should be planted in light, rich material. W.

PORTULACAS AND THEIR CULTURE.

A RECENT visit to Messrs. Sutton & Sons' London Road seed grounds afforded an opportunity of inspecting a large collection of double and single Portulacae which had been planted out to note the best and most striking varieties to select for collections. The plants had been planted out in well-prepared ground in a single line in the border by the side of the main walks, and were exposed fully to the sun, and indeed to the action of the elements. They were doing well, had made a good growth, and were flowering with remarkable freedom and brilliancy. The Portulaca supplies some of the most brilliant colours among flowers, and when the sun shines fully on the plants, and the expanded flowers are open to the sun, the effect of a line or large patch of plants is very fine. Portulacae can be had in both single and double forms. Some prefer the former and some the latter, but both make effective border flowers. Of the single flowers, the best were aurantiaca, golden-buff in colour, some of the flowers having more yellow in them, but both forms very pretty; ocellata, having a yellow centre with a purple ring round it and a broad margin of white, very good and distinct; splendens, a variety well named, the colour rich purplish-crimson (this is one of the very finest varieties); Thellusoni, orange-crimson, very fine; and Thorburni, bright yellow and very distinct. At some time or the other these single Portulacae showed a tendency to become double, and this having been followed up, a race of double varieties has resulted. These are all, more or less, double forms of the single varieties, and by dint of selection they now produce very large and full double flowers. The yellow and buff are double forms of aurantiaca, and, being flushed with red on the interior of the petals, are highly effective. Rosea plena, bright rose, is very handsome, and some of the flowers take on a depth of colour which makes it appear to be a double form of splendens. One of the most beautiful varieties is caryophylloides; its flowers are fully double, and are marked with purplish-crimson on a bluish ground, and broadly flaked with the same. The Sulphur is a double form of

Thorburni. There are other colours, but I have made a selection only of the most distinct, but all are good. These are well worth cultivating, but should be grown well. It is a common practice to starve Portulacae, as if they did best when in this poor condition. I hold the opinion that, like many other plants, Portulacae should be planted in good soil, in which they can thoroughly establish themselves, covering the surface of the ground with a dense coating of foliage, and then when the hot, bright, midsummer sun falls on the plants, hundreds of splendid flowers leap up responsive to its influence. Portulacae are most effective when they are not unduly crowded. Individual plants should have ample space in which to grow, as they quickly cover a good space of ground. The soil being made good, the surface should be covered with $\frac{1}{2}$ in. or so of mortar rubbish, and over this some fine soil should be sprinkled. On this let the seed be sown thinly, and all in danger of being crowded removed as soon as large enough. The roots grow quickly through the grit to the rich soil below, and the plants, becoming thoroughly established, bloom on till autumn dim their lustre. D.

WINTERING ALPINES.

THERE is a large number of these beautiful miniature forms of vegetation, which, though they can endure without injury a greater degree of cold than we may reasonably expect to experience in this country, perish annually from the excessive humidity of our ordinary winters. It therefore behoves every one who wishes to avoid such a loss to provide some means to prevent it. Where a collection is grown in pots this is a simple matter, as the plants likely to be injured can be easily placed in frames, but where they are planted out on a mixed rocky they are not so manageable. Some cultivators lift and pot those which are most susceptible to injury, but as a rule it is a bad policy to do so, as at this season the majority are in a state of inactivity, and to disturb them without taking the greatest care is a very precarious operation. I find the best plan to follow in regard to these is to first place a layer of finely-broken sandstone or spar round the necks of the plants, in order to keep the leaves from being in contact with the damp soil, and then to place pieces of glass in a slanting position so as to throw off the water. During fine and dry days these should be removed for a time, and, thus treated, I manage to keep my plants in a healthy condition. All those with more or less hairy leaves, or with a fleshy rootstock, come under the category of Alpines requiring this protection, such as many of the Androsaceae, viz., *A. sarmentosa*, *lanuginosa*, *imbricata*, *villosa*, &c.; *Eritrichium nanum*; *Onosma taurica* and *ebichoides*; *Anthemis Aizoon*; *Cyananthus lobatus* and *incanus*; *Omphalodes Luciliae*; *Cerastium alpinum*; choice *Primulas*; *Cathartia*; all the Himalayan Poppies (*Meconopsis*); the rarest of the Oxalidaceae; South European Orchisae, any many others. W.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Silphium laciniatum.—What a noble plant this is so far as its foliage is concerned! It is very far from being so free to flower as *S. conatum*, but in good soil the leaves are really remarkable and quite distinct from those of any other. No border is big enough for it as it grows with me.—J. H.

Swertia perennis.—This seldom-seen perennial attains a height of 3 ft. in Messrs. Froebel's garden at Zurich, the plants growing on the edge of a bed of American shrubs in bog soil. We have never seen it anything nearly so large.

Vernonia praealta.—The Vernonias bloom so late with us and so often suffer from our cold autumnal rains, that they are scarcely worth a place as border plants, but *V. praealta*, at least, is a fine plant for the wild garden, being so stately in habit that even if its flowers escape us, or are injured, it may still be considered worth room in a copse, or ditch, or open spot in a wood.—H.

Wintering Salvia patens.—I quite agree with the remarks made by Mr. Groom (p. 305) in reference to this matter. There are quantities of this *Salvia* growing in mixed flower borders here, and we never think of covering or protecting them in any way whatever during winter; in fact, we just treat them like Phloxes and they grow most luxuriantly.—CAMBRIAN.

Hibiscus Manihot as a Bedding Plant.—This fine plant forms a striking feature in some of the beds at Kew. It is a very old inhabitant of gardens, having been introduced more than a century and a half ago from China, but it is seldom met with even in greenhouses, where formerly it was grown extensively. It forms handsome pyramidal specimens from 4 ft. to 6 ft. high, with stems beset with stiff hairs, and large five to seven-lobed leaves. The flowers

are produced in dense spikes, much in the way of those of a Holly-hock, and measure from 3 in. to 5 in. across. They are a pale lemon colour, with a very dark purple centre, and they are produced very freely, and, although each individual bloom lasts but a day, they open in quick succession.—A.

A New Grass from Cyprus.—*Festuca punctoria* is the name of a very singular-looking Grass from Cyprus, which Messrs. Fröbel, of Zurich, have now in some quantity. It is very glaucous, more so than the well-known *Festuca glauca*, and the leaves very rigid and sharp pointed. Messrs. Fröbel employ it as a silvery bedding plant in certain of their beds and with a very good effect. It has some resemblance to the foliage of a Pink.

Dwarf Marigolds.—Although not general favourites, these deserve a place in our gardens from the continuous way in which they flower and the gorgeous mass of colour which they produce late in the season. When wind and wet impair the beauty of summer-bedding plants, Marigolds continue to flower for weeks, and make beds and borders gay while signs of approaching winter are everywhere visible.—J. G.

Wintering Gladioli.—May I, in reply to "K. L. D." (p. 322), state that I last year made an experiment with some of the finer sorts, which was so successful that I mean to try it on a larger scale this year? I lifted some at the usual time, took off the spawn, and immediately replanted them at a depth of 7 in. I had not one loss in the row thus treated, and had, moreover, some of the finest blooms of the varieties so treated that I had during the season.—DELTA.

Schizostylis coccinea.—At this season, when brightly-coloured flowers are beginning to give place to fading leaves and richly-coloured berries, this useful bulbous plant is exceptionally welcome. We have a long row of it on which the blossoms are just expanding, and a most striking effect they produce, as most of our autumn flowers, such as *Chrysanthemums*, lack brilliancy of colour. It also makes an effective pot plant for conservatory or house decoration, and for cutting its medium-sized spikes are even more useful than those of the *Gladiolus*. It is of easy culture, and should find a place in every garden.—J. GROOM, *Linton*.

Lilies in Pots.—I have read "Dunedin's" articles on Lily culture with much interest, and I should be glad if he would give me a few hints as to the culture of *L. auratum* and *speciosum* in pots. First, should I leave my Lilies, now going out of bloom, in the same pots, or shift them at once into new ones? and if so, into the same sized pots or not? Also, would he tell me what kind of soil in which to pot them, and if I should cut the stems down near to the surface? And would he recommend the same treatment for all Lilies in pots? I had a *Lilium auratum* last year 4 ft. high with four large blooms on it. I allowed the stem to wither away till it was quite dry, according to usual custom, and then put it for the winter in a dry cellar. This spring I potted it in a fresh pot, placing it for a time in the open air. It threw up two stems about 18 in. high only. One had four blooms, the other three. Evidently I had given it wrong treatment. Should the stems increase in size and the blooms also each succeeding year? and is there not a chance of potting them in too large a pot? I should like also to know how plants of *L. auratum* and *speciosum* are increased, if they can be, in this part of the country?—A LOVER OF LILIES, *Aryleshire*.

Transplanting Lilies.—Allow me to thank "Dunedin" for kindly replying to my enquiry (p. 286). I ought to have stated that I had been in the habit of transplanting my Lilies in the early part of November, which "Dunedin" thinks may account for their being better the second and third years after removal than the first. Possibly such is the case. I shall have much pleasure in trying "Dunedin's" plan of transplanting earlier. Last year I moved a few clumps in December, parting them and re-planting immediately. These did fairly well, with the exception of about a dozen bulbs, which have never shown any signs of life above ground. I examined them the other day, expecting to find that the bulbs had perished; but, no; they are quite fresh and plump, and in precisely the same condition in which they were when planted last December, except that the roots on them at the time of removal are gone. Will they remain sound and grow next year? "Dunedin" says (p. 305) he is glad to see that I recognise the fact that Lily bulbs are every year new and successional. I have long considered such to be the case, as will be seen from a note of mine, published in THE GARDEN in July, 1875, on the flowering of *Lilium giganteum*. At p. 20, Vol. VIII., I stated that after flowering the bulb perished, leaving an offspring to perpetuate its species. I was at that time fully persuaded that when a Lily bulb flowered it had completed its course, and that its existence had terminated. I quite agree with "Dunedin" (p. 304) that a Lily bulb is never dormant, as many suppose, but that it is from its earliest existence pushing on towards the flowering stage.—D. UPHILL, *Moreton, Dorchester*.

PLATE CL.

GROUP OF NEW CAMELLIAS.

THE Camellia is not less valuable for the beauty and brilliancy of its foliage and flowers than for its extremely easy culture and adaptability to circumstances which generally prove adverse to the well-being of other plants, natives of more genial climes. As a town plant the Camellia stands unrivalled, enduring the smoke, dust, and dull atmosphere of London without losing its freshness and vigour. There are, indeed, in existence town gardens within a radius of some three or four miles of the General Post Office where this plant grows luxuriantly out-of-doors entirely unprotected, save by the presence of some friendly wall on which it is trained. The flowers from which our plate was prepared were produced at the Waltham Cross Nurseries, where a collection of about 150 kinds is cultivated. The routine of their culture is briefly as follows: As soon as flowering is over, about the end of March, the houses in which the plants are grown are kept closed, and artificial heat given to secure a temperature of about 65° by day and 55° by night. The plants are freely watered to encourage a vigorous growth, and are thoroughly syringed with a garden engine every morning. After about six weeks, in genial weather the air from outside is gradually admitted, at first during the day only, and afterwards at night also. This insures the hardening of the wood and the formation of the flower buds. At the end of June the plants are all taken out-of-doors and placed in a shady position under a hedge with a north aspect, where the hardening process is perfected. They are brought back again into the houses early in October, and are kept entirely without artificial heat until the advent of frosty weather, when just sufficient warmth is given to prevent the frost from spoiling the flower buds. The plants are then allowed to flower naturally, no forcing being resorted to. A few flowers are produced in November, and the number continues to increase until March, when the plants are at their best, some of the large specimens bearing hundreds of flowers. When the flowering is at its height air is given to the plants at top and sides throughout the day, and, should the weather be mild, top air at night also. This materially preserves the freshness of the flowers. The houses used are span-roofed, lofty and airy, with lights for ventilation at top and sides. Many of the most striking Camellias, for effect *en masse*, are not the most desirable for cutting, proving somewhat coarse and, on close inspection, sometimes single. Such are *cospicua*, *rosy-crimson*; *Donckelaari*, *cerise*; *Chandleri*, *crimson*; *reticulata*, *red*; *corallina*, *crimson*; *elegans* (Chandler's), *pink*; *picturata*, *blush-white*; *punctata*, *white spotted with rose*; and many others.

As florists' flowers, the following are the best in cultivation:—

WHITE.—*Alba plena*, *fimbriata*, *innocenza*, *Targioni*, *alba elegantissima*, and *Princess Charlotte* (sometimes dashed with pink, as in the plate).

BLUSH.—*Lady Hume's Blush*.

WHITE, FLAKED WITH RED AND ROSE.—*Lavinia Maggi*, *Bonomiana*, *Adelina Benvenuti*, *Jubilee*, *Adamo*, and *Princess Clothilde*.

PEACH COLOUR AND PALE PINK.—*Principessa Aldobrandini*, *Mdme. de Strekaloff*, and *Mons. d'Offoy* (variable).

PINK AND ROSE.—*Engene Massina*, *angustua superba*, *Comte Boutonrin*, *Marchioness of Exeter*, *Vicomte de Nienport*, and *Comtesse d'Hainault*.

PINK AND ROSE, BANDED WITH WHITE.—*La Costituzione*, *Lucrezia Gazzarini*, *Passimiana*, *L'Avenir*, *Teutonia*, and *Leopoldo Benucci*.

RED AND CRIMSON.—*Imbricata*, *Mathotiana*, *Manara*, *Rafia*, *Benneyi*, and *Coquetina*.

RED AND CRIMSON, BANDED AND STRIPED WITH WHITE.—*L'Insubria*, *Souvenir d'Émile Defresne*, *Auguste Delfosse*, and *Archduc Carlo*.

The varieties represented in the accompanying plate are *Princess Charlotte* (white), *Eugène Massina* (rose), *Mathotiana* (crimson), and *Lucrezia Gazzarini* (pink, banded with white).

ARTHUR W. PAUL.

PROPAGATING.

ANEMONE HONORINE JOBERT.

This plant, so useful for affording cut flowers during September and October, is easily increased by means of root cuttings. In November dig up a plant from the open ground, and cut up the roots into small pieces $1\frac{1}{2}$ in. long, as shown in the annexed illustration. Well drain some pans about 3 in. deep, and fill them with finely-sifted soil, consisting of loam, leaf-mould, and sand, to within $\frac{1}{2}$ in. of the rims; press all down gently, make

Root Cutting of Anemone Honorine Jobert.

the surface level, lay down pieces of root all over it, and cover up to the rim; give a good watering and place them on a shelf in the propagating house. In about three weeks they will push through the soil, and in another fortnight will be ready for potting off. They ought to be kept gently moving till they can be gradually hardened off in a cold frame. Plant them out in March, take them up and pot them in September, and transfer them to the greenhouse as required, *i.e.*, if wanted for indoor decoration.

H. H.

ROSE GROWING IN FRANCE.

(Continued from page 336.)

Propagation.

Rose trees are propagated by seed, by cuttings, by layers, and by grafting. This portion of our subject, therefore, may be divided into four sections, each treating of one of the methods of propagation usually adopted. We take it for granted that our readers are already conversant with technical terms, and also to some extent with the practical operations to be performed. We shall only speak of those operations which relate specially to the Rose tree, referring those who are desirous of studying the subject further to the work of M. Carrière, of the Jardin des Plantes, entitled, "Le Guide du Jardinier Multiplicateur," a book which ought to be in the hands of every body who practises gardening.

PROPAGATION BY SEED.—Of all the methods of propagation, that of sowing seed is certainly the most natural, seeing that it is the way employed in the majority of cases by Nature herself. It has, however, its inconveniences when we have to deal with plants which are not types, but rather variations of a fixed type. Under these circumstances the seed does not always produce the variety from which it was obtained, but gives new varieties, or varieties which have already been obtained from some of its ancestors. This phenomenon has long been made a subject of study by botanists, but it still remains a mystery. We can never tell either what kind of result we shall arrive at by fertilising one variety with another, or what is the cause of the persistence of certain types which reappear suddenly after having disappeared for several generations. But however discordant the varieties obtained from the same seed may appear, close observers can see in the new flowers certain characteristics which connect them with the parent stock. For instance, we can easily see that Louise Peyronny, Mère de Saint Louis, Auguste Mie are descendants of the beautiful Rose La Reine, which was itself obtained by M. Laffay, a well-known rosarian of Bellevue, in 1841. Gloire d'Alger has produced Rose Bohinski, which is more double than its parent while still preserving its beautiful calyx and the general character of its leaves. General Jacqueminot, one of the most beautiful of modern Roses, has itself produced several varieties which equal the parent plant, without, however, surpassing it, and at the same time preserving family characteristics which it is easy to recognise. Unfortunately, it is sometimes by the transmission of a defect that the parentage of a plant is revealed. The Géant des Batailles, a flower remarkable for its form and colour, came into the world a prey to that terrible malady mildew, which it transmits to all its varieties. Sometimes a seedling Rose which is nearly single or a non-climber will, after being propagated by shield bud-

ding, become a double climber. We must not, therefore, be in a hurry to judge of our seedlings, seeing that grafting is necessary to give them a fixed and definite character. From these facts we may conclude that we should sow in order to obtain new varieties, and for the sake of propagating varieties already obtained.

SEED BEARERS.—The seed bearers ought to be chosen from amongst the most vigorous and beautiful subjects. During flowering time they must receive especial attention as regards watering, manuring, and pruning, so that they may arrive at maturity under the best conditions. The number of seed pods left to ripen must be in proportion to the general healthiness of the tree, so as to obtain in all instances well-formed seed of good quality.

GATHERING THE SEED.—The seed ought to be gathered as soon as it is ripe. This may easily be known from the bright red hue of the berries. In ordinary seasons this generally happens about the end of October. The seed should always be collected before the first frosts set in, or it will probably be injured. The seed vessels of each single variety should be gathered separately, and carefully ticketed, numbered, and stored away before the others are touched, otherwise great confusion is liable to ensue. Mice are very fond of Rose seed; precautions are therefore needed against these pests if we would wish to be successful.

CLEANING THE SEED.—The seeds soon become perfectly ripe if put away in a dry place, and in a few days after they are gathered they are ready for cleaning. The seed vessels are opened over a small pot, and the seeds disengaged from the husk are thrown into it. With a small fan or a coarse hard sieve we now separate the husk from the seed, shaking up the latter vigorously in order to get rid of the down with which it is surrounded. The seeds are then thrown into a basin of water, when the good ones fall to the bottom and the bad ones float on the top. The latter are collected and thrown away, and the former are drained and allowed to dry spontaneously. The seed is then mixed with dry sand or earth and put away in its numbered and ticketed pot in a dry place out of the reach of rats and mice. Thus treated, the seed is being slowly prepared for its future germination. When the proper time arrives it is sown, earth or sand and all. The seed of the Rose is a small, spherical or egg-shaped body with flattened sides and angular edges of a dirty whitey-brown hue. The number of seeds in a capsule varies with the species, but, generally speaking, the Roses with globular seed vessels give more than those with longer ones. The dead seed generally amounts to about one-third of the crop.

TIME OF SOWING.—The most favourable time for sowing Rose seed is from the middle of October to the middle of December. The method to be employed is regulated by the mean temperature of the locality, the kind of soil, and other general conditions.

SOWING IN THE OPEN AIR.—A border of light ground with a favourable aspect is dug and the surface raked smooth. It is then covered with a layer of fine sand or heath mould of about $1\frac{1}{4}$ in. in thickness, and beaten down gently with the back of a shovel. The border is then divided into as many squares, 3 ft. to 10 ft. in length, as there are varieties to sow. The edges of each of these squares must be raised above the centre of the bed. The seed having been sown broadcast, it is sprinkled with heath mould or sand to the depth of $\frac{3}{4}$ in., on the top of which is spread a layer of dead leaves 6 in. or 7 in. thick. The layer of leaves keeps the seeds sufficiently damp to favour germination, and protects them from the frost. Towards the end of March, if the weather will allow of it, the leaves are taken away, and are kept in reserve in the paths in case of frost; later on they are taken away and allowed to rot. The beds with their young plants must be kept in a state of the greatest cleanliness, and watered as often as they require it. The soil ought to be always kept fresh, but not damp. In April or May the young plants are pricked out into other beds, which are divided into as many compartments as there are varieties. The young Roses are placed in rows 4 in. apart, each plant being $3\frac{1}{2}$ in. from its neighbour. They must be watered and shaded for several days after transplanting to help them to strike.

SOWING UNDER BELL-GLASSES.—This method of sowing is, perhaps, the best. A border having been prepared, as described in the directions for sowing in the open air, we cover it with rows of the bell-glasses used for growing vegetables, pressing them down so as to leave a strong impression of their edge. The seed is sown in the circle so marked, covered with heath mould, and pressed down (the hand-glasses, of course, being replaced), the intervals between being filled up with dry stable litter or dead leaves, of course leaving the upper portions of the glasses uncovered. In the month of March, weather permitting, the litter or leaves are taken away and the bell-glasses lifted up to dry the soil and change the air. The ground is weeded and watered if necessary, and in the month of April the bell-glasses are taken away altogether, as if they were left over the young plants much longer they would become weakened. No matter how much pains we may take, we must always make up our minds to see a large number of our seedlings wither away and die. When any of the young seedlings are attacked by mildew, they must be sprinkled with flowers of sulphur.

SOWING IN FRAMES.—Roses may be sown in cold frames just as they are under bell-glasses, the border being divided into compartments, as directed above. Sowings under frames must be looked well after during the winter, for all the mouse tribe, especially the field mouse, are particularly partial to Rose seed. As soon as we are certain that the frames are visited by these pests, we must clear them away by means of some kind of trap. Seedlings of Tea Roses, Bourbons, Noisettes, and climbing hybrids, if grown under favourable conditions, are likely to flower the first year; the other varieties not before the second year. The blossoming period ought to be watched for with the greatest attention, and those plants marked which show any distinctive character whether in the foliage or the flower. The shoots of these plants will furnish the shield buds for the late part of the season. These shoots must be managed by pinching off the buds and leaves in such a way as to obtain well-grown buds. Care must also be taken to choose stocks whose vigour of growth is proportionate to that of the Rose seedling from which the buds are to be taken. It is of the utmost importance that the greatest care should be taken with the first budding, without which the new variety will not be permanent. Except all the conditions be favourable, its character will be undecided, and the hopes raised by the seedling will be doomed to disappointment. J. LACHAUME.

GARDENING FOR THE WEEK.

Greenhouse Plants.

Where due provision has been made during the summer months by working up a good stock of soft-wooded subjects, such as *Chrysanthemums*, *Heliotropes*, *Salvias*, *Cinerarias*, *Primulas*, *Solanums*, *Perpetual Carnations*, *Mignonette*, *Eupatoriums*, &c., there will be no lack of free-blooming plants to render the greenhouse or conservatory attractive for several months to come. In order to get these in succession and prolong their season as much as possible, it will now be necessary to forward those that will bear a little heat, and keep back others by placing them in cool, airy positions, thus retarding their flowering to a later period. Few plants are more accommodating in their nature, or will stand either kind of treatment better than the old *Richardia æthiopica*, which, if properly prepared by being grown in the open ground, may be made to afford a constant supply of its lovely pure white flowers from now till May or June, at which time they have to be separated for planting to be again ready for the following winter. *Richardias* will bear quite as much heat as any stove plant, and appear to enjoy it, but when subjected to it stronger than is requisite to get them early in bloom, they are apt to become drawn both in leaf and flower-stem, which not only spoils their appearance, but renders them incapable of bearing the low temperature of the conservatory or greenhouse. In cases, however, where they are only wanted for cutting this drawn appearance is but of little consequence, as it does not materially affect the quantity of bloom they yield nor the time they last in water when cut, although most other plants would at once show the effects of such a style of growth. Their exception in this respect is not much to be wondered at when we consider the great substance of the flower and how readily water is conducted to it by the large sappy stem on which it is sup-

ported. Where large quantities of cut bloom are required, and room for producing it is scarce, as is the case in most places, there need be no hesitation in arranging plants of the *Richardia* a long way from the glass, and in positions that would be of little use for other purposes.

Miscellaneous Plants that are yet out-of-doors, and at all liable to be injured by frost, ought to be at once placed in the houses, pits, or under some temporary shelter; such are *Dracæna australis*, *Agaves*, *Phormium tenax* (both the green and variegated forms), *Aralia Sieboldi*, and *A. Sieboldi variegata*. Those with gardens, either large or small, who have the convenience of only a single greenhouse, will do well to grow plants of the above description, on account of their thorough adaptability to serve a double purpose. In the winter, when placed in a greenhouse or conservatory, amongst the usual kinds of flowering plants, they contribute much to the general effect by their dissimilarity in appearance; and in the summer, out-of-doors, with their pots plunged amongst the bedding plants in the flower garden, or in vases, they do much to relieve the want of diversity in form and superfluity of colour. With such subjects as the above an ordinary plant house can from time to time be changed in general aspect by altering the position the plants have occupied in it, so as to remove the sameness resulting from seeing certain plants always in the same places. They also possess other advantages: they are easily grown; are less liable to suffer from neglect than many plants; and they are but slightly troubled with insects.

Salvia splendens, one of the most useful and showy of all autumnal-flowering greenhouse plants, is now in great beauty, and will remain so for some time to come, if well cared for and kept from damping, to which it is very subject, unless fully exposed to the light and kept in a house moderately warm with a free circulation of air. If confined to small pots, they should now have plenty of manure water, to enable them to push forth bloom on the lateral branches, which they will continue to do when so assisted till Christmas, or even later, when the variety known as *S. Heeri* will be coming in to take their places. These will be growing fast for the next month or so, and should have a light position afforded them with plenty of room between the plants, or they soon become drawn and bare below, which greatly detracts from their appearance. To keep their leaves of a healthy green colour, they should be freely supplied with liquid manure, as the pots they now occupy will be very full of roots.

Large-flowered and Fancy Pelargoniums.—These, although more difficult to grow well than the zonals so much in favour of late years, are much more varied and beautiful in their colours and general habit of growth than the unlimited numbers of new scarlet and pink zonals that yearly make their appearance, many of which scarcely possess a shade of variation in colour from others that have preceded them. The great difference in the treatment required by the fancy and large-flowered kinds from the zonals is, that, through their growth being so much slower than that of the latter, they do not require, nor will they bear, the same quantity of water at the roots, especially during the autumn and winter months, as the others; and many, whose practice has been confined to the cultivation of the zonal Pelargoniums, have at first found a difficulty in managing the other varieties all through the autumn and winter. After the usual potting about the end of August, particularly in the case of plants that have been cut back freely, and a considerable portion of the roots removed, these will not have really filled the new soil with roots, and must be watered very sparingly for the next four months. It is not an easy matter to describe the necessary quantity of water required by any particular family of plants grown in pots, but in the case of these Pelargoniums a safe course to follow is not to give any water so long as moisture can be detected in the soil by pressing the surface with the fingers, as, from the hard potting they require, the pots will very often not respond to the usual test of rapping. If ever the soil in which these plants are grown become too wet at this season the roots will most likely perish. To strengthen them still further, they should be elevated as near the roof of the house as possible, and be kept tied out so that every leaf shall receive its due proportion of light.

Chrysanthemums in most places this year are late, which is an advantage so far as keeping up a supply of flowers until the end of the year is concerned, but to secure this they need some additional care in their treatment. Those that are the latest in forming their bloom-buds are much better out in the open air, so long as they can be protected from frost; to secure this protection a slight temporary framework of wood should be fixed up to the south side of a wall or building and be covered overhead with canvas or any light material that can be removed during the day. An old blind that has been used for shading a plant house or Peach wall will, in most cases, be

quite sufficient to afford the necessary protection for some weeks to come. The advantage gained by placing the latest flowering of the stock in such a position is twofold: it prevents the houses getting overcrowded, and the plants thus out in the open air do not become drawn and a prey to mildew, a condition to which they are very subject when placed under glass for a considerable time before the blooms increase in size. The flowers should be thinned out as soon as they are large enough to lay hold of, reducing their number according to the size of the pots and the description of the plants. The largest-flowered kinds should be more severely thinned than the medium-sized sorts, and these again more than the Pompones. The whole ought to have their buds reduced to about one-eighth of their number, and the plants must be regularly supplied with manure water of a stronger description than that used for other plants in pots. On no account should they be allowed to flag for want of moisture, or the bottom leaves, as well as the flowers, will be sure to give evidence of such neglect. The unremitting attention thus recommended for subjects so easy of cultivation as *Chrysanthemums* may appear to some to be more than necessary, but only by such treatment can these beautiful autumn and winter flowers be grown in the way they so well merit. There is one great benefit derivable from thinning the flowers not generally noticed, and that is, where this is well and judiciously carried out, not only are the blooms much finer, but individually they retain their freshness considerably longer, on account of the greater substance in the petals resultant from all the strength of the plants being concentrated in maturing a limited number of flowers. Should any mildew make its appearance, dust the affected leaves with flowers of sulphur immediately; delay in this respect will be certain destruction to the foliage before the blooming is over.

Carnations in Pots for flowering during the winter should not be exposed to frost or excessive wet. Frequently there is an impression that such plants as these, and others of a similar character that are hardy, will, when cultivated in pots, bear without injury the extremes of wet and cold, as if they were in the open ground, but such is by no means the case; when the roots of any plant are confined in a pot, even when thoroughly drained, and the soil of an open, porous description, they will perish if exposed during very wet weather, while they would receive no injury if planted out in the open ground. They should now be placed in a good light pit or frame until they can receive the necessary heat to induce the flowers to open; this must be regulated by the time they are required and the means at command. To do justice to these valuable sweet-scented flowers, when being brought into bloom they should occupy a place with their tops within a few inches of the roof glass, where they will obtain plenty of light, and a temperature of about 50° during the night, with a rise of 10° in the day, and if possible a little air night and day, otherwise the plants become drawn and spindly, in which state they will not afford the full succession of bloom that they will give if their treatment be such as will keep them stout and bushy.

Roses.

Planting Roses.—Relative to the best time for moving Roses, as in other things, there is often a difference of opinion, many considering it better to wait until the leaves have fallen, others urging that the sooner after the commencement of October they are moved the better. In my own practice I have found it best in this, as in almost every other gardening operation, to be ruled by circumstances. If the Roses have to be moved simply from one part of a garden to another, with the ground which they are intended to occupy properly prepared beforehand, taking the plants up, say half-a-dozen together, and at once transferring them to the new situation, giving them at the time a good soaking with water, treading the soil firmly about the roots, and securing them with a good stake each, the earlier they are removed the better they will flower the next year, as well as being less likely to suffer should a very severe winter follow their being transplanted. In support of this, it may not be out of place to here mention a case that came directly under my own observation. In the autumn of 1860 some extensive alterations necessitated the removal of a number of standard, half-standard, and bush Roses; some of the latter were grafted low down, others were on their own roots, many of them were large plants, the standards with much larger heads than where the object is to grow flowers for exhibition; consequently it may be said that they were less calculated to bear removal without injury whilst fall of leaf. They were moved the third week in September. As will naturally be supposed, although well watered, the leaves flagged considerably and a good portion came off sooner than they otherwise would have done. The winter following, as many have occasion to remember, was intensely severe, the thermometer in the place where the above Roses were transplanted falling down 2½° below zero. Not a single plant of those that were moved early, excepting some half-dozen Tea

varieties, were injured in the least, whilst such even of the hardier Hybrid Perpetuals that I had, which were not removed, were, like most other people's, far the greater portion killed outright; in fact, not one in a dozen was left alive. The moved plants from the check they thus received were evidently rendered better able to withstand the extreme cold than those that were undisturbed, and kept on growing vigorously until later. Since then I have invariably adopted early moving where it could be done under such conditions as above described, as, without a single exception, I have found them flower more freely than when moved later on. I have frequently examined the state of the roots of these early-moved plants about the middle of November, and in all cases they had made new roots from 1 in. to 2 in. in length, a condition that will at once satisfy those acquainted with the nature and requirements of hardy plants, that when Roses are removed sufficiently early to admit of a quantity of new roots being formed in the autumn, they are in a much better state to break strongly in the spring, and flower proportionately freely than if moved late, when the leaves were all off, and there is neither warmth in the air nor soil to induce the formation of new roots, in the place of which these lay dormant until spring with the shoot growth naturally commencing before there is any root development to assist it. Although strongly advocating the replanting of Roses thus early, where after taking up they can be immediately transferred to their new position, it would by no means answer to carry out the work so early with plants that had to be got in from a nursery or elsewhere that entailed the necessity of their being some days out of the ground, for, under such circumstances, unless the roots were enveloped in a considerable body of damp material, the bark on the young wood would shrivel, the result of which would be serious injury, or death if the shrivelling occurred to a considerable extent. But, after the present time, I should not for a moment hesitate getting in Roses from the usual sources. One very considerable advantage in early orders and early planting is that in the trade it is usually "first come, first served;" and those who give their orders and have their plants taken up first have a decided advantage over those who are served when the stock has been picked through.

Kinds to Plant.—As to the varieties which it is advisable to plant, it is well to be guided by the nature of the soil and climate. Many people make their selections of sorts from the splendid flowers they see exhibited at the Rose shows, but it is well to bear in mind that the best seen in the principal competitions are usually grown where both soil and air are especially adapted to the cultivation of Roses, in addition to which more than ordinary skill is often brought to bear in the production of the flowers; and, again, many of the handsomest blooms seen in the competing boxes are of varieties which it is anything but desirable for the general cultivator to grow, inasmuch as, though the flowers seen may be large and fine, they are nevertheless the produce of sorts naturally weak and not calculated to bear through the season many blooms even fit to put in an ordinary bouquet. When such as these get into the hands of less skillful growers, and planted where the conditions are less suitable, it is simply a waste of both time and money, as, from the time they are planted, they gradually dwindle away and die; consequently, it is very much better to stick to well-proved kinds, and though new varieties have an interest attached to them, it is much better to see them tested under the conditions of ordinary cultivation before having them.

Selection of Plants for Different Soils.—The superiority of one kind of stock over another on which to grow Roses in a great measure depends on the character of the soil. Such as is of a strong, heavy, rich nature has, by long experience, proved to be the most suitable for the Brier; whereas on light land that is of a sandy or gravelly description, the Manetti will frequently give fair results where the Brier would fail. A good deal has been said of late years about the superiority of seedling Briers, that is, the ordinary Brier raised from seeds by cultivation in preference to such as are self-sown and obtained in the usual way, as are the stocks for standards and half standards. The seedling Briers may be said almost exclusively to be used, worked low down, for bushes, and the only advantage they can have in imparting greater strength to the Rose is that the seedlings naturally are furnished with a great quantity of more roots than the stocks dug up in the ordinary manner are possessed of, and I have not the slightest doubt that stocks grown from cuttings for these dwarf bushes would be equally well furnished with roots as those raised from seed. But the persistent advice which I would give in the matter to all who grow Roses for ordinary purposes is to as far as possible dispense with stocks altogether, growing them on their own roots, by which all the loss of strength involved in the production of suckers and the continual watchfulness and labour entailed in their removal, with the periodical taking up often found necessary with standards and half standards, to cut away the sucker-shoots formed by the stocks, is avoided, in the place of which every strong

shoot that comes up from below the soil produced by plants on their own roots is a decided advantage, as from these are furnished in the ensuing year the finest individually, as also the largest number of flowers, permitting of the old and weaker wood being cut away.

Depth to Plant.—A matter connected with, and of the greatest importance in Rose planting, of which it may be well to remind beginners in their cultivation, is the depth to which their roots are covered, especially when grown on the Brier, either as standards, half standards, or worked low to form bushes; the Brier, more than most plants, cannot bear its roots being deeply covered; if the collars of the plants are placed 2 in. below the soil that is enough, the extremities of the roots gradually being put a little deeper. In the case of those that are grafted or budded on the Manetti stock, which, as above advised, is usually employed on soils of a lighter character not so well suited to the Brier, they may be planted 3 in. or 4 in. deeper; but, so far as I have always been able to observe, anything beyond this is objectionable in its results.—T. BAINES.

Indoor Fruit Department.

Pot Vines placed in heat about the beginning of the month will be showing as yet but little signs of growth; do not, however, increase the temperature in order to force them on more rapidly, for the slower they start at first the stronger will be their growth. If a slight acceleration be required it should be after the bunches are formed and the berries are set. Be careful not to over water; at present the soil should be kept rather dry than wet, there being as yet little root action. When water is given it should never be colder than the bottom heat if the plants be plunged, or the soil in the pots. If this be 75° the water should be 80°. Chills in all forms must be avoided; young Vines which are propagated from eyes in the spring, and grown on in pots throughout the summer for planting next spring, should now have ripened their wood. Those fully matured should be wintered in a cool airy house. An open shed, covered at top, answers very well for this purpose. The canes of the Muscat take longer to ripen; these and any other sort not yet brown to the extreme points should be retained in heat until they acquire that condition. It is a mistake to move Vines from a warm house to a cold situation before they are thoroughly ripe. In such a case they are starved into rest in a way that is never productive of good results. Pines of the Queen variety intended for early starting and fruiting, should now, as a rule, be perfectly at rest; see that the temperature does not exceed 50°; for, if not allowed to exceed that, they will start into fruit with greater certainty when a higher temperature is applied to them. See that the soil in which newly-rooted suckers are grown does not get in bad condition. The bottom-heat for such stock may now be reduced 10°, too much growth being undesirable at present; slow, substantial, firm growth is what is needed to brave the winter season successfully. Bear in mind that too much water at any time is as injurious as too little.

Melons.—Unless these are ripened during the present month or the first half of the next one, they cannot be expected with much certainty. Therefore maintain a night temperature of at least 70°, and allow an advance of 15° by day with sun-heat. When they begin to ripen, keep the house rather dry; but still retain a brisk heat. Ripe Melons at this season may be cut, and kept on a shelf in the fruit-room for some time without deteriorating.

Cucumbers.—The earliest winter plants should now be bearing, and the others should be well established. Good turfy loam, mixed with leaf-soil, or some thoroughly decayed manure, but without, not too rich, suits them well, and around the necks of the plants the soil should rise in little mounds. Keep the soil moderately moist, but avoid over-watering, and only syringe the plants in fine weather. Do not allow them to set more fruits than they can well carry, and, until they are strong enough for fruiting, pinch all off. With dustings of flowers of sulphur on the affected parts, counteract mildew, and, if the stock of plants be deficient, increase it from cuttings, not from seed.

Strawberries.—By this time these should be thoroughly established plants, with plump and hard crowns, and well-seasoned leaves. The pots also should be quite full of roots, as cold and heavy rains are injurious to them; the first to be started, and also the weakest plants, ought to be placed in cold frames on sifted coal ashes, and near the glass. The main supply may be arranged in the side of a ridge, formed of ashes, so that they will be freed from heavy rains, and kept in better condition for forcing.

Kitchen Garden.

As ground is cleared it should be dug over for the winter. In doing this be guided by the nature of the soil; where both surface and sub-soil are naturally open and porous it may be laid up in the ordinary narrow ridges. Treated thus it gets mellowed by the action of frost, but in heavy, retentive soils, the rains are thrown off the

ridges into the alternate hollows, which become saturated, and in the spring, when the ground is required for cropping, it is not in proper condition for the reception of seeds. In such a soil it is better not to ridge but to dig it over, keeping it level, but at the same time turning it up roughly and leaving it as open as possible without attempting to break the clods. All ground that is used for vegetable crops should be trenched every three or four years, 2 in. of fresh earth being brought to the surface on each occasion. This more particularly applies to old gardens, where, if it be not done, the surface becomes exhausted. It is necessary thus to discriminate between old and new gardens, as, in the latter, at a comparatively small depth, the soil is yet crude. To bring any considerable quantity of this to the top, and to more or less bury the surface soil that has, by stirring and exposure to sun and air, together with the application of manure, become better adapted to the requirements of plant life, would be a serious mistake, which would be most injurious in its consequences to the crops for a year or two afterwards. With such land as this, that is yet deficient in depth of aerated soil, it is better not to bring much of the under portion to the top, but in trenching to loosen about 6 in. of the bottom that has not previously been stirred. In this way it will gradually be mellowed and the manurial elements that are washed down from the surface are incorporated with it, in which condition it may gradually be brought up and mixed with the top soil. In trenching ground of every description, it is well to put some manure in the bottom; its admixture with the soil beneath very much improves the latter, and here it answers as a store for the support of the roots during dry, parching, summer weather. This operation of digging and trenching in the autumn is of the greatest importance to successful vegetable culture, and never should be delayed, after the ground is cleared, longer than can be avoided, as it is much more effective and can be carried out with more ease and expedition before the land is soaked by the rains that may be expected towards the close of the year. In addition to the effects it has in aerating and pulverising the soil, it is the means of destroying quantities of slugs and wireworms and their eggs, and also weeds that have newly vegetated. Where a high system of culture is carried out, weeds and animal pests are alike reduced to the lowest point by frequently stirring the soil. The latest Apples and Pears that may yet be ungathered should be got in and stored, as has been previously directed.

Extracts from my Diary.

October 21.—Sowing Mustard and Cress. Getting a few Hyacinths into gentle heat. Putting a good covering of leaves and long litter on early Vine border. Pruning Vines in second early Vinery and stripping off all loose bark. Covering up Lettuces and Endive to blanch. Clearing off late Peas and storing away the best of the sticks for another season.

Oct. 22.—Potting Ashleaf Kidney Potatoes that had been previously started in gentle bottom-heat. Laying down new turf where required, and taking up old where unlovel and relaying it. Cutting back large deciduous trees where overhanging each other, and lightening the heads, where too heavy, to prevent wind from breaking them. Turning manure for Mushrooms, and gathering in the last of the Apples and Pears.

Oct. 23.—Washing glass and paint in second early Vinery with soft soap and hot water, and painting the Vines with a mixture of sulphur, soft soap, and Tobacco water, to which a little clay has been added to thicken it. Looking over the fruit room and arranging it for the winter. Roping Onions, cutting shreds, pointing nails, and making labels and pegs when the weather is wet.

Oct. 24.—Potting clumps of Lily of the Valley, so as to be ready for forcing. Dividing some old Lobelia plants of the pumila type and putting them in small pots. Earthing up French Beans. Spawning Mushroom bed and moulding it over. Getting up a little Chicory and Dandelion ready for forcing in pots. Rolling down firmly all gravel walks that have been broken up or newly made.

Oct. 25.—Sowing French Beans in pots. Getting up Dahlias and placing them in open shade to dry. Clearing off dead plants from flower borders and planting them with spring flowers, viz., red and yellow Wallflowers, Silenes, red and white Daisies, Myosotis, Iberis, Alyssum saxatile, Pansies, and Nemophilas. Earthing up Celery when the soil is dry and in a workable condition. Clearing off Lettuces and Endive that are gone too far for use.

Oct. 26.—Potting off cuttings of Hathaway's Excelsior Tomato. Filling frames as they become empty with Lettuces and Endive. Getting bulbs planted, such as Hyacinths, Narcissi, Crocuses, Tulips, Snowdrops, &c. Cutting back shrubs in new plantations where growing too closely together, and, where planted too thickly, removing them and filling up gaps elsewhere with them. Fruit in use for dessert: Pines, Grapes, Pears, Apples, and Nuts.—W. G. P., Dorset.

THE INDOOR GARDEN.

FREYCISETIA BANKSI.

THIS is one of the many remarkable vegetable productions of New Zealand, a country possessing one of the most interesting floras of any part of the world. A noteworthy feature of the flora is the number of outlying members of tropical or subtropical families; and Freycinetia is one of them. The genus Freycinetia is generally considered as forming a tribe of the Pandaneae, or Screw Pine family, though some botanists give it the rank of an independent family, because the fruit contains several seeds instead of only one. The species of Freycinetia differ entirely in habit from the true Screw Pines, being straggling or climbing shrubs with slender stems. *F. Banksi*, the only New Zealand species, is a climber, inhabiting warm, humid situations in the northern island of New Zealand. Allan Cunningham states that it there, by means of the twisting radican stems, ascends to the summits of the loftiest trees, attaching itself principally to the swamp Pine (*Podocarpus dactyloides*), whose straight, almost undivided, trunk often rises to a height of 120 ft. to 150 ft. The narrow, prickly leaves are from 1½ ft. to 2 ft. long, and borne in dense tufts at short distances apart on the twisting stem, which throws out numerous aerial roots. The flowers appear in the centre of the tufts of leaves, as shown in the accompanying engraving, and individually they are small and inconspicuous; but as they are very numerous and borne in dense spikes (spadices), like many Aroids, they make a considerable show. The male and female flowers are borne on separate spikes, and perhaps on different plants. But the spathe-like bracts, of which there is one attached to the base of each spike, form the most conspicuous part of the inflorescence. Moreover, these bracts are

Freycinetia Banksi.

fleshy and edible. Some years ago Dr. Hector sent living plants to Kew, two of which flowered in 1873, one bearing male and the other female flowers. The bracts of the male flowers were pure white, those of the female pale lilac. Whether this was the first time the plant had flowered in England, I have not been able to ascertain; but it flowered in 1872 in the Garden of Plants, of Paris. The bracts vary from 6 in. to 9 in. in length, and 2 in. to 3 in. in breadth, when spread open. All travellers agree in saying that the natives are exceedingly fond of them to eat in a raw state; and it is stated that the colonists make a very luscious jelly of them, which tastes like Strawberries. In a note in Kew Herbarium, Dr. A. Sinclair says that they are much prized by the natives, who in some parts of the colony taboo the forests where they grow, till a certain day, when the bracts are ripe, the tribe to whom the forest belongs rush into them at a given signal and satiate themselves with their favourite *tawhara*. The strong, fibrous leaves are used for basket-making. Although this *Freycinetia* grows to a great height in its native country, it flowers under cultivation when only 3 ft. or 4 ft. high. W. B. HEMSLEY.

season, will flower tolerably well. It is seldom, however, that it there retains in full perfection the delicate, powdery bloom which covers the flower-stem, and which constitutes its chief charm. It should be grown where it enjoys perfect immunity from heavy rains and driving winds. Pot several good crowns in 4-in. and 6-in. pots, using rough, fibrous loam, and fill the pots nearly half full of drainage. Winter them in the coolest end of a greenhouse, or in a frame, and water them pretty well every time you come near them; the constant saturation is the main element of success. Under this treatment, both foliage and flowers will attain a high state of development.—J. CORNHILL.

SOLANUMS AND THEIR CULTIVATION.

WERE it said that Solanums are easily cultivated, perhaps not a few might say that the statement did not agree with their experience, and yet some find little difficulty with them. How, then, is it that we find these useful berry-bearing plants so badly grown in places where almost everything else is noteworthy. As a family they are equally suitable for the conservatory, drawing-room, or dinner-table, and few plants last longer in close rooms than they do. To get up a good stock of them is an easy matter, and that is best accomplished by seeds, which should be sown about the first week in February in well-drained seed pans. The soil should consist of loam and leaf soil in about equal parts, put through a ½-in. riddle, with a little sand added to keep it open. The seeds should be covered about ¼ in. deep; the pans should then be placed on a shelf in a warm greenhouse or in a cucumber bed. It is a good plan to cover the pans with squares of glass, as by so doing the seeds germinate quicker than they otherwise would do, and it keeps mice from them. In about three weeks the young plants will be ready for potting off into

3-in. pots, *i.e.*, if the seeds have been good. The soil should be the same as that in which the seeds were sown. When potted they should be put back again into the cucumber bed and kept near the glass. In about a fortnight they will have got established and grown a little, when the centre of each should be pinched out, which will cause them to branch out. They should then be moved into a cold frame, or placed on a shelf in a cool greenhouse, where they can get plenty of light, be kept from cold draughts, and be carefully attended to with water, both at the roots and overhead. If green fly make its appearance, which it is almost certain to do, we find the easiest way of getting rid of it to be lifting the plants down and brushing them clean one by one with a small camel's-hair brush. This is an easy and certain cure. When the plants are in a young state stop all their branches at the third joint, which will lay the foundation for bushy plants. In a week or ten days after being moved into cool quarters they will require to be shifted into 4-in. pots, which should be well drained. The soil should be fibry loam and a little leaf mould, and no sand need be used. Pot firmly and replace them on the shelf, where they may remain for about a fortnight, and then be plunged in coal ashes out-of-doors in full sunshine. Here they may stop all summer, and will require no attention beyond giving them water in dry

Primula denticulata in Pots.—This plant is, as is well known, hardy enough to stand unprotected fair

weather. This being the first year they must not be allowed to fruit; therefore all flowers must be picked off as soon as they appear. About the middle of September they should be taken indoors and placed on a shelf or in some position near the glass in a cool house or pit from which frost can be excluded, and where they should only get a moderate supply of water—just enough to keep them from flagging—until about the first week in February, when they should be slightly pruned and placed in a gentle heat. Here they should get no water, except a dewing with the syringe twice a day; this will cause them to break freely into fresh growth. When the young shoots are about $\frac{1}{2}$ in. long the plants should be partially shaken out and repotted in well-drained 6-in. pots. The soil should consist of pure fibry loam broken into pieces about the size of Cob nuts, with a little sand added but no leaf-mould, as it induces them to grow long jointed; they should be firmly potted and replaced in heat; water sparingly, and shade when the sun is bright, until they get established in their new pots, which will be in about ten days or so; they can then be moved into a cold frame, and kept there until the middle of May, by which time they will be good bushy plants, provided they have been stopped regularly. They should then be moved to their summer quarters, viz., a square bed made up out-of-doors, about 2 ft. high, composed of cow manure and leaves in alternate layers, which will create a gentle heat. In this the pots should be plunged up to their rim at a good distance apart, so that as they grow they may not crowd each other; the bed should be in a sheltered situation where the sun can shine on it all day. Here they should be allowed to grow and flower as they like. We find it a good plan to give them a light dewing with the syringe on bright days about two o'clock. This helps to set the fruit, and, besides, if there be any appearance of green fly a little Tobacco liquor put into the water used for syringing will kill it. This should be applied when the sun is hot, at which time the effect is much greater without injury to foliage or flowers than at other times. The gentle heat of the manure will soon induce them to flower, and the first and second lot of blooms produce the largest berries. If the variety be good, the blossoms will set in clusters of from three to five; the points of the shoots should then be pinched off at the first joint above the uppermost clusters, and the pots should be lifted up and let down again to prevent their roots getting established too firmly in the manure. This should be performed twice during the summer. About the middle of September they should be taken up, and after their pots have been well washed placed in a cool greenhouse or pit where they are exposed to full sun until their berries are coloured, when they may be moved to the conservatory. There are several ways of treating them besides this; one in particular, the planting-out system, I practised for two or three years, and with a considerable amount of success, but the planting-out plan is not to be compared with plunging the plants out in summer.

H. E. A.

BOUVARDIAS AT CHRISTMAS.

THESE are the best plants in cultivation for producing large quantities of delicate and charming flowers from this time until the new year. No one who has a greenhouse should be without Bouvardias; they are easily cultivated, and are unsurpassed by plants of any other kind. In a cut state their flowers are all that can be desired; for this purpose we grow large quantities of them, and they answer well for decorating the conservatory until they are out, as they do not go out of flower in a day or two, nor do they come all into flower at one time; on the contrary, one good plant will yield a succession for some weeks. The flowers are, moreover, of all shades of colour, and many of them are as finely scented as those of *Stephanotis floribunda*. In fact, altogether it is quite impossible to over-estimate the value of Bouvardias, and wherever choice flowers are wanted, from this time and for some months onwards they should be grown by hundreds. We double the number of our plants every season, and I do not think we will ever have too many of them. Some plant them out during summer, and others grow them in pots; we grow them both ways with success. Where plenty of time can be devoted to them, the pot system is the best; but when this cannot be spared, they

should be planted out. Planting them out, however, is a matter which need not be discussed; but lifting and potting them, as well as their treatment, for a short time afterwards, are matters of importance at the present time. It is a mistake, I think, to lift them too early, especially if the flower buds are showing up prominently, and, as a rule, it is not desirable that they should bloom much before November. It is not too late to lift them about the middle of October, and about a week previous to doing so each plant should be cut all round, 4 in. or 5 in. from the stem, with a spade. This prevents the plant, when finally lifted, from receiving a check, which must be particularly guarded against, as the slightest check often causes the bloom-buds to drop or fail to open properly. Placing them in strong heat just after they are potted has the same bad effect; the best place in which to put them after they are potted is a cold frame, which should be kept quite close, and partially shaded, if necessary, for a week or ten days after potting. When treated in this way, all sizes of plants may be lifted and grown on successfully. Bouvardias are very subject to green fly, and it is generally about this time of the year, when they are being housed, that it attacks them worst; therefore it is always a good plan to fumigate them two or three times before the flowers open, an operation that will keep them clean until they have done flowering. Plants which have been grown in pots all summer should be treated in the same way. As it is desirable that a succession of choice flowers like these should be had as long as possible, the plants should be introduced into heat at different times, the late-blooming batches being kept in a cool place until a week or two before they are wanted in flower. At all times the flowers open freely in a temperature of 60°, and remain much longer in good condition than when placed in a higher temperature.

CAMBRIAN.

STEPHANOTIS FLORIBUNDA IN BASKETS, ON ARCHES, AND ON WALLS.

THIS is the very best, sweetest, and most useful and pliable of all climbers. If a choice specimen be wanted, no plant forms one sooner or to more strikingly effective purpose. It looks well on globe, balloon, half-spherical, or flat trellises, or even trained more loosely to a few stakes, and the branches allowed to trail with considerable natural freedom. The *Stephanotis* flowers remarkably well treated in this free and easy style. It is also admirably adapted for the furnishing of large baskets, allowing the shoots to depend freely over the sides to a length varying from 1 ft. to 3 ft. or more. It is surprising that large basket plants are not used more freely than they are for the decoration of large plant stoves. The weakest place in the majority of these is found between the heads of the taller specimen plants and the drooping sprays of the roof climbers. Introduce between these a few large basket plants of *Stephanotis floribunda*, and the effect would be immensely enhanced. What, for example, could be more welcome than a snow-like shower of flower-covered branches of the *Stephanotis* falling amongst the spray of scarlet or pink Passion-flowers, or such magnificent old stove climbers as the *Ipomœa Horsfalliæ*, one of the grandest and far too seldom seen stove plants? The *Stephanotis* is seldom used for baskets, though it is one of the most effective plants for the purpose. Again, plants allowed to droop in accordance with their natural habit look well depending from brackets, or elevated shelves, or masses of rock or corkwork in stoves. The plant has an appearance in these new positions so different from what it usually has, that it is difficult to recognise it as the same. Again, few plants equal the *Stephanotis* for the clothing of walls. Its glossy leaves alone make it rank high as a wall climber; and when to these are added its myriad bunches of waxlike flowers of snowy whiteness, the effect is rich in the extreme.

For the covering of arches the *Stephanotis* is equally well adapted. Arches are always effective in plant stoves; they may be defined as the only lines of beauty in many houses that break the monotonous stiffness of straight rafters, or render them endurable through the welcome change of curve, which is refreshing as the sight and sound of a waterfall on a sultry day in June; and arches never look more lovely than when clothed with the verdure and draped with the beauty and sweetness of the *Stephanotis floribunda*. Every one is familiar

with the uses of the *Stephanotis* on roofs and rafters. In fact, these are the orthodox places for growing this lovely and valuable plant, and they are, perhaps, the best places for obtaining a full profusion of bloom, for the *Stephanotis* is greedy of light when growing and ripening its wood, and unless it enjoys a large share of it, the flowers will be comparatively few and far between. In recommending the plant as a wall clother, it must be borne in mind that the walls ought to be pretty fully exposed to the light if a full harvest of blossom is to be reaped. I have known the *Stephanotis* removed from a roof to a wall, and refusing to flower till it was restored to its light, sunny quarters. So much does this plant enjoy the light, that it does best trained across the roof, cutting the rafters at right angles. Trained up or down the rafters, the shade is too much for the development of its full floriferousness. As a rule, too, the *Stephanotis* is trained too stiffly on roofs and rafters. A few leaders should be carried along at distances of 1 ft., 2 ft., or more apart, if the space be ample, and from these the flowering shoots should be permitted to depend to any convenient length. This free mode of treatment is the best as regards picturesque effect and profusion of bloom.

The culture of the *Stephanotis* is very simple. No soil suits it better than equal parts peat and loam with a dash of leaf-mould in it, or well-decomposed manure and a liberal admixture of sharp silver sand. It enjoys a high temperature, from 70° to 80°, when growing and flowering, though it will consent to continue in flower, with little or no injury, for some considerable time in the conservatory at a temperature of from 50° to 55°. It is, however, emphatically a stove plant, a native of Madagascar, and, consequently, delights to revel in a high temperature and an atmosphere bordering on saturation. While in full growth and flower it enjoys shade from direct sunshine several hours on either side of noon. This preserves the full verdure of the leaves, which are apt to assume a somewhat discoloured hue either in an arid atmosphere or a low temperature. This verdure of leaf is a chief element in the perfect beauty of the *Stephanotis*. The drainage should be liberal, as the plant is greedy of water, and also specially sensitive of stagnant water at the roots. Provided the drainage be sufficient, it can hardly be overwatered, but should a block occur in the drainage, or the latter prove insufficient, the plants can hardly be preserved in health. The *Stephanotis* continues long in flower, say from April to June or July, according to its mode of treatment. After flowering it enjoys a rest for several months, and by having several plants, and varying the growing and resting seasons, it is possible to have their lovely flowers throughout the greater part of the year. After flowering and the ripening of the young wood is the proper season for pruning. The *Stephanotis* is one of those plants that bears the knife well, to use a cultivator's phrase, and the modes of pruning adopted are very varied. Some lay in a few leading shoots every year, and cut out the old and exhausted ones; others prune in the leading shoots almost as severely as Grape Vines are spurred, and of course there are infinite gradations of practice between these two extremes. The plant thrives and flowers well under almost any system of pruning and training. One point must, however, never be lost sight of, and that is that the main object of one or both of these processes is to get rid of all weakly or diseased shoots or leaves. The main purposes of skilful pruning are concentration of strength, improvement of form, establishment of health, and production of flowers. In the case of this plant, too, it becomes an indispensable aid to cleanliness; for with all the merits of the *Stephanotis* it must not be concealed that it has one great drawback. The juices of the plant seem as sweet to insects as its flowers are to us. Hence thrips, scale, mealy bug—especially the latter—fasten upon and often disfigure it. As to the two first, skilful cultivation and proper care should render them impossible. Should they appear, however, Tobacco smoke and the scrubbing-brush will speedily make an end of them. But mealy bug is a different matter. The more congenial the cultural conditions and the greater the skill, it often happens the faster the mealy bugs increase, multiply, and grow. The only efficient remedy for these is cold water dashed on them with such force as to disturb and disarrange their mealy coats. They cannot thrive or live long with these filamentaceous appendages tattered and

torn. Repeated streams of water from the syringe or garden engine succeed in washing off or displacing their mealy coats, and thus aid in removing or destroying the mealy bug. Fortunately, too, the plants and even the flowers enjoy these deluging shower baths. The flowers are of such substance as not to be injured by them, and the leaves look fresher after a washing with cold water. During the free growth of the plants they enjoy a weekly watering at the roots with clear manure water. House or stable sewage, if not too strong, weak guano water, or Standen's manure suits them well. From these details of cultivation it is refreshing to turn to the usefulness of *Stephanotis* flowers. They seem to be formed by Nature for the manufacture of bridal wreaths—so spotlessly white, and so admirably shaped, and so inimitably sweet. For bouquets they are equally useful mounted in bunches or in smaller numbers, say fives or threes, with settings of small Rose or Myrtle leaves, Lycopodiums or Ferns. They are the flowers that please the bouquetist. The *Stephanotis* is not only superbly beautiful in itself, but it associates well with all other flowers, such as *Panacratium*, *Eucharis*, *Roses*, *Camellias*, *Lily of the Valley*, *Deutzias*, *Spiræas*, *Heaths*, *Primulas*, *Azaleas*, *Begonias*, *Heliotropes*, *Forget-me-nots*, *Violets*, *Lilacs*, *Quisqualis*, &c. And then for small baskets, vases, dwarf table decorations, what more beautiful than *Stephanotis* floribunda, either alone or in conjunction with *Myosotis dissitiflora*, *Quisqualis indica* (this must be seen to be appreciated), bright-coloured *Begonias*, and the different shades of *Pelargoniums*, ranging from the brightest scarlets to the softest pinks or magentas? D. T. FISH.

CULTURE OF MASDEVALLIAS.

MR. BURIDGE, in an article on the culture of *Masdevallias*, published in THE GARDEN for September 2, 1876, suggests as the best compost for growing these plants a mixture of "fresh fibrous peat with a small addition of dried horse manure, turfy loam, and a fair proportion of coarce river sand." The article, accompanying the finely coloured plate of *Masdevallias* presented with your number for February 2, 1878, recommends, on the contrary, the old compost of "rough peat and living Sphagnum, with a small portion of sharp sand." Would Mr. Anderson be kind enough to decide the question, for the benefit of all your readers, by giving us the exact composition of soil which he thinks the best for *Masdevallias*? The article which he has published in THE GARDEN for May, 1875, gives only general hints on that point, and does not enter into any details. At the same time Mr. Anderson would perhaps tell us also which liquid manure he finds the best for *Masdevallias*? In what proportion the solid manure ought to be mixed with water? how many times a week it ought to be applied, and at what season? I have begun only last summer to give liquid manure to my Orchids. I have used fresh horse manure thrown into an open cement tank. My *Masdevallias* especially seem to have benefited very much by it. One very pale variety of *M. igcea* has given six flowers of the most intense fiery red deeper than in the best varieties I have seen, and a small plant of *M. Chimæra* has got eight flowers hanging from the sides and bottom of the basket. Only the Sphagnum which, before the use of manure water was beautifully green and growing freely, has become entirely rotten. Is basket culture advisable for the generality of *Masdevallias*? *Chimæra* does so extremely well under that treatment, that I should feel inclined to extend it to the other types.

ISTAMBOL,

[In reply to the above queries, I have to state that *Masdevallias*, according to my experience, undoubtedly thrive best in Sphagnum and peat, fibry peat with a proportion of fully one-half of Sphagnum, and dried horse manure rubbed through the fingers among the compost. A little gritty sand, something like the quantity you would use of salt to preserve meat, is quite enough, because of its comminuting tendency. Too much sand for Orchid culture is bad—very bad—mainly on account of this. If the *Masdevallias* be in first-rate health, and the pots getting well filled with roots, then manure water, chiefly from horse manure will be powerful for good. It may be used once a week during summer of about the strength, well, I would rather say the colour, of pale ale. Used in this way, under the influence of a cool climate, the leaves will grow as green as Grass. Many people aver that it is impossible to have *Masdevallias* without the sooty-looking patches on the back of the leaves. I am of a different opinion, but it requires careful cultivation. Compost nor feeding will not do it of themselves, but, taken together with an imitation of an Alpine climate during spring and summer, and not allowing the mass of growths to get bridled together without

judicious separation, and a setting away again of each clump on its own account, will together work to bring about a first-rate state of health—a state, by the way, permit me to say, which is seldom if ever seen. Moreover, to have flowers full sized, finely coloured, and splendidly developed in every way, the plants must be kept near the glass, and the pots ought to be full of roots. This encourages and evolves short peduncles, and stout, broad, well-conditioned flowers. In winter no stimulant should be given; water, which before could scarcely be too copiously administered either at the root or in the atmosphere, must be considerably withheld. A little artificial heat is requisite, but each one ought to be careful that firing is not overdone. *Masdevallias* are perpetual growers, and the young growth under hap hazard winter treatment will die back, and possibly carry some of the maturer growths with them. This is the rock ahead which every cultivator ought to guard against. It matters little whether any or all of them be grown in pots or baskets, provided the course

of the pinnae are crested in the same manner as many of our British Ferns. Being a free-growing plant, it cannot fail to be useful for many decorative purposes.

Pelargonium Corsair.—We find this to be the best for winter blooming. We grow all the best varieties in cultivation, but none of them are equal to *Corsair* for late autumn and winter flowering. In pots from 3 in. to 6 in. in diameter it flowers most freely, the blooms opening well and lasting for a long time in good condition in a greenhouse temperature. Their colour is bright orange-scarlet, and for mixing with white *Primulas*, *Hyacinths*, &c., nothing surpasses them. When in small pots the plants should have liquid manure at every alternate watering.—CAMBRIAN.

Ivy Growing in Houses.—It is interesting to note, both at home and abroad, how freely green Ivy grows in passages or rooms, sometimes with very little light. Has this tendency of such an

Microlepia hirta cristata.

of treatment touched upon be followed up. Most of the *Masdevallias* are beautiful, particularly *Harryana*, *ignea*, *Veitchiana*, and *Lindeni*. *M. Chimera* belongs to what we may call the grotesque section, and is particularly interesting; but give me a well-cultivated plant of any of the showy species above named, particularly the hull's blood variety of *Harryana*, the variety named *splendens*, and the one named *sanguinea*, and I will venture to challenge the whole rare for a strikingly beautiful effect.—JAMES ANDERSON, *Meadowbank, Uddingston, N B.*]

Microlepia hirta cristata.—This fine crested Fern has been introduced by Mr. Williams, of Holloway, from the South Sea Islands, and will be welcomed on account of its graceful character and free habit of growth. The fronds droop in a charming manner, and well-grown plants form effective objects for basket as well as pot culture, or they may be planted out with advantage in a warm conservatory. The fronds grow to a length of from 2 ft. to 4 ft. The peculiarity of the present very ornamental variety is that the apices of the frond and

adorned plant been taken sufficient advantage of? On the contrary, the plant is very seldom seen indoors. However, a plant so beautiful in form of foliage and in its growth is capable of being used with charming effect in various positions in the house; and we have so many different varieties of green Ivy, that some pretty effects might be produced by means of them. The growth is, if anything, more graceful indoors, from being usually somewhat attenuated for want of light. As to growth, it is very easy in pots, or boxes, or vases. Small sprays may even be grown in water, and in many cases shoots might be introduced from the plants growing on the outside of the house.—V.

Long Roots of Tropical Arums.—Some of the tropical species of *Arum* send down long roots towards the ground from a surprising height, and the peculiarity might be taken advantage of from an ornamental point of view. Some specimens of the curious *Arum* with the perforated leaves, commonly known as *Monstera deliciosa*, are placed near the top of a very high house in the Botanic Garden at Munich with a view to the embellishment of certain pillars.

They are planted in baskets and in pots, and while growing round their pillars fairly well they send perfectly straight, even rootlets about as thick as a common wooden pencil down from a height of from 20 ft. to 30 ft. They would probably grow much longer if they could, as when out off near the ground they sprout vigorously and begin to descend again. They are elegant as well as curious, as they fall like slender ropes among the tropical foliage.

ANSWERS TO CORRESPONDENTS.

When may Roses Raised from Cuttings be Transplanted?—In October, last year, I put a quantity of Rose cuttings (Hybrid Perpetuals) in a box in a cold frame, and about 60 per cent lived. These I planted out in April 1 ft. apart each way, and they are now good, bushy plants, but they are not where I intend them to remain permanently. Would it be better to plant them out next month, or let them remain where they are until spring, and then remove them?—Q. J. [Let your Roses remain where they are till April. Lift them carefully at the beginning of that month, and replant them in some richly-prepared soil. If you can mulch them with some good manure, all the better; pig manure is, perhaps, the best, but, failing that, give them water occasionally if the summer be a dry one, and the plants should yield some good blooms.—A. W. P.]

Ranunculus anemonoides.—This is said to be a very beautiful and distinct species. Do any of your readers grow it, and will they kindly tell me what it is like, and what treatment it requires, i.e., whether most likely to be at home as a rock garden or border plant?—J. H. [Your correspondent doubtless refers to *Thalictrum anemonoides*, alias *Anemone thalictroides*, a beautiful little, dwarf, miniature plant, with single or double, pure white flowers. It most resembles *Thalictrum tuberosum*. It does well both on the rockwork and in the open border, where it is quite at home, but is a capricious plant as to soil. It is impatient of extreme moisture and drought, and, as far as my experience goes, does not like chalk.—H. HARPUR CREWE.]

Winter-blooming Greenhouse Climbers.—I can strongly recommend to "J. W." (p. 319) *Tacsonia exoniensis*. In a temperature of 45° it went on flowering profusely all last winter and spring, the flowers being larger and of a brighter pink than those produced during the summer. It is also an admirable plant for cutting, the flowers lasting long in vases, either on the bunch or detached from it, with the stems inserted in water. Another plant of quite a different character also flowers freely in water, viz., the *Solanum jasminoides*, the delicate bunches of whitish flowers of which are also useful for cutting for bouquet or vase work. Heliotropes of different sorts will flower freely in a temperature of 50°, and are valuable for cutting.—D. T. F.

Wintering Young Nut Trees.—Last spring I planted some Wood-nuts, which have grown up about 18 in. How ought I to treat them in winter? Ought I to take them under cover, or leave them out-of-doors?—E. W. SIMPSON. [Leave them out-of-doors; they are perfectly hardy.]

Preserving Filberts.—Allow me to inform "Z. P. A." (p. 319) that I keep Filberts good not only till Christmas, but also until new ones come in, as follows: They are gathered when quite dry, put into Cucumber glasses, and stored in a dry, cold room. I do not hold with putting them in salt. If they are gathered dry and put into boxes, say 1 ft. in depth, they will keep far better than if they are salted. I have stored them in this way for years with the best results. The secret is to keep them both dry and cold.

Grapes in a Warm Greenhouse.—Will the following ripen their fruit in a warm greenhouse, viz., Bowood Muscat, Kempsey Alicante, Madresfield Court, White Tokay, and Lady Downes Seedling? The house is at present planted with Black Hamburg and Buckland Sweetwater. Would it be best to keep to these two sorts? or can I have any of the others for the sake of variety.—T. B. [If you want variety, all the kinds you name would succeed, with the exception of Muscats, which require more heat to enable them to set properly than any other kinds.—S.]

Vines in Pots.—What Vines do you recommend for early forcing in pots to start, say in November? The house is a lean-to, facing due south, and we can command plenty of heat. I have room for about twenty Vines, and should like a mixed collection (say not more than three whites), including a few Muscats; but if a mixed collection will not do, would it be advisable to force nothing but Muscats—say half Alexandrias and half Mrs. Pince?—G. E. L. [Of Black Grapes, take Black Hamburg, Mill Hill Hamburg, Madresfield Court, and Black Fontignau; and of White, Buckland Sweetwater, White Fontignau, and Golden Queen. You may try Muscat of Alexandria, but it requires a good deal of heat. Golden Champion does well in pots.—S.]

Celery Running to Seed.—What is the cause of Celery running to seed? Is it in some cases inevitable? or is it a consequence of neglect?—D. M. [Celery frequently runs to seed or "bolts," as it is termed, on account of the plants having been subjected to sudden checks, or through being planted in poor soil or allowed to become dry at the roots. From the time Celery plants are up in the seed pan to the time when they are finally planted out into the trenches they should be kept continually growing, and, in order to make provision for this, the seed should never be sown too early; in fact, the trenches should always be prepared when

the seed is sown in order to be ready to receive the plants immediately they are fit for planting. Sow the seed in rich soil in pans, boxes, or in a frame. When the plants are up prick them off 2 in. or 3 in. apart, barrow them, and when again becoming overcrowded plant them from 4 in. to 6 in. apart, in a bed of rotten manure or good leaf-mould, placed on a hard bottom and firmly trodden. The bed of manure need not be more than 3 in. deep, covering it with 1 in. of fine soil. Keep the plants well watered, and when ready to plant out run a spade or turfing iron between the rows of plants each way; thus treated, they can be readily removed to the trenches without their receiving any serious check. In dry weather water must be applied regularly, unless the soil be very deep and highly manured. A mulching of half-decayed manure or leaves placed round the plants during the summer months will prevent evaporation, and thus keep the roots moist and the plants continually growing.—S.]

Worm-eaten Celery.—My Celery this year is very much worm-eaten. If I put lime on the bed in the spring when I manure, will that prevent a repetition of the evil next year? if so, how much lime must I use?—FERN. [Add to the manure some lime previously to applying it to the ground, a liberal quantity of soot, salt, and lime, and turn it over several times before it is used. If you add a good dressing of lime to the ground and leave it in a rough state until wanted in spring, that will also to a great extent counteract the evil of which you complain.—C.]

Shedding of Fruit in the Red-berried Elder.—In THE GARDEN last week (p. 323) allusion is made to this shrub, of which we had half a dozen small plants sent to us direct from Germany nearly two years ago, and as they looked more dead than alive when they reached us I put them into small pots. I planted them out in spring in good soil, and the following summer (that of 1877) they made good growth, and last spring they flowered and set a great quantity of berries, which unfortunately all dropped soon afterwards. This season they have grown very strongly, throwing up stout succulent shoots. One of these I measured to-day, and found it to be upwards of 10 ft. in height and 7 in. round the base level with the ground. We have also an old plant here of this Elder which flowers and sets berries every spring in profusion, but they always drop in an immature state. Do other growers find this to be the case? and is there any method of inducing this Elder to perfect its fruit?—S. K.

Late Flowering of Tritonia aurea.—Can anyone tell me why *Tritonia aurea* here (Doncaster) does not show flower buds till Oct? They are poor, dwindling attempts at flowers and hardly colour or come to maturity, while those in the neighbourhood were in full beauty in Sept. Can any treatment be recommended to cause the flowers to push earlier?—C. W. S. [Your plants probably suffer from want of food. After they have ceased blooming and their tops have died down, lift the bulbs and store them in a dry shed till spring; then choose a warm border of deep soil, well enrich it with rotten manure, and, if the soil be stiff, add a liberal supply of road sand; in this plant the bulbs, and next year the result will probably be more satisfactory. *Tritonia aurea* is not thoroughly hardy in all parts of England, and in your case may require a little warmer situation than that in which it now is.—C.]

Spruce and Scotch Firs.—What is the best month in which to plant these Conifers?—P. S. [The proper season for transplanting the Spruce and Scotch Firs depends much upon the nature of the land; but in moderately dry and warm soils I should recommend moving them from the middle to the latter part of September, and if the permanent site is not ready, putting them in by the heels in a dry, warm border for a few weeks. The Spruce may afterwards be planted out in October in any fairly-sheltered spot with a cool-bottomed soil, and the Scotch Fir upon a high and dry sandy or gravelly loam, or upon Moss land which has been well drained. Autumn planting is decidedly best for large plants of either kind, as they get a firmer hold of the land, and are not so liable to injury from rocking by wind in the spring. Where small seedlings are planted out in their permanent situations, spring is probably the best time, as these are very liable to injury from sharp frosts. Such may be successfully removed up to the middle of May.—A. J. B.]

Names of Fruits.—*Coldstream*.—Insufficiently stamped to the amount of 2s 2d., therefore refused. *H.*—Hollandbury. *F. D. B.*—1, Hawthornden; 2, Old Nonpareil; 4, Rhymer; 7, King of the Pippins; others not recognisable.

Names of Plants.—Correspondents wishing plants to be named will oblige by complying with the following rules: To send the specimens as complete as possible, i.e., both stem, leaves, and flowers, and fruit, when possible. To carefully pack them in gutta-percha tissue, or other impervious material which will prevent evaporation. Not to send varieties of popular flowers, such as *Fuchsias* or *Pansies*, which are best named by experienced growers of such plants, who have the means of comparison at hand. Not to send more than four plants or flowers at a time. Always to send, in addition to whatever pseudonyms or initials they may desire to use in the paper, their full name and address. To pre-pay all packages containing plants or flowers.—T. W.—For *Veronica lutea* (p. 234) read *V. lactea*, which is synonymous with *V. repens*. *X. C.*—13, *Thuopsis dolabrata*; 14, *Pinus austriaca*; 15, *Rhus glabra*; 16, *Juniperus chinensis* (male). *Anon.*—The large leaf and flower belongs to an Indian *Acanthad*, *Adhatoda vasica*; the smaller pieces are so very insufficient that it is impossible to say with certainty whether the plant from which they were taken is *Abelia rupestris* or *Abelia serrata*. *S. F.*—*Fuokia grandiflora*; *Pteris umbrosa*. *T.*—The name of the fungus is *Helvelva crispa*, one of the edible species. *R. G.*—Certainly a *Pentstemon*, but from a single bloom it is difficult to say what variety.

SOCIETIES AND EXHIBITIONS.

ROYAL HORTICULTURAL SOCIETY.

OCTOBER 15.

SELDOM has such a fine display of flowers, fruits, and vegetables been seen at South Kensington at this period of the year as was furnished on this occasion. The principal nurserymen contributed groups of new and rare plants, and there were fine collections of hardy fruits and Grapes. A pot Vine grown for the decoration of the dinner-table by Mr. Sage, Ashridge Park, Berkhamstead, attracted much attention. It was trained on an umbrella-shaped trellis, and bore eleven good bunches of well-coloured Grapes. The pot in which it was growing was a 9-in. one, but the roots had been supplied with food from larger pots below, or from being allowed to enter the border, but the soil and roots contained in the pot were sufficient to keep the plant perfect for several weeks after the fruit was ripe.

First-class Certificates.—These were awarded to—

Pernettya mucronata lilacina (A. T. Davis).—A free-growing kind of bushy habit, bearing a profusion of handsome, pink-coloured, glossy berries.

Bomarea Carderi (Bull).—A free-growing plant, well adapted for training along the rafters of the greenhouse, and bearing a profusion of bell-shaped, rosy-pink, green-tipped blossoms. Mr. Green, gardener to Sir G. Macleay, was awarded a cultural commendation for a cut branch of the same plant, furnished with a large truss of drooping blossoms.

Anthurium Scherzerianum album (Veitch).—A white-flowered variety of this well-known plant, and one likely to be grown as a companion to it.

Lastrea aristata variegata (Veitch and Bull).—A fine greenhouse Fern having glossy green pinnae, the midrib being of a greenish-yellow; well worth growing in pots or vases.

Aspidium crinitum (Bull).—A stately Fern of erect habit, and having brown, woolly fronds, and finely-cut, handsome pinnae.

Mammillaria sphaeclata (Boller).—An interesting species of low growth, and very ornamental.

Botanical Certificates were awarded to *Phalænopsis violacea* (Veitch), and *Masdevallia velifera* (Bull).

Groups of Plants.—Messrs. Veitch & Sons, Chelsea, contributed a neat little group of Orchids, Ferns, &c., amongst which were the white-flowered *Anthurium* just alluded to, the rare *Phalænopsis violacea*, *Dendrobium bigibbum superbum*, and a fine panful of *Begonia Queen of the Whites*. Mr. Heims, gardener to F. A. Philbrick, Esq., St. John's Wood, exhibited a very pretty *Odontoglossum* of the *Andersonianum* type named O. Philbricki. Mr. C. Green, gardener to Sir G. Macleay, showed cut flowers of the fine blue-flowered *Dichorisandra thyriflora* and a plant of *Dendrobium album*, well flowered, which had been grown in quite a cool house. Mr. William Ball furnished a group of new and rare plants remarkable for variety both of flower and foliage; among them may be mentioned finely flowered examples of *Dendrobium bigibbum*, *Oncidium varicosum*, the chocolate-flowered O. Forbesi, and *Odontoglossum vexillarium rosenum*. Intermixed with these with good effect were well-grown plants of *Phyllanthus nivosus*, *Dracaena Goldieana*, *Croton triumphans*, *Bomarea Carderi*, *Sarracenia*, *Lilium neilgherrense*, the white and rose-flowered *Lapageria*, and the beautiful violet-scented *Oncidium tigrinum*. For these a gold medal was awarded. Mr. B. S. Williams, of Holloway, was awarded a large gold Banksian medal for a collection of choice Orchids and stove plants. Noticeable in this group were fine panful of *Indian Crocuses* (*Pleione lagenaria*), several well-flowered, healthy plants of the beautiful white-flowered *Dendrobium formosum giganteum*, *Oncidiums*, and *Lady's-slippers*. With these were also associated fine-leaved Palms, Ferns, and *Crotons*, including the graceful new *Croton Prince of Wales* and several fine-leaved *Coleuses*.

Mr. Parker, of Tooting, showed a fine collection of cut flowers of hardy plants; amongst them were numerous kinds of *Michaelmas Daisies* and *Phloxes*, *Tritoma grandis*, a fine autumn plant, large and well developed flowers of *Stokesia cyanea*, so much prized in the flower markets at this season of the year, various *Pompona Chrysanthemums* and *Dahlias*, *China blush Roses*, *Rudbeckia Neumannii* and *R. purpurea*. This collection also contained fine blooms of the beautiful yellow *Coreopsis lanceolata*, *Fuchsia Riccartoni*, the curious-flowered *Cynara Cardunculus*, *Helianthus multiflorus major*, *Neja gracilis*, *Colchicums*, and good spikes of *Schizostylis coccinea*; also *Verberna venosa* and *Erigeron speciosus superbus*, together with good spikes of *Liatris pyrenostachys*, two varieties of *Glycerium argenteum*, and the tall-growing *Helianthus orgyalis*.

Mr. Thos. Moore sent from the Botanic Gardens, Chelsea, single *Dahlias*, a collection of which also came from Mr. Cannell, among which were fine blooms of *D. Paragon*, *lutea*, *Cervantesi*, and *coccinea*. The latter exhibitor also showed a bright-leaved *Iresine*, named *Cannell's Brilliant*, early-flowering *Chrysanthemums*, and *Violets*. Messrs. Hooper & Co., Covent Garden, sent from their Twickenham nurseries well-grown plants of *Gesneras* with rich and varied foliage and yellow, rose, magenta, scarlet, orange, and other coloured flowers. Messrs. Osborn & Sons, Fulham, contributed plants of *Skimmia japonica*, finely berried, *Yucca quadricolor*, *Palms*, *Dracaenas*, *Phormium tenax variegatum*, and *Eurya latifolia*. Mr. W. Smith, gardener to C. Lane, Esq., Henley-on-Thames, showed a fine plant of *Vanda cœrulea* bearing five spikes and eighty-four

fully-developed blossoms. Messrs. Paul & Sons, Waltham, exhibited numerous stands of cut *Roses*, including a fine boxful of the white blooms of *Niphedots* and other good autumn-blooming kinds. Messrs. Laing & Co., Forest Hill, sent a collection of *Begonias*, representing not only the best kinds in cultivation, but also illustrating how showy such plants are late in autumn when flowers are comparatively scarce.

Messrs. W. Paul & Sons, Waltham Cross, sent a collection of sprays of ornamental deciduous trees remarkable for bright leaf coloration; amongst them were the following kinds, viz., *Cornus Mas variegata* and *alba*, *Ulmus aurea* and others, *Acer Negundo variegatum*, *Pyrus arbutifolia*, *Quercus concordia*, *Q. coccinea*, and *Q. Cerris*, *Enonymus atro-purpureus*, *Weigela rosea variegata*, *Liquidambar styraciflua*, *Cerasus Mahaleb*, *Hippophae rhamnoides*, *Spiraea prunifolia fl.-pl.*, *Fraxinus excelsa aurea pendula*, *Castanea dissecta*, *Rhus Cotinus* and *typhina*, *Philadelphus coronarius*, *Betula purpurea*, *Catalpa syringefolia aurea*, *Legustrum ovalifolium*, *Sambucus nigra argentea*, various dwarf *Junipers* and *Retinosporas*, *Taxus baccata aurea* and elegantissima, *Biota orientalis aurea* and *sempervirens*, *Thuja dolabrata*, *Yucca recurva*, *Thuja Lobbi*, *Bambusa aurea* and *Metake*.

A large gold medal was awarded to Messrs. Veitch & Sons, who exhibited in baskets a collection of miniature plants suitable for winter outdoor decoration. Among them were the following: *Various Aucubas*, *Andromeda floribunda* and *Catesbæi*, *Aralia Sieboldi*, *Azalea amœoa*, *Azara microphylla*, different kinds of *Buxus*, *Cotoneaster microphylla*, *Daphne Cneorum major*, *Elaeagnus pungens variegata* and *japonica maculata*, various kinds of *Enonymus*, *Eurya latifolia variegata*, four sorts of *Erica*, *Menziesia polifolia atropurpurea* and *polifolia erecta alba*, *Osmanthus ilicifolius* and others, *Ligustrum coriaceum*, various *Mahonias*, *Gold and Silver Hollies*, *Kalmia latifolia*, *Rhododendrons*, *Skimmia japonica*, *S. fragrans*, and *S. oblata*, *Sedum thymifolium*, *Laurustinus*, *Veronica Traversi* and *angustifolia*, *Vinca elegantissima*, *Ilex crenata*, *Gaultheria Shallon*, *Vaccinium Vitis Idæa*, *Berberis Hookeri*, *Hedera arborea elegantissima*, *Hypericum calycinum*, four hardy *Heaths*, *Diplopappus chrysophyllus*, *Daphne elegantissima*, *Abies pumila*, different kinds of *Cupressus*, and *Cryptomeria elegans*. From the Society's Gardens came plants of double zonal *Pelargoniums*, *Michaelmas Daisies*, *Begonias*, and *Improved Mignonette*. Mr. F. T. Davis, Ogles's Grove Nursery, Hillsborough, showed plants of *Pernettyas* lifted from the open border and loaded with berries. Messrs. Maule & Son, of Bristol, contributed fruit of *Pyrus Maulei*, figured in THE GARDEN (Vol. XIII., p. 390); also jam made from the fruit this season, which was pronounced to be good. Mr. Dean showed bright-looking blooms of yellow and scarlet *Tropæolums*, consisting of kinds valuable for culture in the greenhouse for winter blooming; also African *Marigolds* and some hardy, green, carpet-bedding plants.

In competition for Messrs. Pearson's prizes for *Grapes Golden Queen* and *Mrs. Pearson* the exhibits were neither so numerous nor good as might have been expected, but, nevertheless, several good bunches were shown. The prize takers for *Golden Queen* were, first, Mr. J. Atkins, gardener to Colonel Loyd-Lindsay; second, Mr. Henderson, gardener to Mr. Deacon, Mableton Park, Tonbridge; third, Mr. Anderson, Clifton, Notts. For *Mrs. Pearson*, the prize winners were, first, Mr. Allan, gardener to Lord Suffield, Gunton Park; second, Mr. Taylor, gardener to Mr. McIntosh, Oaklands Park.

Fruit and Vegetables.—Messrs. Lane & Son, Great Berkhamstead, sent a collection of *Grapes*, large in bunch and berries, and finely coloured. They consisted of *Black Prince*, *Black Hamburg*, *Muscat Hamburg*, *Barbarossa*, *Alicante*, *Gros Coloman*, *Muscat of Alexandria*, *Golden Queen*, *Trebbiano*, *Lady Downes*, *Dr. Hogg*, and *Madresfield Court*. The same exhibitors also sent several dishes of *Apples* and *Pears*. Mr. G. F. Wilson, Weybridge, furnished ripe fruit of *Doyenné du Comice* Pear plucked from a pot tree in his orchard house. Mr. Goodacre, The Gardens, Elvaston Castle, exhibited fine bunches of *Lady Downes Grape*, and Mr. Harrison Weir sent good examples of *Muscat Champion* grown in a cold Vinery. Mr. Miles, The Gardens, Wycombe Abbey, showed a new Pine-apple named *Lord Carington*, which was considered to be one of the best keeping Pines. It was awarded a silver medal. Mr. Maunden, gardener to J. S. Budgett, Ealing Park, sent two smooth-leaved *Cayenne Pines* of great weight and good quality. Excellent collections of *Apples* came from Messrs. Paul & Son, Cheshunt; Messrs. Veitch & Son, Chelsea; Messrs. W. Paul & Son, Waltham, who also sent fruit of *Raspberry Belle de Fontenay*, an October-fruiting yellow kind in good condition; and 100 varieties of *Pears* were sent from the Society's Gardens at Chiswick. Mr. R. Dean showed an extensive collection of *Potatoes*.

Pelargoniums from Root Cuttings not True to Name.

—Some twenty years ago I sent to a contemporary two small plants of *Pelargoniums* raised from root cuttings, with the pieces of root attached; also a note describing the way in which they were propagated. In about a fortnight afterwards I was not a little surprised to see figures of my plants, and also the note in print. Since that time I have propagated many thousands in the same way. Plants having perfect flowers come true to name, but sports or semi-double varieties, such as *Prince of Pelargoniums*, *La Ville de Caen*, *Queen Victoria*, &c., never come true from root cuttings. It would be interesting to know if the plants that produce those semi-double varieties are still in existence; and if so, to compare them with plants propagated from roots, which no doubt would prove to be identical. —W. WILLIAMS, Ryde, Isle of Wight.

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

SCHÖNBRUNN.

VERSAILLES has much to answer for besides the more hideous parts of the grounds of the Crystal Palace. This is one of its children, so to say. As at Versailles, the gardens here are behind or spread out from a palace. Passing through the centre of this, the "glories" of this famous garden burst upon one like a scene in a theatre, with which all such gardens have a good deal more to do than with pure gardening. The chief elements are gravel, clipped trees, and a hill beyond with a colonnade on its top. And such enormous alleys and such Brobdingnagian hedges! As at least one catalogue describes a little Alpine plant as a "tremendous" bloomer, an equally strong term may be applied to the effects here. There is gravel enough on which to mass the whole Austrian army! Versailles is nothing to it as regards Saharas of gravel! Imagine a walk over 60 ft. wide and a mile long. In the vasty distance a black object, which on closer inspection proves to be a human being, may be seen now and then crawling across the waste. Everywhere one looks stretch enormous walks. Only in the middle vista is there a bit of Grass, and beyond on the hill which rises up and relieves the scene somewhat like the background at Caserta. It would take more than a day to traverse all the walks, made, of course, in most cases without the slightest need, except to carry out in its purity the "style." But more imposing than the walks are the "hedges." Every walk is bordered with these rising to the height of a large two-storied house. The walk running along the front of the palace and to the right and left may be compared to Gower Street with a rusty clipped hedge instead of (and as high as) the houses on each side. The trees, although clipped, have, from being allowed to grow so high, all formed large trunks, mutilated and guillotined at the top when they arrived at the desired altitude. As they are all clipped alike, of course nobody can see any beauty or individuality in them. Perhaps it was rather to use trees as a background for their statues that the old designers so arranged the trees. In any case the statues are here—many of them fitted into clipped niches in the green and rusty walls (the trees give in very sadly to the clipping). How easy it would be to give some more useful employment to the persons guilty of bringing so much rubbishing "art" into the world as we see displayed in so many Continental gardens. Public gardens will not always, it is to be hoped, be a posing ground for the costly failures of the studio. Was it really such a misfortune that the image-breakers once had their way in Europe? Certainly they would do no harm in smashing up multitudes of the statues that now disfigure gardens, and no one need fear their destroying in them anything so valuable as the Psyche of Capua. The statues seem all "dots" of equal value a little way off; the giant hedges everywhere prevent one seeing what is behind them—the whole forming a scene of hedges, alleys, and roads, with here and there the never-failing water-jet, the sham ruin, and the cascade. But there was one thing more, a specimen of the scaffolds with which the walls are clipped, a huge machine which might be very useful in erecting one of the noble workhouses which now form the most imposing buildings in the west end of London. The green hill, with the colonnade above, looks refreshing after all this. But on climbing it the same orthodox principles are seen to have been applied in its case; for it, charming hill that it was, is now embellished with two full-sized formal duck-ponds and broad rectangular walks, that are placed exactly in the best manner to spoil the beauty of the Grassy slope. Some may say in answer to this, "Well, I like it as it is; I like it all," meaning every kind of garden. The answer is, that this garden and others like it prevent the seeing it "all." The vast extent and the great cost of such an establishment tend to prevent

any due attention being paid to many branches of the art of infinitely greater importance and greater beauty from any point of view. The great public, for whose instruction such gardens should aim, learn that there is perhaps a little more in the world of trees and plants than in a crater; the effect on those who ought to know something of the world referred to is scarcely less evil, for do we not often find them without any apparent idea of the inexhaustible treasures of beauty of the vegetable kingdom, and therefore grovelling in trifling formalities? The things described are ugly in themselves and occupy space that might be devoted to real tree and real flower gardening, and to many pictures composed of these, and a few other elements.

As at Caserta, there is the stately English garden, and at Versailles the well-stored tree garden of the Little Trianon, so at Schönbrunn, in a somewhat obscure corner, there is a botanic garden of considerable interest, and different in some ways from gardens of a similar kind in other parts of Europe. It is instructive in avoiding, almost wholly, the beds and borders with which so many botanic gardens are spoiled. Even among those one likes best, such as the College Gardens at Dublin, there is such a sacrifice of all repose and verdure to rectangular beds, miles of alleys, and walks, all supposed to be necessary for the accommodation of the plants, that it is pleasant to see a botanic garden where there is a little repose, and where the plants are disposed in what may be termed a more natural way. The garden is fairly rich in trees and shrubs, and to these are added from the houses in summer a great number of specimen plants that will only bear the hot season out-of-doors in Vienna. These plants are treated so as to seem part of the open-air collection in summer, so to say. Many of them, stored in large houses with lights only on one side, are so preserved, that they naturally make their growth and flower out-of-doors in summer and autumn. They are placed in the Grass in easy groups, in many cases, so as to associate with the hardy occupants of the ground. In case any of the pots or their surfaces should be too evident, they are frequently surrounded by a few worn "rustic" stones from the mountains. The result is frequently very good, and allows of a great variety of plants to be seen. Among plants yet in flower were some enormous old Coral trees, with gnarled stems 10 ft. high and handsome standard heads. Sometimes one can pass from beneath the shade of a stately group of fine Sophoras and other exotic hardy trees, and pass easily on one side and at its outer edge among specimen shrubs, stove plants, greenhouse plants, and hardy herbaceous plants all growing on the turf. Here all the best features of the so-called "sub-tropical gardening" may be seen—in fact, the best points in the system carried out in this way about London have evidently been long illustrated in German gardens, and from them were adapted. Here in mid-October the garden was alive with colour from hardy deciduous bushes and trees, the most noticeable being *Hamamelis virginica*, lovely in gold and brown leaves, and with a string of pale flowers along each shoot. This low tree is well worth growing for its fine colour in autumn. The specimen alluded to had room to grow and to receive the sun. An Ash, labelled the "aurea" variety of the common Ash, was a large tree of lemon-yellow foliage. There are many beautiful specimens of the Japan Sophora in this garden with branches touching the Grass, and great boughs ascending and spreading in the most picturesque manner, all the foliage still green and fresh, and it is also rich in American trees. Pæonies, both herbaceous and "tree," are grouped and dotted to a large extent on the Grass; their effect must be very fine, the more so, as the beauty of such "landscape" as was possible in so small a garden has not been destroyed; and it is possible to see their great flowers from distant points as well as close at hand. There are many huge "houses" here. It is a pity that when these have to be spoken of a dampness comes over the spirits. The day will, no doubt, come when most of the houses in such gardens will be placed in a large yard, along with the bears, unless in the meantime the architecture and arrangement should be wholly altered. Here an immense series of tall houses flank the garden on one side, but after so many weary miles on the gravel of the great garden, who could find time in one afternoon to fairly glance at all their weariness in red pots and tubs? Notable among them, however, is an immense collection of the

tropical Arums, not all grown in pots, but many of them on the stems of trees placed in the earth-floor of a large house and leant against its high back wall. Many of these dead stems of trees were more than 15 ft. high, and covered from top to bottom each with a species of climbing tropical Arum with large foliage. This is a simple and effective mode of growing such plants that may be carried out profitably by those having large, warm houses.

TREES AND SHRUBS.

TREES AND SHRUBS FOR AUTUMN EFFECT.

IN addition to the trees and shrubs mentioned last week (p. 348), there are many others remarkable for the beautiful tints assumed by their foliage during autumn. The following are some of the most striking observed in several places in the neighbourhood of London during the past week. Although the effect created by the decaying leaves of many of our common trees is exceedingly charming, yet the golden-yellow and orange of the Elms, Poplars, and Horse Chestnuts cannot vie with the brilliant hues of the American Liquidambar, many of the American Oaks, and numbers of other exotic trees. For instance, where, even in the flora of all Europe, can a counterpart be found for the Persian Ironwood, *Parrotia persica* (see THE GARDEN, Oct. 5, p. 320)? The splendid colours of this Eastern tree are indescribably beautiful; deep green, scarlet, crimson, and deep orange-red combine to make a truly magnificent picture. As a wall plant this is much more satisfactory than when grown on the open lawn. The Silver-leaf Maple (*Acer dasycarpum*), which, on account of its rapid growth and beautiful foliage, is much planted as a shade tree in the United States, is one of the finest of deciduous trees; in early spring it is covered with myriads of reddish flowers; then its handsome leaves, green above, silvery-white below, turn in autumn to a golden yellow. The Red Maple (*Acer rubrum*), more compact in form and less rapid in growth than the preceding, is also at the present time very ornamental; in spring its deep red blossoms render it even more conspicuous and beautiful than the last-named. The Sugar Maple (*Acer saccharinum*) is one of the noblest of American trees, and is much valued, both for its wood and for the beauty of its form and foliage; in summer its leaves are a light green, but now a clear yellow. The South European *Acer platanoides* is also a most desirable deciduous tree, whose Sycamore-like leaves are now aglow with a pure, rich, golden-orange colour. The Tulip tree (*Liriodendron Tulipifera*) is one of the largest and most beautiful of North American trees; as an ornamental tree it is at any time hardly surpassed, but now that its foliage is suffused with a rich golden glow it is especially striking, a fine specimen making quite a feature in the landscape. *Corylus americana*, the New World representative of our common Hazel Nut, which it much resembles in leafage and habit, changes from green to rich purplish-red and crimson-scarlet, and is one of the most gaudy of autumnal shrubs. What a splendid effect could be obtained by a judiciously-planted group of this beautiful foreigner! *Amelanchier Botryapium*, a pretty white-flowering shrub, is now gay with orange-yellow and reddish-brown foliage. The scarlet-fruited Thorn (*Crataegus coccinea*), apart from its large, handsome fruit, has large leaves, now red and yellow. A variety of the Wild Thorn, of the Eastern United States, has enormous spines and bold foliage, which turns from dark green to a lovely combination of yellow and red. *C. pyrifolia* is another sort with splendidly-coloured leafage. The Hop Hornbeam or Ironwood (*Ostrya virginica*) is now clothed with rich brownish-yellow leaves. The Canoe or Paper Birch (*Betula papyracea*), a large and handsome tree, is in autumn a pyramid of golden-yellow; although it lacks the grace and elegance of some forms of the common Birch, its brilliant white bark—from which, in its native haunts, Indians and traders construct canoes, and which also forms the basis of a great variety of Indian fancy work—renders it very striking. The brilliant autumnal colours of the Sweet Gum (*Liquidambar styraciflua*) are too beautiful to be passed over without notice; rich orange-scarlet, crimson, and yellow give place in

some individuals to a dull purple, the long-stalked, star-like leaves, when well coloured, being especially handsome. The Purple Birch (*Betula purpurea*) becomes more and more purple as the season advances, although the dark, handsome foliage is sufficiently pronounced in colour, even in early spring. A new deciduous shrub, a variety of the Cornelian Cherry (*Cornus Mas*), which bears the varietal name of *aurea elegantissima*, is of rare beauty in the nurseries of Messrs. J. & C. Lee, the golden blotches of summer giving place at the present time to red of several shades. Another shrub in the same nursery, a golden variegated variety of the common Syringa (*Philadelphus coronarius*), is also worthy of special mention, its still living foliage being of the richest golden colour.

G.

NOTES AND QUESTIONS ON TREES AND SHRUBS.

Moving Trees without Balls of Earth.—Some have an idea that a tree cannot be moved successfully without a large ball of earth attached to it, but where there is not machinery sufficient for that purpose, failure in that case is often the result. My system is to begin at some distance from the base of the tree—rather farther, in fact, than is usually practised, and to comb the soil away from the roots, injuring them as little as possible. If a tree be gone properly round in this way, and the roots saved, one is often more certain of success than when trees are transplanted with large balls; such, at least, is my experience.—D. S. GILLET, *The Heath, Weybridge.*

The Pyramidal Oak.—This fine tree ought to be well known, and much planted, and yet it is not so. Can anyone say what it is that causes so little attention to be paid in England to any but the commoner kind of deciduous trees? This is an "old" tree, to use a nursery phrase, and yet we do not remember to have seen a really fine specimen of it about London. Yet it is a variety of British Oak with the habit of a Lombardy Poplar. In Vienna, in one afternoon, we met with a dozen good specimens of it, some of them as slender and as graceful, and as erect-growing as the Lombardy Poplar, others somewhat more pyramidal towards the lower part. This variety in form makes the tree all the more valuable for lawn or garden; and, as a tree with character for landscape planting, there exists nothing more valuable.—V.

Rapid Growth of a *Pinus insignis*.—About fifteen years ago I had a *Pinus insignis* planted on the lawn in front of my house. The plant was then about 5 ft. high. The situation is a sunny, sheltered one, in the south-east of Ireland, and the soil and climate are good. The plant has become now a tree of 48 ft. high, and measures 70 in. in circumference at 1 ft. from the ground. It is a beautiful object both in summer and winter. Except in the Tropics, I have never seen an instance of such rapid growth. Can any of your correspondents inform me if they have observed a similar case as regards this tree, and if they can tell if this beautiful and fast-growing Conifer is fit for general planting in the open ground; and also if the wood is of a good and useful quality?—P.

Bamboos at Tottenham.—The smaller kinds of Bamboo grow well at Tottenham in partially-sheltered places in deep, moist soil, and they form handsome objects during summer and autumn. In all cases it is best, if possible, to cover their roots with a thick layer of leaves during winter. Isolated specimens in front of shrubberies break up the formal edgings which they often possess, and with good effect. The kinds grown at Tottenham consist of *B. Simonsi*, and its variegated variety, *flexuosa*, *guadua*, *glaucescens*, *aurea*, *nigra*, *mitis*, *Furtunei*, *variegata*, and the broad-leaved variety known by the name of *Metake*.

Eucalyptus globulus.—Among the many notices of this Gum tree that have appeared recently I have seen none where the height equals that of a tree in the garden at Glencairn, one of the delightful residences in that lovely place Bournemouth. Though only four years have elapsed since it was taken from the flower-pot in which it was raised, it is now 36 ft. high, its circumference at 3 ft. from the ground being 15½ in. Whether *E. globulus* will succeed in England the first hard winter may determine. I am trying it in woods that are out periodically for pit timber and charcoal, with, I confess, little confidence as to the result. There are, however, other species of *Eucalyptus* which those who have seen them in the colder parts of the south assure me are much more hardy. Could any of your readers inform me which species is the hardiest, and where reliable seed can be obtained?—M. MCGRIDGE, 8, *Bina Gardens, South Kensington, S.W.*

NOTES OF THE WEEK.

Chamærops excelsa in Flower.—It may interest some of our readers who are lovers of this hardy Palm to know that one has blossomed this season on the Cotawold Hills, a locality in which it has been growing for the last five or six years without any protection, and it is now a most beautiful plant.—W. H. G.

The Rose-tinted Pampas Grass.—A group of seven fine plants of this in the Botanic Garden at Schönbrunn has lately looked very attractive from the number, vigour, and grace of the plumes. The plant is of great value for the sake of variety.

Tyerman's Groundsel (Senecio pulcher).—This fine hardy plant has been in bloom in the Tottenham Nurseries for many weeks past, but it has never been more beautiful than at present. Its flowers are even larger than we have ever seen them before, and they are remarkably bright in colour. Should no severe frosts occur, some of the plants will, in all probability, continue to flower until December.

Plumbago Larpentæ.—Though perfectly hardy this plant is well worth growing in pots for the conservatory. It flowers more freely in pots than in the open ground, and dwarf plants of it when in bloom are well adapted for forming an undergrowth for Palms, Ferns, or other tall-growing plants. We lately saw examples of it in 6-in. pots not more than 6 in. or 8 in. high, and full of blossom, the colour of which is unequalled in its way by perhaps any other plant at this time of the year.

The Virginian Creeper.—It is interesting to see the striking use frequently made of this common creeper abroad, in letting it fall in immense sheets over walls, banks, bridges, and the like. On each side of the Palace of Schönbrunn there is a private garden which is completely enclosed on the three outer sides by a high and roomy covered way of iron trellis-work. The whole of this in both gardens is completely sheeted with the Virginian Creeper—immense walls of rich and glowing colours. It was, indeed, the only thing in the great French garden there, or of what was seen from it, that deserved any praise.

Utricularia vulgaris.—This Bladder-wort is well adapted for growing in small aquaria either in the dwelling house or conservatory, or amongst other aquatic plants in greenhouse tanks. We lately saw it growing vigorously in a tank in the large conservatory at Pine-apple Place, where it has flowered freely. It is not often met with under such circumstances, but, being an interesting plant, it might be employed in that way with advantage.

Fortune's Saxifrage (Saxifraga Fortunei).—At this season, when there are but comparatively few hardy plants to attract attention, this Saxifrage is making a fine display, its large panicles of white blossoms rising in profusion from rosettes of dark green, roundish leaves. As it is not particular as to treatment, and, flowering, as it does, at this season, it is a very desirable plant. It is also perfectly amenable to pot culture, making a very attractive greenhouse plant, and for this purpose it should be planted out every alternate year, in order to regain vigorous growth, for if continually confined to a pot it produces but inferior panicles of flowers.—A.

Finely-flowered Dipladenias.—My gardener planted three plants (two of *D. Brearleyana* and one of *D. amabilis*, which were bought in 5-in. pots in July, 1877) in a narrow border in a stove in February, 1878, and trained them on wires near the glass. They began to bloom in May, and have ever since been a blaze of brilliant colour. From a calculation my gardener has made, he considers that each plant of *Brearleyana* has produced sixty-five bunches, and that each bunch averages nineteen flowers. This would give a total of 2470 blooms. The *amabilis* variety has not bloomed quite so freely. These flowers are most useful for cutting. On one occasion we decorated a mantlepiece with them and *Stephanotis* in a bed of Moss, the effect of which was very good. These lovely *Dipladenias* are, I think, well worthy of more extensive cultivation.—R. KELLY, *Kelly, Liffon, Devonshire.*

Plants in Flower at Tottenham.—*Schizanthus coccinea* is now finely in flower at Mr. Ware's nursery. Its spikes are large and well furnished with bright fully-developed blossoms. *Stokesia cyanea* is better this season than usual, and *Sternbergia lutea* is also very showy, as are also *Linnæum luteum*, several fine varieties of Poppy, and Monkshood. The Willow-leaved *Veronica* (*V. salicifolia*) is finely in flower in the shape of large spreading plants on rockwork, and the pretty *Amaryllis crispata* is flowering freely in the open air. The *Colchicum* are also well in flower, as are likewise *Lobelia fulgens*, *Senecio pulcher*, and specimen plants of *Yucca gloriosa*, the latter bearing noble spikes of bloom buds, which ought to be managed in such a way as to have them open at Christmas. Early-flowering

Chrysanthemums are still very showy, the best kinds now in bloom being *Adraastus*, bright magenta; *Chromatella*, golden-yellow; *Precocté*, sulphur; and a very small golden-yellow-flowered kind named *Button*, which is valuable for supplying out bloom. *Viola stricta alba* forms a striking contrast to crimson, blue, and yellow *Violas*, with which it is associated.

A Good Double Violet.—*Viola Blandyana* is the name given to a dark rich purple, double-flowered Violet growing in Messrs. Hooper & Co.'s nursery, Twickenham. The flowers are not large, but very pretty and deliciously fragrant, and they are produced plentifully at nearly all seasons of the year.

The Species of Fuchsia in the Flower Garden.—The species of *Fuchsia* with the ampler foliage and the larger flowers would seem to be very well adapted for flower gardening. At Schönbrunn they are used in this way and look well, the foliage being fresh and abundant and some flowers yet to be seen.

Plumbago capensis Out-of-doors.—I doubt if this *Plumbago* could be grown successfully as a pyramid or pillar plant in this country as it is at Vienna (p. 345) without taking it up for wintering; but for wall decoration I think it would form a valuable plant. The only season during which it would probably need protection is the spring, when late frosts might injure the young shoots. In well-drained and warm positions I feel sure that this *Plumbago* could be grown admirably.—W.

The Willow-leaved Speedwell (Veronica salicifolia).—In addition to this being one of the best of *Speedwells* for the adornment of the rock garden or shrubbery border in autumn, it also makes an excellent pot plant. Cuttings of it strike readily in spring or summer, and if grown on, and the shoots stopped once or twice, compact, bushy plants, well-furnished with whitish-coloured flowers, may be obtained during the winter months. We lately saw sturdy little plants of it in Covent Garden Market.

Poinciana pulcherrima.—This old-fashioned plant is now seldom seen out of botanic gardens, but it is one well worth growing for covering a wall in stoves or warm greenhouses. Its leaves are as handsome as those of *Reidia glaucescens*, to which they are somewhat similar. Its flowers, which are borne in terminal clusters, are of bright orange and scarlet, and very showy. We lately saw plants of it flowering in the Pine-apple Nursery.

Crotons at Holloway.—At no season of the year are *Crotons* more valuable than in autumn, when they have finished their growth and the leaves have assumed their rich and varied colours. Flowers, too, are then scarce, and fine foliage affords some compensation for their loss. *Crotons* now form one of the best features in Mr. Williams' nursery, Holloway. They range from small bushy plants snaped in pans, so as to bring them close to the glass, in order to improve their colour, to massive specimens of large size. The new *Prince of Wales* is a fine addition to this family of plants, as is also *C. Williamsi*, a kind just now being distributed. It is robust in habit, having leaves almost as large as those of *Magnolia grandiflora*; they are of a shining bronzy-green, with rich rosy-crimson markings; and, in the case of large specimens, they retain their colour down even to the base of the plant, a circumstance unusual with *Crotons*.

Polyanthuses and Pansies.—Owing to the mildness of the season, both *Polyanthuses* and *Pansies* seem to be blooming in unusual profusion. Of the former, some good examples have been sent to us by Mr. Caudwell, of Wantage, and of *Pansies* quite a large boxful of new and beautiful kinds has come from Mr. H. Hooper, of Widcombe Hill, Bath. Mr. Dean, of Bedford, has also sent us blooms of a fine dark blue *Pansy*, with a small yellow eye, called *Blue Beard*, stated to be an excellent sort for bedding purposes.

Pears at South Kensington.—The collection of forty dishes of Pears exhibited at South Kensington on October 15 by Mr. Goldsmith, The Gardens, Hollanden, Tonbridge, was remarkable for equality of size, symmetry, and general excellence. Conspicuous amongst the varieties shown were *Conseiller de la Cour*, *White Doyenné*, *Beurré Hardy*, *Triomphe de Jodoigne*, *Beurré de Anjou*, *Beurré Diel*, *Beurré Superfin*, and *Bonne d'Ézée*. For these a silver medal was awarded.

National Rose Society.—At a meeting of this Society, held on Tuesday, Oct. 15, the Rev. Canon Hole in the chair, the treasurer submitted his accounts, which showed a balance in favour of the Society. The dates for the exhibitions for 1879 were fixed (subject to the approval of the annual meeting), the first to be held at the Crystal Palace on June 28, the second at Manchester on July 14. It was also arranged that a paper of instructions on Rose growing should be drawn up and widely distributed. It was announced that the "Rosarians' Year Book" would be issued, as last year, independently of the Society.

NOTES FROM KEW.

Hardy Climbers.—Excepting the hardy Passion-flowers, by far the loveliest of wall plant now in flower is *Solanum jasminoides*, from Rio de Janeiro, its drooping clusters of blossoms—purplish when in bud, pure white when fully expanded—in the centre of each of which is a golden cone formed by the stamens, being very charming.

Hardy Herbaceous Plants.—Now that nearly all outside flowers have passed away, the few that remain possess additional interest. Amongst annuæ the first is *Impatiens amphorata*, a native of India, which was mentioned in "Notes from Kew" several weeks ago. This, now that *I. glandulifera* and many of its relations are quite over, is still a pretty object; it forms a neat, dense bush about 3 ft. high, and is thickly studded with its lovely flowers, the upper portion of which is pink and the lower canary yellow spotted with chocolate. *Salvia angustifolia*, a native of Mexico, merits special mention on account of it being such a late-blooming sort; it is a vigorous grower, of neat habit, and attains a height of about 3 ft. The lovely deep sky-blue and white flowers are borne in long spikes like those of *S. farinacea*. *Dracopcephalum speciosum*, about 2 ft. high, bears large blossoms of a somewhat dull purple ground colour, which is spotted with white and darker purple; this rare and interesting Labiate is found in a wild state on the Himalayas at elevations of from 12,000 ft. to 15,000 ft. *Erodium Manescavi*, with its magenta blossoms, is conspicuous at any time, but much the more so now that outside flowers are scarce; this pretty Crane's-bill is remarkable for its large and handsome flowers and its prolonged flowering season. *Abutilon Darwini*, a South Brazilian shrub, makes a fine object in the open border during the summer and autumn months; the broadly bell-shaped, drooping flowers (bright orange-red with blood-red veins) contrast well with the bold foliage.

Greenhouse Plants.—The different kinds of *Nerine*, a genus of South African Amaryllids, are greenhouse bulbs of easy culture and come in very usefully for autumn and winter-flowering. Among the finest at the present time are *N. flexuosa* with rather broad green leaves and a flower-stem about 2 ft. high, which bears an umbel of eight rose-coloured wavy blossoms; *N. pulchella*, which has larger flowers, also rose-coloured, but with a deeper band running down the centre of each of the six parts; *N. crispata*, which is a much less sort with prettily crisped flowers and narrow green leaves; *N. pudica*, which has narrow, glaucous, Grass-like leaves, and delicate blossoms—white, with a narrow, central band of rose in each of the six floral leaves—and *N. undulata* (with pink blossoms), which is a stronger grower, and has larger leaves than the last-named species. As a raffier or pillar plant for the greenhouse or cool conservatory, *Tecoma capensis*, from the Cape of Good Hope, is most suitable; the deep orange-scarlet blossoms studded among the pretty, pinnate leaves are very handsome. Another South African plant worthy of general cultivation for cool-house decoration is *Indigofera juncea*; its peculiar Rush-like branches bear at their extremities upright racemes of deep reddish blossoms. This plant is alike interesting for the beauty of its flowers and the peculiarity of its growth. *Oxalis variabilis*, a dwarf kind, not more than 2 in. or 3 in. in height, bears large, deep, rosy-red flowers, fully 1 in. in diameter. *Milla subbiflora*, a pretty little bulbous plant which does not exceed in size the *Oxalis* just named, has Grassy leaves and short flower-stalks bearing either one or two porcelain-blue flowers.

Stove Plants.—*Billbergia Liboniana* has green leaves and panicles of showy blossoms, the lower parts of which are a dark coral red, the upper a dark purple-blue. *Arundinaria Khaeyana*, although quite hardy, makes a most graceful and elegant decorative plant when cultivated in pots in the greenhouse or stove; the arching, plume-like shoots, densely clothed with emerald-green leaves, produce an effect totally dissimilar to that exhibited by any other plant.

Orchids.—*Epidendrum purum*, a native of Columbia, grows about 1½ ft. or 2 ft. high, and bears panicles—with long, drooping branches—of small, white, aromatic flowers, which, although individually insignificant, are collectively graceful and beautiful. *Lælia elegans*, with its dark crimson-purple lip, and very light red sepals and petals, is an attractive and handsome kind. *L. Ferrini*, another beautiful sort, has light rose-coloured sepals and petals, and a fringed, trumpet-shaped lip (rather less than that of the last-named), which at the apex is of a deep crimson-purple colour, but shades off at the base into pure white. *Cattleya maxima*, from Columbia, with its large, beautifully-mottled lip—in which crimson, red, purple, and orange-scarlet, shade off into and blend with each other—is one of the most showy and beautiful of epiphytal Orchids.—†.

Phlox Miss Robertson.—This is, in my opinion, the most beautiful of all the white Phloxes; it is so pure, and the pipes are of the finest form. Although classed as an early-blooming kind I have

it now in good bloom in the open ground, its lateness being the result of pinching the shoots in the summer, and thus inducing a late growth from the sides and base of the stems. Where there are several plants some might be allowed to flower naturally, and thus be stopped to secure an autumn bloom. Where there are any bloomless points these should now be put in as cuttings, and after the flowering wood has died down the plants may be lifted and divided. In spring also when the young growth is made the weaker growths may be taken off and cuttings made of them.—A. D.

Trichinium Mangleai.—This very beautiful member of the *Amaranth* family especially deserves a brief notice, as it is one of the most interesting greenhouse plants now in flower. It is not what may be termed a showy plant, but its numerous, small, deep rose-coloured blossoms nestling amongst clusters (about the size of a hen's egg) of dense white hairs, render it a very pleasing and attractive object for a long time. A compost of fibry loam and leaf-mould suits it perfectly, and it should be kept rather dry during winter. It is quite hardy enough for open-air culture provided it be placed on well-drained rockwork with a piece of glass in a slanting position placed over it during winter to protect it from too much moisture. It comes from Swan River, and is one of the numerous introductions of Mr. Thompson, of Ipswich.—W.

Violette in Autumn.—Perhaps "J. G." (p. 345) will be surprised to learn that I have always gathered Violets nine months out of the twelve, and sometimes ten, but I rather doubt whether that can be done in England, owing to its not having a humid atmosphere like that of Wales or Scotland. My plan was to have Violets here and there wherever I had a warm corner to spare in which to plant them. They consisted of the old Russian variety and the Czar, and I also had the last-named variety and the Neapolitan in a frame. Now is a good time to plant these in frames. They should be put into good light loam, syringed, and kept close for a few days; then get them inured by degrees to plenty of light and air, and leave the lights off all night when the weather is mild; cut off all runners, and do not disturb the ball more than is possible. I used to make two or three plantings in spring. I generally began in March on a south border; these got established before the hot weather set in, and came into flower first. The late planting I put on a north-east border to take up in the autumn to put in the frames.—T. ELCOMB, *Aquarium Terrace, Crystal Palace.*

Pelargonium-leaved Erodium (*E. pelargonifolium*).—This exquisite little plant, which is one of the most beautiful of a rather large genus, is seldom met with in collections, yet its merits entitle it to rank amongst the most select of hardy plants. In foliage it much resembles some of the better known kinds, the leaves being heart-shaped and crisped at the edges and produced in a tuft, from the axils of which spring the slender flower stalks from 6 in. to 9 in. long and bearing in an umbellate manner several blossoms about ¼ in. across; the three lower petals are pure white, the two upper ones blotched, and delicately pencilled with purple, and edged with white. It bears a continuous crop of flowers throughout the summer and autumn. Being rather tender and impatient of excessive moisture during winter, it should be grown on rockwork well drained amongst other small-growing kinds, and it is advisable to put a layer of broken sandstone around the neck of the plant as a protection from the dampness of the soil. It is, I believe, a native of Southern Europe, and an excellent figure of it was given in Regel's "Gartenflora" in 1852.—W.

Gaultheria procumbens.—How seldom one meets with this charming little shrub among hardy plants, and yet it is a real gem. A neighbour of mine, who has a most interesting garden of hardy plants, grows this pretty *Gaultheria* well; he has it planted out in one of his beds in a full exposure, but with a flat stone placed upright next to it on the sunny side. This, without shutting out the sunlight from the foliage, serves to keep it from striking directly on the roots; it is always cool there, and it blossoms freely and produces its berries well. It is planted out in sandy peat. I have a good plant of it in a 7-in. pot that is now very attractive by reason of its drooping white flowers, the rich red of its berries, which hang on for a considerable time, and the striking claret colour of its young leaves. I tried it with greenhouse culture, but the flowers dropped, and berries did not follow; but since I have kept it out-of-doors during the summer, it has matured its berries, and is now the pretty decorative object which I have represented it to be.—D.

Melanthium triquetrum.—This is the name of a bulbous-rooted plant, little known to cultivation, now blooming with Mr. Ware. It has long, round leaves, like those of some of the *Alliums*, and its flowers, which are small and have delicate mauve petals and a purple centre, are very pretty, and are produced on spikes from 5 in. to 6 in. long. It is a half-hardy plant, and well worth culture in pots in a cool greenhouse.—S.

THE FLOWER GARDEN.

HOLBOELLIA (STAUNTONIA) LATIFOLIA.

THE genus *Holboellia* with the allied genera *Stauntonia*, *Akebia*, *Lardizabala*, and two or three other small ones constitute an order or sub-order of shrubby-climbing plants remarkable rather for the elegance of their foliage than for the splendour of their flowers. Two or three of the genera *Lardizabala* and *Boquila*, comprising three species, inhabit Chili, whilst the others are from the mountains of Northern India, China, and Japan. All the members of this group hitherto introduced are hardy in the southern or south-western counties of England and Ireland and along the western coast of Great Britain, but in other parts they should be treated as cool greenhouse plants. Several of them, as *Holboellia latifolia*,

Holboellia (Stauntonia) latifolia.

Stauntonia hexaphylla, and *Lardizabala biternata*, are very rampant climbers, quickly covering large spaces. The accompanying engraving represents a very much reduced branch of *Holboellia latifolia*, and a portion of a cluster of flowers of the natural size. This plant, which has a wide range of distribution in the Khasia and Himalaya Mountains, was introduced into this country many years ago. Dr. Lindley gave a coloured figure of it in the "Botanical Register" in 1846 from a plant which flowered "perhaps for the first time in Europe," on a south wall in the garden of Mr. L. W. Dillwyn, at Sketty Hall, near Swansea. It flowered in March, and had received no protection beyond that afforded by the wall. It still exists, especially in some gardens in the south-west, as it is occasionally sent to us to name, but, like some of its allies, it is not a favourite indoors, where it grows too vigorously and rarely flowers. In its native country it inhabits the mountain woods from an altitude of 4000 ft. up to 9000 ft., and is exceedingly variable in the size, configuration, and number of leaflets forming the leaves, as well as in the tinge of the flowers, which

are green, nearly white, or more or less tinged with purplish-red. Most of these differences are, doubtless, due to the altitude and situation in which the plant grows, whereas others may be ascribed to the age and degree of vigour. The stem sometimes attains a diameter of 4 in. to 6 in. and the leaves have from three to nine leaflets. In the branch here figured they vary from three to five. Two distinct varieties are distinguished in Hooker's "Flora of British India," namely, *H. latifolia*, having three to five ovate or oblong leaflets, and *H. angustifolia*, having seven to nine narrow leaflets. Lindley and Paxton, "Flower Garden," plate 45, figure under the name of *H. acuminata* a variety with abruptly-pointed leaves and purple-tinged flowers. The young pistil usually consists of three (four are shown in the figure) carpels, of which often only one or two attain maturity. When ripe they are fleshy, oblong berries 2 in. to 4 in. long. The fruit, which is figured in THE GARDEN (Vol. VIII., p. 543), is not exactly luscious; but it is eaten by the natives of Nepal. *Holboellia latifolia* is perhaps better known in gardens under the name of *Stauntonia latifolia*, but it differs from the true *Stauntonias* in the stamens being free from each other, and in having six minute petals within the six sepals; the latter only are shown in the figure. It should be mentioned, however, that after the name *Holboellia* had been given to these woody climbers, the author, Dr. Wallich, thought they were not sufficiently distinct to form a genus separate from *Stauntonia*, and accordingly applied the same name to a very singular genus of Grasses. This genus, now renamed *Lopholepis*, consists of a single species, figured in Hooker's "Botanical Miscellany," vol. ii., plate 76, as *Holboellia ornithocephala*. This name has got into some gardening works as a congener of our plant. Respecting the merits of *Holboellia latifolia*, it has been described as one of the best hardy evergreen shrubs in Devonshire, where it succeeds well on walls of any aspect. It soon covers large spaces, making annual shoots 10 ft. to 12 ft. in length. Old plants flower profusely out-of-doors, as various writers testify, and, although the flowers are of a dull colour, they are highly fragrant; indeed, it has been asserted that their perfume is superior to that of the Orange blossom.

W. B. HEMSLEY.

BEST WAY OF WINTERING TUBERS AND BULBS.

THE winter treatment of these depends much on circumstances, especially as regards soil and situation, for although it would be perfectly safe to leave out such plants as *Salvia patens* and choice *Gladioli* in some places, to do so in others would be almost sure to lead to their destruction. This would be the case in cold, wet land, as there the fleshy roots decay and conduct the rot to the base of the bulbs or tubers, and once they begin to go in this way they are not long in losing their vitality altogether. It is not so much the action of frost or cold, as it is a well-known fact that one of the tenderest tubers of all, the Potato, will live if buried only a few inches deep, but then its nature is such that it does not absorb moisture in the way other tubers do; hence its immunity from the ills to which they are liable if left out under similar circumstances. There can be no question that where bulbs and tubers can be kept with safety in the ground the whole year round they are far better and stronger in the spring than those that are lifted, as however well they may be stored, they will in a measure become more or less shrivelled; whereas if left where they grow, their weight and size would rather increase than diminish. Nothing shows this more strikingly than *Gladioli*, the corms of which are not generally half so large and plump at the time of planting as they are when taken up; and it must be obvious that what they have lost is so much strength gone, and therefore the flowering spike cannot come so fine as it otherwise would do. Having a very light, dry soil to deal with, I never hesitate to leave such *Gladioli* as I have out for the winter, except it may be any fresh choice varieties that I do not like to run any risk with, and I always find that they are in every respect much superior to what they were when they were dug up and stored. This is not to be wondered at, as they are altogether under more natural conditions; but there is one thing which I find much in their favour at the time of planting that should not be omitted, and that is to scatter some

clean-washed sand about them so as to keep the soil from coming in immediate contact with them. If this be done it counteracts any tendency to decay by insuring free drainage, to aid which the beds or positions where they are grown should be deeply trenched or broken up and have plenty of leaf-mould or other decomposed vegetable matter worked into them. Treated in this way and planted in a sunny aspect, *Tritonia aurea* does remarkably well, and comes with fresh, healthy-looking green leaves free from red spider, an insect that always sadly disfigures it when grown in a pot in a house. This beautiful free-flowering plant is generally considered tender, but planted out in a border and protected a little during the winter it will endure any amount of cold, and supply bloom in abundance for cutting. *Ixia*, than which there is not a more lovely class of plants in existence, may be grown in the same way, but to do these well the border, which ought to be under a south wall, should be well drained and specially prepared by having plenty of sharp sand and light mould added, after which, all that is necessary is to keep out severe frost by strewing a few inches of sifted leaf-soil over the surface. This will lie close, and is one of the best non-conductors that can be used; besides which, it is so neat as a top-dressing that its appearance cannot be objected to. A little heap of it placed over the crowns of any bulbs, or around the collars of any plants of doubtful hardiness forms a fine protection to them, and a store of it should always be kept for use for that purpose at this time of year. As regards *Dahlia*s, the only way to insure their safety is to take them up immediately frost kills down their tops, and lay them in any shed where the tubers can be covered over with dry soil. To leave them without this for the air to act on them produces the evil results already referred to, and yet one often sees them hung up and subjected to the desiccating influence of the atmosphere. In the case of bulbs and other tubers that have to be taken up from soils that are stiff and heavy, the best way of wintering them is in paper bags or in small boxes of dry sand in a room or shed, where frost can be excluded without the use of fire or other means of warming it. So favoured, they gradually form roots and start steadily in the spring, much in the way they do in the open ground, but the planting requires to be carefully done, in order that they may not be injured. For years I have had *Salvia patens* out in winter, and very fine, when fully established, it is, many being quite bushes, with stems 3 ft. high. Such masses of rich blue flowers have a grand effect.

S. D.

— As regards bulbs of *Gladioli*, they will, doubtless, winter safely in the ground, as I have found that many of the commoner kinds live throughout the winter scarcely covered with soil at all. My impression is, that lifting *Gladioli* and storing them in dry boxes has nothing but custom to recommend it. That they withstand such treatment and grow after it is rather a proof of their amount of vitality than of their being benefited by it. Roots like those of the *Canna* or *Indian Shot* left out in beds all winter protected by external coverings grow perfectly well, and they are surely as tender as *Dahlia*s or *Gladioli*. The fact is, we have killed many plants with kindness, and weakened the constitution of many more by excess of heat at all seasons of the year. It is asked (p. 331) why *Bouvardia*s are not available for open-air decoration, and the advice given in the "Gardeners' Assistant" as to this plant needing a high stove temperature is quoted. Yet we all know that this plant is grown in cold frames and even in the open air, and sent to market in quantity in finer condition than it ever attains in our stoves. This is only one of the numerous examples of how we cling to old practices. J. GROOM.

UTILISATION OF THE CLEMATIS.

MANY attempts have been made to induce the showy hybrids of *C. Jackmanni* to conform to the strict formality required in the flower garden, and though now and then a good group has been met with, yet the adaptation has not always been a success, and unless they could be used in combination with something else, the short period of their duration will be a bar to their employment in any design requiring a fair amount of durability as regards effectiveness. But though the *Clematis* is not exactly adapted for the geometrical flower garden, it is eminently suited for an isolated group, and it is always

at home when rambling over a rustic arch, an old tree stump, or hanging over the precipitous sides of some rocky cliff. *Clematises* in any or all forms, too, are good wall plants, especially when used in connection with something of an evergreen character, like some of the less robust-growing species of *Ivy*. When used for clothing rustic arches they should not be too much or too closely trained. Early attention must be given, or the shoots will get into inextricable confusion, but once get the space fairly covered, then allow the ends of the shoots to festoon in graceful tresses, and the effect will be better than if too closely trained. *Clematises* are best pruned close back for two or three years after planting; it strengthens the base and induces the production of long, vigorous growths. This pruning should be done in spring just before growth begins. Although a great improvement has undoubtedly been effected by cultivation in this family, it has, up to the present time, been mainly in one direction only. The early-flowering species, such as *C. montana*, have not yet, it appears, attracted the attention of the hybridist, or if they have, but little headway has been made. If, however, it were possible of attainment, it would be very desirable to possess a variety of *montana*, with its early, free-flowering habit, and with mauve, blue, or purple-coloured flowers. This species is one of the most vigorous of growers; it often has stems thicker than one's arm, and branches many ft. in length. It will quickly clothe a very large space, and it is not particular as to soil or site; but, like all *Clematises*, it should have a well-drained situation. I once saw an outbuilding completely enveloped by this species, and when in flower in April and May it looked like a huge mound of snow, so densely was it covered with pure white flowers.

The introduction of the new hybrids has led to their cultivation in pots, and as they yield readily to that mode of culture, a new and interesting feature can be brought to bear in beautifying the cool greenhouse or conservatory, and the colours of the new large-flowered varieties come purer and brighter under glass than in the open air. They also do well planted out in the border, and trained up the rafters or on the back wall. A collection, embracing the different colours, planted in an unheated colonnade would also attract attention and arouse interest anywhere, more so, I think, than if grown in pots. *C. Flammula*, one of the earliest introduced species, is still to many the most delightful. It flowers in the autumn, and though its blossoms are small, there is ample compensation in their delicious sweetness and the profusion in which they are borne. As a wall plant or for covering arches its usefulness and beauty are well known and appreciated, and few plants make better single specimens for the lawn when supported by something slight and inconspicuous, and at the same time strong enough to resist the force of the wind. It should be allowed in the matter of growth to have pretty much its own way. Like our own British Traveller's Joy (*C. Vitalba*) when the flowering is over it is not altogether short of its beauty, for the long feathery styles of the ripe carpels have a singular and charming effect. I saw a short time ago a very handsome specimen on the lawn at Hewell Grange, in Worcestershire. It was supported by a light iron umbrella-shaped trainer, which it had completely covered and overhung on all sides, producing a charmingly fresh and graceful effect.

E. HODDAY.

TRANSPLANTING LILIES AND LILIES IN POTS.

MR. UPHILL'S answer (p. 354) to my query (p. 305) makes the task of replying comparatively easy, though, unfortunately, he does not specify the kinds of *Lilies* he is cultivating. The early part of November is a great deal too late for transplanting the general run of *Lilies*. In my paper (p. 303) I have said: "During this last season I have lifted and replanted all my collection as the different kinds went out of bloom." In the case of *L. speciosum* and *L. aratum* I did not even wait until the fading flowers had all fallen so much value do I place on the new bulbs being allowed to continue their growth without the chance of a serious check. Believers in the perennial theory will not be able to comprehend this, though those who believe in the successional bulb system will understand my meaning at once. There is no doubt but what the "dozen bulbs" mentioned by Mr. Uphill as having made no signs of life above ground must have met with a serious check by their having been lifted and replanted so late as December. In such cases there is to me nothing new. The original roots and scales too would, of course, be gone, though he might not have noticed this; and so will the succession bulbs if something be not done to save them. But this, I trust, Mr. Uphill has already done, namely, lifting and giving them a sufficiency of fresh, nourishing food. In answer to "A Lover of *Lilies*" I would say: Do not leave your *Lilies* in the same pots, but shift them at once (if not done already) into new ones, giving them an entirely new supply of fresh congeal soil. The "size" of the pots is often a matter of convenience, but, as respects the bulbs, the pots may be

too small, but they cannot be too large, nor can the food be too large in quantity, for it is the peculiar nature of *Lilias* to be very greedy feeders. As to the "soil in which to pot them," Lily growers differ greatly. But, taking into consideration the nature of the roots and the new bulb itself, I know of no better soil for *L. auratum* and *speciosum*—both for pots and the open ground—than pure sandy, friable peat. This kind of soil is peculiarly adapted for the lower fibrous roots which, by the aid of the microscope, may be seen to be literally covered with minute hairs which absorb a great deal of sap for the supply of the bulb. As to "cutting down the stems," so soon as the plants go out of bloom I cut down the stems to within 2 in. or 3 in. of the soil, just leaving sufficient to form a handle in transplanting. This I would do in the case of all kinds of *Lilies* in pots as well as in the open ground; my reasons, I think, I have given somewhat fully in recent papers. "A Lover of *Lilies*" has certainly not treated his *L. auratum* as he should have done; but I am glad to see that he is already convinced that he was wrong. He should not have allowed the stem to wither away. This is, I admit, a very common custom; but it is a very reprehensible one. He should have cut down the stem as soon as the plant went out of bloom, re-potting it, and then the pot might have been placed on a spare shelf, and the soil kept moist; for, remember that some part of the successional bulb is, or should be, always growing. The stems of the successional bulbs may increase in size, and so may the bloom, but this will depend entirely on culture; as, on the other hand, a want of proper attention may cause them to decrease, and, in fact, may cause the loss of the bulbs entirely. As to increasing plants of *L. auratum* and *speciosum*, this may be done by picking off any offsets that may appear when re-potting and replanting them in pots, or in some spare place in a warm border. A fruitful source of injury to the successional bulbs is the "stem roots," which some actually encourage by top-dressing and heaping up the soil around the lower part of the stems. These stem roots are some of them of great length; they go down, and not only impoverish the soil, but they twine themselves in and out among the scales, suck out the sap, and destroy the bulbs for the next season's bloom. Rose growers wage war against suckers coming up; Lily growers should wage war against suckers going down. Every now and then remove the soil for 1 in. or 2 in. deep, and then carefully clip off every vestige of a stem root, returning the soil again. A professional writer says, "As the flower stems advance in growth, they put forth a number of young roots from the stem above the bulb; when that is perceived, place round each stem some rough, hard pieces of manure for these roots to strike into; this will encourage the flower stems to grow strongly and flower firmly, besides increasing very much the size of the bulbs below." Worst advice than this it is difficult even to imagine.

— Will you allow me to correct an error in my note on transplanting *Lilias* (p. 332)? "They should be moved when *not at rest*" is a misprint for *most at rest*.—GEO. F. WILSON, *Heatherbank, Weybridge Heath*.

WINTERING PELARGONIUMS.

THE plan we adopt here for wintering all young stock of *Pelargoniums*, and it is one I can strongly recommend, is to put three cuttings triangularly around the sides of a 3-in. pot, in which they are propagated in August. It is not the quantity that has to be particularly considered, as one good plant will do more towards filling a bed and making a display than two or three poor ones, and in wintering them in the above-named way they can easily have a little more space afforded them in the spring by setting the pots further apart, whereas in boxes they must remain thick as they are till they can be singled out separately, and to do this much room under glass is required. For all purposes of bedding, one-year-old plants are preferable, and it is surprising what a quantity of these may be kept packed away in boxes such as your correspondent "J. G." describes (p. 322). In order, however, to preserve them from damping off, they should, if possible, be taken up before they are injured by frost and then cut hard back, leaving only a joint or so to a shoot, and the roots may likewise be shortened considerably. This done, the next thing is to pack them in rows across the box, and fill in amongst them with light sandy soil as the work proceeds, after which they should have some water to settle the earth about them, and then be set on light, airy shelves or other similar positions near the glass. There they will gradually break, but having so little foliage, they will not require water beyond what is necessary to keep them from shrivelling up, as the drier they are kept during the winter the better. In spring if pots and room be not over plentiful, a good way of treating such plants as these, or young stock either, is to take a handful of soil and a piece of Moss and tie their roots up in it, when they may be plunged in leaf mould in any spare frame till the time arrives for turning them out in their summer quarters. Managed

in this manner, it has a restricting influence on their growth, and causes them to flower with remarkable freedom, very different from what they do when their roots have full liberty to ramble wherever they will. Plunging them in pots has a similar effect, and such plants come in admirably for vases or for similar purposes the following year.

S. D.

BOG PLANTS IN BOTANIC GARDENS.

THE best way we have seen for growing the various running-rooted and rapidly-growing bog plants is in the Botanic Garden at Munich. The question is of some importance for others than curators of botanic gardens, for the culture of bog plants has of late years had some more attention paid to it in private gardens. No plants are more interesting among hardy flowers than various species that bloom in bog or marsh land. To cite a few of those in cultivation, we may mention *Rhexia virginica*, *Calla palustris*, *Cypripedium spectabile*, the commoner and hardiest *Sarracenia* (*S. purpurea*), *Helonias bullata*, the Bird's-eye Primrose, the various Butterworts, and a number of others, many of which are not in cultivation. If one tries a number of these in a well-made artificial or any other bog, the probability is that they will very soon be overrun or injured by rampant Sedges, or some of the many too vigorous bog and waterside plants (planted in a moment of weakness, or that have been introduced in the bog earth). These destroy any kind of success or pleasure with a bog garden, as even Bindweed is easy to eradicate compared with them. And yet some of these plants are very ornamental and singular, as, for example, the taller and larger species of *Scirpus*, such as *S. Rothii*, *Cyperus longus*, and various kinds of *Carex*. In the Munich Garden these are arranged, so as to be out of harm's way, in long cemented canals, so to say, nearly 18 in. across. There are divisions somewhat below the water line for each species, a length of 4 ft. or 5 ft. being allowed it. These little canals are sunk in the earth, and run between beds of hardy plants about 7 ft. wide, the small canals forming, so to say, an "alley" between the beds. So arranged, a great variety of marsh plants are grown better than we have ever seen them before. Each species is kept distinct, and cannot easily overrun or exterminate its neighbour, while every part of the plants can be easily seen by the student or the cultivator. A little way off one scarcely noticed the cemented canals, owing to the way in which they were placed between the beds.—V.

MENTZELIA ORNATA AND OTHER SPECIES.

"V." ASKS (p. 332) for information respecting the culture of this lovely biennial. As far as my experience goes I find it necessary to sow the seed as early in the season as possible, and to grow the seedlings on in a frame, giving liberal shifts, using a compost of fibry loam and a small quantity of leaf mould and sand. After the final shift they should be plunged in a sunny border until autumn, when they should be removed to a frame for wintering. In the spring they should be again plunged in the open air, and by assisting them with weak manure water occasionally strong and healthy flowering specimens will be the result. When beginning to show flower they should be removed to a cool greenhouse or frame, as excessive humidity at this stage is injurious to them. The large size and beauty of the flowers amply repay the extra attention they require, though they may be grown entirely in the open air, and with good results if the weather be favourable, yet in our climate the former mode is by far the most satisfactory. The following is a selection of the most showy of those that are at present in cultivation. With regard to the others the flowers are rather small, and, on the whole, scarcely worth the trouble of cultivating.

Elegant *Mentzelia* (*M. ornata*) is a biennial, growing from 2 ft. to 4 ft. in height, of a branching habit, with leaves 4 in. to 6 in. long, irregularly lobed almost to the midrib, and are, with the branches also, covered with numerous barbed hairs. The flowers are borne singly at the apex of the branches, and are from 2½ in. to 4 in. across, composed of ten petals, the inner five being rather smaller. The colour is a creamy-white, and they are also fragrant. It belongs to the vespertine section of the genus, or those in which the flowers fully expand only towards evening. It is found growing in clayey soil on the banks of the Missouri and other places, and, though long known to science, is not as yet very common in cultivation, but should be sought after by every lover of plants.

Naked-stemmed *Mentzelia* (*M. nuda*) is also a biennial, 2 ft. to 4 ft. high, with foliage much resembling the preceding, but with

scarcely any hairs on them or the stems. The flowers much resemble those of the last both in size and colour, and expand about the same time in the day. It is a native of the gravelly hills in Oregon, extending to California.

Smooth-stemmed Mentzelia (*M. levicaulis*) is another fine kind, with whitish stems 1 ft. to 3 ft. in height, and with leaves much resembling the last, both covered with short and stout bristles. The flowers terminate the branches and are about the same size as the preceding, but are of a rich, deep yellow colour, and unlike them also in only opening in bright sunshine. It is of biennial duration, flowering in June and July in the second season after sowing. It is a native of Oregon and California.

Few-seeded Mentzelia (*M. oligosperma*) is a perennial growing from 1 ft. to 3 ft. high, with oblong and toothed leaves; flowers terminating the branches, about 3 in. across, of a bright yellow colour, and opening in sunshine. It flowers annually from May to July. It is found in rocky places on the banks of the Missouri, and also in the prairies and plains.

The mode of treatment, recommended for *M. ornata*, is applicable to all the others, except the last-named, which, being a perennial and flowering early, should be grown on well-drained portions of the rougher parts of a rockery, and in severe weather should be afforded a layer of mulching on the surface of the soil. Of course, in some favoured localities, where they are generally free from excessive humidity in autumn, the others may be grown and flowered under similar treatment, but that is the least satisfactory mode of treating them. W.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

Pelargoniums Grouped.—The sight of these plants in rings and lines is so familiar, that a little mass of plants of a scarlet kind, forming in a public garden at Vienna an irregular and small group on the Grass in a green nook, surrounded by trees and shrubs, deserves a note of commendation. The effect was such as any one could enjoy; the brilliancy afforded by only five plants was intensified by the verdure of the Grass and evergreens, and there was no geometrical twirling to divert attention from the essentials of the little picture—the plants.—V.

Early Primroses.—We have already quite a display of the hardy double white Primrose, and it is greatly prized for its purity and sweetness. Where no heated structure exists for furnishing out flowers during the winter, such plants as this should receive a little protection, as they fill a void that would otherwise occur, and that, too, when flowers are most appreciated.—JAMES GROOM, *Linton Park, Maidstone.*

Cyclamens Planted Out.—Cyclamens, though ordinarily grown in pots, thrive best when planted out. We are now lifting a quantity of them, just producing a dense mass of flower, that have been planted out in frames where a temporary protection could be given them during extreme changes of temperature. One of the reasons why Cyclamens planted out start with greater vigour than those in pots is that they never get so excessively dry as those in pots often do. An ordinary flower-pot offers but poor protection against a scorching sun, unless it is plunged in some non-conducting material.—J. GROOM.

Earliness of the Chrysanthemum.—I have a large bed of Mrs. George Rundle Chrysanthemum now in good flower, and should the weather remain open it will be fully in bloom by the last of the month. I had purposed lifting them to flower under glass, but they are ready before I am, and, farther, are blooming far too early, as flowers in December are more valuable than now. These plants have not been pinched, and their present state indicates exactly natural growth. No doubt I ought to have pinched them early, but Mrs. G. Rundle flowers so freely from the side shoots that it does not need stopping, except to ensure very late flowers. Should the weather hold open and dry the bloom will be as good outside as under cover.—A. D.

Fuchsias amongst Ivy.—The objections raised by Mr. Smith, Newry (p. 346), against carpeting a bed of Fuchsias with Ivy seem to me to be unsatisfactory. The very purpose of my proposal (p. 321) was to afford the stools of the Fuchsias during winter the natural protection which a covering of Ivy would give, and Mr. Smith seems to forget that the very essence of outdoor Fuchsia culture lies in giving the plants where they stand such protection in hard weather as shall enable them to be permanent deciduous shrubs, and not birds of passage flitting from house to bed and from bed to

the house as the season changed. There are thousands of examples of successful permanent Fuchsia growth about the country, and Mr. Downie has told us of miles of permanent plants of Riccartoni on the west coast of Scotland, but there are plenty of such nearer home that are cut back every winter, and, starting again, make fine bushes several feet in diameter during the summer. What Riccartoni will do others of a free-growing character will doubtless do also if encouraged. In planting a bed of Fuchsias as previously suggested, it does not follow that the Ivy should be so thick as to prevent the application of liquid manure or water if required, but as the thickest coating is needed around the stools during winter, it is evident that the Ivy could be cut away all around the Fuchsias in the spring, the soil be forked up and manure given. The Ivy would of course cover the soil again during the summer, but not to root into it to any considerable extent. There need be little difficulty about the plan if done with good will and with an anxious desire to make it successful. Whilst so much energy and labour can be expended in the planting and care of carpet beds that last only for a short season, it is not too much to ask for just a little attention to be paid to my proposed Fuchsia bed.—A. D.

I cannot quite coincide with the opinion expressed by Mr. Smith regarding Fuchsias amongst Ivy. According to what I have seen of the hardy Fuchsias, they appear to be able to thrive under circumstances to which most other flowering plants would succumb. There is no doubt that Fuchsias enjoy liberal treatment; but I have, at the same time, observed them flourishing amongst trees and shrubs, where both moisture and nutriment were at a minimum. With respect to their association with Ivy, an instance came under my notice of a plant that flowered well every year, springing up each season from amongst the Ivy with additional vigour, and not a particle of manure of any description was ever given to it. I believe that the better way would be to grow the Fuchsias liberally for a season, getting them well established, and then plant the Ivy; the Fuchsias would, by that time, hold their own. At any rate, it is an experiment well worth trying.—J. CORNHILL, *Byfleet.*

Florists' Varieties of Fuchsias for Open-air Culture.—Some of your correspondents have directed attention to the value of the florist's varieties of the Fuchsia for open air decoration, a purpose for which, though but seldom employed, they are eminently suited. Long as we have possessed the Fuchsia in many and variable forms of colour and growth, its capabilities in this way appear never to have been generally recognised. Probably our eagerness for close-growing, dwarf, flowering subjects has had something to do with the matter. The Fuchsia is just one of those plants that cannot well be made to fit into geometrical designs; it has a free natural growth of its own, which will not admit of much restraint. It has, therefore, been in a great measure banished from our pleasure grounds. When we take delight in seeing plants develop themselves as Nature intended them to do, we shall then fully prize the good properties which Fuchsias possess when allowed the privilege of a free, unrestricted root run. Those who have hitherto grown Fuchsias in pots can only form but a slight idea of the luxuriance and flowering capabilities which they exhibit when planted in rich soil. When it is intended to form a bed of them, or to plant them in isolated positions amongst shrubs, the soil should be well prepared, as the more nourishment the finer the growth will be. They should be planted out early and kept well watered, otherwise they fail in freedom of growth. If protected in winter they will during the next and succeeding seasons spring up with renewed vigour, and towards the autumn, when zonal Pelargoniums are beginning to look shabby, the Fuchsias will be fresh, bright, and handsome. Many growers of the Fuchsia are loth to discard their old pot-bound plants; but by planting them out they have the satisfaction of still possessing them, and at the same time make room for young thrifty specimens, which, for pot culture, are better than the old, worn-out plants.—JOHN CORNHILL.

Lychnis coronata grandiflora.—I have only met with two plants of this in my lifetime; the last one which I saw was in a botanic garden. In both cases the plants died, and, this being so, I should imagine that it is a difficult plant to manage, especially when young—a fact which may account for its scarcity. "K. L. D." (p. 345) may well be proud of her plant, and feel assured that the flower is the proper colour, as most of the plates in the "Botanical Magazine," in which scarlet, red, or orange enters, seem through age to have undergone some chemical change, and notably so in the figure of the scarlet Lychnis.—THOS. WILLIAMS, *Ormskirk.*

Plumbago capensis in Paris Parks and Gardens.—During a recent visit to Paris I was much struck with this plant as used in the Paris parks and gardens. To my mind, no other plant was so effective or gave such an air of refinement and grace to its surroundings as this did. A large elongated bed in the Parc Monceau

was entirely filled with it. The plants, too, grow away most vigorously, being 5 ft. to 6 ft. in height, and bushy in proportion, and they were producing such clusters of flowers as are never seen in conservatories. Evidently it is one of the best bedding plants for that climate, as one meets with it in every direction. I do not remember to have seen it used at home in this way, but it was altogether so charming that I intend growing on the Paris fashion in my bedding arrangements next year, for though one cannot expect it to do as well in our climate, it was so good there that if it only does half as well with me I shall be quite satisfied.—W. W. H.

GIANT COCKSCOMB.

SUBJOINED is an exact portrait of the gigantic Cockscomb sent to us the other day by Messrs. Carter & Co., of High Holborn. The comb measured 3 ft. 2 in. lengthwise, and in the thickest part 1 ft. 4 in. across. The leaves were large and

Cockscomb 3 ft. 2 in. by 1 ft. 4 in.

healthy, and the comb itself of the richest velvety crimson, very double and highly ornamental. It is called the Empress Cockscomb.

FLORAL DECORATION IN CHURCHES.

(HARVEST THANKSGIVINGS.)

SOME years back churches were seldom decorated, except at Christmas, but now it has become customary to decorate them at Easter, and also during harvest thanksgivings. A pretty example of this style of decoration was observable in St. John's Church, Upper Norwood, on October 13, where a service of the above description was held on that date. The decorations were not very extensive, being confined to the chancel and font, but they were very chaste in design, and a description of them may prove useful hereafter to those who are interested in such work. Round the base of the font, which is of stone, were grouped pot plants, and behind these rose a few stems of Asparagus, which were very light and feathery-looking. On a ledge above the plants lay different kinds of harvest produce, not even forgetting Mushrooms, and round the edge of the basin was a heap of

Moss, reposing on which were blooms of Eucharis, white Asters, and other white flowers. Out of the centre of the basin rose a graceful Palm, and round the hedge were hung bunches of Grapes and Vine leaves, and one long spray of Passion-flower in fruit drooped over and was twined round the pillar of the font with good effect. The Passion-flower is a most useful plant for decorative purposes, being equally effective in bloom and in fruit. The chief decoration of the pulpit consisted of long Fern fronds and a few blooms of Eucharis. Across the chancel, dividing it from the body of the church, was a pretty little screen in the form of Gothic arches made of Pampas Grass springing from a prettily decorated base. From the highest part of each arch hung a bunch of Grapes; along the top ran a fine wreath of berried foliage, and in the little triangles formed by the arches and wreaths along the top were stars of crimson and brown-tinted leaves, which showed up well against the dark green background. The choir stalls and reading desks were decorated as follows: Over the front of the stalls was draped a piece of crimson cloth about 1 ft. wide; from the edge of this hung a fringe formed of Wheat ears, with a beading composed of sprays of small, dark green-leaved Ivy, through which at intervals were interspersed little bunches of Acorns and Oak leaves, and between each bunch of Acorns was a small, bright gold-coloured Tomato. Along the top of the drapery, at about 5 in. apart, were triple ears of Wheat arranged in the form of spear-heads, and across the stalks ran a wreath of silver Ivy, each leaf being not larger than a sixpence. The fronts of the reading desks were decorated in much the same style, except that the crimson cloth was narrower, and at the top of the straw fringe, in place of the Ivy wreath, was one composed of tinted foliage, through which were worked in little bunches of light and dark Grapes, Cob Nuts, and Acorns. The upright ends of the desks were outlined with small-leaved Ivy and trellised with fine wreaths of tinted foliage, such as the crimson leaves of the Blackberry, Virginian Creeper, Silver Poplar (the white side turned out so as to show off well against the crimson creeper), brown Oak leaves, dark Ivy, and such like, with little bunches of light and dark Grapes at intervals, and where the wreaths crossed they were stopped with a small-sized red Tomato. The top of the trellises were finished off with large bunches of Grapes hanging against a mat or background of Vine leaves, one bunch to each desk, the light Grapes being on dark, brown-tinted leaves, and the dark ones on crimson-tinted foliage. Large bunches were also similarly arranged in front of each desk, and the tops of the desks and stalls were finished off with sheaves of Corn, some Barley, and Oats, each sheaf being bound with sprays of Ivy, and the Ivy sprays joined with a band of berries of the mountain Ash. Under the stalls ran a wide wreath of Corn with plumes of Pampas Grass at the back at intervals. The back of the communion table was quite a reeded formed of flowers and foliage. The form was almost that of a half circle, and this arch was a solid formation of Brake Fern fronds worked into Moss; it was edged with Corn and large bunches of mountain Ash berries. Inside of this wreath was one formed of bunches of dark Grapes. In the centre was a cross also formed of dark Grapes edged with Corn, and four rays were formed out of the cross with four Arum blooms. On the table were four bouquets composed of white Asters, Eucharis, Primulas, Pancreatum fragrans, scarlet Pelargoniums, Allamandas, and light Fern fronds, while at each side were staged growing plants with Corn and other harvest trophies at the base. In the afternoon a children's harvest festival was held, all the children being expected to bring fruit or flowers. At the conclusion the flowers were taken to the Children's Hospital in great Ormond Street, and the fruit to the Newport Refuge for Homeless Boys.

ANNIE HASSARD.

Ivy Growing in Houses.—It may interest "V." (p. 362) and others to know that Ivy is largely cultivated in many places in England. For dwelling rooms, as a rule, it is most satisfactory when planted in boxes and trained on wire or wicker-work trellises, so that when not required it may be moved out-of-doors, to be thoroughly cleansed from dust, &c. Indoors it may be trained in any form, either round doorways, pier glasses, or window frames; it will keep for months in good condition, and, as it requires but little root-room,

a small box will suit it, and, if necessary, spaces may be left for a few flowering plants at the base. But perhaps the best effects are produced in corridors or covered ways which are only partially lighted. We have here such a corridor running the whole length of the mansion, and it is densely covered with Irish Ivy, which, either by day or under artificial light, has a charming effect. The culture of Ivy is so simple, that it is frequently allowed to fall into neglect and, consequently, into disrepute from its receiving no attention at all. When allowed full scope on a roof it soon disturbs both slates and tiles; but when kept closely cut in, so that young foliage may be freely produced, it will at all seasons be bright and cheerful.—J. Groom, *Linton Park*.

PROPAGATING.

CAPE HEATHS.—All the free-growing varieties of these, such as *hyemalis*, *Willmoreana*, *Sindryana*, and others, are best increased in March and April. The cuttings, which must be young and fresh, should be made as represented by the accompanying illustration. The leaves should be carefully cut off with a small sharp knife, or a pair of small propagating scissors, which are much the best. The cutting pots for all sorts of Heaths must be prepared with care, in order to ensure success; 4½-in. and 6-in. pots are best for the purpose; a 2½-in. pot should be inverted at the bottom, and the space around it should be filled up with crocks broken small, and the dust sifted out of them. The soil must be half peat and half sand sifted fine; some of the rough, or siftings should be placed level over the crocks, then fill up with fine soil and press all down firmly, leaving ¼ in. at the top to fill with silver sand which has been previously washed. It must not be patted down, but pressed rather firmly and level; sprinkle with a fine-rosed pot, and put the bell-glasses on; the latter ought to be at least ½ in. from the edge. The cuttings are best put in in rows across, beginning in the centre, and doing one half first; make a hole with a small dibber (made of Box wood is the best), insert the cutting, and fasten it in with the dibber, filling the holes up with a little dry sand prepared for that purpose; when filled the pots may be plunged half way up in a gentle bottom-heat, and the glasses taken off and wiped dry every morning. In about a month, when the cuttings begin to grow, give air by raising the glasses a little with a small piece of wood, till they are ready to be removed altogether. Watering must be attended to with care, and after the first time only give it to those that get dry over the glasses. Cuttings of the hard-wooded varieties, such as *tricolor*, *Massoni major*, &c., are best put in late in summer and early in autumn. The same care must be taken in preparing the cutting-pots, making the cuttings, &c.; they must be kept on a platform on the shady side of the propagating house, on a cold bottom, for two months, until they have callused, and they must be carefully watered and on no account in any other way except over the glasses; they may then be placed on a gentle bottom-heat, the glasses must be wiped every morning, and in about two months more they may be raised by degrees. All the hard-wooded varieties take three times as long to root as the free-growing, or what are sometimes termed the soft-wooded kinds.

EPACRIS.—These require the same treatment as the free-growing Heaths, except that the plants intended for stock must be got into a house, the temperature of which is from 55° to 60°, to induce them to make shoots for cuttings, which are best made with a knife. If a large quantity of any given sort be required, take off the cuttings from plants in the cold pits that have been cut back after flowering, and let them stand till callused on a cold bottom for two months previous to putting them in heat. I have had very good batches in this way, but the former is the quickest and most successful. H. H.

Aralia Sieboldi.—This has a handsome appearance planted singly on Grass. Several plants of it in the pleasure grounds here have a striking effect. They have a fine, bold habit of growth and handsome foliage, and where the climate allows of their standing out-of-doors permanently they form attractive objects.—J. G.

THE INDOOR GARDEN.

FUCHSIAS AS EXHIBITION PLANTS.

There is a complaint that the Fuchsia is not now the popular exhibition plant which it once was, and that the complaint is well founded there can be little doubt. Why such should be the case is not so much worth inquiry, as it is to show that a plant so easily cultivated, so graceful in its character, and so thoroughly decorative when in bloom, can be grown almost by any one. In the west of England, however, there are still grown and exhibited some of the finest specimens Fuchsias ever seen, a result that occurs not from any speciality as regards climate or position, but solely because the cultivation of the plant is well encouraged, and the encouragement is responded to. Noble pyramids of leaves and flowers from 8 ft. to 10 ft. in height, perfect in form and bloom, are, indeed, objects rarely seen; but if this can be done in one part it is certain that, under similar conditions of culture, it might be done in another. I have grown Fuchsias for exhibition in past years, and, although I have not reached to the high position occupied by Mr. Lye, or the Messrs. Mould, or Devises, yet such fortune as it was possible locally to secure always followed the system of culture I adopted, which was simple, but, nevertheless, effective. I may premise my remarks as to culture by saying that our chief local show was held in the autumn, and therefore it was necessary to provide each plants as would be at their best at that time of the year. These were obtained from early, autumn-struck cuttings taken off as soon as the first bloom on old plants was over. These put in early in September in a mixture of sharp sand and loam would root and be well established in 3-in. pots by Christmas. Beyond keeping the plants in such warmth through the winter as a greenhouse would give no further pushing was attempted until March, when a shift into 4½-in. pots, and further into a gentle bottom-heat, would start the new growth for the season. A few weeks in a little heat would suffice so far as soon to need the first pinching, which should take place at every shoot as soon as bloom buds appear. The object of the grower should be to avoid unfurnished wood, and if all flowering joints are pinched out there will remain only eyes that will start renewed growth as needed. By the end of April, being then fine strong plants well furnished with a good leader and side shoots, they should be got into a cold frame or greenhouse, and there remain and kept growing on until the middle of May when the plants should be shifted at once into their blooming pots which, for that season, should be what are known as sixteens, or about 9 in. in diameter. These offer abundant root room for good plants from 4 ft. to 5 ft. in height, which height, according to the sorts grown, may be looked for. The open-air culture now commences, and this comprises the key to the system. Fuchsias grown in the open air and in the full blaze of the summer sun make less growth, but what there is is firmer and shorter jointed. Ordinarily, it would be recommended that if placed in the open air in pots the plants should be as much in the shade as possible, and this would be good advice if the pots were exposed to the action of the hot sunshine, but it is a part of this system of culture that the pots shall be plunged either in tan, ashes, Cocoa-nut fibre refuse, or leaves, care, however, being taken that each pot stands on a slate or tile to keep the worms from entering the drainage hole. When the plants have received their final shift into the blooming pots and have a well established framework for the formation of specimens, they are then plunged in some material, as mentioned, up to the rims of the pots, and in such a position as shall permit them to receive all possible amount of sunshine and air, and so far apart as to admit of being freely moved round to the sun as the growth may exhibit a tendency to draw one way. Pinching must be regularly continued all over each plant when flower buds appear, and, although the growth is necessarily slow, yet it is certain, and a robust, well-built plant is inevitable. After each pinching, a fresh leader is easily encouraged. Six weeks prior to the date of the show at which it is desired to exhibit the plants pinching should cease, and every encouragement be given to induce the plants to make a free growth. As the pots will now be full of roots, weak manure water should be given twice a week, and both foliage and bloom will show its beneficial effects. A fortnight before the show the plants may be placed in the shade or in a cool house, but a shady spot out-of-doors is the best place, and here they will attain the finest blooming condition, and be all that can be desired as pyramidal Fuchsias. It need hardly be added that such plants as these will, for summer shows the following year, make grand plants, and although it is well to keep up a succession of such young plants from year to year, yet older specimens will continue with care to be good for exhibition for several years. Sorts that are now worthy of special mention as good exhibition kinds, and that flower with great freedom and carry their blooms well when travelling, are, of red kinds, *Gazelle*, *Warrior*, *Queen*, *Elegance*, *Charming*, and *Lizzie*; of whites, *Wilt-*

Heath Cutting.

shire Lass, Arabella, Beauty of Wilts, Blushing Pride, alba coccinea, and Letty Lye. These are but a few of many that are good, but they have the highest recommendation of a very successful grower and exhibitor of Fuchsias.
A. D.

ANEMONE-FLOWERED CHRYSANTHEMUMS.

ANEMONE-FLOWERED CHRYSANTHEMUMS have an elevated disc of quilled tubes, surrounded by an outer row or fringe called guard petals. This class of Chrysanthemums is somewhat limited as regards number, but all of them are so very beautiful that it is almost impossible to have a variety that will not well repay the trouble taken in growing it. All that is necessary in a cultural point of view in reference to Anemone-flowered Chrysanthemums may be summed up in a few words: Procure cuttings as early as possible after the blooming season is over, and insert them round the edges of small pots which can be put anywhere out of the reach of wet and frost. They will be sure to strike, and in spring, when well rooted, pot them off singly, shifting them on till the blooming pot or last shift is reached, when, if ordinary attention has been given

Double Anemone-flowered Chrysanthemum (Vilmorin).

them, a splendid bloom cannot fail to be the result. For exhibition purposes the large Anemone-flowered kinds are shown singly, and the Pompones in trusses of three in a bunch. Among the most desirable large kinds are the following:—

FLEUR DE MARIE.—Pure white, rather small, but most exquisitely pure in colour. This is largely sent to Covent Garden Market, where it meets with a ready sale. Where out bloom is required in large or small quantities this variety is absolutely indispensable. George Hock is synonymous with this kind.

VIRGINALE.—This is also a very fine white, much like the preceding, but differing from it, inasmuch as it does not commence to bloom till the other has faded, that is, after the second week in December, and it continues in good condition throughout that month, and even well into January.

LADY MARGARET.—Pure white, and a very fine large variety, with long guard petals. It is not quite so neat as the other whites named, but it is a charming flower either for the conservatory or drawing-room.

GLUCK.—This is a fine yellow, somewhat early, and, whether for colour, shape, or habit, certainly unsurpassed.

SUNFLOWER.—A fine, large, Primrose variety, somewhat late; a good flower, and, although rather pale in colour, one of the best.

MRS. PETHERS.—A fine flower, of a silvery-lilac shade, and dwarf in habit, as is also the preceding.

PRINCE OF ANEMONES.—Lilac blush, with a fine disc, early, and one of the best; a very plump flower, dwarf in habit, and invariably good.

PRINCESS LOUISE.—This is somewhat wanting in fulness of guard petal, but it is so early, dwarf, and fall, that it should be grown where out bloom is required.

KING OF ANEMONES.—If a dark flower be wanted, this should be grown; colour, cherry red, with lighter centre; rather tall.

Anemone Pompones rank amongst the most beautiful of flowers, being free bloomers, and affording such happy combinations of colour, that when once grown there is but small chance of their ever again being discarded. For cut bloom and conservatory decoration the following are desirable:—

MADAME MONTELS.—Guard petals pure white, centre gold; a fine fall Anemone, and one which is invaluable for cutting.

MARIE STUART.—Very delicate blush, with pale yellow centre; a chaste and exquisite variety, and one which cannot fail to be of use for decorative purposes or for bouquets.

ZOBEIDE, PERLE, AND ASTREA are three silvery-rose-coloured varieties, large and full, and kinds that should be grown in every collection, however small.

ANTONIUS.—A flower with a very fine disc; and what doubly enhances its value is the fact that it emits a pleasing fragrance.

MR. ASTIE.—This in all points is a most perfect flower, and one which is fine in habit.

EUOENE LANJAULET is also a very fine yellow.

Amongst dark flowers, Firefly (scarlet), Dick Turpin (ma-genta), and Calliope (ruby-red) are sure to recommend themselves. There are many others useful for exhibition purposes, but the foregoing are the best for furnishing cut flowers and for the decoration of the conservatory.

Plumstead Common.

CHRYSANTHEMUMS IN POTS.

In the neighbourhood in which I reside Chrysanthemums generally are the reverse of being late, and the growers for exhibition at our local show on November 20 are fearing if the mild, open weather continue the flowers will be in advance of the time when they are required, especially those plants which have been housed under glass. The plants are coming into flower with marked rapidity, even in the open air, where they can be kept much later than usual owing to the nights being soft and mild. I have a few specimens of good varieties that are in a rare healthy condition in 7-in. pots. The plants were set out-of-doors in a slightly-shaded place all the summer, and not plunged, as is usual. They were well watered and syringed, as required, and treated to occasional doses of Amies' Chemical Manure. When a dressing was given the soil was gently stirred on the surface, a little of the manure sprinkled over it, and worked into the soil when water was given. As soon as the weather promised to be dry a surfacing of what might be termed rich, juicy manure was given, piling it up round the rims of the pots, and leaving an opening round the stems of the plants for water. Since this was done the foliage of the plants has greatly improved, and the flower buds are swelling up in good style. I have not thinned out the buds to one on the point of each shoot, but have left about four to each. The plants are wanted for conservatory decoration, not for exhibition, and I cannot afford to dispense with so many blooms. Some of my plants are carrying from twenty-five to thirty-five flowers, and they will be fine objects in my cold conservatory during November. I am unwilling to introduce them yet as there are so many plants in bloom. There are Fuchsias—folgens and Dominiana—also some of Mr. Lye's new varieties, which are extremely well adapted for conservatory decoration, because of their continuous free-flowering qualities; several zonal Pelargoniums, Abutilons—Lemoinei, Boule de Neige, roseoflorum, and vexillarium—Tuberous-rooted Begonias, Plumbago capensis, Trachelium cornutum, and a few others. Summer is, indeed, lingering, and it is helping to pass away the dull season of the year in a very pleasant manner.
D.

PELARGONIUMS THROUGHOUT THE SUMMER.

GENERALLY speaking, the large-flowered Pelargoniums are considered to have ceased to flower by the end of July or the middle of August. The common practice is to grow a set of plants all propagated at the same time and grown on together; consequently, they come into bloom *en masse*, and when the head of flower is gone Pelargoniums are done with for the summer. I do not say that this is the universal practice, but it is a very general one. To-day (Oct.

18) I have cut some fine trusses of *Triomphe de St. Mandé* from plants in a cold greenhouse, and if the fine, genial, sunny weather continue, other trusses of bloom will spring up to reward my labours in endeavouring to have flowers as late as possible in the season. This is easily brought about by keeping some of the autumn-struck cuttings pinched back till the first week in July, and giving them a slight shift to carry them through the autumn blooming. A few cuttings struck in May and kept growing all through the summer and winter, without allowing them to flower, come into bloom in early spring, and so from six to seven months of *Pelargonium* flowers is secured. This is done in a house, where autumns damp and gloomy, winters wet and cold, and early spring frosts have to be contended with. I find young plants do better for flowering in early spring than old ones cut back in August and repotted early in Sept. *Triomphe de St. Mandé* is one of the best varieties for such work as this, because of its vigorous growth, continuous free-flowering properties, and bold trusses of bloom. The market growers say it is too vigorous and irregular in growth; but this is just the quality for a cold greenhouse. It blooms and throws out vigorous shoots at the same time, and there is never in the case of growing plants an absence of blooming wood. Of other good, free-flowering varieties, I have grown *Crimson King*, *Rob Roy*, *Empress* (a very pretty white), *Duchess of Cambridge* (bright scarlet), and *Heroine* (rosy-pink). I find them very valuable for cutting from, and visitors are always pleased to be able to take away a handful of flowers. Cuttings are struck with great ease almost all through the year. I put in two batches of cuttings, a few in early spring, the bulk in August. I ripen off a plant or two for the purpose, so as to have some good, matured wood at the heel of the cutting at least. These are put into small pots, three in a pot round the sides, and, as soon as they are rooted, potted off singly into 3-in. pots. While they are in these pots you can do what you like with them; either grow them on quickly into flower, or, by pinching back, lay the foundation of larger specimens to flower at a later period. A large grower of *Pelargoniums* for market once remarked that he cared not for his plants so long as they were in 3-in. pots and doing well. Mr. Turner would be found quite willing to admit the truth of that. Only lay the foundation of a good plant while it is in this stage of probation, and when it is shifted into a larger pot it cannot fail to develop into a handsome specimen if intelligently cultivated. D.

GROWING ORCHIDS WITHOUT HEAT.

THE culture of Orchids would be no doubt much extended, and especially among amateurs, who possess a small greenhouse or conservatory, were it not for the idea which exists with the uninitiated, that they require a certain fixed temperature and special treatment not easily adopted. Such an idea is, however, a mistake, as regards, at least, some of the most useful as well as beautiful Orchids in cultivation. In the Pine-apple Nursery there is just now a houseful of Orchids, which, for health, vigour, and freedom of blossom could not easily be surpassed, and these have been grown without any fire-heat whatever since March last; and, indeed, have at no time had any more fire-heat applied to them than just sufficient to keep out frost. It is stated that by such treatment the plants make larger, stouter, and healthier bulbs than they otherwise would do, and short, thick leaves, whilst those to which fire-heat is applied systematically make long, thin leaves at the expense of the bulbs, which do not develop themselves so well, and, consequently, do not bloom so profusely. These plants, moreover, have never been syringed overhead, as this causes the tops to grow, but not the roots, which it is obvious cannot be conducive to the welfare of the plants. To insect plants thus treated are seldom subject. The following are among the kinds grown successfully under the treatment just alluded to: *Odontoglossum Alexandræ*, *Pescatorei*, *niveum*, *cirrhosum*, *Andereonianum*, *Halli*, *roseum*, *Bictonense*, *Uro-Skinneri*, *gloriosum*, and *nehuliosum*; *Oncidium macranthum*, *tigrinum*, *crispum*, *Forbesi*, *Marshallianum*, *varicosum*, and *Rogersi*; all the showy kinds of *Masdevallias*, *Indian Crocuses* (*Pleiones*), *Cymbidiums*, *Celogyno cristata*, *corymbosa*, and *barbata*, and *Lælia autumnalis*. These and many others, could be grown well in any light, inexpensive, built house even in London, and the pleasure they would afford would be tenfold greater than that to be gained from scarlet *Pelargoniums* and similar plants, which usually constitute the stock in such houses, and which entail quite as much or, perhaps, more trouble and expense in their cultivation than the Orchids just named. C. W. S.

Paraffin Oil an Insecticide.—I have lately heard good accounts of the value of this oil for destroying insects. Several years ago an experienced cultivator told me that paraffin oil applied in the manner described by your correspondents was his remedy for green or black fly.—J. G.

PLATE CLI.

VARIETIES OF LAPAGERIA ROSEA.

THE history of the beautiful genus *Lapageria* is not without interest, independently of the value of its members as ornamental plants. Few persons, probably, are aware of the origin of the name *Lapageria*, given by Ruiz and Pavon as long ago as 1802. The genus was described by the botanists mentioned in the third volume of their "*Flora Peruviana et Chilensis*," and dedicated to Josephine Beauharnaise de *Lapageria*, first wife of Napoleon I., and a great patroness of botany and natural history. Only the rose, or rose and crimson, variety was known to them, and in their figure (plate 297) they show the spotted interior of a flower similar to that to the left of the centre of our plate. According to the same authors, this variety was common in the neighbourhood of Conception, where its roots were employed for the same purposes as *Sarsaparilla*. The fruit, which is occasionally produced in abundance in this country, is a pulpy berry of a delicious flavour, highly esteemed by the aborigines of Chili. Almost every botanist and plant collector who has since visited the country has naturally dried specimens of so showy a plant, and it appears to be common throughout the coast region of the province of Araucan, from Conception to Valdivia. Gay, in his "*Flora Chilena*," expressly states that it grows in the vicinity of the sea, and that it prefers a humid, somewhat shady, situation. This is fully borne out by our experience of the plant in this country, as it nowhere succeeds better than out-of-doors in the south-west of England and Ireland. Contrary to what is the case with many plants, the *Lapageria* produces flowers in a wild state as large or larger than when under cultivation. Dried specimens collected by Mr. Reed have flowers $3\frac{1}{2}$ in. long. Living plants of the ordinary *L. rosea* were sent to Kew in 1847 by an American gentleman named Wheelright, and the following year Messrs. Veitch received a consignment of it through their collector, Mr. Thomas Lobb. The Kew plants did not flourish, and although Messrs. Veitch's plants grew well, they did not flower for some time; but in 1849 a coloured plate appeared in the "*Botanical Magazine*" which was prepared from dried specimens and Lobb's coloured sketch of the flowers made in Chili. In 1850, however, it is recorded that it flowered in several gardens in this country. *L. alba* was originally sent from Chili to the Botanic Garden of Paris by a Mr. Labadie in 1851, and it flowered there the following year, and was described and figured by Prof. Decaisne in the "*Revue Horticole*." The varieties named *superba*, *rubra*, &c., are the fruits of subsequent importations or improved seedling varieties raised in this country. It should be mentioned, too, that there is considerable difference in the so-called white varieties, some of them being more or less tinged with pink, as were those figured in the "*Revue Horticole*" and "*Botanical Magazine*." W. B. HEMSLEY.

FLOWERING OF THE LAPAGERIA.

IT has been stated that a floriferous habit in this splendid greenhouse climber depends upon the variety, which is no doubt true to some extent; but much more depends upon situation and culture, as I think the following experience will prove. When I came here, now a number of years ago, I found a pretty old, but not large, plant of *L. rosea* growing in a 12-in. pot in a cool conservatory. It had not flowered freely, I was told, but it was desired that it should be kept in the pot for a particular reason, and so I allowed it to remain, shifting it occasionally or top-dressing it as required. The plant continued to flower in an intermittent way throughout the year, but not profusely. At last I determined to plant it out against the back wall of a *Camellia* house in a moderately shady situation, and had a trellis attached to the wall to train it to. Here it grew with astonishing vigour each summer, producing shoots from the bottom as thick as moderately strong pot vines and more than 12 ft. long; but still it did not flower so freely as was expected, though what flowers it did produce were fine. At the end of two or three years, I forgot which, I determined to transfer the plant to another house, a span-roofed one, where it would receive plenty of light and air, the two things necessary to the perfect ripening of the

VARIETIES OF *LARKSPUR* PUELLA

wood. This was in January, 1876. With much labour the plant was untwisted from the wires and taken up with a heavy ball of fine roots and planted out in a prepared bed of loam, leaf-mould, peat, and sand loam predominating. The shoots were trained in a systematic way to wires stretched about 9 in. from the glass, and no shade was given during the summer, the house being kept cool and airy, and only the frost excluded in winter. In August of the same year the plant began to flower profusely, and continued to do so till November. For a long while 200 flowers, not to mention buds, could be counted upon it at one time. I sent examples of trusses and wreaths of it to Messrs. Veitch for their opinion as to the variety and its free-flowering habit, and they pronounced it to be very fine indeed. This season the plant has not made so much growth, and I begin to be afraid it has been partially weakened through flowering so much last autumn; still, it has flowered well, and is now blooming just about as well as it did last year. It began to flower in August again freely, and has at the present time 150 flowers upon it, besides buds. I counted at one time seven or eight trusses of fives and sixes, and plenty of threes and fours. In two cases two trusses of sixes were produced from two terminal buds close together, making clusters of twelve. I imagine clusters of twelve from one bud are not common, if such have been recorded. The production of clusters is a matter of pinching the shoots at the right time. I noticed that particularly last season, and pinched, in consequence, rather perseveringly during the past season, hence the number of clusters, of which we have more than single flowers. All the clusters, without exception, are produced from terminal buds where the shoots were pinched, and I think I may say this treatment will produce them unfaillingly if the plant be otherwise well treated. I do not say, however, that clusters are desirable; I would rather have the flowers come singly at every joint. Last year we had wreaths of eight and nine flowers from as many buds, each about one or two inches apart, and I found these very useful on some important occasions for decorating tall vases that required to be draped with drooping flowers. I am sorry to say that a fine young plant of *L. alba* which was planted in the same bed at the same time as the other, in fact close beside it, with the object of mixing the two together, has this season died down to the root in an unaccountable manner. The shoots perished from the top downwards, and the other day I took out the root quite dead. The plant flowered well last autumn. I can only explain its dying from the fact that the sun shone rather strongly in at the gable end of the span-roofed house upon the plant, and killed it by sun-stroke. Although I had the glass thickly whitewashed as soon as the first injured leaves were observed, the foliage and shoots continued to wither and die. In other respects both plants were treated alike; only *L. rosea* has no foliage exposed to the gable of the house, and consequently does not receive the sun's rays so directly. Have any of your readers noticed a similar case?

J. S.

Wortley.

A Good Winter-flowering Plant.—*Tydaea Robert le Diable* is not only the most showy and best in its class, but it also ranks amongst the best of plants which afford a good display of blossom in winter. I lately saw some well-grown plants of it in the Pine-apple Nursery; they were growing in 8-in. pots in soil consisting of loam and cow manure. Each pot was furnished with five or six vigorous plants, having large healthy leaves and a profusion of flower-buds, which will continue to open in succession for several months to come. Such plants are equally valuable for their easy culture, and for the display which they give at a season of the year when flowers are most esteemed.—S.

Impatiens Jerdoniæ.—When grown in a cool house near the glass, this old, but comparatively little cultivated, plant makes one of the most attractive objects for the conservatory at this season of the year. If grown in 5-in. or 6-in. pots it forms compact, bushy, little plants with bronzy-green leaves and bright scarlet and orange blossoms, which are very useful for the ornamentation of small vases, or for the front row on the conservatory stage. Such plants also look well when placed from six to ten together in pans among Club Mosses. Numerous plants of it now may be seen in flower in several of the London nurseries.

GARDENING FOR THE WEEK.

Indoor Plant Department.

Anguloas.—Orchids of this class are not so extensively grown as they deserve to be; why, it is difficult to say, as the large size and totally distinct character of their flowers at once commend them to the notice of Orchid growers. Amongst them there is nothing that approaches the yellow-flowered *A. Clowesi*, whilst *A. eburnea*, *A. virginalis*, and *A. Ruckeri* are fitting companions to it. Where these Anguloas are grown it often happens that they do not possess the strength and vigour which they easily attain where their treatment is favourable to their full development. The most frequent cause of a deficiency in strength may generally be traced to their being grown in too high a temperature. Under such circumstances, and a deficiency of light, they keep on lingering without acquiring the power to produce more than half the number of blooms of which they are capable where the treatment to which they are subjected is more favourable to their natural requirements. The best I have ever had or seen were grown in a temperature some 6° or 8° higher than that of an ordinary greenhouse, but in speaking thus of these plants, and almost all other Orchids, it is necessary for the inexperienced to bear in mind that, with very few exceptions, those that in a state of cultivation succeed best with comparatively little artificial heat, as thus described, must not be submitted to anything like the full volume of air, and consequently dry state of the atmosphere, that exists in an ordinary greenhouse, where the lights—top and sides—are, for a great portion of the day in mild weather, thrown wide open, for wherever, through an absence of knowledge of the real requirements of the plants, such a course is followed, it is sure to end in failure. Anguloas are also plants that appear to thrive best with considerably more root moisture than the majority of Orchids require. Whilst on this subject of water to the roots I would recommend all beginners in the cultivation of Orchids to diligently study the moisture requirements of the various families and species of plants which they grow. This is a matter of primary importance. There is often too great a disposition to generalise by speaking of East Indian plants, intermediate heat-requiring kinds, and the still cooler sorts, as if the whole of the plants in each of these divisions required to be treated alike, or nearly so, in the matter of water. To this more than to anything else may be traced the want of success which even many extensive growers experience through giving too much or too little, as the case may be, to many of the plants which they attempt to cultivate. In proof of this I may remark that in many of the most noted collections of Orchids it will be found that one or other section of the plants succeed in a way that leaves nothing to be desired, whilst the others are a comparative failure; and I have no hesitation in saying that the want of a full realisation of the different requirements of the plants in this matter of water to the roots is one of the primary causes of such a state of things. Where these Anguloas are subjected to the treatment above indicated, they will be found to succeed and add a charm to any collection of these most attractive plants, in which diversity of form and colour is one of the most important considerations.

Lycaste Skinneri.—This is even a more useful plant than the foregoing, from the fact of its blooming over a lengthened period, the flowers lasting long, and coming in not only through the spring, but during the winter, when there is a comparative scarcity of bloom. A few more degrees of heat than are required by the Anguloas will answer for this *Lycaste*, such as placing the plants at the warmest end of the house. Yet it will also be found to succeed better with less heat than that to which it is often subjected. It is a species that I should recommend those forming collections to have plenty of, being little liable to disease. Imported plants of it, too, possess such variety that scarcely two will be found alike, from the deep rosy-coloured *L. Skinneri atrovirens* to the pure white *L. S. alba*. If placed when in flower in an atmosphere where there is not so much humidity as will spot the blooms by condensation upon them, they will last for six or eight weeks. Although it requires a much moister condition of the soil whilst in active growth than many Orchids, it will from this time forward, when growth is nearly completed, necessarily need drier treatment.

Barkerias.—Like most other Orchids, the completion of growth with these in a great measure depends upon the time when they were started. In most cases their leaves and pseudo-bulbs will be about attaining their full size, but until that is the case water must not be quite withheld, for, grown as they generally are on blocks suspended from the roof, or in pots filled with the lightest material, they will bear keeping somewhat moister than the majority of Orchids without being subjected to the injurious influence of making second growth. The most satisfactory kinds are *B. spectabilis*, *B. Skinneri*, and *B. elegans*, for though these plants are of comparatively small

growth, and seldom find a place in the large collections met with on exhibition tables, they are most desirable subjects.

Brassavolaa.—These comparatively small-growing plants will now be about finishing their season's growth. The yellow-flowered *B. glauca* generally does better with cooler treatment than most of the other kinds. If cultivated in too high a temperature it rarely flowers freely or at all. The singular and large generally solitary-flowered *B. Digbyana*, *B. cordata*, *B. nodosa*, *B. lineata*, and *B. grandiflora* are also well worth growing.

Camarotis purpurea.—This is another small-growing subject, which succeeds best on a block. Its miniature *Saccolabium*-like spikes produced freely in the spring, combined with the little space which the plant occupies, render it deserving of better treatment than it generally receives from those who confine their collections largely to species that are popular for the time being. It will yet be making growth, and should be watered regularly. It will succeed best at the coolest end of the East Indian house.

Cymbidiums.—Though a rather extensive family, some are so much more attractive than others as to make the more inferior varieties of little importance. Amongst those holding a first place are the ivory-white *C. eburneum* and the somewhat less esteemed *C. Masteri*; these, likewise, will now be about completing their growth, and should gradually receive less water.

General Treatment.—Everything possible should be done to place the many species that have yet considerable growth to make under the best conditions as to light, giving less moisture especially in the atmosphere, than hitherto. Its influence in promoting extension of leaf surface at the expense of solidity in texture is much greater now than during bright weather. Then the sun's heat not only quickly dries up the vapour given off from troughed pipes and the moistened surfaces of paths and stages, but it also has a direct influence in solidifying the tissues of the leaves and pseudo-bulbs as they extend. Take, therefore, every opportunity when the weather is favourable to give air for a time each day in a way that will not only tend to the requisite drying and sweetening of the atmosphere, but so as to effect a complete displacement of the effete, pent-up air, replacing it with that which is fresh and not exhausted.—T. BAINES.

Poinsettias.—In order to assist these to push large and brilliant floral leaves, and to obtain them of stout, firm texture for cutting or other decorative purposes, the plants should now be placed in gentle bottom-heat, with their heads as close to the glass as possible without actually touching it. Should they, however, be required for removal to assist in furnishing the conservatory, it will be better to avoid the bottom-heat, as they retain their lower leaves much fresher, and are far more enduring when they have to remain in a low temperature. Liquid manure, if used in a tepid state (by the addition of warm water), will now be of the greatest assistance in increasing the size of the flower-heads, and imparting a brighter and richer colour to them.

Eucharis amazonica, always so valuable for cutting, is doubly so during the dull months of winter, when its pure white flowers show up in such pleasing contrast with the beautiful *Euphorbia jacquiniæflora*, and the rich, glowing scarlet of the *Poinsettia*. In order to have it successfully in bloom at the present time, it is necessary that a portion of the stock should have been rested by having been placed in a cooler temperature without bottom-heat, with only just sufficient water at the roots to keep the leaves in a fresh, green state. If this mode of treatment have been carried out for the requisite period, there will be no difficulty in inducing them to flower if at once placed in brisk bottom-heat, and well supplied with water at the roots. If the drainage be free and open, and the soil in the same condition, there need be no fear of over-saturating them with water, as they will take and enjoy more than most plants, especially after they have been a week or two in strong heat, and their roots thereby urged into a state of activity. Before starting them see that they are entirely free from bug, and give the leaves a thorough sponging to clear them of any dust or deposit of any kind that may have collected on them. *Eucharis* have a special liking for being watered overhead as well as at the roots; and, therefore, if the atmosphere in which they are placed be at all dry, they should be frequently syringed, always using clear warm water for the purpose. Any that have ceased blooming, and have become thick and crowded with bulbs, should be shaken out and divided, and the small and medium-sized plants laid aside to grow on by themselves, while the largest and best should be potted in large pots, putting from twelve to eighteen bulbs in each, according to the sizes used.

Euphorbia jacquiniæflora, than which a more charming or useful winter-flowering stove plant does not exist, should now have every attention paid it to make the growth firm and mature, without which they never flower in a satisfactory manner. Where they are

required for cutting it is a good plan to place them along the front of a cool stove, with their heads kept down by straining a few pieces of twine under the rafter, by which means the whole of the stems of the plant will then be within a few inches of the glass, in which position they will derive full benefit of all the light it is possible for them to receive at this season. Flowers that are produced under such favourable conditions last in a cut state nearly twice as long as those that are allowed to expand far away from the light and air, and where they have to endure the same amount of heat and moisture necessary for the general stock.

Greenhouse Plants.—All soft-wooded greenhouse plants are now liable to damp; the atmosphere of the house, therefore, which they occupy must be kept as dry as possible, and well ventilated. In wet weather a little fire-heat, with ventilation at the same time, may also be used. Pick off every damping leaf or portion of leaf; and should a shoot be damped through, cut it off under the diseased spot, and rub the incision with powdered charcoal. Allow no fallen leaves to remain lying about the house, as they are sure to generate damp, and will certainly communicate it to any plant coming in contact with them.

Heliotropes that have been kept in pots during the summer for early blooming should now be placed on shelves close up to the glass, so that they may receive all the sun and light possible, or be put in a dry, warm pit, where they can enjoy the same advantages. For late blooming, plants taken up from the flower garden, cut back, and potted in small pots, and afterwards placed in heat to grow them on again, make fine plants by March or April, when they are most useful for cutting or conservatory decoration, for either of which purposes they are always highly prized.

Mignonette that has been grown in pots for flowering through the winter, and also that which was sown later to come in during the spring, and which has been placed in the open air, will now need protection. As it is no longer safe from frost out-of-doors, it should be removed to frames, where it will be secure for some weeks to come, as we have not usually more frost before Christmas than can be kept out with an ordinary covering of mats. For all such purposes the frames should stand on a good bed of ashes, in as dry a condition as can be had, which will tend in some measure to counteract the effects of the damp state of the atmosphere from which we generally suffer in the last months of the year. Place the frames in the lightest situation available, and let the plants stand on inverted pots sufficiently large to raise the tops close up to the glass, by which means they will be in a position to admit of a free circulation of air amongst them as well as to receive all the light possible. Take the light completely off during the whole of each day when there is no rain, and tilt them back and front when it is wet, the object being to keep the growth now made as stout and compact as possible, upon which in a great measure will depend the quantity and quality of the flowers which the plants will produce. There is a double advantage in keeping *Mignonette* in frames through the autumn as late as it can be done without suffering from cold or damp, inasmuch as treated in that way it is less liable to get drawn up weakly than in a greenhouse, and it prevents houses from getting so much crowded as they otherwise would be. Do not over-water; at the same time the plants must not be allowed to get over-dry; give liquid manure with a little soot in it every other time water is required; the soot will give a deep green colour to the leaves in place of the yellow, sickly hue so often seen in the case of *Mignonette* grown in pots. Above all avoid having too many plants in a pot, or a weakly condition, with little flower, is certain to be the result; two, or at most three, are enough for a 6-in. pot.

Flower Garden.

Pelargoniums, Calceolarias, and Verbenas.—Where it is not intended to preserve the plants, they may be allowed to retain their position in the beds as long as they remain attractive. Some of the winter and spring-flowering bedding plants, such as *Aubrietias* and the *Forget-me-nots*, which are already showing flower, will be in proper condition to take the place of the summer bedders as soon as the latter are removed. The two systems, *i.e.*, spring and summer bedding, may therefore thus be made to unite with each other, and in that way prevent the flower garden ever being entirely devoid of flowering plants. All bedding plants intended to be preserved should now be in a place of safety, and will, together with rooted and partially-rooted cuttings, require to be frequently attended to in the way of removing all decaying leaves. Water should be given sparingly at present, as about this time damp is more to be dreaded than frost. A glass roof will, probably for some time to come, be sufficient protection against frost, and an occasional brisk fire during fine days, when abundance of air can be given freely at the same time, will be found to be beneficial in warding off damp. Most of the many

varieties of *Fuchsias* form very ornamental and permanent flower beds, more particularly the white-corrall'd varieties of the Madame Corneliessen type. When planted out in the open air they may generally be treated as ordinary hardy herbaceous plants, or during very severe winters the surface of the beds containing them may be matted with a slight covering of cinder ashes, old tan, or sawdust. The *Cineraria maritima* is also an exceedingly useful hardy bedding plant; as a white or silver-foliaged marginal plant it is, perhaps, unsurpassed, and will last for any number of years; indeed, the older the plants the more white the foliage becomes. It requires no protection during ordinary winters, but should not be cut down until about the beginning of May, when it will be found to be breaking close to the surface of the soil; after being cut close down it will immediately break into growth and become at once effective. It is of the greatest value in ribbon bordering, contrasting, as it does, agreeably with the *Perilla*, or, better still, with *Dell's* dark-leaved bedding *Beet*. For this purpose it is generally to be preferred, as a silver-leaved plant, to the *Centaurea*, as it can be cut or pinched in with impunity.

Hardy Fruit.

At this season it is usual, though the practice is not universally adopted, to loosen or unnaill Peach and Nectarine trees from the walls, the theory, which is no doubt a correct one, being that such a proceeding assists in keeping the buds longer in a dormant state, thus retarding growth in the spring, as, of course, the later the trees are in flowering the greater is the probability of their having favourable weather. Our spring season is so treacherous, and the fruit crops depend so much on the character of the weather when the trees are in flower, that any method that will successfully retard the blooming period is worth adopting, regardless of labour. When unnailling, see that the main branches are securely fastened to prevent rocking or wind-waving.

Kitchen Garden.

Cauliflowers and Broccoli.—One of the best vegetables for this time of the year is Veitch's Autumn Giant Cauliflower. It is not only excellent in quality, but the plant, being robust, produces a great weight of crop upon a given space. The heads are compact, white, and remarkably tender, even when they have attained a large size. It thrives well in almost any soil, without the assistance of so much manure as is required by some sorts. Where sowings were made at two or three different times, the first will have been fit for use some time back, and the successional sowings will furnish a supply almost to the end of the year, but to ensure this the crop will require some attention. In this variety the leaves do not turn inwards to protect the heads in the least; on the contrary, they leave them fully exposed to the weather. For this reason it has not found favour with some growers, but we find it very easy to supply this want by drawing the leaves together and tying them round with a piece of bast. This should be done when the plants are dry and as soon as the heads begin to form. They should not be tied so tightly as to injure the leaves or exclude air and light, otherwise they become blanched and decay. By using the means just recorded, the heads will escape unscathed from the effects of 8° or 10° of frost. Later in the autumn, when an open shed, in which there is a fair amount of light and air, is to spare, some ordinary soil may be put into it, and a number of plants, the heads of which have attained a usable size, may be placed in the soil, but not too thickly, or the leaves will turn yellow and injure the heads. If this be done in succession as the plants form heads, there will be in hand a supply of Cauliflowers to fall back upon should severe weather set in early. Frames or pits are of course better than a shed in which to keep them, but these are generally required for other purposes. The practice of taking up Cauliflower or Broccoli in autumn when nearly fit for use, and hanging them head downwards in a shed or other building, is not good, for, although they will keep for a time in that way, they get tough and inferior compared with such as have had their roots in moist soil. The later crops of Broccoli that are intended to come in during winter and spring, should at once be laid in order to prepare them for enduring severe frost. The object in laying Broccoli is twofold—First, to check growth; disturbing a considerable portion of the roots naturally has the effect of hardening and solidifying the whole plant, and of enabling it better to withstand severe weather. Secondly, to place the plants in such a position that the sun, during alternate frost and thaw, will not get to the hearts, as these suffer more from frost in the night after being thawed by the sun in the day than when continuously frozen. For this reason the heads should always be laid so as to face the north or west. To accomplish this, if the rows run east and west, commence on the north side of the first row, and take out an spit of soil just the width of the spade, so as to form a trench within 2 in. or 3 in. of the stems of the plants, laying the soil, as the work

proceeds, on the side away from the row. This will necessarily remove it from the roots, no more of which should be broken off than can be avoided. All the plants in the row should then be regularly bent over, until their heads rest on the ridge of soil taken out of the trench. When this is done, commence with the next row, taking the soil out so as to form a similar trench, and laying it in a ridge upon the stems of the row of plants bent over, so as to cover them right up to their bottom leaves; and, in this way, proceed until the whole is completed. If the rows stand north and south, the work must be begun on the west side. By this process, as will be seen, all the roots on one side of each row, and a portion of those on the other, are considerably disturbed. This will cause the leaves to flag a good deal for a week or two, which has the desired effect in checking growth. The more vigorous and large the plants, the greater is the necessity for thus preparing them for winter. In light soils, where they can be got up without much mutilation of the roots, should it be desirable to get the ground ready for some other crop before the Broccoli is off in spring, they may be taken up altogether and laid in some more convenient place, lifting them, as far as possible, with all their roots intact. Where Broccoli is properly managed in this way, it is only during exceptionally severe winters that it gets destroyed, and the drier the land is the more frost the plants will bear without injury. The length of time during which this vegetable affords a succession, at a period of the year when there does not exist much variety, makes it worth while to do all that is possible to preserve it.

Turnips, Carrots, and Onions.—Late crops of Turnips should be gone over and handweeded, as Chickweed, Groundsel, and other annuals will continue to grow and seed, if not removed. It is now of little use to hoe such weeds up and leave them, as they take fresh root directly, through the insufficiency of solar heat to kill them. Autumn-sown Carrots, to stand the winter for spring use, should also be kept clear of weeds, and thinned out sufficiently to allow them room to grow; as they will be used whilst small, 4 in. or 5 in. apart in the rows will be sufficient. Tripoli Onions may now be planted, and should be lifted with a trowel or small fork, so as to preserve all the roots unharmed, and this cannot be accomplished if they are pulled up. They ought to be planted with a dibber, in rows 14 in. apart, a distance of 3 in. being left between the plants in the rows; this will allow for losses in the winter, but, should all live, they can be thinned out in the spring, so as to leave them 9 in. asunder. Care should be taken not to put them in too deep; the roots and the base of the plants should be just covered, so that they may be held in an upright position. If the weather be dry give them a moderate watering at the time of planting. These transplanted Onions are less liable to injury in a severe winter than those that are permitted to remain where they were sown; they also often make finer bulbs. They are much esteemed for cooking purposes, on account of their mild flavour, and the larger they are grown the better they are in this respect; consequently, a good piece of ground should be selected, which must be deeply dug and well broken, plenty of manure being added. All these operations should, so far as possible, be carried out when the soil is dry, for treading upon it when in a wet state does much injury. Continue to thin out winter Spicach; if the thinnings cannot be used as fast as the crops require more space, the plants that are drawn out should be consigned to the rubbish heap, as overcrowding thus late in the season will prevent those that are to remain attaining a condition to enable them to survive severe weather. The principal crops of Celery for winter use should now have the earthing-up process completed, drawing the soil well up to the leaves, so as to form at top a sharp ridge, by which means water will be thrown off. In damp situations it is no uncommon occurrence during wet weather to see water standing in the spaces between the rows; means should always be taken to admit of its running off, otherwise it is almost certain to cause the crop to rot. Late Potatoes have suffered from disease, and should be carefully looked over two or three times in the course of a few weeks, so as to remove those that are affected. Late-sown Turnips have grown very fast; the wet has also had the effect of causing the tops to grow larger than usual, and if at all crowded, these will interfere with the roots increasing in size as they ought to do; as they will yet grow considerably if space be allowed them, more should be thinned out.

Extracts from my Diary.

October 28.—Sowing Mustard and Cress in boxes placed in heat. Potting off Sweet Basil into 6-in. pots, and placing them in a warm house to give a supply during the winter; also potting Tomato cuttings to grow on for early fruiting. Putting a good coat of long litter round the shoots of Globe Artichokes. Clearing off old Rhubarb and Seakale leaves and manuring the ground. Filling pit with manure and leaves that had previously been well prepared for top

Vines. Getting a little Chicory and Dandelion into the Mushroom house to blanch.

Oct. 29.—Potting a batch of late Primulas and Cinerarias. Removing Pelargoniums from cold frames into Vinerias. Nailing up Ivy, Roses, and other climbers on walls to prevent them being injured by wind, and to give them an orderly appearance. Turning over a large heap of manure, and adding 20 lb. of salt and 1 bushel of soot to the cartload. Putting some new stakes to young trees.

Oct. 30.—Removing Cinerarias and Primulas from cold pits to warmer quarters. Stirring the soil among Spinach, Endive, Lettuce, Cabbage, and Cauliflower plants. Cutting for use Veitch's new Autumn Self-protecting Broccoli in fine condition. Mowing, cleaning up leaves, and rolling gravel walks.

Oct. 31.—Taking up August-sown Cabbage plants, and planting borders with the small plants, placing them 6 in. apart, for spring planting. Turning a large heap of leaves and manure for making hotbeds, and covering up Seakale and Rhubarb. Earthing up late Celery when the soil is dry and in workable condition. Getting manure on the ground whilst it is dry.

November 1.—Sowing French Beans in pots and placing them in heat. Covering up Endive, and tying up Lettuces to blanch. Clearing out Melon frames, and preparing them for wintering Endive and Lettuce. Clearing leaves off the walks, and getting them all rolled down. Giving Leeks and Cardoons a final earthing up. Looking over the Cauliflowers, and turning down leaves where required, and placing some of the forward ones in an open shed.

Nov. 2.—Potting Lily of the Valley for forcing. Planting Daisies, Wallflowers, and Myosotis. Getting up Dahlia roots, and storing them away in a dry room. Clearing away Scarlet Runners, and storing away the best of the sticks for the earliest crop another year. Spawning Mushroom bed and covering it with mould. Watering the Pines all through that require it. Fruit in use for dessert—Pines, Grapes, Pears, Apples, and Nuts.—W. G. P., Dorset.

THE FRUIT GARDEN.

APPLES AND PEARS FOR NORTHERN DISTRICTS.

It is a well-known fact, as is evidenced by the reports of the fruit crops annually given in THE GARDEN, that intending planters cannot be too careful in selecting such varieties of fruit trees as are known to succeed best in their own particular locality. More especially is this the case in districts where the climate is peculiarly capricious, as it is in Lancashire, where the more tender class of hardy fruits do not grow well, and sometimes do not even survive the effects of a severe winter. Apples and Pears are, however, so numerous and rich as regards varieties, that by making a judicious selection of them ample supplies of culinary and dessert fruits may be secured. During the last three seasons one disaster or another has marred the prospect of a well-stocked fruit room. In the years 1876-77 the blossoms were frozen to death, and this year the crops of Pears and Apples, though not, generally speaking, abundant, were in many localities fair average crops; but what escaped the frost last spring were destined to meet a worse fate. During the recent equinoctial gales, it was sad to see really fair crops strewn hither and thither in all directions, and that, too, within a few days of their being ready to be harvested. Bush-fruit culture seems to afford the only remedy for such disasters; or perhaps a more general adoption of the dwarf pyramid system of growth would yield the most profitable returns. It is obvious, from recent experience, that where it is possible to introduce various systems of fruit culture the opportunity should be at once embraced.

Arches of fruit trees, for instance, would be suitable in some parts of most gardens. Then there is the horizontal and oblique cordon planted in narrow borders where root extension is in some degree proportionate to the progress made by the branches or spurs, which, of course, are restricted to space; and there is also the espalier mode of training, which has been recommended in THE GARDEN a short time ago. Before forming plantations of young fruit trees it is a good plan to keep them in a small nursery for twelve months. The roots sometimes suffer in transit; and although they look none the worse for the time being, yet the progress made by the trees may not

turn out satisfactory the first season. This plan also affords an opportunity of weeding out all cankered trees or discarding old varieties. Apple and Pear trees are now so cheap, that a small nursery full of them would cost but little; and the possession of them would enable one to weed out the old trees about the place by degrees. In other words, operations of this character should be anticipated by having young trees in a fruit-bearing state before the old ones are discarded. They need occupy but little room, and by being replanted annually they can be kept fit for removal whenever they are required. I have seen a very large garden restocked in this way without the supply of fruit ever being cut off. There is one other point in hardy fruit culture of paramount importance, and that is, shelter. This I have seen exemplified in a remarkable manner a few days ago when visiting a neighbour's garden. It is walled in all round, and its position is such that destructive winds sweep over the tops of the trees without injuring the crops in the smallest degree. The soil is, of course, thoroughly drained; and the consequence is, that failure as regards hardy fruits is almost unknown. Even Coe's Golden Drop Plum bears freely on a north wall in close proximity to Marie Louise Pears, which also do well on moderate-sized standards in the same garden.

The following selection of Apples and Pears is suitable for Lancashire and the north of England generally, viz. :—

APPLES (*Culinary*).—Alfristoc, Cox's Pomona, Dumelow's Seeding or Wellington, Hawthornden (new), Dutch Codlin, Emperor Alexander, Galloway Pippin, Lord Suffield (indispensable), Northern Greening, Stirling Castle, Tower of Glamis, and Yorkshire Greening. *Dessert*.—Oslin Pippin, Eve, Ribston Pippin, Blenheim Orange, Cellini (a great cropper), King of the Pippins, and American Mother.

PEARS.—Doyenné d'Été (July and August), Citron des Carmes (August), Aston Town, Marie Louise, Louise Bonne of Jersey, Beurré Clairgeau, Chaumontel, Duchesse d'Angoulême, Napoleon, Passe Colmar, Beurré d'Aremberg, Easter Beurré, Beurré Diel, Beurré Rance, Hacon's Incomparable, and Ne Plus Meuris.

W. HINDS.

Otterspool.

NOTES ON APPLES.

As is the case with most other fruits, we have far too many kinds of Apples, and hence the question so frequently asked, "What is the name of this or that variety?" The following illustrations may, therefore, not only assist owners of nameless sorts to recognise them, but also prove a guide as regards selecting the best kinds.

CALVILLE ROUGE D'AUTOMNE (fig. 1) is one of the best of kitchen Apples, having a reddish-white flesh, which never fails to cook well. It is too large for a table fruit, otherwise it is equally well adapted for dessert. It is very handsome, having a bright red skin somewhat yellow streaked with red on the shaded side. The tree has a vigorous constitution, and is a free bearer.

GRAVENSTEIN (fig. 2) is a well-known Apple, though not so generally grown as it should be. It is classed, as a rule, amongst kitchen Apples, but it is also one of those kinds that answer equally well for dessert, being both handsome and fine in quality. The skin is perfectly smooth, and in colour a pale yellow streaked with red, and when fully ripe bright yellow and crimson. It generally ripens during November, but I have known it to be good at Christmas.

REINETTE FRANCHE (fig. 3) is one of the handsomest, as well as one of the best, of dessert Apples, and one which keeps as long as Cox's Orange Pippin or Court Pendu Plat. Its skin is pale yellow dotted with russet, and the flesh is at once tender and crisp, with a strong aromatic flavour. The tree has an excellent constitution, and is a profuse bearer. It is worthy of a first place amongst dessert kinds.

CALVILLE ROUGE D'HIVER (fig. 4) is a large red kitchen Apple, having a deep bloom, which gives it a rich appearance. The tree is an excellent bearer, but its fruit is not so good in quality as that of many others, and it has also the undesirable quality of retaining the red tinge of flesh when cooked. It ripens in November, and will not keep long after that time.

CALVILLE BLANCHE (fig. 5).—To my mind this is one of the most beautiful of all Apples, and certainly one which when cooked has the most delicious, as well as the whitest, flesh imaginable. It is not nearly so largely grown in this country as it is in France, and no other Apple is in such demand or fetches so large a price in the Paris markets. The illustration faithfully represents its shape. It has a smooth, pale yellow skin, and is deeply ribbed, especially near the apex. The tree is a free grower and bearer, and the fruit will keep well till February or March. It is an Apple which should be in every collection.

REINETTE DE CANADA (fig. 6) is one of the largest of all kitchen Apples. It was shown in nearly all the collections at the Paris Exhibition, which opened on the 1st of this month, and was by far the finest-looking Apple there. The skin is greenish-yellow, strewn with russet, and sometimes quite

Peach in this country is yet in its infancy. As a tree it is quite as rapid a grower as the Vine, and as willing a hearer if it is only trained in a rational manner, and not cut down almost as fast as it grows, as has been the practice hitherto, except in a few instances here and there. We have before alluded to this matter, and now propose to state some recent experiences on the subject of training, which may perhaps help to show that the training of the Peach—and, indeed, all stone fruits—is a far more simple affair than it is generally made to appear, and that it is quite an easy matter to have both large trees and crops of fruit in a great deal less time than is usually supposed, or than any one might well be led to believe from what has been taught on the subject. We have once or twice before recorded some experiences on this matter; but during the past summer we have made experiments on a more extensive scale than we had had an opportunity of doing hitherto, and which we propose to describe. In November last we had ten young trees from the nursery, which were planted in a late house as soon as received. As we would be quite

Fig. 6.—Reinette de Canada.

covered with it. The flesh is of the finest quality for kitchen purposes, but second-rate for dessert. It will keep in good condition till March. The tree makes a handsome pyramid, and is an excellent bearer in most seasons. W. W. H.

EXPERIMENTS IN PEACH CULTURE.

WITH those who seek information on the subject of Peach culture, the question asked in almost every case is, If I plant young trees now when shall I have fruit?—which question might be answered thus: It entirely depends upon the mode of training adopted. If you adopt the plan almost invariably recommended in standard works on English gardening, you will have crops in four or five years; but if you disregard such instructions, and train your trees in a natural way, you may have crops in less than half that time, or, in other words, the first year after planting. Our opinion is, that the culture of the

without Peaches during two months in the autumn till these trees came into a bearing state, it was determined to get them on as fast as possible, on the extension principle of encouraging all the growth possible, and cutting little or none of it away at pruning time, in order to have a crop of fruit the year after planting—that is, next year. Our purpose so far has been fully carried out. Though the trees had only stumps of roots when they came from the nursery about ten months since, stems not much thicker than one's thumb, and about half-a-dozen one-year-old shoots 1 ft. long or so to each, they have grown well, and the smallest tree in the lot, a Royal George and a rider, is now 7 ft. across to the extremities of the branches, and the largest, a Victoria Nectarine, a dwarf, is 12 ft. in diameter and 6½ ft. high. Some of the trees have made about 100 ft. of young wood, and some branches originated from a single bud last March contain 13 ft. of wood, which could have been extended to 20 ft. had the main leaders not been stopped some time ago. The trees are in the highest health, and crowded with bearing shoots, already plumping their fruit buds at every joint, and, if we have

ordinary success, we should, according to all past experience, have a good crop of fruit from each tree next summer. Few of the trees have less than thirty shoots, and, as very few of these are under 2 ft. in length, most of them nearly 3 ft., and some above 4 ft., it would be only moderate cropping to take one or two fruits off each, which would give us a good supply from the ten trees.

This may appear like counting one's chickens before they are hatched, but it is neither more nor less than we have done before on more than one occasion. Had we chosen to train the branches as thickly as is commonly done, the trees would have had twice the above quantity of wood upon them; but, as it is, the shoots are trained 6 in. apart or thereabouts, so that the ann can get to every leaf. Nothing in the way of pinching or pruning has been done to the trees since they were disbudded in spring, except in the case of an unusually vigorous shoot here and there which has had its top pinched off, or shoots cut clean out in one or two places where they were thought too crowded. Of course, useless side laterals have been stopped in the usual way, but all the earliest of these have been laid in where room could be found for them, and they now constitute the best portion of the bearing wood. For example, some of this season's shoots are over 5 ft. long (they would have been 7 ft. had they not been stopped); and, instead of pinching all the side laterals of these at the first joint in the orthodox manner, which would have given us a shoot like a fishing-rod by this time, and few or no fruiting buds, they have in most cases been laid in on the upper side of the shoots, and now these secondary shoots might be taken for this season's growth, and the main shoot that produced them for last year's wood, were it only divested of its leaves. In this way the vigour of the tree has been expended in its legitimate channel, viz., in the natural extension of the tree and the production of bearing wood. No attempt has been made to restrain vigour and induce fruitfulness by a persistent system of pinching, as some recommend; but, instead, the said vigour has been directed into as many channels as possible, and expended in the rapid enlargement of the tree and the production of a large quantity of fruiting branches and buds.

And now just a word or two about the training of the trees. They were planted, as stated, in November last, but were not tied in to the wires, except a shoot here and there to keep them apart, till the young shoots of this year were about 18 in. long, when both young and old wood were tied in loosely. About the beginning of August the trees had filled up so much with wood that a redistribution of the branches became necessary; and so they were unfastened again, and the bottom branches, in the case of the riders, were brought down to the perpendicular, or nearly so, and the central branches spread out more, but not more so than they required. Hence all the riders except one have now quite circular heads, and in some instances the bottom or depressed shoots reach nearly to the ground. It is generally thought that this depression of the side shoots weakens them; and so it does, but not seriously. With us few of these shoots are under 2 ft. in length, and one shoot, which has been trained quite perpendicularly since it was 1 ft. long, is now 4 ft. in length. As the wood in any case promises to ripen thoroughly to the extremities of the shoots, the trees will hardly be reduced in circumference at pruning time, but only balanced; and next year, if they grow as well as they have done this, they will add some feet to their branches on all sides. They are, indeed, so crowded now that we think of removing some of the trees this autumn if we can prepare a place for them in time. They will certainly have to be moved next year.

We are more convinced than ever that if we want to succeed thoroughly with the Peach under glass, and escape the necessity of continued root-pruning and cutting the natural growth of the trees because we cannot find room for it, we must build larger houses and give the trees more room. Each vigorous-growing tree should have at least a clear space of 30 ft. by 20 ft., and it will fill the same in a marvellously short time. It will pay to put the trees in thickly at first—say 10 ft. apart; but they should be removed before they interfere with the permanent trees. Riders or standards should always be planted alternately with the dwarfs, as they can be extended more rapidly than the latter, owing to the facility with which the branches can be spread out. We have seen a rider not many years old with a perfectly round head, nearly 20 ft. across in any direction. The old Peach trees at Chatsworth show what can be done by the extension system. They cover, or have covered, quite as much space as we have given above, if not more, and have had room to grow.—“Field.”

Standard Gooseberries and Currants.—These are by no means new. At Duxbury Hall, in Lancashire, they formed quite a feature thirty-five years ago. If I understand Mr. Garland (p. 344) rightly when he states the height to be about 3 ft., I take it to be length of stem, and I should say plants of this height, with heads 5 ft. or 6 ft. through, would look very cumbersome. 6 ft.

through would appear a very large bush grown in the usual way. The plants that I have seen were in total height about 5 ft. with heads about 6 ft. in circumference. They require the utmost care and attention to make them worthy of a well-managed garden. The advantages of the system are as follows: 1. A symmetrical row of these by a walk side has a very fine and somewhat unusual appearance, and the berries are always accessible to invalids or others who may wish to gather their own fruit. 2. It is peculiarly adapted to Gooseberries of a drooping or prostrate habit, such as the Warrington or Aston Seedling, the best flavoured of all Gooseberries, and, perhaps, the worst grower. No one would think of cultivating the most symmetrical-growing plants of all Gooseberries—the Manchester Red, for instance—in this manner. 3. The fruit being elevated so far from the damp earth attains a ripeness and flavour which fruit growing nearly on the ground never can acquire, and it is easier netted and can be longer preserved than fruit grown in the ordinary way. 4. Gooseberries grown in this manner, and not too closely together, do not in the least interfere with the cropping underneath.—THOS. WILLIAMS, *Ormskirk*.

FRUIT AT THE PARIS EXHIBITION.

I VISITED this exhibition between the 1st and the 8th of this month, and was therefore in time to see one of the fortnightly series of competitions of fruit, which opened on the 1st and continued until the 15th; and though I confess I was somewhat disappointed at the comparatively poor display made, I am glad to have had an opportunity of inspecting perhaps the largest collection of Apples and Pears that has ever before been brought together. The grand display of fruit which I had seen at the Crystal Palace during the preceding week doubtless had a tendency to lower my estimate of the Paris one; and well it might, for, if we except some four or five dozen dishes of Duchesse d'Angoulême Pears and the same number of Reinette de Canada and Emperor Alexander Apples, there was nothing approaching the show at Sydenham. The collections from various Continental horticultural societies, which consisted nearly wholly of Apples and Pears, were arranged under a projection in the open air alongside the main building of the Exhibition, and filled tables running the entire length of it. The latter were much too high, and the loose gravel upon which one had to walk covered the fruit with dust. Notwithstanding this drawback, however, the display was a good one. No special prizes were offered, and when I inspected them on the 5th no awards had been announced, so I simply noted a few of the finest-looking fruit. Amongst Pears, these were Duchesse d'Angoulême, of which splendid fruit appeared in every direction, General Todleben, Beurré d'Arenberg, Beurré Clairgeau, Easter Beurré, and Josephine de Malines. Amongst Apples, Reinette de Canada took the lead, then Calville Blanche, Bedfordshire Foundling, Emperor Alexander, Gloria Mundi, and Calville Rouge. The Apples generally, both dessert and kitchen, were inferior to those shown in England, and certainly not nearly so well coloured, though one expected in such a climate to have seen them better in that respect. There were a few Grapes and Peaches also on this table, but nothing calling for special remark. The principal Grape display was held in a building situated between the large exhibition building and the Trocadero, and consisted entirely of Grapes grown in the open air—to me a most interesting exhibition, though I could not help thinking that in the matter of setting up the fruit one might have given the exhibitors a lesson which most certainly was required; for here some of the bunches were thrown on to dishes, others were laid on boards, others on old boxes, others placed in flower pots, and some in what would be considered by the owners ornamental stands, which, however, did not make the fruit approach anywhere near the worst fruit that was shown at Sydenham the week previous. The principal varieties were Chassela de Fontainebleau (Royal Muscadine), Esperione, Frankenthal, Muecat Noir, and Black Ichia.

In an adjoining building the great Parisian Potato Show was held, and was poor indeed—not but that there were plenty of tubers, for there were many hundreds of dishes, but the only good lots were furnished by Mesars. Carter & Co., High Holborn, and Mr. Porter, Old Meldrum, N.B. There were classes for twelve sorts, twenty-five sorts, and unlimited numbers. Mr. Porter easily beat his opponent in the limited classes, but in the other Mesars. Carter won the day, showing over a hundred against some fifty kinds put up by Mr. Porter. Mesars. Carter's tubers were all excellent, though a little discoloured, doubtless through exposure at Sydenham previous to going to Paris. Mr. Porter did not show at the Palace, hence the beautiful clearness of his specimens. W. W. H.

Storing Fruit in Malt Dust.—To “W. W. H.’s” reasonable remarks on storing fruit (p. 260), allow me to add an admirable recipe

for keeping Apples and Pears given me a year or two ago, and which may not be so well known as it deserves to be. The plan recommended (and proved by most satisfactory results) is to pack the fruit in malt dust—easily to be obtained from any brewery—in ordinary flour barrels, and to store them away in a dry place.—WINCHMORE.

ROSES.

ROSE GROWING IN FRANCE.

(Continued from page 356.)

SOWING IN PANS.—In cold climates Roses should be sown in pans. Each pan, after being properly drained, is filled with heath mould lightly pressed down. The seeds are scattered over the surface and covered with a layer of heath mould $1\frac{1}{2}$ in. or $1\frac{3}{4}$ in. thick, which is flattened by being pressed down with the bottom of another pan. The pans, after having been labelled, are taken into a cool house and placed in a frame close to the light. The young plants will begin to make their appearance about February or March. The pans must be kept clear of weeds, and the soil should be kept slightly damp, but not moist, until it is time for planting out, which is performed in the way already described.

PROPAGATION BY CUTTINGS.—It may be asserted that all Rose trees may be multiplied by cuttings; the soft-wooded kinds, however, are most likely to yield the best results when propagated in this way. In consequence, these varieties are generally chosen for the purpose. On a large scale well-known varieties are propagated in this manner in the open air and under bell-glasses between the beginning of August and the end of October. The method adopted is nearly the same as that already described; there are, however, certain details connected with it upon which commercial horticulturists lay great stress. The method about to be described is that used by M. Louis Vacher, of Petit Vitry, well known as a successful Rose propagator, who has done great service to horticulturists by making known the system on which he works.

Propagation by Cuttings in the Open Air.

PREPARATION OF THE BEDS.—A border from 2 ft. to $2\frac{1}{2}$ ft. in width is dug at the foot of a wall having a favourable aspect. The surface is then raked smooth and the edge of the bed is kept firm by a bordering of wood fastened by pegs. A layer of very dry and well-broken-up horse manure, about 6 in. thick, is then spread over the surface of the bed and made smooth with a fork. On the top of the manure is scattered a layer of fine sand, from $2\frac{3}{4}$ in. to 4 in. thick, the surface of which must be carefully levelled. The bed must be kept just damp, but not wet.

PREPARATION OF THE CUTTINGS.—The cuttings are generally prepared in the shed where the shoots which have been cut off the parent plants are stored. The leaves are all cut off with a pair of scissors, and the shoots are cut into lengths of from 2 in. to $6\frac{1}{2}$ in. long, according to the size of the slip, but always so as to obtain as many cuttings as possible. The slips are cut at right angles to the axis of the shoot, and immediately below an eye. As the cuttings are prepared, they are thrown into a basket containing a damp rag. Generally speaking, the last fragments, which have a heel to them, are put on one side, as well as those which have been previously detached from the parent stem, as these cuttings are more likely to strike easily than the others.

PLANTING THE CUTTINGS.—In planting the cuttings we always begin with the longest, which are placed close under the wall. They should be thrust into the soil to the depth of from $\frac{3}{4}$ in. to 1 in., according to their thickness, and should be placed at about $\frac{3}{4}$ in. from each other. The bed is continued until it is full, always taking care to plant the cuttings according to size—the longest nearest the wall and the shortest in front. A slight watering should now be given with a fine-rosed can or, better still, with a syringe. The beds must next be covered with frame-lights, which are laid over them so that the upper edge rests against the wall and the lower on the wooden edge of the border. M. Vacher, who plants cuttings at the

rate of 30,000 a year, found one day that he had run short of lights, so it struck him that it would do just as well to use sheets of zinc, 4 ft. long by 2 ft. 8 in. wide. He was afterwards struck by the fact that the cuttings so sheltered seemed to thrive better under the zinc than under the glass; he, consequently, renewed the experiment and proved the fact in the most conclusive manner. A little consideration will, however, show that in this case theory and practice are in perfect agreement. The metal, which is a good conductor, absorbs the heat without reflecting it as the glass does, in addition to which, zinc being a more powerful radiator than glass, the heat absorbed by the metal is much more readily transmitted to the plants. For this reason the cuttings under the zinc receive more heat and less light than those under glass; they, consequently, lose much less by evaporation, being very much in the same condition as cuttings struck in closed dark frames. At night the zinc is covered over with straw mats. Cuttings grown in the open air begin to take root from the thirtieth to the fiftieth day. Gentle waterings are given whenever the soil shows signs of becoming dry, and the zinc coverings are taken off at night during the months of September and October to prevent the cuttings from growing too fast. In November and December M. Vacher's cutting beds present a verdant appearance, which, from a distance, resembles that of a piece of turf. When the cold sets in, the planks supporting the beds are protected by a heap of dry stable manure mixed with dead leaves and the glass or zinc shelters are covered with straw mats, which are taken away whenever the sun shines. These precautions are sufficient for successfully wintering cuttings in the climate of Paris. In those countries where the thermometer falls as far as 20° or 30° Fahr. below the freezing point we must double the straw coverings. It is, however, safer to remove the cuttings when the severe weather has commenced, transplant them into small pots, and put them into frames thickly surrounded by stable manure, or else into a well-protected greenhouse.

PLANTING CUTTINGS UNDER BELL-GLASSES.—Cuttings struck under bell-glasses are prepared in the same way as those intended for propagation in the open air. The ground is also prepared in the same way. The bell-glasses are pressed down on the surface of the bed, and the cuttings are inserted at the rate of 200 to 500 slips for each bell-glass within the arch left by the rim, after which they must be immediately covered with the bell-glasses. During the cold weather the glasses are surrounded with dry stable manure and dead leaves, and covered over with straw mats which are taken away when the weather is fine. The glasses should be propped up whenever the weather is warm enough to give the cuttings air and drive out the moisture.

TRANSPLANTING THE CUTTINGS INTO THE OPEN GROUND.—During the month of May the beds which are intended for the transplanted cuttings are dug and manured. The beds should be about $4\frac{1}{2}$ ft. wide, and separated from each other by a path about 16 in. in width. Each of them will hold four rows of cuttings, 14 in. from each other and 6 in. from the edges of the bed. When all danger from the cold is over, which in Paris happens about the end of April or the beginning of May, the cuttings are removed with a trowel, or some such tool, care being taken not to injure the roots. They are then placed in a basket and covered over with a damp cloth to prevent evaporation, after which they are planted out in the beds prepared for them in the usual manner. The distance at which each cutting should be planted from its neighbour in the same row depends a great deal on its hardness and kind. Generally speaking, the distance for Perpetuals is 12 in.; for Tea, Bengal, and Bourbon Roses, 8 in.; for Noisette and China Roses, from 16 in. to 12 in.; and for Dwarf Lawrence and Pomponne Roses, 4 in. The cuttings are planted with a dibber, holding the young stem in the left hand; it is placed in the hole made by the dibber, which should be about $2\frac{1}{2}$ in. deep. Some of the soil is then thrown into the hole so as to cover the roots and fill up the hole, after which a few strokes of the dibber are given to the earth round the stem so as to fix the cutting firmly in its place. This operation prevents any empty spaces being formed round the roots. After the whole of the bed is planted, the cuttings are watered. The surface should

be well forked about May, and a quantity of stable litter or well-rotted manure dug in. During the summer the beds must be watered and weeded whenever they require it.

STRIKING BENGAL ROSES IN THE OPEN AIR.—In cold climates horticulturists who propagate Bengal Roses for

Fig. 7.—Cuttings struck in the open air.

market adopt a system which is somewhat different from that described above. Fig. 7 shows two cuttings struck in the open ground, one with a boss and the other well rooted. The Rose trees which are intended to remain in the ground and furnish cuttings for striking should be planted in open beds. In the autumn, before the frosts set in, the shoots which are to form the slips are cut and divided into pieces of from 8 in. to 10 in. in length. These slips are tied up in bundles of 100 each, each bundle containing slips of the same general appearance. They are divided into two classes, the first including those of from 1-5th in. to $\frac{1}{2}$ in. in diameter; the second, those which are cut from the lower part of the shoot, and which ought, if possible, to be provided with a heel. The bundles of slips are placed in a cellar and laid by the heels in some fine sand or heath mould, or they may be laid by the heels under glass in a frame which is well protected from the cold. In the spring the slips are planted in the borders prepared for them as described above.

PROPAGATING BY HERBACEOUS CUTTINGS IN WINTER.—This method of propagating is used by practical horticulturists to multiply new varieties with great rapidity so that they may be ready for the market in November or December. The plant

from which the cuttings are to be taken is kept in the propagating house, and the mature shoots cut off and grafted on dwarf stocks prepared for the purpose. The parent plant, under the influence of the heat of the propagating house, which should be kept at from 60° to 70° Fahr., throws out herbaceous or soft shoots, which are allowed to grow to the length of from 8 in. to 10 in., not only that they may be of a certain thickness, but for the sake of obtaining as many slips as possible from each shoot. The shoot, after it has been cut off from the parent plant, is divided into slips, each slip having two or three eyes, the leaves being left on. It is planted in a small pot $1\frac{1}{4}$ in. in diameter, filled with heath-mould (see fig. 8). The earth is sprinkled with a few drops of water and the pot is set aside until some seventy or eighty have been filled. A large bell glass is then taken, and the rim pressed down on the surface of the sand or tan of a frame, so as to leave an impression. Within this circle some seventy or eighty of the pots containing the cuttings are plunged up as far as their edges. The bell-glass is then placed over them and pressed down firmly so as to keep in the heat of the frame. Cuttings propagated in this manner require a great deal of care. The bell-glasses must be lifted up every day for a certain time, in order to change the air. The condensed moisture on the inner surface of the bell-glasses is wiped off, and those pots whose soil shows symptoms of becoming dry are sprinkled with a few drops of water. In about eight days' time the swelling of the cellular tissue which precedes the formation of the roots may be perceived; about the

Fig. 8.—Cuttings struck in heat.

twentieth day the whole of the cuttings will have struck, and about the thirtieth the roots will appear at the surface of the soil. Towards the fortieth day the cuttings which show the most roots are examined. For this purpose we must lay hold of the edge of the pot with a couple of fingers of the left hand, the cutting passing between them. On reversing the pot and giving the bottom a few smart taps, the cutting with its ball of earth will come out of the pot. If the roots surround the whole of the ball the cutting is returned to its

pot, and it is placed in another frame, but without plunging it in the tan or sand. The same thing is done with all the other cuttings which show the same development of roots. They are then covered over with a second bell-glass, which must be propped up by an empty pot so as to accustom the young plants to the air. The slips which show but few roots are returned to their frame after having well stirred the sand or tan. In about a week's time the first set of slips are repotted into pots of from 2½ in. to 3¼ in. in diameter, which have previously been properly drained. For this purpose the pots are filled with heath mould, a sufficiently large hole is made in the middle of it, and the cutting with its ball is dropped in, care being taken to press the earth well down all round it. The cuttings or plants, as we may now call them, should be watered and placed on shelves, or in another frame in the same propagating house. At the end of a month they may be removed to a cooler house. By adopting this mode of proceeding we may obtain in three or four months a hundred grafted stocks or well-grown cuttings.

J. LACHAUME.

ROSE GROWING IN FRANCE.

M. LACHAUME writes well, understands his subject, probably is possessed of ground suitable for the cultivation of even the shyest-bearing Roses, yet he lays down laws where he should give opinions. In the first place, what ordinary amateur Rose grower distant three miles from London or Paris ever could confound the ordinary Dog Rose with the Sweet Brier. As to stocks, they should be taken from the coppice before the sap rises and the buds should be inserted as soon as they can be procured, thereby ensuring prompt assistance from the Brier. Many times have I cut Roses the same season, but I do not consider the plan wise, for often a dormant bud makes the best tree. In the second place, no "clever labourer" could get from 150 to 200 stocks in a day; if he did, he would not do it long. Every stock in England fetches at least one penny; therefore, although he smashed a spade, pickaxe, and half-a-dozen new-fangled instruments for extracting the Wild Rose from the hedges, yet his earnings would amount to a considerable sum. In the third place, M. Lachaume's directions about length of instruments and manner of propagating Roses are fallacious, as there is only one (I have tried all) way of succeeding. All must be done by striking cuttings. Wild Briers, unless earth be rubbed on the cut stock, die back. Grafting is equally bad. No; take your cuttings now in October, give them moderate care, and do not let trees drip on them. When struck, put them in a very little heat, and then you are right for next season.

EUGENE E. P. LEGGE.

Litton Cheney, Dorset.

REPLANTING ROSES.

FORMAL geometrical Rose gardens seem to me an anomaly. The Rose does not take kindly to a formal garden; for a year or two they may look bright and prosperous, but after a time deaths become numerous, and only a few of the most vigorous appear really at home. It often happens that when the plants in the Rose garden are dying off in a most unaccountable manner, those standing in the kitchen garden borders, where budded, are doing splendidly. Such is the influence of fresh soil; hence the importance of frequently changing it if Roses must be confined to one spot for a number of years. No crop that occupies the land the whole year round can be continued beyond a certain period without deterioration, and to plant young plants where others have died without a renewal of the soil is courting failure. The Rose is more susceptible of the injurious effect of this than almost any plant I know. A few of the vigorous growers will do well under almost any circumstances, but many of the greatest beauties are capricious in their tastes, and thrive all the better for a little fresh turfy soil being placed round their roots. In dealing with Roses in the formal garden, or in any other position where it is necessary they should occupy the same site for a number of years, I have always found an advantage in taking the plants all up every four or five years, partially renewing the beds or borders with turfy loam or manure, adding a little clay if it be light, trenching and mixing it all together, and then re-planting. In pruning the following spring I cut back rather closely, and delay the operation a week longer than usual. Many a plant showing signs of debility has been restored and brought back to vigor by this means, and on some soils it is the only way to keep a Rose garden in a presentable condition. Even those to be depended on, such as Jules Margottin, Gloire de Dijon, &c., are none the worse for being lifted occasionally, unless they cover a large space on a wall or a pillar; then, indeed, their

rampant growth will find scope, and be converted into blossoms. I have often thought if the strong growers and the weakly, delicate kinds were grown in separate beds, or in some way managed so that the latter could have extra pains bestowed upon them, the result would be more satisfactory.

E. HOBDAY.

ANSWERS TO CORRESPONDENTS.

Tacsonias.—I have Tacsonia Van Volkemi growing in a conservatory the leaves of which are unhealthy and shrivelled like the enclosed. Will you kindly say what is the cause of it, and the best remedy?—AMATEUR SUBSCRIBER. [We can see nothing alive on the leaves. They appear to be shrivelling on account of the soil being dry or the stem being bruised in some way.]

Netting Melons.—Allow me to inform Mr. Gilbert (p. 314) that his plan of netting Melons is not new. I have been in the habit of netting my Melons artificially for years past; that is, any that I had reason to believe needed assistance in that way. I was first made acquainted with the plan through Mr. Blair, the gardener at Sbrubland Park. I fix the pin in a small piece of wood, leaving just sufficient for my purpose of the point protruding; by this means the operation is easily performed and the results are most satisfactory.—J. J., Co. Cork.

Re-potting Azaleas.—Will you say if large specimen Azaleas, that seem to want a little help, and which have not been re-potted this year, may be repotted now? They are just showing flower buds.—AMATEUR SUBSCRIBER. [Assist them with Standen's manure, and shift them after they have flowered.]

Pampas Grass not Flowering.—I have a plant of this that once (twelve years ago) sent up many heads of bloom, but has never flowered since. It has protection during the winter, and liquid manure has been tried, but without result. What had I best do?—C. W. S. [According to my experience, Pampas Grass always flowers freely after being well established. If the plant be large, transplant it at once to where it will be exposed to the full blaze of the sun. If small, delay doing so till the middle of April.—A. F.]

Winter-blooming Greenhouse Climbers.—Allow me to inform "J. W." (p. 319) that the harder being outside, it will be necessary to protect the stems of the plants up to the point at which they enter the house. If that be done the following will grow and flower well all the winter in the temperature named, viz.: *Tropæolum Lobbianum*, *Perfection*, and *Ball of Fire*; all kinds of *Heliotrope*; *Abutilon Boule de Neige* and *A. Lemoinei*; *Tacsonia exoniensis* and *T. mollissima*; and *Gloire de Dijon* and *Souvenir de la Malmaison* Roses.—W. W. H.]

Preserving Nuts.—I can strongly recommend to "Z. P. A." (p. 319) the following way of keeping Nuts fresh: Gather them on a fine day, and lay them out in the sun for a couple of days till thoroughly dry; then store them in large earthenware or stone jars with lids, and on top of the Nuts put 3 in. or 4 in. of Cocoa-nut fibre refuse. Keep the jars in a cool, dry place. I have kept Nuts fresh in this way till new ones came in. Walnuts may be kept in the same way, and would be quite fresh at Christmas, but they do not keep good so long as Filberts or Cob Nuts. I do not recommend the use of salt, as it invariably goes damp, and if the Nuts get damp they begin to grow, and are then bitter and uncatable.—DEVONIAN.

Lapageria rosea superba Out-of-doors.—I, and no doubt others, would like to know how Mr. Stephen Williamson (p. 315) has been so successful with the above out-of-doors. How long has it been outside? for from its size it can hardly be a young plant; and what protection is given it in winter? Is this the first year in which it has flowered outside? I fancy perhaps it has been an established plant in some house that has fallen out of repair and been taken down, and so it has gradually become accustomed to a cooler temperature—"A LADY OF DEVON." [Mr. Williamson writes to say that the *Lapageria* in question is all that the paragraph states respecting it; but it is in a cool greenhouse, and not in the open air. The *Lapageria* will live out-of-doors in this country, but it would certainly not flower so profusely as under glass.]

Wintering Gloxinias and Achimenes.—What am I to do in winter with my Gloxinias and Achimenes? I have bloomed them this summer in a Cucumber frame. The temperature of my greenhouse averages during winter 45°. Can I keep them there, if so, am I to let them get drier, or must I occasionally water them.—JOHN BERTRAM, *Dulwich*. [Give them a little water occasionally until all the leaves have died down, when they may be stored away in a warm corner under a greenhouse stage, laying the pots on their sides, or you may turn the bulbs out of the pots and pack them in dry silver sand in a large pot or pan. In this way they keep best, but they should not be turned out until a few weeks after the tops have died down.—S.]

Select Fruit Trees.—What are the most suitable Cherry trees, Currants, Gooseberries, or other fruits for the following positions, viz., an angle where the south and west walls of the kitchen garden meet, enclosed with wire netting to keep out blackbirds. The aspect is, therefore, north and east, only visited by the early morning sun; consequently, I want those fruits that require least sunshine to induce them to ripen. I should also prefer somewhat choice and late kinds to succeed the fruits

in the unprotected parts of the garden. The cage, if I may so term it, is about 50 ft. long, 12 ft. broad, 11 ft. high on the wall plate, sloping to 4 ft. in front.—J. H. W. T., *Carlou*. [Of Cherries plant the Morello and Late Carnation; Currants and Gooseberries, all kinds; Plums, Kirke's late Green Gage, Reine Claude de Bavay, and Late River's; Pears, Marie Louise, Josephine de Malines, Thompson's, and Van Mons, Leon le Clerc. We have all the above in Northern positions, or on north walls, and find them do well.—W. W. H.]

Cutting Down Evergreens.—What is the best time for doing this? Some of my plants have got much too large.—J. S. [They may be cut down at any time, but the best time is when growth is commencing in March or April, for then the wounds quickly heal. It is not always convenient to leave such work till the end of April, though if it can be done there is then no danger of the young shoots getting sufficiently advanced to be injured by late spring frosts.—W. W. H.]

Lamp Heating.—As no one has ventured to reply to "J. L." (p. 275) respecting this subject, perhaps an amateur's experience might be useful. My plant house, a lean-to, 15 ft. by 9 ft., was kept warm during two winters by means of a paraffin lamp, costing 17s. 6d., burning petroleum at (at that time) 2s. 3d. the gallon—much less now, I believe. It had a flat base or well about as large over as a dinner plate, an upright iron body, and a domed top pierced with holes. The well was easily filled by a side tube, and the wick, having the charred part cut off occasionally, was quickly lighted or extinguished, and in summer the whole affair could be removed. No smell could ever be detected; and what I would like to direct particular attention to is, there was not the slightest sign of blight of any kind during those two winters, and the plants were perceptibly of a brighter tone and crisper than they otherwise would have been. Two faults were noticeable; firstly, the expense (a winter's night of twelve or fourteen hours costing 6d. or 8d., as dear, or dearer, than coals); secondly, the power of resisting cold. Rarely could the warmth inside the house be made to exceed that of the outside 10° or 12°. Suppose a frost occurred outside registering 30°, the inside temperature would be about 40°. If it has been 20° outside, then the inside would have ice over the roof, and the thermometer 32°. I, therefore, discarded the lamp and tried quite a different kind of heating, the result being extremely interesting, though not, perhaps, sufficiently so for the generality of your readers.—GWENCOLNE.

Names of Plants.—*Mrs. D.*—1, *Euphorbia fragifera*; 2, *Euphorbia angulata*. *Anon.*—The Fern is *Polypodium normale*, East Indies; the shrub, *Pittosporum tenuifolium*, New Zealand.

Names of Fruits.—*H. F.*—Benrre de Capiaumont.

Alnwick Seedling Grape.—I recently saw this truly noble-looking Grape in excellent condition, the colour and bloom being faultless. Will anyone furnish a few details as to its suitability for general culture?—J. GROOM.

THE KITCHEN GARDEN.

VEITCH'S GIANT CAULIFLOWER.

AUGUST and September are the worst months for Cauliflowers if we wish to have them firm and good. Formerly, when I had to depend upon such kinds as the London and Walcheren, there was much trouble and anxiety, in our hot, porous soil, in keeping up a succession through those months, that is, in securing good, white, close hearts. Now, with Veitch's Giant I have no trouble at all. I sow the latter in the autumn with the other kinds, and plant out at several times in the spring; sow again a few seeds in heat in spring, and plant these out at different times also, and they follow on in succession as evenly and naturally as possible. I had one bed of the Giant from autumn-sown plants planted early in April, which commenced to turn in just about the time the Early London were finished in July, and we were cutting from that bed till the middle of September. The successional character of the crop adds to its usefulness in a private garden, as when a bed of Cauliflowers nearly all come in together many of them either have to go to the pigs or the rubbish heap. According to letters in a contemporary there has been some disappointment felt in some places with this Cauliflower coming in late this season, and this may occur sometimes if sowing be made only in the open air in spring, as, like all other things, Cauliflowers are affected by times and seasons. But there is no danger of a break in the supply if a few seeds are sown in autumn and a few more in March, the latter in a slight hotbed. There is yet time to sow these, only now, at this late season, they should be sown in a box in a cold frame close to the glass. When the plants are up and large enough to handle, prick them off into other boxes, or, better still, singly in small pots, and place them on a shelf near the glass in the greenhouse, or in some place where the frost can be kept out. They might remain there till February, then be removed to a cold pit to be hardened off, and finally planted out on good, well-prepared land early in April. If large heads are wanted plant 3 ft. apart; but usually

small heads are more appreciated than large ones, therefore 2 ft. or even less space will suffice. I have cut good close heads 1 ft. in diameter, but few people care about them so large; but by close planting and cutting early they may, of course, be had as small as anyone likes. I may perhaps be told that it is a waste of hense room to grow Cauliflower plants under glass in this way. Well, it is so pleasant to have the different crops come in just at the time they are required, one does not begrudge a little extra trouble to secure it; and as such shelves are usually taken up with bedding plants in winter, with a little management I have never found any difficulty in making room for a few hundreds of Cauliflower plants. By helping them on in this way the sowing may be delayed a little beyond the ordinary time. And such plants never button prematurely; indeed, when treated thus, October is quite early enough to sow. E. HOBDAY.

Late-sown Scarlet Runners.—At this season of the year when outdoor vegetables are comparatively scarce, and when forced productions have not yet made their appearance, a good crop of Scarlet Runners is extremely valuable, as they continue bearing long after the more tender French Bean is over. For this supply a good sowing should be made about the middle of June, and the plants should be treated in other respects exactly as those from earlier sowings are. They should be securely staked, as rough winds invariably prevail in autumn, and as sheltered a position as possible should be selected for them. It is too often the case that only one sowing is made in spring, and when the plants from this cease to produce pods fit for gathering the season is considered over; any one, however, who gives the late-sowing system a trial, will, in average seasons, greatly prolong the gatherings, and will find the Scarlet Runner even more useful as an autumn than as a summer vegetable. It may be remarked that gathering the produce as soon as it is fit for use, and not allowing any pods to get old and seedy, is most important, as seed-producing is an exhausting matter, and soon brings the productive power of the plants to a standstill. Thin sowing is also advantageous. Upright rods securely fastened to horizontal ones make a good support on which to train the plants.—JAMES GROOM, *Linton, Maidstone*.

Tomatoes—Smooth v. Wrinkled.—Nearly all things that come under the improving hand of man in course of time lose their ruggedness of outline. Refinement of form and expression is one of the effects he seeks to produce, and, consequently, raggedness of petal in the case of flowers, or roughness of exterior in the case of fruits sooner or later gives way. It is so in the case of the Tomato, for nearly all the newly-raised and introduced varieties are either circular or oval in shape. Formerly, when Tomatoes were only used for making sauce, form or shape was of no consequence; but now, when Tomatoes are coming into general use, not only as sauce, but also as vegetables, often served up whole, regularity of shape and size assumes an importance it did not formerly possess. Possibly, in the future the Tomato may be useful as a dessert fruit. I have often gathered fruit of Tomato ripened in a warm house that have possessed a rich flavour, containing quite sufficient saccharine matter to suit many palates, and in this direction still further improvement may be expected. Three of the best smooth kinds at present are Hathaway's Excelsior, Vick's Criterion, and Carter's Green Gage. The first possesses size and beauty of outline. The second is a handsome, oval-shaped, amber-coloured fruit, of medium size. The fruit should be thinned out well when quite small, as it bears freely. It is a good kind for growing in pots under glass. And the last is a yellow kind, well known and appreciated everywhere. Even where the wrinkled kinds are highly prized, it is as well, in order to keep pace with the times, to grow some of the smooth sorts in addition, as they are nearly sure to be inquired after for serving up whole, and for using in various ways.—E. HOBDAY.

Sutton's King of the Cauliflowers.—This has been very fine with us this season. It is quite a cottager's Cauliflower, as upon the same ground it will produce nearly four times the weight of any other Cauliflower. We had quantities of heads weighing over 15 lb. each, and one fine head weighed 28 lb. It is very close and white.—J. MILLES, *Clumber*.

Vegetable Marrows on Railway Embankments.—We notice that Vegetable Marrows grow vigorously on railway embankments on the south side of London. They have a deep and, as a rule, a loose soil in which to grow, and, being in an exposed but sunny position, they not only grow well, but fruit with marvellous freedom. Bare spaces of this kind might be more frequently devoted to the growth of this vegetable, which, if left to ripen and stored, will furnish wholesome food all through the winter, and go far to compensate for the losses sustained by the failure of the Potato crop.—S.

"This is an art
Which does mend Nature: change it rather: but
The ART ITSELF IS NATURE."—*Shakespeare.*

LAXENBURG.

THIS is the favourite summer and suburban home of the Emperor of Austria, and a notable garden in various ways. To begin with, the superintendent (or "inspector") of the very extensive gardens and grounds, M. Rauch, lived more than ten years with Loudon in Porchester Terrace, a fact which in itself would make a visit to Laxenburg interesting to anyone acquainted with the history of English gardening. And it is fitting that one who worked so much at the "Arboretum Britannicum" under Loudon should be entrusted with the charge of the many fine trees that surround these noble lawns. The place is the very opposite of Schonbrunn. No green Gower Streets here; but a rich variety of stately tree-life surrounding great lawn-like vistas, many of them emblazoned with such glory of golden and crimson colour as is seen in the Indian summer in the woods of North America. The house is not set in a terrace garden, but on level ground; only a broad walk separates the palace from lawns fringed with flower beds and stately masses of fine-foliaged plants. Perfect ease of movement from the rooms to the turf on which stand so many objects that invite attention is one of the good points thus secured. Indeed, this grateful ease of movement (without the steps and walls and impedimenta, of which a small catalogue might be made in many gardens) is noticeable throughout the grounds, except in one place where certain remnants of an old Dutch garden are allowed to remain. One can pass from wide, sunny, breezy lawns, delightful in the October days, to the shade of great groups of Honey-Locust, or Oak, or Abele; and then, if so disposed, among climbing and other Roses, numerous fine-leaved and flowering plants, all arranged so on the Grass that one can move about among them as easily as in a well-arranged room. There are many beds, but the majority of the more striking plants are placed on the turf, singly or in groups. Sometimes the more distant groves are furnished with underwood, but more frequently the turf passes beneath the great trees, which leaves the views more extended and interesting. It may be more convenient if a few notes concerning such things as seemed most instructive be thrown into a paragraph form.

ACCESS TO THE GARDEN.—This garden is open to the public without any kind of reservation whatever every hour in the day and every day in the year to anyone who wishes to visit it or anything it contains. Let it be noted that it is the private and favourite garden of the Emperor, and not one founded and supported for purposes of instruction and study like Kew. No difference whatever is made whether the Emperor is at Laxenburg or not. No sunk fence or railing reserves any particular part of the ground near the palace from which the public are cut off. And in consequence of the wide extent and good landscape gardening (for perfectly flat grounds), full collections of European and American hardy trees, it is more instructive than most Continental botanic gardens, even from a botanical point of view. It is worth while to compare this perfect freedom of access to the garden not

with the system that obtains in Her Majesty's own gardens, but with Kew, an establishment avowedly for public teaching. One or two other instances may be mentioned of wise liberality to the public in Vienna on the part of private individuals, who, of course, support their gardens and palaces wholly at their own expense. One is the large and pleasant garden of Count Schwarzenberg in Vienna itself; the other that of Prince Liechtenstein, behind the precious gallery of pictures, which is also so freely open to the public. The Schwarzenberg garden, which is by far the largest and most important, is open to all from an early hour in the morning till evening—the gates only being closed during very bad weather when nobody would care to go. These last instances are not mentioned because it is rare for proprietors of gardens to open them freely to those who have none. We have not a few in our own country who are liberal in this respect. But these gardens are opened throughout the day in the heart of a great city, and hence their interest for us as regards the regulations concerning our own public gardens. It is almost needless to add that the Botanic Gardens of Vienna, situated in the city, are open to the public throughout the day.

OCTOBER LEAVES.—It would be worth the while of the owners of many acres to plant trees for the beauty of their autumn colours alone. At Laxenburg many of the trees were beautiful in this autumnal glory, noticeable among them being the Honey-Locusts (*Gleditschia*)—some branches green and others clear yellow—the larger branches sweeping the Grass; the Yellow-wood (*Virgilia lutea*) of which there were many trees; the Black Walnut (*Juglans nigra*), now so much used for furniture in London, was in many cases a mass of golden leaves from top to bottom, its useless fruit abundant on the ground, while the common Walnut near it had no beauty of colour. The Kentucky Coffee trees were also fine in colour and very numerous; though finest of all were the Black Walnut and the Tulip tree, which is grand in its autumn dress where the trees are large and there are a few sunny days to cause the leaves to "ripen well," so to say, before falling. The most vivid spots among these richly-hued groves—the lightning among the clouds of gold—came from the well-known Venetian Sumach (*Rhus Cotinus*), which is a native of Austria and many other cold parts of Europe, in none of which it thrives better than in Britain. The common Spindle tree (*Euonymus europæus*) was also most striking in certain positions, not for its fruit, but for its leaves. One crimson flake near the edge of a grove, splendid at a long distance off, was traced to this. Not the least remarkable, however, among such trees was the dwarf *Æsculus macrostachya*, which all who know it admire for its fragrant spikes of flower. Here, where it was exposed to the light, the ample leaves were rich in gold and brown. There is probably no other tree so dwarf (good specimens being under 4 ft., and spreading) which would give such fine masses of colour so near the ground. Therefore it has another merit for our gardens besides its sweet flowers and ample foliage.

SOME OLD PLANTS CULTIVATED.—Some very old and wholly neglected garden plants are here grown so well, that they astonish one with their beauty and vigour. For example, who out of a botanic garden grows the old Persicary (*Polygonum Persicaria*) now-a-days? In the Regent's Park, by accident probably, some of it grows in a shrubbery among plants that nobody ever takes any notice of. Here there are many specimens of it 8 ft. high with leaves 20 in. long, and the inflorescence so well

developed that each plant droops down gracefully at the top, where, in fact, it becomes a long plume of crimson racemes. No lovelier plant has been seen in the flower garden. This result was brought about by cultivating the plant (as Castor-oil plants are grown) instead of sowing it as most hardy annuals are sown; that is to say, it is raised in frames, each plant being well grown before it is planted out in rich ground for the summer. This plant, so treated, is a valuable addition to the resources of those who care for variety and grace in the flower garden. The old and well-known *Love-lies-bleeding* and *Prince's Feather* were treated in like manner, and with results nearly as remarkable. *Zinnias* grown in much the same way were 5 ft. and even 5½ ft. high! This is a plant the capacities of which do not seem to be recognised with us, it being so often treated as so many annuals are, that is to say, starved or half grown. A brilliant scarlet variety was the most plentiful here; it was quite double, the overlapping petals raised like a cone, and the colour as vivid as that of the most brilliant forms of *Anemone fulgens*. The large form of the *Evening Primrose*, commonly known as *Oenothera Lamarckiana*, and which is such a valuable plant for the wild garden, is here well grown in small beds near the Palace; its habit of opening a number of small terrestrial moons to illuminate the scene during the night having made it a favourite with the Emperor.

SOME OLD GREENHOUSE PLANTS IN THE FLOWER GARDEN.—The previous paragraph concerns annuals; some old-fashioned inmates of the greenhouse are grown to grace the flower garden in an equally happy way. *Plumbago capensis*, for example, which is so admirable when its blue flowers are depending from pillar or rafter in the greenhouse, is grown here into pyramids from 3 ft. to 8 ft. high, and placed out of doors in such condition that it flowers throughout the summer and autumn as a free and graceful pyramidal bush. Those who know the plant when grown so that its flowers hang down naturally may form an idea of the effect which it produces. The *Heliotrope* is grown exactly in the same way, only in some cases a foot or two higher. These pyramids are plunged in small groups in Grass, so that those who admire them can pass easily among them. Perhaps more valuable than either—though nothing can be more lovely than the *Plumbago*—are many specimens of the old white *Brugmansia*, single and double, also grown for placing in the open air in summer and flowering throughout the summer and autumn. It may be imagined how well a group of these plants, with their numerous great white trumpets, look in a green nook backed by evergreens and trees. All such old plants as these are taken up in October and stored in cool houses for the winter. The taller and finer specimens are the growth of a good many years. With such materials it is easy to diversify the surface of the flower garden. Here, however, a variety of other subjects are used for this purpose, the masses of fine-leaved plants being so bold, that they give quite a tropical aspect to some parts of the ground even from long distances.

A GROUP OF TREES.—Very fine were the trees here where allowed to group themselves naturally and with plenty of room. Particularly interesting was one group of a tree which, owing to the general plan of crowding trees together so as to form a monotonous green mass, is never taken much notice of. It is *Eleagnus angustifolia* which grows so here that it may well serve to show how much we lose in our botanic and other gardens by not securing the full development of and showing the cha-

racteristic beauty of each tree. Here, near the palace, a group of this tree forms a cloud of silvery leaves through which the picturesque black stems of the trees are distinctly seen. The group being isolated, the trees have attained their full size and assumed their natural form, some of the main branches crossing a stream that runs hard by, and many of the others sweeping the Grass. If so much beauty is afforded by a tree of fourth-rate importance, how much may we not expect from the same principle being carried out with the nobler ones—that is to say, showing them well developed in groups as well as singly.

NOTES FROM KEW.

Hardy Shrubs.—Amongst the very few hardy shrubs that enliven the present dull season none are so beautiful as that charming Chilean evergreen *Azara integrifolia*; it has a neat habit, dark green, roundish leaves, and clusters of yellow, aromatic blossoms. For a dwarf wall in most parts of England, and for the open shrubby border in sheltered spots of the southern and western counties, this pretty shrub is a decided acquisition.

Hardy Herbaceous Plants.—*Bœninghansenia albiflora*, a member of the *Rue* family, is a truly elegant and graceful plant; it grows about 2 ft. high, has finely-divided, glaucous green leaves, and large, much-branched, leafy panicles of small white flowers; the only drawback to this beautiful herb is that it possesses in a slight degree the somewhat disagreeable scent common to many of its relatives. *Cuphea silenoides* and its varieties *Zampsri* and *purpurea* deserve mention on account of their being nearly the only annuals which retain now any of their summer beauty; the three were mentioned in "Notes from Kew" some time ago. *Chrysanthemum frutescens grandiflorum* forms a dense bush, 1 ft. to 1½ ft. in height and from 2 ft. to 3 ft. through; it has bright green leaves and large white blossoms, which are produced in such profusion as to render it one of the most valuable of outdoor flowering plants at the present time. *Heliotropium floribundum*, about 3 ft. high, has also been already noted in these columns, and its golden-orange flower heads are still in full beauty; this is one of the most showy and desirable of late-flowering Composites. The *Asters*, which merit special mention by reason of their being in flower after nearly all the others are past, are *A. tenuifolius*, a very floriferous sort, 5 ft. high, with small, narrow leaves, and a great profusion of white flower heads; *A. miser* var. *pendulus*, which grows about 4 ft. high, is somewhat spreading or even drooping in habit (not erect as *A. tenuifolius*), and has white flower heads, smaller than those of the first-named kind; *A. ericoides*, 2 ft. to 3 ft. high, which has pretty, Heath-like foliage and innumerable small white flower heads, and is now one of the best of outdoor herbaceous plants to put out from; and *A. Nova Angliæ*, and its varieties *pulchellus* and *atro-roseus*, three of the very finest of all the *Michaelmas Daisies*, the type having fine rose-coloured flower heads, *pulchellus* deep blue, and *atro-roseus* deep rose-red. Of the three, *pulchellus* is the dwarfest, being about 4 ft. or 5 ft. high.

Greenhouse Plants.—Of all the Cape Fig *Marigolds*, *Messembryanthemum fragrans* is now the finest; it is a very dwarf sort, with large, thick, fleshy leaves resting on the surface of the soil, and large, golden-yellow, fragrant blossoms. *Begonia geranioides*, a South African kind, is not seen nearly so frequently as its merits deserve; its neat, round foliage sets off to good advantage the pure white flowers. *B. Richardsoniana* is of branching habit, and forms a neat little bush; it has peculiarly cut leaves and white flowers.

Stove Plants.—*Tradescantia fuscata*, a lovely little Brazilian *Spider-wort*, has short, broad leaves densely clothed with reddish hairs, and large, blue, shortly-stalked blossoms nestling in the rosettes of foliage.

Orchids.—*Oncidium ornithorhynchum* is conspicuous in a genus in which yellow is almost universal by its small and pretty rose-coloured blossoms; the colour varies in intensity and the flowers in size in different plants, some individuals bearing blossoms of good size and of a clear rose, and others smaller, much paler flowers. *O. crispum* is a very showy kind from the Organ Mountains, Brazil, where it is found growing on dead trees; in good specimens the flowers are large—from 1½ in. to 2 in. in diameter—and are produced in bending racemes numbering sometimes from fifty to sixty; the colour is deep brown broken up near the centre with yellow. *Pholidota articulata*, though more curious than pretty, deserves mention; it has strange jointed pseudo-bulbs and very numerous drooping spikes of whitish flowers.—†.

NOTES OF THE WEEK.

Tyerman's Groundsel (*Senecio pulcher*).—We have received from Messrs. Backhouse, of York, large and finely-coloured blossoms of this excellent border plant, showing that it succeeds in the north of England quite as well as in the south. It is a plant which, when better known, will be found in every herbaceous border, and it may be added that it lasts long in good condition in a cut state.

Cuphea Zampari.—I may state without hesitation that this is one of the most ornamental and useful of annuals. It is nearly allied to the old-fashioned *C. silenoides*, but it is much finer. It grows about 1½ ft. high, has numerous branches arising from the base, and when but a few inches high in early summer it begins to produce its blossoms from the axils of the small-pointed leaves, and the branches continue to lengthen and produce flowers till frosts cut them down. The flowers, which are of a rich deep purple colour bordered with a lighter hue, resemble those of an ordinary Sweet Pea, and are about the same size. They are admirably adapted for cutting, as the branches continue to lengthen and the flowers to expand for a long time when placed in water. Altogether, it is a very desirable plant, especially at this season, when most other annuals are gone, and flowers even of perennials are scarce.—W.

A Dried Palm Tree.—In the Imperial gardens at Vienna there is a fine specimen of a Date Palm, with leaves, fruit, and all in a dried state placed erect in a circular, high-roofed structure. It affords a far better notion of a Palm tree than the great majority of those grown in tubs, or even planted out in hothouses. The consistence of the leaves, fruit, stems, &c., is such that the tree will long remain in perfect preservation. This fact may be worth the notice of the curators of museums, and also of those interested with the embellishment of large rooms or buildings.

Lachenalia pallida.—Though not very showy, this *Lachenalia* is effective when mixed with the scarlet and yellow-flowered kinds in baskets or pans. All the *Lachenalias* are easily cultivated and may be used in various ways; therefore, any addition to existing kinds is acceptable to the cultivator. We lately saw the variety above alluded to flowering well in the Hale Farm Nurseries.

Oncidium Lanceanum.—This is one of the finest species of the genus, but it is somewhat difficult to keep in good condition. It, or rather a good variety of it, has been flowering finely in the East India house at Loxford Hall. Its sepals and petals are spotted with crimson, and the lip is a rich violet-purple. This plant does not thrive well in pots. It should be grown in baskets of Teak wood in a mixture of Moss and peat, plentifully intermixed with clean potsherds and lumps of charcoal. As it flowers in June, it makes a good exhibition plant; but when grown strongly it also blooms well in the autumn, and nothing can be sweeter than the perfume of its blossoms.

Haberlea rhodopensis.—I find this beautiful and rare hardy Generaceans plant to succeed best in partial shade and kept continually moist. It should be planted in a compost the largest part of which consists of fibry peat and sandstone grit. I have tried several modes of treatment, but the above appears to suit its requirements best. Though I have not succeeded in producing flowers, I look forward to being rewarded in the spring with the first sight of them.—W.

Eupatorium ligustrinum.—This beautiful Mexican shrub is one of the most desirable of a rather numerous set of autumn and winter-flowering plants. For outside wall decoration it forms an attractive object, producing, during summer and till late in autumn, abundance of broad clusters of pure white, feathery blooms that contrast finely with the deep green of the oval-shaped leaves. The flowers, which are very fragrant and borne on long slender stalks, are admirably adapted for cutting, a state in which they last a long time. In many gardens it is well known and appreciated for the winter decoration of the conservatory, and for this purpose young plants struck from cuttings the previous year and planted out in spring should be taken up early in autumn, potted, and afterwards retarded, if required, for the winter months. It is an old inhabitant of gardens, and is probably known under the more recently-applied names of *Weinmannianum* and *fragrantissimum*.—W.

Proposed New Park for London.—A public meeting in furtherance of a movement for providing a new park for the inhabitants of the north-western extremities of the metropolis was held on Monday last. It was explained that there was a deficiency of open spaces in the neighbourhood of the proposed park. Hyde Park or Regent's Park were, it was stated, obviously at too great a distance from Kilburn to be made a convenient recreation ground for people residing in that locality. It was further explained that the north-

western portion of Paddington and the district adjoining it had a population of 100,000, chiefly composed of the working classes, to whom a park and recreation ground would prove a welcome place of resort. Resolutions were adopted affirming that the physical and moral welfare of the people rendered the duty of preserving open spaces one of urgency and moment, and expressing a hope that the adjoining parishes would give their support to the scheme.

Atraphaxis spinosa.—This curious shrub is now full of its small, pinkish blossoms in the Botanic Garden at Schönbrunn, where it is allowed to spread out by itself on the Grass, which well suits its peculiar and fragile shoots. There has long been a fine plant of it in the College Botanic Garden at Dublin.

Geonoma Seemanni.—This is a handsome Palm, well worth growing in small pots for vases or for table decoration. It is robust in habit, and its young leaves are of a rich bronze colour, a circumstance which gives it an effective appearance. It is grown in Messrs. Hooper's nursery, Twickenham.

Bryony (*Bryonia dioica*) **in the Garden**.—Modest merit is acknowledged in the case of this wild British climber in various gardens in Vienna, where quite recently it was fresh, green, and beautiful. No doubt it is chosen for its enduring verdure as well as for its graceful growth and foliage. It forms many wreaths in one of the town gardens of Vienna, and it is also trained up at the angles of large statue pedestals in the garden of Count Schwarzenberg. So trained, it looks well, and pleasantly relieves the mass of stone.

Alpine Daphnes.—In the very good collection of Alpine plants in the Belvedere Gardens, at Vienna, are included, in addition to *D. Blagayana* (figured in THE GARDEN during the present year) *Daphne Philippi*, *D. alpina*, and *D. buxifolia*. There is evidently a group of these little *Daphnes* which claim a place in the select Alpine collection.

Begonia Frœheli in Winter.—If properly treated, this *Begonia* forms one of the most useful of plants for blooming during the winter months. We lately saw hundreds of plants of it in Messrs. Hooper & Co.'s nursery, Twickenham, destined to serve this purpose. The bulbs were planted early in June in the open air and in light, rich soil, where they grew well and produced a limited quantity of blossom. These plants were lifted a short time ago, potted, and placed in a cool greenhouse, where they are now throwing up abundance of bright scarlet flowers, that contrast well with the large, healthy, *Cineraria*-like leaves with which the plants are furnished, and a good display of bloom may be expected for several months yet to come.

An Effective Group of Orchids.—This may with truth be said of a group of flowering Orchids now to be seen in Mr. Williams' nursery, Holloway. It consists of large pansful of Indian *Crocuses* (*Pleione lagenaria*) plunged in a bank of Club Mosses, edged with Grasses and backed up by *Lady's-slippers* and *Odontoglossum grande*, and flanked by well-flowered examples of *Oncidium Rogeri*, *O. tigrinum*, *O. crispum*, *O. varicosum*, and *Lycaste Skinneri*, the whole being overhung with fine plants of *Dendrobium formosum giganteum*, growing on blocks of wood and in baskets, furnished with numerous large and handsome white yellow-blotched flowers. We also noted in the same house flowering examples of *D. bigibbum* and its white-flowered variety, and *Cattleya exoniensis asperba*.

Berkeley Portrait.—The portrait of this gentleman will be presented, on behalf of the subscribers, by Sir Joseph Hooker to the Linnean Society at its first meeting for the present session on November 7. The portrait will be on view at all reasonable times. Those who have not paid their subscriptions are requested to do so at once to the Treasurer, Dr. Hogg, 99, St. George's Road, Piccadilly; or to the Hon. Sec. to the Committee, Dr. Masters, 41, Wellington Street, Covent Garden.

Chrysanthemums in the neighbourhood of Liverpool are very early this year; mine are a fortnight earlier than usual, and, on inspecting a few collections belonging to our principal exhibitors, I find that a good many of their best show varieties are fully out.—H. E. A.

Horticulture at the Paris Exhibition.—It would seem that English horticulturists have acquitted themselves well in Paris, judging by the number of medals which they have been awarded. Messrs. Carter & Co., High Holborn, have received five gold medals for seeds and their general collection of horticultural and agricultural produce. Messrs. Sutton & Sons, Reading, have obtained gold and silver medals for their exhibition of Grasses, models, &c. Mr. Wills, South Kensington, has won fifteen first prizes for his collection of plants, as well as the grand prize of honour for his whole exhibition.

NEW OR INTERESTING PLANTS.

UNDER this head it is proposed to record popular descriptions and any useful information we may be able to glean respecting new garden plants published in THE GARDEN, originally, or in any other English or foreign periodical, or exhibited at our shows. It is intended to render it as complete an enumeration from the date of commencement, as circumstances will permit, but plants of purely botanical interest only will be merely mentioned with an indication of their nature. Old favourites re-introduced will also find a place here as well as improved varieties of known species, but varieties of recognised florists' flowers will be excluded.

Veronica Traversii.—One of the numerous shrubby species inhabiting New Zealand. Though not so showy as *V. speciosa* and *V. salicifolia* from the same country, it is a neat, compact, and attractive little evergreen shrub which produces a profusion of white flowers during the summer months. It forms a dense, spherical bush 2 ft. or more in diameter, with slender branches well clothed with small spreading leaves in four rows. The narrow leaves are of a somewhat pale green, shining on the upper surface and about 1 in. in length; flowers, snowy white, about one-third of an inch in diameter, arranged in short, dense racemes at the ends of the branches. Although this plant has been cultivated by Messrs. Veitch for at least five years, it is only the current number of the "Botanical Magazine" (plate 6390) that a coloured figure of it has appeared. It is a native of the Alps of the Middle Island (now usually called South Island) of New Zealand, from Nelson to Otago, by margins of streams up to an elevation of 5500 ft., and will, therefore, be perfectly hardy in the west of England and Ireland. For several years it has stood uninjured at Kew, but a severe winter would, doubtless, kill it outright or cut it to the ground in the neighbourhood of London.

Aristolochia trilobata.—This singular species is not new in gardens, but it is figured in the "Botanical Magazine" (plate 6387) for the first time in an English publication. Two species, Sir Joseph Hooker states, of *Aristolochia* from South America, characterised by the wonderful tail at the tip of the perianth and curious spurs at its base, have been cultivated in England and confounded with a third (*A. caudata*) which has not hitherto been introduced. These are, first, the old *A. trilobata* of Linnæus's first edition of the "Species Plantarum"; secondly, *A. macourna* (Gomez), a Brazilian species figured in the "Botanical Register" (plate 1399) under the name of *A. trilobata*, and under that of *A. caudata* at plate 1453 of the same work, and at plate 3769 of the "Botanical Magazine." The true *A. caudata* is a small-flowered species with no spurs at the base of the perianth. *Aristolochia trilobata* is a very slender climber with three-lobed, stalked leaves of a bronze green, relieved by the reddish tinge of the principal nerves; those on the flowering branch figured are about 2 in. across. The flowers are borne on stalks rather longer than the leaves, and are of a yellowish green traversed by red lines, the mouth bristly and spotted with a brighter red, and the long tail of a rich brown; altogether, the perianth of the flower is 8 in. or more in length whereof one-half at least is attenuated in a narrow tail hanging over the mouth of the tubular portion, which is suddenly bent back upon itself in the middle. This species is a native of the West Indies and the north-eastern part of South America, and requires hothouse treatment. It deserves a place where there is not sufficient space for the more rampant but more showy species, such as *A. Goldiana*.

Cœlogyne (Pleione) Hookeriana.—A charming little Orchid, flowered by Mr. Elwes, who imported the plant from Sikkim, and figured in the "Botanical Magazine" (plate 6388). It is singular among the Pleiones in producing leaves and flowers at the same time, the leaves subtending the solitary flowers much as the leaves of the Lily of the Valley do the spikes of flowers. Whole plant about 4 in. high; pseudo-bulbs naked, not covered with a network; leaves sheathing at the base and scarcely so high as the flowers; flowers rosy-purple, except the convolute labellum, which is white with seven brownish crests on the terminal lobe and yellow within. A native of the Himalaya Mountains at an elevation of 7000 ft. to 8000 ft.

Hedysarum Mackenzii.—A showy herb of the same group of the Leguminosæ as the Sainfoin, of which it has much the habit and foliage, but it is not so robust a plant, having slender straggling branches. The flowers are of a rich rosy-red, passing into crimson. They are very numerous, and borne in spikes from 6 in. to 9 in. long. This plant was first discovered by Sir John Richardson during Franklin's arduous journey to the shores of the American Polar Sea in 1823, which it inhabits; and it has since been found in the Rocky Mountains, as far south as Utah and Colorado, and in Eastern Siberia.

Hedysarum Mackenzii flowers freely in the herbaceous ground at Kew, and is figured in the "Botanical Magazine," plate 6386.

The remaining plants figured in the current number of the same publication are *Stachys Maweana* (plate 6389), a tall Dead Nettle, with silvery, hoary foliage, and pale yellow flowers with purple blotches on the lower lip, and deep red stamens. A native of Morocco; collected and cultivated by Mr. George Maw, of Benthall Hall, Broseley. *Antirrhinum hispanicum* (plate 6391), a dwarf annual Snapdragon from Spain, having pink and white flowers with a yellow crest. It is not a plant of value for ornamental purposes.

W. B. HEMSLEY.

Continuous-blooming Sweet Peas.—We have two short rows of Sweet Peas that have been in bloom since the beginning of July; they are still flowering profusely, and to all appearance will do so till frost cuts them down. I attribute their continued flowering to our having the seed-pods picked off regularly every week, and to giving the roots a good soaking of manure water occasionally.—W. W., *Eaglehurst*.

Saxifraga ligulata.—Now is the time to lift and pot this fine old Nepalese Saxifrage, and a finer plant for conservatory decoration in winter, especially when in the form of large specimens, could not be found. Its bold, round leaves and large, dense spikes of sweet-scented, pink blooms render it very attractive, and under glass they retain their beauty so much longer than when fully exposed in borders or rockwork. The later-flowering and equally well known *S. crassifolia* and its variety *cordifolia* are also very suitable for similar purposes, and they should also soon be lifted and potted and placed in cold frames, as they flower better so treated than if the operation be deferred till spring.—W.

Autumnal Tints.—I never recollect seeing these so well developed as they are this season. Horæ Chestnuts are masses of bronze and gold, which, when in close proximity to Elms or Yews, are simply unique. Lime, Birch, and Ash also revel in green and gold; Oaks, as a rule, are still green. The different kinds of Acers, but especially *A. rubrum*, ought to be planted largely on the outskirts of woods, associated with Laburnums, Mountain Ash, and Thorns; the latter consisting of some of the large-leaved kinds, such as *Cratægus Douglasi*; these I would recommend being planted in groups sufficiently large to be distinguishable from a distance; in shrubberies single specimens will have the desired effect. The common flowering Currant, too, at this season is most noticeable, the outside of the leaf being quite red and the centre green. The Sumach (*Rhus glabra*) is another grand plant, its fine, large leaves assuming the most varied tints of gold and bronze. *Cotoneaster Simmsii* is also a very distinct and pleasing shrub, being erect in habit, and its leaves being neatly laced with crimson; to this should likewise be added its bright coral berries, which amongst Evergreens are very effective. Veitch's Virginian Creeper, too, with us is superb; this year, the majority of its leaves being fiery red dashed with bronze, and as it retains its foliage much longer than the common variety, it is doubly valuable, and, besides, it requires no nailing. The black fruit of the Japanese Honeysuckle, and the faint crimson hue of its beautifully-veined green and gold leaves, likewise form attractions not to be overlooked. Both these plants are admirably suited for the decoration of the dinner-table.—A. HOSSACK, *Ragley, Alcester*.

Chrysanthemums at St. John's Wood.—In a collection of Chrysanthemums in the Wellington Nursery there are some new kinds which are well worth notice. Orphée is an excellent sort, belonging to the Japanese section, with large, ragged flowers of a fiery crimson, the centre petals being yellow. Le Negre is one of the most striking kinds in the whole collection; it is a Japanese variety of good habit and a very free bloomer; its flowers are flame-coloured, with a rich golden centre, and, associated with the swan-white, cushion-like blossoms of Elsie, are remarkably effective. La Frisure is a fine new Japanese kind of excellent habit; it is represented here by standard plants having clean stems from 12 in. to 18 in. long, surmounted by large branching heads of delicate blush or pink blossoms, as many as five being borne on each branch. As a market plant this would doubtless be a most desirable kind on account of its dwarf habit and excellent blooming qualities. Neat little plants, consisting of five or six shoots, might with little trouble be got into 6-in. pots, and if well furnished with foliage down to their bases and applied with numerous large, graceful blossoms, would be very desirable. Fleur Perfaité is also a fine Japanese variety, having large, rose-magenta blossoms. Amarantine is a Pomponé kind, with well-formed, smooth-petalled flowers of a bright magenta, which are, moreover, sweetly scented. Rosa Bonheur is another excellent Japanese flower of a rosy-purple colour, very showy and distinct. There are also in this collection many well-flowered plants of older kinds, all of which are worth inspection.

GARDEN DESTROYERS.

THE CODLING MOTH.

(CARPOCAPSA POMONANÆ.)

THERE are few persons to whom the grub of this little moth is unknown, as it is found only too commonly in Apples and Pears, and at times in such abundance as to seriously injure the crop. Like many insects which are injurious to the plants in our gardens, it is a very difficult one to keep in check, and, unfortunately, its natural enemies are not very numerous. The grubs in the fruit are safe from the attacks of birds and insects which would otherwise destroy them; but the chrysalides, which are generally found on the stems of the trees, are, doubtless, often a prey to ichneumons and other nearly-allied parasitic insects. Many of the moths are killed by birds and bats, and if the weather be cold and damp about the time they make their first appearance many, no doubt, perish before they have laid their eggs. As the fruit containing grubs generally ripens and falls some time before the sound portion of the crop, it should be collected and destroyed, for each Apple or Pear is nearly sure to contain a grub. In gardens where there are espaliers or dwarf trees, the fruit on them should be carefully looked over from time to time, particularly in May and June, and any showing signs of a grub being within should be gathered and destroyed; these may be known by their having a black or reddish-brown spot on them, which is the entrance to the gallery the grub is forming. In the spring any rough loose bark on the stems should be scraped off, and any chrysalides which may be found destroyed. The moths should be

The Codling Moth (*Carpocapsa pomonana*).

killed whenever they are detected. They, however, in common with all moths, are very difficult to find in the daytime, as they generally select as a resting place some spot where they are most likely to escape observation and which is just of the same colour as themselves. They may be caught when on the wing of an evening with a net, but the result would not, I imagine, repay the trouble. The moth makes its appearance in the month of May, and shortly afterwards begins to lay its eggs, generally depositing them in the eyes of the Apples or in the hollows near the stalk, usually selecting the firmer kinds of fruit. In favourable weather the grubs are hatched in the course of a few days, and immediately begin to eat their way into the fruit and take up their position near the core, eating the flesh of the Apple and making a connecting gallery with the outer world; this allows a little air to reach the grub, and also enables it to get rid of some of its droppings, which are found in great quantities in any worm-eaten Apple. The fruit continues to grow in spite of the grub, and, as before stated, falls often with the appearance of being ripe long before the uninjured fruit. The grub becomes fully grown in about three weeks or a month (in June or July), and then leaves the fruit, whether it has fallen or not, and chooses some sheltered place on the stem of the tree or beneath the surface of the ground, and spins a cocoon like a silkworm round itself, in which it changes into a chrysalis. In a few days the moth comes out and commences to lay its eggs on the fruit, so that in July, August, and even September, the fruit is attacked by a second brood of grubs; this shows the desirability of the Apple grower taking every precaution to

destroy the grubs of the first brood, as on the number of those which become moths depends in a great measure the amount of damage caused by the second brood. The moths from this brood do not appear until the following spring, the insect remaining during the winter in the chrysalis state. The moth measures about 8-10ths of an inch across the expanded wings; the front wings are pale grey, with curved, transverse, darker fine lines and bands; on the lower and outer angle of each there is a large reddish-brown spot surrounded by a golden band; the lower wings are of a brownish-orange; the thorax and body are brownish-grey. The grubs are about $\frac{1}{2}$ in. long when fully grown, and are fat and fleshy; they vary in colour from a yellowish-white to almost flesh colour. The head and a large spot on the first joint of the body are black or very dark brown, and on each joint are several small blackish tubercles, from which grow a few fine hairs. They have fourteen joints, not including the head on each of the three first, as well as on the sixth, seventh, eighth, and ninth, and, last, there is a pair of legs. The cocoon is oval, and about 6-10ths of an inch long, whitish in colour, and when found on the stem of the tree small pieces of the bark are mixed with the web of which it is formed. Within this cocoon will be found the reddish-brown chrysalis.

S. G. S.

Paraffin Oil an Insecticide.—I am able to verify all "J. S. W." (p. 340) says respecting this matter. Having a large Camellia, 10 ft. high, covered with white scale, I had the whole tree painted with paraffin oil, diluted to about the same strength "J. S. W." recommends, but we were very careful not to touch the dormant buds; the consequence was, the tree was cleared of scale and made fine growth the same season. We applied the paraffin with a camel's hair brush in the end of February, as soon as the flowering was over, and before the tree had made any new growth. Being in the show house we left a little air on for a few nights, in case the paraffin might affect more tender plants. I did not syringe it off for some days. I then put the tree in a Vinery that was started, where it had the benefit of a good syringing twice a day. I can with confidence recommend paraffin for fruit trees in the open air, but one must be careful not to touch the buds. I painted some espalier Pear trees affected by American blight, and the trees never looked so healthy as they did the next season.—T. ELCOMB, *Aquarium Terrace, Crystal Palace*.

Ailantus as a Fine-foliaged Standard.—This is one of the trees we have often spoken of in THE GARDEN as suitable for planting and cutting down every year so as to get a fine growth of leaves from a single stem. A still better use is made of it in the great courtyard of the palace at Schönbrunn. The long wings to the right and left of this immense gravelled space are saved from a too glaring barrenness by a single line of Ailantus planted in front of them and treated in a peculiarly successful way. They have clear stems about 10 ft. high, and heads about 15 ft. in diameter, the leaves being frequently 4 ft. long. This result is brought about by cutting the heads in boldly every year. In the middle of October the leaves are quite green. The trees are not allowed by this means to grow so high as to obscure the building, and their effect is much better than that of the clipped Lime and other trees so often used. The trees are on a narrow strip of Grass, and have a well-furnished Thuja between each pair of Ailantus.

Removing Fallen Leaves.—At this season of the year, when fallen leaves give an untidy appearance to even the best-kept gardens, it is well to bear in mind that they are the provision made by Nature for restoring to the earth the food that has been extracted from it during the growing season, and that where it is imperative that the leaves should be removed, some means of restoring an equivalent amount of nutriment by artificial means should be resorted to; otherwise, we shall not have far to seek for the reason why trees thus treated fail in health long before those in more neglected positions. Where many deciduous trees exist the walks at this season need constant attention, for if the leaves get trodden on them, they spoil the gravel, and, consequently entail more labour than their frequent removal would do; but, in shrubberies or beds of evergreens, it is best to permit the leaves to remain until they are all down, and then only remove such of them as disfigure the outline or margin, substituting some manure or leaf-soil for them. Digging amongst the roots of trees and shrubs should be practised as little as possible, as the best feeding roots are those near the surface, where there is anything in the shape of food, such as decayed leaves, afforded them. That digging checks rather than promotes their health and well-being there can be no doubt, and fallen leaves, though considered an eyesore by many, are of much importance to the trees themselves.—J. GROOM.

THE FLOWER GARDEN.

TUBEROUS-ROOTED BEGONIAS.

THE following remarks on these Begonias may be of use to those who are at present comparatively unacquainted with their successful cultivation. Let us therefore begin with raising them from seed. The best time to sow is in July or August, as this gives time enough to enable the young plants to form small tubers before winter sets in, a circumstance which gives so much of a start in spring as to insure that most of the plants thus raised will come into bloom before the close of the next season, which, in the case of spring-sown plants, does not always occur. The best plan for getting the seed up is to prepare a sufficient number of pots (6-in. ones) with drainage, rough compost, and then finer soil, which should be made firm to within $\frac{1}{2}$ in. or $\frac{3}{4}$ in. of the rim of the pot. Water well with scalding water, and when the mould has cooled sow the seed and place the pots in a moderately-heated house in a light position, where they can be shaded from the sun for a few hours during the middle of the day. Do not cover them with glass or anything else, as if the seed is good it will commence to germinate in a few days after sowing, and, as these plants are very impatient of confinement, anything approaching coddling must be avoided. On the contrary, from the very first allow air to circulate freely around them, keeping the pots moist by sprinkling water amongst them. As the seed is so very small great care is needed during the earlier stages of development. As soon as the seedlings are fairly up, and before they begin to crowd each other, they should be transferred to other pots or pans, prepared as directed, for the seed, omitting the watering. They should be shifted in small patches, being too small to handle singly, and should be still kept in the same house, for these Begonias will endure and require much more heat at this early stage than at any future period of their growth. They will now begin to grow rapidly, and soon cease to require shade; they will, on the contrary, require a freer circulation of air, and in a short time they should be placed singly in other pots or pans, in which they may remain if in autumn, and be grown on as long as they will continue to do so. Many, indeed, will not go to rest at all, or, at least, not before the beginning of the new year. They must not be allowed to become dust dry, but must be kept quiet until they start again in spring, when they may be potted off singly. After that their progress will be most rapid, and they will soon require a shift from 2½-in. pots to 6-in. ones, and soon afterwards many will need an 8-in. or 9-in. pot, in which they may continue during the season; or they may be placed in small pots in a cool frame to harden off and grow slowly until the weather is sufficiently warm, when they should be planted out-of-doors. Of course, in the case of spring-sown seedlings, the growth should be continuous, but, so far as potting is concerned, the same kind of treatment would be necessary.

A good compost for these Begonias is fibry loam, with a liberal mixture of leaf-mould (not too much decayed) and some sand. The best results which I have obtained were with half-decayed Couch Grass and other weeds, gathered from sandy uplands, and half-decayed leaf-mould used in a very rough state; in fact, I usually shake out most of the finer particles. This contains a good deal of food, and keeps them for a long time in good condition. They do not succeed well in fine close soil; they dislike peat, and they never do well in rotten manure under pot culture; whereas, on the contrary, when planted out-of-doors they revel in it, as they do also in vegetable refuse, or anything rich in humus. In fact, the soil for outdoor culture can scarcely be too rich. No specific time for planting out can be laid down; every one must be guided by the temperature and conditions of the locality in which they reside. For these Begonias I never use liquid manure of any sort, as I find that if the soil be good none is required.

As to position in the open air, some recommend planting in full sunshine, but, according to my experience, they will not endure the full force of a June or July sun, at least, during the hottest part of the day; therefore, a position slightly shaded during that part of the day, or a little artificial shade is best. It should be mentioned that the light-coloured sorts—white, yellow, buff, and orange tints—require mere shade

than the high-coloured ones do, as their flowers are liable to burn at the edges if fully exposed. After July is over and the nights begin to grow longer and cooler, they seem to enjoy the fullest exposure, and then grow with great rapidity. It is astonishing how hardy these Begonias are, and persons seeing them for the first time planted out and doing well are struck with their beauty. As evidence of their powers of endurance I may mention that a large number of them here (close upon 10,000) planted out were exposed to the full force of the late equinoctial gale, accompanied by a deluge of rain, and yet were unhurt. The fact of their growing close together would account in some measure for their not being dashed to pieces; but still their rain-enduring capabilities are wonderful. After a deluge they appear fresher than ever, while beds of Pelargoniums close by are quite flowerless. Again, a sharp frost occurred here on the morning of October 1; Amaranthus were killed, Heliotropes injured, Vegetable Marrows blackened, and other plants were more or less hurt, but after the most careful scrutiny, not the smallest sign of injury could be found on the Begonias, and this frost followed a day and night of heavy rain.

These Begonias are easily propagated by means of cuttings, and the earlier in the season they are put in the better, so as to allow them to mature good-sized tubers before going to rest. Cuttings with one, two, or three joints are large enough; they should be allowed to dry for a short time, and then be inserted in damp sand in a little warmth, when they will quickly root. Some of the best sorts increase very slowly; in fact, I have had some choice seedlings for two years, and never get a single cutting from them. Such kinds must ever remain scarce.

These Begonias should be allowed their own time to go to rest when grown in pots, and those planted out may be lifted when it is considered unsafe to leave them any longer in the open air. They should be put in pots, when they will continue to bloom in the greenhouse for some time longer. As soon as the stems have fallen off they should be stored away, still in their pots, in some situation where they will not become dust dry, and where they will just be secure from frost and no more. They might be packed away under a stage or even in a cellar, but where room can be spared I find the best of all ways is to place the pots on the cool earth in a house and cover them up with Cocoa-nut fibre refuse or sawdust, or some similar material. Thus circumstanced they may remain until they start into growth, naturally in the spring. Where they are grown in very large numbers, I find it quite easy and safe to reduce in bulk most of the earth about them and pack them closely together in shallow boxes, filling the interstices with some of the soil shaken off, and using one, two, or three layers until the box is full and level. I then place these boxes one over the other under a greenhouse stage, taking care that they do not get watered from above, or in a frost-proof shed. In this way they remain until they start into growth naturally in the spring. I attach much importance to this latter point, as nothing is gained whatever by forcing them into a state of premature growth. If left to themselves they come away much stronger, and their aftergrowth is so rapid as to quickly make up for any fancied loss of time. The best time to replot them is just as they are beginning to grow. Shake the old soil completely away from them. I replot them in fresh pots just large enough to hold the roots, shifting as may be necessary. I am convinced that any one with a cold frame and sufficient covering to exclude frost may grow and keep these beautiful plants safely over winter; in fact, some of my brightest results have been obtained in cold frames with the lights tilted on their sides, so as to allow the very fullest circulation of air, the bare covering of glass being sufficient protection, and in this manner plants may be grown, if necessary, for exhibition to any size. It cannot be too strongly urged that they are not by any means stove or even warm greenhouse plants, but plants which enjoy plenty of light and the freest possible circulation of air. T. SMITH.

Newry.

Phlomis armeniaca.—There is always a distinction belonging to these plants which makes them worthy of a place in collections even when their beauty is not of the showy order. The above is a very

dwarf species with neat silvery leaves. It is so different in habit from the rest of the species, that it is well fitted for association with dwarf plants on the rock garden.—V.

LILY GROWING.

SINCE the introduction of that grandest of all Lilies—*Lilium auratum*—much attention has been devoted to this beautiful class of plants, which, till then, were comparatively neglected; but besides the sensation this created in the horticultural world, THE GARDEN has done much to bring them under public notice. From the thousands and tens of thousands of the above that have been imported, and are still being brought over, one would think that the country was well-nigh stocked with them, but as such does not appear to be the case, their comparative scarcity must be owing to many being lost through planting in either soils or situations that are unsuitable to their growth. Of the many Lilies I have to deal with none are more particular in these respects than the above named, the bulbs dwindling away and disappearing in the most mysterious manner possible. Happening to have them in different situations, I soon found out the cause of this, or, at least, to me, what appeared to account for it—dryness at the roots, arising from the plants growing in an open, exposed position, where the sun shone with full force on the ground around them. In every instance where this occurred the stems were always shorter, and came considerably weaker than others in soil that sloped to the north, or received shade from such shrubs as *Rhododendrons*, whose roots do not ramble far to rob the ground of its moisture. It would be interesting, as well as profitable, to Lily growers to know exactly under what conditions *L. auratum* and others are found growing in their native habitat, that they might, in planting, shape their course accordingly. The formation of the stems, and the great length of most of them with their sparse foliage would lead one to infer that Nature has adapted them to find their way through amongst scrub or low-lying herbage of some kind, clear of which they can raise their magnificent heads of bloom. Be this as it may, I have always found that they do much the best in a situation that accords in some measure with conditions similar to those just mentioned, and that partial shade and moderately moist, cool soil are the principal essentials to their successful cultivation. If we examine the lower part of the stem of a Lily we shall find that when in a young state they begin to emit a quantity of roots around their base, which roots, of course, are intended to forage for them and afford the requisite support to the flowers. It must be obvious, therefore, if these feeders be dried up, or suffer from lack of moisture, that the tops have to draw the whole of their sustenance from the bulbs, which tax on their energies prevents the formation of others to supply their places the following year. This would necessarily occur with any growing where the surface soil became parched from the heat of the sun, and therefore any that are at all exposed should have a mulching of some non-conducting material or other, such as half-rotten leaves or very mild hotbed manure, so as to intercept evaporation. This, with a good watering or two during the active growing season, and when the blooms are showing, will be found of the greatest assistance to them.

Although Lilies are such moisture-loving plants at a certain time of the year, anything approaching a wet, stagnant condition of the soil is fatal to them; and more especially is this the case during winter, when they are in a semi-dormant state, as then they take up water slowly. The best way before planting is to thoroughly trench the ground by breaking it up to a good depth, and when doing so, to work in plenty of peat if it can be readily got, or if not, a liberal dressing of leaf-mould in lieu of it. A bed or border so prepared will grow any of the kinds well, but with many of them it is a great help if holes are dug out where the bulbs are to be placed, and filled in with rough, fibry peat and sharp, clean sand, a mixture that is highly congenial to them and keeps them clean and free from decay. In all cases where peat is not used the sand should not be omitted, as a handful or two of it placed around each cuts off their contact with the moist earth that would otherwise press too closely about them. Where it is intended to grow Lilies in shrubby or herbaceous borders, in isolated patches or groups, the same kind of preparation may readily be carried out, only the holes dug for them in that case should be made to hold at least a bushel of the mixture above referred to, as then their well-doing will be a matter of certainty. The only natural soil I have ever seen them succeed in in a really satisfactory manner is a greasy, moist sand, in which they grow with great vigour and increase at a rapid rate compared with what they do when not so circumstanced. I have noticed that most of the imported bulbs of *L. auratum* are coated with the same kind of soil, thus showing that in Japan, where they must grow in immense quantities, the soil

they are found in is of a similar nature. As regards the time of planting, the earlier it is done in the autumn after the leaves and stems are ripe the better, as immediately these die down large fleshy roots at the base of the bulbs begin to form, and it is almost impossible to interfere with them later on without bruising or damaging these to some considerable extent. Such as come from a distance or have been long out of the ground are destitute of these feeders, and every day's delay in planting detracts from their strength, as they are then living, as it were, on themselves, instead of drawing their supplies from the soil. The proper depth at which to place the bulbs is about 6 in. below the surface, or even a little more than that for the large, strong growers, that require so much extra moisture. In potting, however, it is much the best way not to cover them deeply, but to leave space to top-dress with large lumps of soil as the shoots progress, and these they seize hold of greedily and derive additional strength therefrom. Potting, like planting, should be done early, and the ball disturbed as little as possible, at least that portion of it below the base of the bulbs in which the large fleshy roots are embedded. That on the top will break away with the old stems and leave the crowns bare, among which some silver sand should be scattered so as to work in and fill up the interstices among the scales. For pot culture there is nothing equal to a mixture of rough, fibry peat and loam in about equal proportions, through which the roots of the Lilies run easily and water percolates readily. Any cold frame where there is a firm, hard floor of coal ashes to place them on answers admirably for their winter quarters, as there they come gradually on and are in every way better than they would be in a house far from the light and air. S. D.

— I am a novice in Lily culture, and am trying to learn. I confess I am puzzled by much that "Dunedin" writes. Does he mean to say that the stem roots are of no service to the growth and development of the flower stem? If not, what do they feed? They do not reproduce the plant, like the suckers of Roses and other trees with which he compares them. Again, I cannot agree that a large Lily bulb is no better than a small one. If to obtain a single flower stem is the object, I grant that he may be right; but experience shows me that a large Lily bulb, if planted in a healthy condition, will produce three or four stems, and if lifted next year will have divided into three or four bulbs; a small bulb will produce one stem, and have grown at the same time into one larger bulb. In this way we gain a year's growth by buying a large bulb. Also, I am at a loss to know how the reproduction of Lily bulbs, on which "Dunedin" lays so much stress, differs in its main facts from the reproduction of all other bulbs. This takes place, it is true, in various ways. The Hyacinth, the Narcissus, the Tulip, the Snowdrop, and others, like the Lily, are reproduced occupying nearly the same space as the old bulb; the Crocus, the Gladiolus, and the Ixia produce their new bulbs entirely external to the old bulb, but adhering to it. Others, as the *Tritonia aurea*, produce them at some distance, sometimes as much as 18 in. from the old bulb, and connected with it by suckers, but in all cases the old bulb inevitably perishes, and the new bulb is formed in layers or scales, which are concentric either round the germ or stalk of this year or the germ of next year, yet we speak of the Crocuses, the Gladioli, or the *Desfodils* "I bought last year," not the bulbs which have succeeded to the Crocuses, &c., I bought last year, as some of your correspondents particularly do in talking of Lilies. The experienced in bulb growing know that the success of a flowering bulb depends in a great measure on the development of the new bulb in the previous season's growth. C. W. Don.

TRANSPLANTING LILIES.

I AM glad to see that Mr. Wilson has (p. 371) corrected his note (p. 332) by substituting "most" for "not," as I felt at a loss to guess what he meant. I now entirely agree with him, that Lily bulbs "should be moved when most at rest," and I have expressed this opinion in all my writings. So lately even as October 5 (p. 304), I said, "When the parent plant is beginning to bloom is the time when there is the least motion in the new bulb, for the roots alone may be said to be moving; and until they move with greater activity, they cannot draw from the soil the nourishment necessary to fill the cells and swell out the bulk of the new bulb." This, then, is the time when the new bulbs are "most" at rest; and, as I said, in answer to Mr. Uphill (p. 370), "I did not even wait (in the cases of *L. speciosum* and *L. auratum*) until the fading flowers had all fallen, so much value do I place on the new bulbs being allowed to continue their growth without the chance of a serious check." Agreeing, as we do, thus far—that the best time to move is when the bulbs are most at rest—another question seems to force itself on our attention, and that is: How can Mr. Wilson reconcile his correction with the introduction to his note? He begins by saying, "Some of your correspondents

ask as to the best time for removing Lilies; I think the safest guide is the appearance of the stems. When they begin to change colour and show that the growth is checked is the time when the old roots have done their work, and the new ones just showing themselves." There is certainly something radically wrong in this statement. In the first place, the "appearance of the stems" can be no guide whatever, for they often keep green for many weeks after the new bulbs are most at rest; and, in fact, after the new bulbs have sent down very long roots. Lift a bulb and look at it. As to the "change of colour showing that the growth is checked," this is a mistake, for the growth in the new bulb is never checked, unless it be moved at an improper time. As to that being "the time when the old roots have done their work," this is also a mistake, as the fading of the flowers themselves is the only true sign that the roots have done their work. Lift a bulb and look at them. And as to "the new roots just showing themselves" at this time, this is a very great mistake, for the new roots of the new bulb begin to show themselves some weeks before the parent bulbs begin to bloom. Lift bulbs and examine them, for no mere theory should be our guide. DUNEDIN.

NOTES AND QUESTIONS ON THE FLOWER GARDEN:

Irises.—In a public square in Vienna there is a long series of small beds of various Irises planted within a few feet of and following the line of a shrubbery. The effect is very good. The plants in small circles on the turf have a better chance of growth than if within or on the edge of the shrubbery. At some little distance the foliage of the Irises (the beds are only a few feet apart) breaks the hard line of the edge of the plantation, and it may be imagined that the flowers look well seen against the green. The plan might be carried out in the more retired portions of the pleasure ground.—V.

Lobelia fulgens.—Groups of this old-fashioned plant now make a fine display in Mr. Ware's nursery at Tottenham, where, grown in deep, rich soil, they thrive luxuriantly and yield large spikes of brilliant blossoms. Before all the flowers are expanded, however, it is probable they will be cut down by frost, and this suggests the idea that were such plants lifted just before their flowers commenced to open, and planted in groups in large pots, a brilliant display might by that means be obtained in November in the conservatory, where, intermixed with white Camellias and other plants then in flower, they would be shown off to good advantage, and produce a striking effect.—S.

Conspicuous Flowers in the Herbaceous Border in October.—These in our cold district consist principally of the Michaelmas Daisy (blue, pink, and red, and the old pale blue sort, which hereabouts this season is quite conspicuous and striking, owing, probably, to the favourable autumn), Anemone japonica (white and red), Sedum Fabaria (a pretty succulent), late Phloxes, Verbena venosa (still flowering profusely), Tritoma, and the old pot Marigold, which is still as bright and yellow as at midsummer. On the same border we have many fine blooms of Gloire de Dijon, Souvenir de Malmaison, and La France Roses, which three, if the weather be ordinarily open here in our high latitude, continue to flower till late in the winter. Last winter we gathered a number of really fine half-blown buds of La France in the middle of January.—J. S.

Undergrowth for Fuchsias.—May I suggest that the golden variegated Periwinkle would make a handsomer undergrowth for Fuchsias than Ivy? It would not smother the Fuchsias, and would protect the stools during winter equally well as Ivy. Snowdrops on this Periwinkle have a fine appearance; and it is a good addition to the bed in which they are growing. I am much interested in the subject of permanent beds of hardy plants and flowers.—Mrs. L.

Fuchsias as Bedding Plants.—It appears that the Fuchsia is now attracting attention as a bedding plant, a circumstance not so much to be wondered at as the fact of its having been so seldom used for that purpose. There is here a line upwards of 100 yards in length, in front of a low wall, of a white-coral's variety named Madame Corneliessen, which has been planted some seven or eight years. It has never failed to bloom very freely, and, consequently, it is very much admired. Even at the present time (third week of October) it is in full beauty, and if the weather keeps moderately mild, it will continue in that condition for some time yet to come, as a slight amount of frost does not greatly affect it. When the stalks are fairly killed down by frost they are cut off close to the soil; about 2 in. of cinder ashes are spread over the roots, and these are not removed until the young shoots begin to grow through them. This line or hedge of Fuchsias was first formed by planting rooted cuttings from store pots which had been inserted the previous autumn, but which had not been potted off singly. There is also a

bed here of another variety known as Corallina, which has been still longer in existence. It receives no protection further than a slight mulching of rotted manure occasionally; and, nevertheless, it continues to bloom each season as beautifully as ever. There are also numerous isolated bushes of the old *F. gracilis* in front of shrubby borders which receive no protection whatever; also a dwarf-growing variety apparently of *F. gracilis*, named Tom Thumb, which forms a pretty and easily-managed bedding plant.—P. GRIEVE, *Culford, Bury St. Edmunds.*

— There is nothing, in my opinion, better suited for the flower garden than Fuchsias, either planted out singly or massed in beds. I have frequently had them planted close to Roses, using the Rose as a support for them; this obviates the nakedness of the Rose stem, besides affording an abundance of bloom. When at Court Garden, Great Marlow, our Fuchsia bed was a great favourite. This consisted of our old plants that had been grown in pots for indoor purposes. They were wintered in an archway under the conservatory in the dark, and gave us no trouble, except giving them a drop of water now and then, to keep them from getting dust dry. About February they were brought out, pruned, potted, and placed along the back of a Vinery, when the damping down and syringing commenced. Here the Fuchsias soon began to grow rapidly. In April they were removed to a cool orchard house, where they remained until planted out. Plenty of manure and other water was given them, and they soon grew into large specimens. A bed of this kind is no mean feature in front of a drawing-room window. They give us no more trouble than a common Pelargonium, and were not so easily injured by wet, for the more rain the better Fuchsias thrive, and no amount of sunshine will affect them, provided they are well supplied with water.—D. S. GILLET.

Pentstemons for Cut Flowers.—As border plants these are invaluable on account of their brilliant colour and continuous habit of blooming; lasting, as they do, gay until very late in autumn, they are extremely valuable for supplying the flower basket with brilliant spikes of colour when the more tender subjects in the garden are cut off by early frosts. I am pleased to find that they are becoming again as popular as their merits deserve.—J. GROOM.

Phloxes on Turf.—Among the various plants placed on the turf in groups in German gardens, Phloxes are not the least fitting for the plan. Their brilliant colours and good habit when well grown make them look peculiarly happy when so treated. Of course the ground must be as well prepared for them as it is in ordinary cases. Much will also depend on the taste of the person who disposes of the group on the Grass; its distance from the wall and from other objects have to be considered. This kind of flower gardening is not quite so easy apparently to some people as planting in lines and circles, but, notwithstanding, it is the true way onwards and has in itself endless and great capacity for garden embellishment.

Close-growing Plants for a Wall.—Those who wish to cover a wall with plants that require no training or nailing whatever will find the following to suit their purpose, viz.: Ivy—*Hedera pulchella marginata* (silver-leaved), *Hedera aurea densa* (golden), and *Ampelopsis Veitchi*. These three cover the surface of the wall evenly as they grow, and lie as close to the stone almost as if they were pasted on, and are at the same time very pretty. The Ivies show up brightly in their gold and silver variegation during winter and spring, and the *Ampelopsis* is successively bright green, dark chocolate, and crimson from May till Christmas, or later. This plant on a south wall here did not shed its foliage last winter till the middle of January. If these be planted in a tolerably good soil they will grow rapidly and need no farther attention. There are other Ivies nearly as good, but these are amongst the best, habit and colour of the foliage considered. As a berried plant the *Cotoneaster Simmonsii* may be added to the list. It also grows very flat and close to the wall, but wants just a nail and a shred here and there to keep the shoots in their places.—J. S.

Standard Double and Single Pelargoniums for the Flower Garden.—These look best when grown from 2 ft. to 3 ft. high, and as much through for the centre of large beds or dotted about in nooks on the lawn as single specimens, which at a distance look like standard Roses. Any neglected plant can be trimmed up as a standard, and will soon make a fine head. Single varieties grafted upon double kinds will make fair-sized heads in one season. I have tried Vesuvius grafted upon double varieties, and found it to succeed admirably. I put on a kind of whip-graft in April, and by the end of the season it measured fully 15 in. in diameter. They may either be budded or grafted, but with me, where budded, the union was not so complete as where grafted. By this system several varieties can be had on one stock. I think standards look better when placed, or rather sunk, in the Grass singly than where several plants are crowded together.—D. GILLET, *The Heath, Weybridge.*

THE INDOOR GARDEN.

MAMMILLARIA ERECTA.

As its specific name implies, this is an erect, narrow-growing plant, which attains a height of from 12 in. to 18 in. Its spines, which are yellow, are in whorls of from eight to twelve, the central one being of the same length as the others. So many of this group have yellow spines, that I cannot at all times distinguish them; *M. clava* and *Schlectendalli* I believe to be only

Mammillaria erecta.

variations of one species. They have yellow flowers, and are near relations of the *Echinocacti*.

J. CROUCHER.

Sudbury House, Hammersmith.

BALSAMS IN POTS AND OUT OF DOORS.

THOUGH classed as a florist flower, the Balsam has not yet been taken under the protecting wing of the florist so-called; and what excellencies it possesses are due, not to the laws and rules laid down by straight-laced florists, but rather to the free and unfettered action of seed growers, who have ever been selecting the best, and now see their efforts rewarded in the existence amongst us of the best and most varied strains of this charming flower to be found anywhere. Even horticultural exhibitions have done little for the Balsam, as at any such plants of it are seldom seen, or, if any be present, rarely are they such as do justice to the merits of a good strain. Perhaps this defect of quality may have had something to do with the comparative neglect with which horticultural societies have treated the Balsam of late, as prizes are now seldom offered and good specimens are more seldom seen. And yet the Balsam is a plant singularly easy to grow and singularly beautiful when well grown, and if those who profess to be good cultivators of it would, during the month of August, visit such a collection

in pots as may then be seen at the Messrs. Smith's at Dulwich, at Messrs. Carter's at Forest Hill, at Mr. Cannell's at Swanley, or growing in the open ground at the Bedford Seed Grounds, they would be not a little astonished. The truth is, that too much has been done to produce a specimen by means of stopping and pinching, and taking off the first blooms to enable the plant to show its natural character and beauties, and thus the fine qualities seen in the plants as grown for the production of seed in the places above named are not found. Plenty of growth and an abundance of small flowers are found, and there the results end. On the other hand, far too many who grow Balsams for the greenhouse in pots starve them and draw them, and generally show them entirely spoiled. The Balsam is a gross feeder and likes an abundance of moisture. It does best in pots of moderate size, such as those measuring from 7 in. to 8 in. in diameter, if plenty of water be given with a frequent dose of liquid manure; or it thrives as well in the open ground if the soil be not too rich and kept moist during the flowering time. In either case, however, the simpler the treatment the better the plants thrive, and, as a rule, the finer the blooms. At Messrs. Smith's, where several thousand plants are grown, all are placed under glass in broad span frames, and the pots stand on ash bottoms. As the plants are near the glass, and the lights can be drawn off on either side, so that plenty of air is admitted, the plants are dwarf and robust, and it would be easy to select hundreds that would grace any exhibition table in the kingdom. The seed is sown in pans and boxes and raised in a gentle heat in cool houses near the glass; the seedlings are pricked out singly into 3-in. pots, placed in frames, and kept near the glass, and finally shifted into 8½-in. pots, in which they flower; then when in August the plants are about 1½ ft. high, the centre stem covered with the finest blooms imaginable, many 3 in. in diameter and of many diverse hues and markings, and the side shoots are also well covered with flowers, these Balsams are, indeed, a sight to see and to admire, and even to be enthusiastic over. At the Bedford Seed Grounds the Balsam is chiefly grown in the open ground, and is doubtless in this way productive of much interest to those who love to decorate their gardens with old-fashioned flowers. Some plants of every kind are grown in pots under glass to make sure of the stocks, as such a misfortune has before now happened that no seed has been obtained from the open ground, either because the season has been too wet and cold, or frosts have set in with unusual earliness. As a rule, however, the plants give a good crop of seed-pods, and a loss of crop is the exception. Most people in planting out Balsams in the open ground first get them well established in small pots, and so plant them out. This is a mistake, as it simply results in the production of a perfect bush of growth and leaves and few flowers, these few being obscured by the foliage. At Bedford all the plants are simply dibbled out in rows, just as Stocks, Asters, &c., are; and although it takes rather longer for the plants to get established, nothing could excel the fine feature presented when in bloom. Soil too rich is avoided, and such as was manured for a previous crop, and has been well pulverised and broken up by forking, suits best, as this produces the finest flowers and a less sappy growth. This is a point which those who may be disposed to try the Balsam as a bedding plant would do well to heed, as many, having regard to the fact that the plants are gross feeders, manure the soil heavily, and thus promote foliage at the expense of flower. The love of gross feeding is rather displayed under pot culture, when, the pots being full of roots, manure water may often be given with advantage. For seed-saving it is found desirable to pinch out the points of the branches when well covered with flowers and thus check their production after a given time; it is well also to pinch off all the small numerous side shoots that form late upon the plants; these would produce flowers profusely up till the frost comes, but for seed production they are rather doing more harm than good, and therefore are best removed. Where the plants are grown to produce flowers only these may remain, but the strong branches should be stopped to keep the plants in proper form. If it were proposed to plant a bed of Balsams in colours, say of half-a-dozen kinds, it is desirable to know what are the habits of the various colours, that the plants may be arranged

to the best advantage. Some colours are produced on plants that are taller than others, and the habit is always the same from year to year, so that if the colours be obtained they may be relied upon to produce the required effect if properly planted. Here are six sorts that should be planted thus: Centre of bed, or back row of border, carmine, a glorious kind; white, pure and of great size, a very fine kind; purple, the flowers sometimes spotted with white, even when seed be saved from self flowers, so liable are some colours to sport; pink, a beautiful and chaste kind; scarlet, a deep rich hue, very brilliant and very free flowering; and, last, the dwarfest of these tall kinds, buff-white, a wondrously free-blooming sort, that produces large double flowers. These are but a few of the colours found, as I will presently show, but they are self colours, and would make a charming arrangement if planted as proposed. These are also very pretty for small pots and suitable as window plants—a dwarf or bijou strain, the plants averaging 9 in. in height and of several colours. These, however, are not suitable for exhibition. Colours and markings in any good and valued strain of Balsams include the following, and probably a few others, as some sorts sport continually. These are taken from plants in bloom, and not from any seed list: Pure white, buff-white, rosy-white, lavender-white, pale mauve, peach, pink, carmine, scarlet, cerise, crimson, violet, purple, purple-white blotch, scarlet-white blotch, carmine-white blotch, crimson-white blotch, white-carmine flake, white-purple flake, carmine Bizarre, and crimson Bizarre, all clearly distinct and beautiful. These show that it ought not to be difficult to have a really varied selection of Balsams in any garden.

A. D.

THE ALLAMANDA AS IT OUGHT TO BE GROWN.

This has long been recognised as one of our finest stove climbers and it should be grown as such, and not as a pot specimen. When it has room, it grows at a rapid rate, and soon flowers. A specimen here, which two years ago was newly rooted in a 3-in. pot, is now a large plant, covering a large amount of space, but not so much by a long way as it might have done had it had more room. From the 3-in. pot it was transferred at once to a 12-in. pot, started early in a stove, and pushed on in a genial temperature, and it flowered well towards the end of the same season. Last year it produced a great quantity of flowers on till near Christmas, and this season it has not produced less than 600 or 700 flowers, all of large size and good substance, from an area about 20 ft. by 3½ ft. The same flower-spikes continue to flower during the greater part of the season; and I have examined some to-day that have produced no less than forty-five blooms each, in succession of course. There are many flowers on the plant now. The Allamanda exemplifies in a remarkable manner the wisdom of the practice, now finding favour in the culture of both fruits and flowers, of permitting the shoots to extend so as to run them out into flowers, as we have more than once advocated, particularly in the case of the Bougainvillea. If one keeps cutting too much at the Allamanda, we simply encourage growth of more wood, that is less and less inclined to flower. The best way is only to thin the shoots, removing such as are not wanted entirely, and allowing the others to extend. In winter, when the wood is partially ripened, the branches may of course be pruned back, according to circumstances; but once growth begins again it should not be interfered with. This is the treatment our plant receives, with the above results. Probably I have understated the number of flowers, as we have been cutting from the plant every day for months, and I only calculate from the number of spikes left on the plant, and the flowers they have produced. Many of the individual flowers measure 6½ in. across. The plant has been growing in strong loam, chiefly in a pot plunged in the bed. Opposite it, to match, is a plant of *Dipladenia Brierleyana*, but we do not find it to be such a free flowerer as the Allamanda—nothing like it, in fact, though it has flowered continuously all the summer too, and is flowering still. It also is allowed to climb along the wires. I was told by the nurseryman who sent it that it was not suitable for the situation, as it would not extend above 12 ft. or 15 ft.; but our plant has shoots upon it 30 ft. long, and it looks as if it would grow as far again. It is, however, getting rather bare at the bottom, and we propose taking some of the leaders back next year, to clothe the bare stems. C.

Casuarina sumatrana.—This is a very pretty plant when in a small estate for table decoration, or the sprays of it may be used in many floral arrangements, and they are even more delicate in appearance than Fern fronds, and the soft green of its thread-like growth

contrasts well with the deeper colour of its stem and older branches. For the adornment of cool conservatories this plant is well adapted, as it excels in appearance many plants grown for the effect their foliage produces, and which require a high temperature for their proper development.—J. GROOM, *Linton Park, Maidstone*.

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Conservatory Climbers at Birmingham.—Visiting recently the Botanic Gardens at Birmingham, I was struck by the effect produced in the conservatory there by the training together at one end of the roof *Lapageria rosea*, *L. alba*, and *Lasiandra macrantha*, all of which were profusely in bloom when I saw them. They were not trained in the orthodox style on wires stretched tight and straight; on the contrary, the branches were suspended in festoons which intermixed in what appeared to me to be studied confusion. The effect was striking and rich in the extreme.—O. THOMAS, *Drayton Manor*.

***Chlora perfoliata grandiflora*.**—This large-flowered form is much handsomer than the type, and is, moreover, a very useful plant for cutting, as its fine yellow blossoms are borne on slender stalks, and last a long time in good condition. It delights in stiff and rich soil with plenty of moisture and partial shade; under such treatment it yields a fine crop of flowers; and, though of biennial duration, it should be in every collection; it grows freely from seeds.—A.

Ornamenting Plant-house Walls.—The walls of stoves and greenhouses, which are too often left bare and unsightly, might, with a little trouble, be rendered the most effective parts of the houses. As an illustration of this we lately saw in Mr. Bull's nursery, Chelsea, some walls covered with plants, which had a charming appearance. Square pieces of peat soil, stacked edgewise one above the other, and firmly secured to the wall by means of wire, is the best material in which to grow the plants, and, if preferred, this could be covered with Virgin Cork. Amongst subjects used on the walls alluded to were noticeable fine, healthy plants of *Anthurium crystallinum*, *Carolinigo recurvata variegata*, *Alcascia Lowi*, *Selaginella coccinea arborea* and other Club Mosses, *Maranta Lindeii*, *Adiantum ciliatum* (Edgworthii), *Fittonias*, *Maiden-hair Ferns*, *Monstera deliciosa*, *Phyllanthus rosea*, *Philodendrons*, *Syngoniums*, *Paullonia thalictrifolia*, *Stag's-horn Ferns*, &c. Such plants as these love a moist temperature, and grow vigorously if kept well syringed overhead, an operation which keeps the soil and wall moist, a condition which renders the plants proof against insect pests; and if they be arranged artistically, as is the case with those alluded to, a really charming and picturesque effect can be produced with little trouble, and without taking up so dearly any room.—C. S.

A Fine Stephanotis.—When allowed plenty of room and properly treated, it is astonishing to what dimensions the *Stephanotis* will attain, and what a quantity of blossom it will yield. One of the largest plants with which I am acquainted is growing in Mr. Wills' nursery, Anerley. It is trained lengthwise on wires, under the roof of a lean-to house 70 ft. in length. There are about thirty-five wires about 9 in. apart, giving altogether 2450 ft. or nearly half a mile of wires, to each of which are tied quite bundles of shoots. This plant, which yearly furnishes thousands of flowers, receives but little pruning, neither are the shoots ever disturbed in any way, excepting when they get very thick indeed. In February and March the old wood pushes out abundance of bloom from the axilla of the leaves, and when this crop of flowers is gathered, some of the rougher or worthless wood is cut out; young growths are made freely, and in June the plant is again a sheet of blossom. If the plant gets attacked by insects, the garden engine and clear water are brought to bear upon it with such force, that the insects are dielodged. This operation is repeated at frequent intervals during the time in which the plant is out of blossom, and it is considered a much more satisfactory method than that usually adopted, viz., that of unfastening the shoots from the wires, pruning them back, and sponging them, an operation which disturbs the buds and destroys a large quantity of blossom. Where trimness and order are required, the cutting back and thinning system is doubtless the best; but where the largest quantity of blossom that can be produced is aimed at, the plant must be disturbed as little as possible.—S.

Bouquets in Covent Garden.—I recently noticed when passing through Covent Garden that the bouquets in the florists' shops presented a great improvement on those I had seen there in former years, the colours being not so much mixed, but more decided in design; as, for instance, where only one spray of flower of any kind was originally employed there are now several used in bunches of two or three together, and they consist only of a few bright, distinct colours with a liberal admixture of foliage, which produces an excellent effect.—J. GROOM, *Linton*.

THE KITCHEN GARDEN.

IMPROVING LIGHT VEGETABLE SOILS.

ONE way of dealing with light soils in dry seasons is to mulch them with such material as can be purchased at an inexpensive rate, and laid up for the purpose during the winter and early spring months. Light stable litter—which is cheap enough even if it has to be purchased, but which is common enough about most gardens—will answer the purpose well if it be turned over a few times during the winter and mixed with other manurial refuse, such as spent hotbeds and similar material, which, having lost the greater part of its nutritious elements, is of little use, except for surface dressing. All such spare refuse being collected together and incorporated well with each other will make capital material for encouraging surface roots and protecting them from the unhealthy action of parching weather, as well as retaining the natural moisture of the soil. It is a fact but too well known that light, porous soils—although their condition is improved by mulching—require considerably more labour than that of mere surface dressing to make them productive and capable of sustaining good crops in dry seasons. Having succeeded in improving a portion of the kitchen garden here, which is naturally of a poor, sandy character, the plan which we adopted may be of benefit to others. I may state that during the alterations here we came across several veins or beds of yellow clay, which was in due course removed to an out-of-the-way corner near the portions of the garden where it was required to be used. As the crops were gathered the clay was wheeled on to the surface of the ground and spread regularly over it to a depth of 6 in. It was thus exposed to what frost we get in winter and the action of the weather generally till spring, when the ground was dug over in the following way: An opening was taken out at one side of the plot, and a thick layer of cow manure, the best that could be procured, was put in the bottom of the trench; on this the layer of clay was laid, and the natural soil was dug to one spade's depth and laid over it; this was repeated till the work was completed. Before cropping commenced in the spring the ground was deeply forked over, the object being to work the clay and the ordinary soil as much together as possible. That year such crops as Peas, Broad Beans, Cauliflowers, and Brussels Sprouts were greatly improved, but of course the experiment was as yet only half tried. During the following autumn we kept burning clay and every other rubbish that was within easy reach, such as Pea straw, old Pea rods, thinnings of plantations, and stumps of trees—anything and everything, in fact, that could be converted into wood ashes. The clay fires were kept going for months together till the wintery rains drowned them out, the wood ashes and burnt clay being spread over the surface as the unburnt clay was the year previous. In addition to this all the decomposed vegetable matter that could be collected together, as well as the surfacings of fruit borders that were being renewed, and worn-out potting soils, were all utilised to swell the heap of ingredients, which in process of time accumulate to no inconsiderable bulk. These soils were likewise spread over the same plot of ground, which was ridged up last winter without the addition of manure. In the spring the ground was again forked over thoroughly, and this time the operation of mixing the soils was accomplished more satisfactorily than before, from the fact of there being no manure worked in that would impede the process of incorporation. When the land was in the best of order a dressing of short manure was given, and the surface made fine before the seeds were sown. The ground was chiefly cropped with Peas, Broad Beans, and other vegetables intended for exhibition, and the results, especially as regards Peas, were such as to inspire one with confidence as to what can be done in the matter of improving light soils. We have never had such crops of Peas before, the quality being in all respects excellent and the yield something extraordinary, the pods being of a fine size; but perhaps the most remarkable feature of the whole was the beautiful green colour of the pods and the dense bloom, a result which I attribute solely to the application of burnt clay and wood ashes. I have used both these substances for fruit-growing purposes largely with the best re-

sults, and the elements contained in them seem eminently adapted to vegetable culture as well. In preparing land for future crops, I would recommend that each plot be set apart for its own particular purpose, and prepared accordingly. It is also necessary that prepared soils, composed of several parts of clay, should be turned up to the influence of the weather early in the season; for instance, land that will be required for summer crops of Peas, Beans, and Cauliflowers will be improved by being dug over and manured as the crops are cleared away. In digging the ground it is advisable that all added or rich matter be kept near the surface, and that no bad subsoil be disturbed, except to remedy defective drainage. When the opening is taken out, a shallow trench, 1 ft. or so in width, will be sufficient. The layer of manure is laid on the bottom and covered over with 3 in. or 4 in. of the surface soil turned bottom side upwards; then the soil is turned over to one graft in depth and laid angle-ways roughly across the trench. This plan I consider an improvement on the old ridging system, as every spadeful of soil is fully exposed to the weather during winter, causing it to become thoroughly pulverised before sowing or planting takes place in the spring.

Otterspool.

W. HINDS.

NOTES AND QUESTIONS ON THE KITCHEN GARDEN.

Canadian Wonder Bean for Forcing.—I observed in the kitchen garden diary that this Bean was mentioned as suitable for present sowing. If it will answer well as a forcing Bean for mid-winter, it will be very valuable. Hitherto I have obtained the best results from the dwarf varieties, such as Osborn's Prolific. I have had splendid crops of Canadian Wonder out-of-doors in the hottest months, but for late crops it was not so prolific as dwarf varieties. Its size and other good qualities render it an acquisition at any season, and any remarks as to obtaining it in quantity during the winter months would be acceptable.—J. G.

Vick's Criterion Tomato.—I have given this Tomato a fair trial this season by growing it alternately with the old common red kind, which is still the best, generally speaking; but Vick's Criterion is, to say the least, equal to it, if it does not surpass it as a grower and bearer late in the season. In other respects it does not surpass the old variety. Its fruit, too, is smaller; but it produces a greater number of clusters. The fruit is also smoother and rounder, if that be any advantage, which I do not suppose it is. Our cook uses the one as readily as the other. Of the other varieties of Tomatoes sent out of late years, I have found none to equal the old red for general excellence, and we have always grown it; and we grow a large quantity of Tomatoes, as I find we can dispose of the spare fruit readily and at a good price, in exchange for Jersey Pears and dessert Apples, which we have to buy. I see the French growers still continue to grow the old red exclusively—at least, when in the Halles Centrales lately I saw immense heaps of it and no other.—S. W.

Smooth v. Wrinkled Tomatoes.—I agree with Mr. Hobday (p. 386) that smooth Tomatoes are best, and in this respect I find none to beat Vick's Criterion. Of the Orangefield I have grown a large quantity of late by keeping the old plants growing. I placed them on the back flue of a Vinery, and trained them up the wall. They had the depth of a brick on edge of ashes under them, and they soon got full of roots. The plants were in 6-in. pots; the Vinery is 72 ft. long. The flue has been a double one, as the house was formerly used for Pines and Vines; sometimes now it is heated, but, as a rule, it is very little used. I stimulate the roots amongst the ashes at times, for there is a great advantage in keeping the old plants growing. When that is so, one seems never to be without fruit, and the growth is not over luxuriant; on the contrary, we get short-flowering shoots that produce an abundance of fruit from, I may truly say, March to December. I have this year uprooted all but one plant of the Orangefield to give place to Vick's and a plant or two of a very large variety given me by Mr. Wallis, of Keele Hall. These I have got in much larger pots, and even now there is a good crop on Vick's and a few fine fruit of Mr. Wallis's variety.—Geo. BOLAS, Hopton.

Telegraph Cucumber.—This when true to name still occupies a prominent position both for market and for private gardens, and in my opinion, taking it all round, it is the best Cucumber grown.—D. S. GILLET, *The Heath, Weybridge.*

PLATE CLIII.

THE AURICULA.

(WITH COLOURED FIGURES OF SOME OF THE BEST VARIETIES.)

AMONGST what are termed florist flowers the Auricula is the first to gladden our eyes in spring with its rich and varied blossoms, and so popular has it become within these last few years, that the choicest and scarcest varieties are wholly unobtainable. The section of the genus which is most esteemed is that which was brought to a high state of perfection nearly a hundred years ago. Let me, therefore, briefly describe the points of excellence to which attention has so long been directed. The first class comprises green-edged flowers, and includes all that have the outer margin of the flower quite green, or very sparingly dotted with white points of meal, so that the edge at first sight still appears green. Inside this edge is the body colour; black is most esteemed, but it is also of different shades of maroon, violet, and plum colours; the body colour flashes into the edge, and is never found in a compact ring, as one often sees it in the "model" Auricula represented in drawings. If the body colour, as it often does, strikes through the outer edge it is a serious defect, and the beauty of the best flowers is marred thereby. Next is the paste, which should be circular, dense, and pure white. The beauty of many otherwise fine flowers is marred by the angularity of the paste. Booth's Freedom and Campbell's Admiral Napier have this defect. The tube should be bright orange, as a pale tube quite as seriously mars the beauty of the flower as the body colour striking through to the outer edge. Beeston's Apollo is an example of a flower with a beautiful green edge, and the body colour and paste are also right, but its pale tube is a demerit, a fault even more strikingly exemplified in Trail's Prince of Greens. The beautiful emerald green edge of the latter incloses a perfect black body colour, and solid pure white paste, but its watery tube ruins all. Auriculas, indeed, are still far from perfection as regards green edges, although many are very beautiful.

The next class is the grey edges, and in this are to be found the most perfect flowers yet raised. The points in this, as in the next class, are the same as those indicated above. The best flowers in this section have not the same defects as the best flowers in the green-edged class. Headley's George Lightbody, for instance, is an example of the very best Auricula in existence; its parts are evenly balanced, and the paste is circular. Lancashire Hero (Lancashire) is also a noble grey-edged flower, and one which is not always second to Mr. Headley's Masterpiece itself, though not quite such a decided grey as that flower; the meal, too, is so thinly laid on the edge that it is sometimes classed with the green-edged sorts. A defect not yet mentioned, but one which cannot be overlooked, is a scollopy paste. An example of this is to be found in a fine flower of my own raising named Silvia; the tube, body, colour, and edge are all that can be desired; the edge has that silvery-frosted appearance, which is most esteemed in the grey section, and it received a first-class certificate at the Crystal Palace National Auricula Show. Still, it has that defect, and, as the raiser of it, I would like to point it out.

The white-edged flowers are distinguished from the grey by the greater density of meal on the edge. In some cases this is laid on so heavily that the edge is almost as white as the paste. This may be observed in Walker's John Simonite, a very fine new flower, and perhaps the best white-edged flower yet raised. Yet another defect, and one most frequent in the white-edged kinds, is the body colour being dusted with the meal intended for the edge. Summerscale's Catherina, a small, neat flower, has this peculiarity; indeed, some varieties, such as Lightbody's Fair Maid, has this fault to such an extent that they cannot be tolerated in a select collection.

Selfs are flowers that have all the margin outside the paste, one decided colour without shading, and they are necessary, having brilliant colours to form an effective contrast to the three other classes. Their edges are variously coloured, yellow, slate, bluish-violet, violet-purple, maroon, black, and crimson.

The Alpines must constitute a section by themselves. Those who are not intimately acquainted with them may ask what is an Alpine? Are Auriculas not all Alpines? They are; and I

can only surmise that the section in question, being distinct as a class, were thus named provisionally to distinguish them from the "florist" varieties. In Alpines the tube is yellow or pale as in the other class, but the part surrounding the tube is yellow or cream-coloured, and has no paste. This is surrounded by an edge of one colour which should be darkest near the centre, shading off to a paler colour at the edge. The finest Alpines are those with bright yellow centres and maroon or crimson-shaded edges. Flowers with cream-coloured centres have usually mauve or light purple edges shaded in the same way. There are Alpines with very richly-coloured edges or, as some term them, self edges, but they have a dull, heavy appearance in comparison with the shaded flowers.

Auricula trusses should be well formed of five, seven, nine, and eleven flowerets or pips; even numbers do not fill in quite so well as odd ones. The truss should be supported by a stout elastic stem, long enough to carry the head of bloom bravely above the foliage. The diversity amongst the latter is very striking, and is at all times a source of enjoyment to Auricula growers. Some have the foliage quite as thickly dusted with meal as the flowers. Green-edged flowers, as a rule, have foliage destitute of meal. Many of the grey-edged sorts have meal on the foliage, and some have it dusted with a very fine powder, and edged with a silver thread, as in Douglas's Silvia and Lightbody's Richard Headley.

Propagation is effected by means of offsets, or by dividing the plants, and by seeds, from which alone new varieties can be obtained. Seeds should be saved only from flowers that have been artificially fertilised, and it may be worthy of remark that the pollen parent exercises the greatest influence on the progeny. Seeds may be sown as soon as they are ripe, or they may be kept until February, and be sown in a gentle hotbed. If they be sown in July, when they ripen, the largest proportion of them will not vegetate until the spring. Some varieties increase much more rapidly than others, and many fine sorts remain scarce from the difficulty that exists as regards getting offsets. With the view of increasing scarce varieties, I have sometimes boldly cut their heads off near the surface of the ground. The top will make a strong cutting, and will soon form roots under a bell-glass, and the old stump will also soon throw out growths. I have obtained six or more in this way from one stump. Some varieties will not produce offsets so freely as others, even in this way. Lee's Col. Taylor is very shy, but Taylor's Glory is quite the reverse; Cunningham's John Waterston is also a good breeder.

Auriculas are plants well adapted for owners of small gardens, inasmuch as they take up but little room and are easily managed. No plant, indeed, is easier to cultivate, but they require considerable attention, and that, too, at the right time. Though natives of high-lying regions, where the air is clear and untainted by smoke, they will, nevertheless, thrive where less beautiful plants would pine and die. In Mr. Benjamin Simonite's garden, in the midst of the sulphureous atmosphere of Sheffield, where the sun at noon reminds one of Coleridge's lines in the "Ancient Mariner":—

The blood-red sun at noon
Right up above the mast did stand
No bigger than the moon.

In such a place the Auricula grows and flowers almost as well as it does in the vicarage garden at Kirkby Malzeard, where the air is pure and bracing as in an Alpine valley. Careful potting is a prime element as regards insuring success; the drainage must be free, as stagnant water will cause the stems to rot. Cleanliness, too, must not be neglected. Green fly, a troublesome pest, can be most readily destroyed by fumigating with Tobacco. It is best to do this during the winter; at other times the fly may be kept in check by brushing it off with a camel's-hair pencil. Decaying leaves sometimes induce the stems to decay if not promptly removed. During winter water must be applied with caution. I never water a plant until it is quite dry at the roots.

The centre flower in the annexed plate is a green-edged seedling of my own, and, like all the violet flowers, has a pale tube which does not stand. The green-edged yellow is a seedling raised by the Rev. F. D. Horner; it is one which he would not tolerate in his own collection, and yet Mr. Harrison Weir, looking at it from an artist's point of view, is charmed with it.

The flower on the left of the centre bloom has an inky tube; it is a grave fault when a flower has a tube that dies off in that way. If that inky tube were bright yellow what an improvement it would be! The artist found a discoloured tube and painted it so, and we owe him our thanks for the fidelity with which he has brought out the faults as well as the beauties of our favourites. The names of the flowers in the plate are as follows, viz., 1, Catherine; 2, George Lightbody; 3, Robert Trail; 4, Mercury; 5, Seedling; 6, Ne Plus Ultra (Fletcher); 7, Seedling (Douglas); 8, Seedling (Hornor); 9, Queen Victoria; 10, Formosa; 11, True Briton; 12, Lord Palmerston; 13, Ne Plus Ultra (at its best).
J. DOUGLAS.

PROPAGATING.

BORONIA SERRULATA.—This is one of the most difficult of this genus of plants to propagate. The cutting pots should be new or washed very clean, well-drained with small crocks, and have a 2½-in. pot inverted over the hole at the bottom. The soil must be finely-sifted peat, mixed with one-fourth of silver sand. Put a layer of the rougher siftings over the crocks, and then fill up firmly with fine soil, putting ¼ in. of clean-washed silver sand on the top; press all down level, water, and place the bell-glass in position, marking where the cuttings are to go. The latter should be made in the way represented by the annexed illustration. Then make a hole with a small dibber, and fasten them in in the usual manner; the holes should be filled up with dry sand. Then sprinkle with water, and place the bell-glass over them. Set the pots on a gentle bottom-heat, and wipe the glasses dry every morning. Under the best circumstances it generally takes nearly three months before roots make their appearance, but after that occurs they begin to show signs of growing; then the glasses may be tilted a little with a small piece of wood or crock, afterwards increasing the amount of air given by degrees. They should then be gradually hardened off by placing them on a cool bottom in another part of the house. They will be ready for potting off in July.

Cutting of
Boronia serrulata.

H. H.

Cineraria maritima from Seed.—Mr. Fish (p. 330) asks for my opinion as to the reason of the leaves of seedling plants of this *Cineraria* having a greenish tint the first year, and therefore being inferior in appearance to those raised from cuttings. My own impression is that the luxuriant growth of seedlings causes the same effect as that produced on variegated Ivies and similar plants by supplying them with an unlimited quantity of rich soil, viz., that of causing them to revert to the original type or green-leaved form. Some plants of a variegated-leaved character appear to be of a much more fixed or permanent character than others, and less susceptible to the influence of soil or climate. Doubtless Mr. Fish has remarked a similar disposition in the common *Pyrethrum Golden Feather*, and knows that seedlings of it are superior to plants raised from cuttings.—J. GROOM.

Ornamental Solanum Blighted in a Night.—I had a bed of a strong-growing *eculent Solanum* (I do not know its name), the seed of which I brought with me from a garden in The Riviera, which was blighted and blackened in a single night early in the month of September. Not one escaped of a large bed that promised to be so beautiful when in flower. About the very same time, I believe, our field Potatoes were more or less affected with disease. Is it possible that the same agent—atmospheric or fungoid—brought about the same results? I draw attention to the circumstance to ascertain, if possible, how far the experience of others agrees with my own observations. Has the Potato blight been known to affect other *Solanaceae* beside *Solanum tuberosum*, our well-known *eculent*? I should really be glad of any definite information on the subject from eye-witnesses. Can there be anything in the sap of the *Solanums* that would attract and foster the disease? It may be well to mention that other *Solanaceous* vegetation was growing in close proximity to the affected flower-bed. *Cestrum*, *Ichroma*, *Brugmansia*, *Habrothamnus*, and *Petunia* were all in the open borders, as was also *Solanum pseudo-capsicum*; but all escaped the blight.—PETER INCHBALD, *Hovingham Lodge, York.*

GARDENING FOR THE WEEK.

Roses.

Pot Roses.—The production of Rose blooms weekly throughout the year would at one time have been considered impossible, and no doubt it was the market growers, prompted by the high prices which their beautiful half-expanded buds realised, especially during February, March, April, and May, that first gave evidence that Roses could thus be had. In many private gardens winter Roses are now produced equally good, and there are numbers who would, if they felt there was a likelihood of success, make similar attempts. In order to be successful a house must be devoted wholly to them, for there are no plants that require exactly the same kind of treatment. Such a house must in size be in accordance with the quantity wanted. Indoor-grown Roses, although they do not expand so quickly as in the open air during summer, or fall quite so soon when open, are, nevertheless, flowers that do not last long; consequently, where even a small handful or less of buds is required every day, it will be necessary to accommodate as many plants as will frequently furnish more than are wanted, even with the best judgment as regards regulating the supply. Acting upon this, it is well not to have the house too small. Another and most important consideration is to have it so constructed as to admit every ray of light possible. A span-roofed house with both ends and sides glass, and with no more timber in it than is necessary to give sufficient strength, is the only suitable one for Roses. It should be placed away from walls, trees, or any other darkening influence, and there should be a sufficiency of hot-water pipes to command at all times an intermediate temperature, particularly in the depth of winter. One of the greatest sources of failure with those who have attempted winter Rose growing, is their treating them more or less in accordance with some of the principal conditions under which they exist out-of-doors, particularly in the matter of air. Contrary to what might naturally be supposed, Roses grown under glass with more or less heat require, and will bear, comparatively but a small amount of air. Some of the most successful growers for the London market scarcely ever give any air to their Roses, except through a moderate opening of the roof-lights, none being given at the side-lights or ventilators at all; its admission in that way would be certain to be followed by an attack of mildew, the greatest enemy with which the forced Rose grower has to contend. Only a short rest is given after the production of a spring crop of flowers, sometimes by turning the plants out-of-doors for a few weeks, but as frequently by keeping them under glass altogether and discouraging growth for a time. I am now speaking of Tea Roses, on which the grower of winter flowers must almost wholly depend. In fact, to manage these Roses successfully under glass, it becomes necessary to some extent to completely shut our eyes, or forget the conditions under which they exist outside. A great advantage in growing Roses under glass is, that, through the fact of the soil need in potting having to be selected and prepared in the way usual for pot-grown plants, the limited quantity required permits of that being procured which is best suited to the growth of the plants in situations where the natural soil is such that Roses do not do well out-of-doors; and it is on pot plants in a great measure that reliance must be placed for the continuous supply that I am now speaking of, for although Roses when planted out in a well-prepared border soon grow to a very large size, and produce periodically quantities of flowers, yet the fact of their attaining these dimensions at once prevents the possibility, without several houses being devoted to their cultivation, of having that continuous succession obtainable from the very much larger number of pot-grown plants that can be accommodated in a limited space, and amongst which some or other, when fairly managed, are never out of flower, as the Tea varieties, when kept all or through a great portion of the year under glass, keep on continually making more or less growth, and with this flowers; for it appears that when so treated they are never totally at rest nor seem to require it, the difference in this respect simply being that more growth is made during the summer than in the autumn and winter, even under the application of fire-heat.

Heat Required by Roses.—In a thoroughly light house, similar to that just described, with the plants well up to the glass, these Tea varieties will bear more artificial heat than those not actually conversant with this method of cultivating them would suppose; 45° or 50° at night at the present time will answer for them, with 6° or 8° above this in the daytime, and even a few additional degrees when it is sunny, giving, as before indicated, during the day air at the roof lights according to the state of the weather, but scrupulously avoiding any draughts by its admission at the sides of the house, for now that the external temperature is considerably cooler than the mean of that in which the plants are grown, it would create mildew. For the same reason it is essential not to let the temperature fall much lower

than that which I have stated; and even with these precautions, mildew will from time to time make its appearance. In order to counteract its spreading, it must be diligently sought for; its presence will be made known by a curl and discolouring of the leaf, when not a day should be lost in dusting flowers of sulphur on the affected plant or plants, for if left only a very short time the fungus will spread over almost all the occupants of the house, and even if afterwards destroyed, its injurious effects will be unmistakable by quantities of the leaves falling off, which is fatal to the growth necessary for the production of bloom.

Watering and Potting Roses.—The plants at this season must be carefully watered, never letting them get too dry, as the roots under this system of culture are continually at work, but still so much must not be given as will produce anything like a saturated condition of the soil, a result which will follow if water be applied in nearly the quantity necessary in summer, when, independent of what the plants absorb, the drying powers of the sun and air are so much greater. Under this method of Rose growing, with a number of plants, many that make more vigorous progress than the others will require potting at times apart from those at which the general collection are thus attended to, and at whatever time in the year a plant gives evidence of needing more root-room, I should recommend a shift being given. It will usually be found that those specimens that are thus treated apart from the rest are the ones that do the most to keep up a succession of flowers. Roses that are kept on growing in this way for a considerable portion of the year will from time to time, as they gain strength, throw up stout sucker-shoots from the bottom. It is from these that the largest number and finest flowers are produced, and to make room for them the weak, small shoots that do not appear inclined for further development should by degrees be cut away, not going through the whole collection at once, but a few at a time. This treatment will be found to favour the having always some in flower better than subjecting all the occupants in the house to similar treatment at stated intervals. Again, where flowers are thus continuously wanted from a somewhat limited space, the plants must not be allowed to get too large, for though such will afford an abundance for a time, like the planted-out specimens, still they will not keep on like a larger number of smaller plants. When they get large enough to occupy 12-in. pots the knife may with advantage be used so as to keep them within the limits afforded to the roots by pots of this size, not by actual heading down at any one time, but by progressive reduction of the weakest shoots, for, as will easily be understood, the result required under this system of cultivation are of a continuous character, and quite different from that which aims at a blaze of bloom during any given time.

Soil.—It is well to remind beginners in this most desirable method of Rose growing that besides the all essential description of house in which to grow them, to which I have alluded, they require a suitable soil, which should be of a strong, unctious, adhesive nature, for though the Tea varieties succeed out-of-doors in a lighter description of soil than the other kinds, still under pot culture it can hardly be too strong or close, provided it be not impervious to water. Where strong, heavy soil is not available, if good yellow clay be taken and thoroughly dried by exposure to the atmosphere, or placing it on the top of the hot-water pipes, on the brickwork which encloses a boiler at work, a flue leading therefrom, or any position which will effect the same purpose, that is to dry the clay so thoroughly that on being moistened it will crumble down into small particles almost like lime, mixing it one-half with lighter sandy loam and some good rotten manure, and in the operation of potting ramming it into the pots as solid as it can be got, this will grow even the most delicate Tea Roses in perfection. I have been induced to enter somewhat into detail on this most desirable way of Rose growing to produce flowers all the year round for the reason that the present is not a bad time to commence, as the plants to begin with can now be bought in and conveyed without the check and injury that even potted plants receive through package and transit at a time when the opposite conditions of the most active growth or severe frost are certain to some extent to interfere with them. Where only one house of rather limited extent is devoted to their growth, it is well to have considerably more plants than it will accommodate, keeping some during the summer and autumn plunged out-of-doors in coal ashes, from whence during the winter and after the present time they can be transferred to a light pit or roomy frame which will give an opportunity of introducing some of them to the growing house to replace any that may be making little progress and require a rest, which transfer should take place during the spring or summer, but not now or through the winter, when to remove plants that had been in warmth and with more or less tender growth upon them into cool quarters would be courting death or serious injury. That, at least, is my experience in the matter.—T. BAINES.

Indoor Plant Department.

Watering.—By those who have only an imperfect knowledge of the cultivation of plants it is often supposed that any one is capable of giving them water, or, in other words, of knowing when they require it, the too general impression with the uninitiated being that if a sufficient supply be given all must be right, and that the plants will go on and flourish. Yet it is a question if many, in their first attempts at plant-growing, do not kill greater numbers by the too free use of the watering-pot than those who are neglectful on that point, more especially at this season of the year, when plants of all descriptions are not in an active condition. When a plant is placed with its roots in the open soil, or even when it is similarly situated in the bed of a conservatory, it is much less likely to suffer from either extreme of too much or too little water than when confined in a pot, for if the soil at any time have too much water applied it will more quickly drain off than it will from a pot, and the roots naturally keep more to the surface when they have room to spread out in a horizontal position, which renders them less likely to suffer if the soil happen to get too wet; on the other hand, if the soil become too dry, the roots, from the increased space allotted to them, have a better chance of extracting the moisture they require from the greater body of earth available, and, lastly, the roots and the whole plant collectively are usually in a more robust, vigorous condition, and less likely to succumb from any extreme of treatment to which they may be subjected; hence, the necessity of a closer attention to the watering of plants grown in pots. During spring and summer, when growth is in active progress, if the water supply be short, most plants will exhibit their want of moisture by the flagging of the leaves and young shoots, and from which injury is not nearly so likely to result in the case of free-growing subjects as by any excess at this time of the year, particularly with those that make slow growth, and that have fine roots. For the inexperienced the two latter characteristics, which generally accompany each other, will be one of the safest guides as to the quantity of water a plant requires to keep it in a healthy state. Herbs and slow-growing, hard-wooded plants may be taken as examples of the greatest impatience of excess, and the least requirement of water at any time of the year. Beginners are frequently tempted to purchase these, yet it would be much more advisable for them to confine their practice for a time to quick, free-growing plants until they have acquired the knowledge requisite to enable them to manage these before they undertake the more difficult subjects. Written or verbal instructions cannot do more than point to general practice in this most important operation, as not only will the quantity of water required by any particular species or variety of plant be in a great measure regulated by its more or less vigorous condition, but also the point of dryness which the soil should be allowed to attain before water is given, should be determined by the same conditions of growth in the plant. Yet, still some hints may be given that will enable the inexperienced to acquire the necessary knowledge in this matter by pointing out the greater or less requirements of water by plants during the autumn and winter.

Soft-wooded Plants.—Amongst those that need the soil moist at all times, even in winter, are Cinerarias; these, when well treated, make considerable growth at all seasons, and cannot bear to be dry for even a short period, it being a sure sign when the leaves flag that the plants have received injury. Calceolarias both shrubby and herbaceous come next in their requirements of water, especially the herbaceous kinds. Calceolarias and Cinerarias, in addition to a moist condition of the roots, revel in a humid atmosphere, and should never be placed on a dry surface, such as the front shelf of an ordinary greenhouse. Through the winter the best position for them is on a bed of ashes in a shallow pit, a slight distance below the aperture for the admission of air, so that it will in a measure pass over rather than come in direct contact with them. Where there is no alternative but to put them on shelves, it is well to have 1 in. of Moss spread on the shelves, which, if kept moist, will counteract the drying effects of the situation. The beautiful old Calla (*Richardia*) *athiopica* needs to have the soil moist; although it is almost an aquatic, it is of such a hardy nature that it will bear to be completely dried up without fatal results, though, of course, it feels the effects of such treatment. *Heliotropes*, *Petunias*, *Lobelia*, *Carnations*, *Salvias*, *Lachenalias*, *Vallotas*, and *Cyclamens* do not require to have the soil kept quite so moist as the first-named plants, yet they should always receive water before being allowed to get quite dry. Lilies do not need much water in the winter, but though not making much progress in their tops at this season, the roots are actively at work, consequently the soil must never be without moisture, or they will receive a check that will seriously affect their flowering the ensuing year. The different sections of *Pelargoniums* vary considerably in their demand for water; the zonals of all colours and the bronze and white variegated-leaved kinds being mostly freer growers than the large-flowered sorts, the fancies, and the

tricolors, must have the soil kept somewhat more moist, but those who have not yet acquired the knowledge of the exact condition of moisture these plants like had much better err by keeping them too dry than too wet, as the latter state will cause destruction of the roots, resulting in disease from which they will be slow to recover, whilst a moderate degree of dryness will not affect them to a greater extent than slightly stopping their growth. The above-mentioned more tender-rooted, slower-growing sections, particularly the fancies and the weakest-growing varieties of the tricolors, should never be watered during the winter, until the soil has got so dry that little moisture can be detected in it by pressing the fingers on the surface. There is a considerable difference in the strength of growth of the yellow-leaved varieties of Pelargoniums; the old Cloth of Gold, still retained by many, cannot do with much moisture in the soil through the winter; the freer growers will bear somewhat more. All the varieties of Kalosantes must be watered with caution until they begin to move freely in spring, when they will need more; during the autumn and winter do not apply any until the soil has got almost dry, yet water must not be withheld too long or the under leaves will shrivel up and die, which detracts much from the appearance of the plants, yet does not usually interfere with their flowering.

Hard-wooded Plants.—Amongst these Camellias require more water at all seasons than the generality usually grown. If ever the soil be allowed to get dry from the time the buds have attained a considerable size until they expand, it results in their falling off. Those who have not had experience in the cultivation of Camellias frequently do not attribute the buds thus dropping to the true cause, as it often happens that they do not begin to come off for one or even two months after the injury has been inflicted. The same result will follow if the atmosphere be too dry, but injury from this cause mostly shows itself much sooner in the case of plants having been dry at the roots. This disaster is most commonly brought about by too much fire-heat, and by neglecting to provide means for supplying the atmosphere with the requisite moisture. The useful autumn-flowering Veronicas require the soil always kept moderately moist, especially while they are blooming, or the flowers will be liable to drop. *Cytisus racemosus*, *Acacias*, *Neriums*, *Myrtles*, *Statice*, *greenhouse Rhododendrons*, *Lapagerias*, *Lasiandras*, *Monochætums*, *Croweas*, *Clinthus punicens*, *Cassia corymbosa*, and *Abutilons* are plants that should never be allowed to get so dry as the more tender kinds; they are free growers and equally free in producing flowers, afford great variety, and are altogether much more suitable for those to grow whose experience is limited than plants that are of more difficult management. *Azaleas*, although fine-rooted subjects, should never be permitted to become so dry as with some cultivators. The plants whence the present race of hybrids now in general cultivation have sprung grow principally in the humid hill regions of India, and, although much more tenacious of life than the majority of hard-wooded subjects, they are seriously injured if kept too dry at the roots. The exquisitely-scented *Daphne indica*, held in universal estimation for its perfume, is often killed by over-watering; except during the season when it is making growth, it should never be watered until the soil has got almost dry. *Oranges*, especially the small-growing *Otaheite* variety, need careful watering in the winter, when its roots are at rest. *Fuchsias* are often completely dried off during the winter, but in the case of old plants that are cut back in the autumn after flowering, they are much better if the soil be kept very nearly dry. In all cases, except with subjects the tops of which die completely down, or nearly so, when water is applied, no more should be given than will moisten the whole moderately in the winter season; to pour water to a plant until the soil is saturated during the winter, when at rest more or less, is as bad a treatment as can possibly be followed, especially if light potting (the bane of plant culture) have been adopted, as in this case the soil will obviously hold water like a sponge. When a plant of any description is growing in a pot comparatively small, it should never be so dry before water is given as if it had a larger body of soil surrounding its roots.

Flower Garden.

In favoured localities the beautiful *Chamærops Fortunei*, *Dracæna indivisa*, *Phormium tenax*, *Aralia papyrifera*, and many others of a similar character may be trusted out if they be provided with a good coat of dry leaves or Fern made secure around the stem and collar of the plants so as to preserve the most vital part from frost. Sheltered in this way it is surprising what an amount of cold many plants will endure if the soil in which they are growing be not of a wet, retentive nature. Where any doubt exists as to the safety of any choice specimens of the above, they should be lifted at once with as large a ball of earth attached as convenient, and placed in any spare cool house, or light, dry shed, from which light is excluded. *Aralia papyrifera* may be wintered in almost any out-of-the-way place, as it mat-

ters little about the loss of its leaves so long as the stems are preserved, the crowns of which start again in the spring and appear all the more vigorous for the rest they have received. *Aralia Sieboldi* is perfectly hardy, and one of the most strikingly ornamental plants for the centres of beds, the backs of shrubby borders, or for grouping amongst others in the sub-tropical garden. Now that this kind of embellishment is so much in vogue it is very desirable to introduce as many hardy plants as possible, so as to lessen the labour and expense attendant on raising a fresh supply each year, or the inconvenience of having to take up valuable house room to winter them. *Cannas* are still looking as well as at any time during the year as far as their foliage is concerned, and may be left to display their beauty till cut down by the frost, when they can be lifted and stored in any dry shed, or left in the ground if covered with half-rotten leaves, or any other safe non-conducting material that will preserve them from frost. In well-drained beds, treated in this way, they become much stronger than they do if dug up now and replanted in the spring, as they lose many of their large, fleshy roots in the drying they undergo when stored in the winter. *Echeveria secunda glauca*, now so much used for bedding purposes, should be laid in thickly on steep, sloping banks, under south walls or other sheltered positions, where, with a mat thrown over them during severe frosty weather, they will be found to winter safely; or they may be laid in under any old spare light just to keep the crowns dry, in which state they will remain quite hardy. *Gladioli* now ripe should be lifted and laid on the floor of a damp shed or cellar, or some other position where the crowns are not likely to become sufficiently dry as to cause them to shrivel, for when that takes place, they lose much of their strength and vigour, and not unfrequently die altogether. If the tops are still green, they should be allowed to remain till they fall off naturally, and not be cut away, as is sometimes done when the bulbs are dug up.

Indoor Fruit Department.

Vines.—Prune all Vines from which the leaves have fallen; remove all loose bark; wash clean with soft soap and water as hot as the hands will bear it; search every corner for insects, and place the Vines reserved for starting in position; wash well or paint the house; examine the drainage and borders, and see that all necessary for their welfare is completed. The inside border of the early Vinery, now ready for starting, should be covered with a bed of leaves and stable litter, turning it occasionally to make the ammonia available; use the syringe twice daily, and keep the temperature at 50° at night, increasing it with sun-heat during the day; where the borders are chambered and heated beneath, the heat should only just be sufficient to warm the pipes. After a growing season the roots will be found close to the pipes, attracted to them by the heat, if previously applied judiciously. Water well inside borders with tepid water about 80°, which operation is most essential in the first growth of the Vine. In cold weather never allow the pipes to give off that odour of heated air, which is so injurious to the Vine. Grapes now hanging should be looked over daily, and all bad berries removed on the first signs of decay; up to the present time the autumn has not been favourable for the preservation of Grapes. A drop of water should not be spilt, nor should plants requiring water be allowed to remain in the same house. Immediately before the fall of the leaf is the most precarious time for them. Where it becomes necessary to fill the houses with plants the Grapes should be cut with a portion of the wood and placed in bottles of water in which some charcoal has been put, in a room with a dry temperature of about 45°. Remove all foliage as soon as a tap of the hand causes it to drop; warm with fire-heat, and air well houses on fine days where fruit is hanging; keep ventilators closed in heavy, damp weather. Where Grapes are intended to hang through the winter, or where early forcing is to take place, outside borders should be protected by wooden shutters or other means that will allow the rain to run off.

Pines.—The second batch of Queen Pines should now be allowed to go to rest by lowering the temperature and keeping them moderately dry at the root; 55° with fire-heat will be sufficient for them. Growth among any kind of Pines should not now be encouraged; on the contrary, the aim should be to keep that which they have made as undisturbed as possible. Continue to give fruits swelling weak supplies of manure water when necessary, and maintain a temperature of about 70° at night, allowing it to rise 10° or so above that during the day. Plants, the fruit of which is just emerging from the socket, should be fully exposed to all the light possible, otherwise, the fruit will come up reluctantly, and deformed development is often the result. Subdue the aridity of the atmosphere by sprinkling the paths with water, and the surface of the plunging material in pits where no paths exist. Avoid syringing overhead. Never let the evaporating troughs become empty.

Peaches.—From trees in early houses from which the foliage has dropped, prune and remove all old ties; wash well as directed for Vices; let all inside walls be properly whitewashed; paint pipes and hoses if necessary; if not, clean thoroughly. Take away all the surface soil off the roots, replace it with fresh soil and manure to the requisite height, both outside and inside, and protect the borders as recommended for Vices. Trees in late houses should have the assistance of a brush to remove those leaves that are ready to drop, and all young, green shoots attempting to grow should be at once displayed. Give a little fire-heat by day and a free circulation of air to assist the wood in ripening. In tying in all trees be careful not to lay them in too close, as the result will be weak, unripened shoots.

Kitchen Garden.

Aparagua.—Tops of this will now have turned yellow, and should be removed; but, as in other cases of a similar nature, they ought never to be cut away whilst they have life in them. If there are any weeds on the beds, they should be cleared away. The beds should then have their winter dressing applied. This ought to consist of 3 in. of well-rotten manure evenly spread over the surface. This not only has the effect of enriching the soil, by its fertilising properties being washed into the ground by the rains, but it also protects the crowns from frost; for, although a perfectly hardy plant, yet, like many others under a system of cultivation, it is better not to have the roots exposed to severe frost. If the alleys contain plenty of soil, an inch or two may be thrown over the manure; but the old method of sinking these two deep frequently did much injury to the roots, which grow persistently in a horizontal direction, often extending into the alleys, and when these were cut to such a depth as to throw a considerable portion of soil over the beds, the roots, of course, were more or less injured. The great mistake in the cultivation of this vegetable is in too close planting; two rows are quite enough for a 4-ft. bed, instead of three or four. There is nothing gained by close planting; when plenty of room is allowed, the heads, if they are not so numerous, are double the size, and the beds will last much longer.

Extracts from my Diary.

November 4.—Earthing up French Beans in pots with loam and manure. Grubbing out old Apple trees, and preparing holes for young ones. Getting ice-house cleared out ready for refilling on the first opportunity. Getting frames and lights cleared and washed ready for painting before bad weather sets in. Clearing off flower borders and faking up the ground for fresh flowers.

Nov. 5.—Potting on a batch of Dracaenas and Crotons for table decoration. Looking over Calceolaria cuttings and removing any that are damping off, taking off the lights whilst the weather is fine. Hoeing among growing vegetable crops. Taking up and stacking away Salefy and Scorzonera in a cool shed in dry soil. Looking over Grapes in bottles, cutting out decayed berries, and filling up the bottles where required.

Nov. 6.—Patting early potted Hyscinoths into gentle bottom-heat to get them forward. Moving large trees from nursery into pleasure grounds, and planting them in prepared holes. Nailing up Ivy and Roses on walls where blown down by wind. Pruning and nailing Morelo Cherries on north walls. Turning over Mushroom manure to sweeten.

Nov. 7.—Sowing Mustard and Cress; also French Beans in pots. Planting out Daisies, Silenes, Myosotis, and Wallflowers. Looking over all Cauliflowers, and turning down leaves where required, to protect them, and removing the most forward into the shed. Covering up Endive and tying up Lettuces to blanch. Turning over leaves and long manure for making hotbeds.

Nov. 8.—Looking over fruit-room and clearing away frosts that have begun to rot; also looking over seed Potatoes and removing any that are diseased. Washing plants and paint. Roping Onions, and making labels and pegs.

Nov. 9.—Getting tender plants from pits into Vineries, and placing Strawberries in pots into cold pits. Clearing the leaves off the pleasure ground walks, and rolling the gravel down firmly. Weeding Box edging, and cleansing kitchen garden walks. Nailing Fig trees on walls closely, and covering them over with thatched hurdles, to protect them from severe frost. Watering the Pines all through and tying up any that may require it. Fruit in use for dessert: Pines, Grapes, Pears, Apples, and Nuts.—W. G. P., *Dorset*.

Potatoes at the Paris Exhibition—"W. W. H.'s" report (p. 352) on the Potato competition at Paris is not quite correct. The highest number of marks in every class was awarded to our collections by the jurors, and the three classes were ultimately blended together when the gold medal was awarded to us.—JAMES CARTER & Co., *High Holborn*.

ROSES.

ROSE GROWING IN FRANCE.

(Continued from page 385.)

PROPAGATION BY LEAF CUTTINGS.—It was the celebrated Agricola to whom is due the discovery that certain leaves when treated like cuttings will produce plants. His first experiments, which were made in 1752, were with Orange leaves. With the Lemon and Orange tribe this method of propagation may succeed well enough, but in the case of the Rose it is altogether different. Rose leaves planted in 2½-in. pots in the frame of a warm propagating house soon form a swelling and produce roots, but at the end of six months, in spite of the development of what appears to be roots, there is not a vestige of a bud to be seen. This method of propagation applied to the Rose tribe produces a result which is more curious than useful, from which fact we are led to conclude that the supposed roots are nothing but prolongations of the fibrous tissue of the leaf.

CUTTINGS STRUCK IN HEAT WITH THE LEAVES LEFT ON.—This method of propagation is largely practised by professional Rose growers. The operation may be performed from the end of July to the end of September, and even during the winter. In certain establishments the propagating house is near the Rose nursery, in which the different varieties are all grouped together. Each plant bears the number belonging to its particular variety in the catalogue, so that the propagator whose duty it is to cut the slips passes from bed to bed, collecting from each of them his bundle of shoots, to which he immediately ties the corresponding number in the catalogue. He lastly wraps them in a damp cloth and deposits them in the entrance of the propagating house. This entrance is a sort of porch, with a second door, which is built either outside or inside the propagating house, so that the two doors are never open at the same time. It also serves as a kind of workshop, in which all the necessary appliances for propagation by cuttings are kept, such as prepared heath mould, thumb pots of different sizes, a set of punches for numbering the labels, a mallet for striking them, and the lead labels themselves. These labels are cut into the form of a long triangle, as shown in fig. 9, the base

Fig. 9.—Label.

being ½ in. in width, and the sides 1½ in. in length. The number is struck upside down, for a reason which will be explained presently, on the larger end of the label, which is stuck into the soil with the sharp end downwards. A tray, too, is necessary for carrying the potted cuttings backwards and forwards. It should be made of Pine, and should measure 2 ft. 4 in. in length by 1 ft. 4 in. in width, with edges 1½ in. high on the long sides, and 6 in. high on the narrow ones. The edges on the narrow sides are provided with holes, so that they serve for handles for carrying the tray to and fro. The shoots are cut up into slips, each having three leaves and, consequently, three buds; the joint of the lowest slip is allowed to remain on after having been pared with the pruning knife. The shoot is cut at right angles to its axis, about the 20th of an inch below a bud. The two upper leaves are generally cut off, as they would be inconveniently in the way when the cuttings were placed under the bell-glass. Each slip is placed in the middle of a small pot of about 1¼ in. in diameter and filled

with heath mould, into which it is thrust to the depth of about $\frac{1}{2}$ in., the mould being pressed round it firmly to keep it in its place. If we use pots of $1\frac{1}{2}$ in. or $1\frac{3}{4}$ in. in diameter, we place two cuttings in each, inserting them at a distance of about $\frac{1}{2}$ in. from the edge, as shown in fig. 10; if we use pots $2\frac{1}{2}$ in. in diameter we may plant three cuttings in them, in the form of an equilateral triangle. A lead label, bearing a number, is stuck into each pot, point downwards, and bent over the edge, so that it may not be accidentally misplaced. This is the reason why the number, as shown in fig. 9, is reversed. The pots are then watered and carried on the tray into the propagating house. The cuttings are placed in the frames and covered over with bell-glasses, as described under the heading of herbaceous cuttings. Where two or more varieties are placed under the same bell-glass the pots containing the same kind are placed together and distinguished from their neighbours by a piece of straw or Rush stuck into the mould. The cuttings are taken from under the bell-glass as soon as they have struck, and ought to be at once replaced by others, so as to make the work continuous. The rooted cuttings are placed in cold frames, which are protected during the winter by being

that yellow or black fungi will spring up in the tan, which, if not checked, spread very rapidly, and will at last extend to the soil round the cuttings. The best remedy is to remove the pots which are nearest to these growths and stir up the tan, removing those portions in which these troublesome visitors are growing. If the evil be widely spread, the only thing to do is to remove all the bell-glasses and renew the whole of the tan in the frame. If green fly make its appearance on the young plants, they must be well fumigated at night before the frames are covered over with the straw mats. It is hardly necessary to remind the Rose grower that, as the cuttings increase in size, they must be removed to larger pots. It sometimes happens that mites or very small worms will invade the soil in the pots. In this case, the mould must be entirely renewed and the pots replaced under the bell-glasses. The propagating house should be kept at a temperature of from 60° to 70° Fahr., and should be well shaded with straw mats or other appliances for keeping out the direct rays of the sun, which are fatal to cuttings. The straw mats, therefore, ought to be used whenever the sun is shining, and taken away every evening to be replaced in the morning.

INFLUENCE OF THE CUTTINGS OF THE CONDITIONS UNDER WHICH THEY ARE GROWN.—If we attentively investigate the various conditions under which cuttings struck on different systems are grown, we shall find reasons for everything, and may easily discover which system is best suited to our particular requirements. Cuttings without leaves struck in the cold during the autumn are generally successful and form healthy Rose bushes; these slips throw out roots during both autumn and winter. The bud during all this time appears to make no progress. It is, however, growing stronger; and when the genial warmth of spring is felt, it bursts into a shoot and finds a root system already provided, which, keeping pace with the leaves, maintains the proper balance between the subterranean and aerial growths. The successive development of the two parts of the plant depends on the conditions under which the cuttings are struck. In the autumn it is clear that the soil is still warmed by the heat of the summer. The air, on the other hand, is kept cool by cold fogs and longer nights; hence, in striking a cutting at this time of the year, the heat of the ground draws down to the portion under ground the whole of the sap in the shoot, and, by bringing it into contact with the ingredients of the soil, thereby favours the formation of the callus and the rootlets. During this time the circulation is checked in the upper part of the cutting by two causes; first of all by the temperature of the air being too low to stimulate the sap, and secondly, by the temperature of the soil being higher, thereby drawing the sap downward. We might almost say that at this time the only part of the cutting which is living is the lower part. When the spring arrives the conditions are reversed, and the aerial portion of the cutting becomes the most vigorous; in fact, the current changes and the sap flows upwards. With cuttings struck under bell-glasses matters progress more rapidly, but not so surely. The lower end of the slip, being placed in a frame which has a temperature of about 60° Fahr., finds sufficient heat to develop its rootlets, but the upper portion is in a medium, whose temperature is from 78° to 86° Fahr., which draws up the sap, and the formation of the leaves goes on much more quickly than that of the roots, hence it arises that we frequently see cuttings with well-grown heads, but which are, nevertheless, very weak. The underground half of the cutting can only furnish all that is required of it by the upper portion when it is allowed to grow in its own natural way without any adventitious aid. It very often happens that cuttings struck under bell-glasses, after having thrown out a number of beautiful buds, fade away and die. If we examine the lower ends of such cuttings, we shall find that they have either too few roots or else none at all, that is to say, that the growth above ground has predominated over that below ground, and the equilibrium has been broken. We may learn from this, therefore, that when striking cuttings under bell-glasses, we must not allow the buds to develop themselves too rapidly. This may be accomplished by so regulating the temperature of the soil in the frame, and that of the air under the bell-glasses, that the lower part of the slip may develop itself at the same rate as the upper part. Practical Rose growers are well aware that cuttings taken from the lower part of the shoot are

Fig. 10.—Cuttings struck in heat with the leaves left on the shoots.

surrounded with stable litter and covered over with straw mats. If the mould in the frames be light, the pots are buried in it up to the rim, but if it be heavy it must be covered first with a layer of fine sand. During the winter the cuttings require but little attention; they must, however, be kept clean, that is to say, the Mosses which spring up on the surface of the mould must be removed; they must also be kept very moderately watered and exposed to the air from time to time whenever the weather is fine enough.

TREATMENT OF CUTTINGS STRUCK IN HEAT UNDER BELL-GLASSES.—The cuttings must be examined every day, the bell-glasses wiped, and those pots watered which seem to require it. All dry leaves and dead cuttings, that is to say, those which turn black at the lower end, must be cleared away. The watering must be performed with a small watering pot with a long spout ending in a pipe of about 1-6th of an in. in diameter, into which two or three pieces of straw have been inserted so that the water may flow out drop by drop; the dead leaves must be removed with a pointed stick or piece of iron wire, so as not to disturb the cuttings. It often happens

more easy to strike than those taken from the middle, and these latter again than those taken from the upper part. This fact confirms what we have just said concerning the balance which should be kept up between the upper and lower parts of the cutting, and also shows that it is better for the lower part to develop itself before the upper part. It is well known to every one that the eyes at the base of the shoot are but slightly developed; they are, in fact, almost dormant; and if things follow in the natural order, the eyes at the top of the shoot develop themselves first, and then those in the middle, in accordance with the natural wants of the plant. The eyes at the base seem to constitute a kind of reserve, which only develops itself in extreme cases. It follows from this that these eyes not being sufficiently developed, are but little influenced by external circumstances. They draw towards them but little sap, and the lower part of the shoot has plenty of time to develop an abundant mass of rootlets, so that later on when the bud opens it finds a good supply of roots to feed it. There is another reason why slips taken from the lower part of the shoot should succeed better. It is because their wood is more mature, so that it can take up the supply of sap and elaborate it without any danger of becoming rotten, as is the case with cuttings with imperfectly developed wood.

LAYERING IN TRENCHES.—This method of propagation is adopted in the case of those varieties of the Rose which are difficult to strike from cuttings, and which generally furnish stocks on which to graft the more delicate kinds. They include the Quatre Saisons or Royal Perpetual, Manetti, Hundred-leaved Rose, the Burgundy Pompon, and several Damask Roses. Roses chosen as parent stocks ought to be free stocks or, at any rate, grafted level with the soil. They should be at least two years old, and be provided with good roots and of vigorous habit generally. They are planted in small, open beds, each bed holding only one variety. The ground is divided into beds 1 ft. 4 in. wide and 2 ft. 4 in. long. The soil must be dug down to a depth of 1 ft., the earth being thrown out on the space between the beds so as to form a mound. The trench being thus opened, the bottom is turned over thoroughly, and we may at once proceed to plant out the parent stocks, an operation which is generally performed in November. The roots are pruned, the stems are cleaned, and the trees are planted in the middle of the trench, keeping them from 2 ft. to 1 ft. 4 in. apart, according as we have to deal with a long or short-branched variety. The planting out being finished, the soil at the bottom of the trenches receives a dressing of well-decayed night soil or stable manure brought to the spot in baskets carried on men's backs. One basket-load of manure is divided into three heaps, 2 ft. from each other, which makes one basket-load for every 6 ft. run of bed. The manure being spread over the ground, things are allowed to remain undisturbed until the spring, when the stems of the trees are cut down level with the ground. Every time that the soil is dug up a little mould is taken from the top of the mounds and thrown round the parent stocks. By this means they are preserved from the effects of drought. In the spring of the second year and before the rising of the sap takes place, the trenches are filled up with the earth forming the mounds, an operation which provokes the formation of roots round the collar of the young shoots. During the summer and autumn the usual forking and weeding required by the season takes place. In the month of November the layer is separated from the parent stem. For this purpose the parent plant is partially uncovered and the layer is cut off above the part which has taken root, taking care to leave a portion of the shoot projecting beyond the root and bearing two or three eyes. It is from these eyes that the future shoots will spring, which, after they have been allowed to grow freely during the first year, must be pruned down and cut off altogether at the end of the second year. This kind of work may be carried on continuously for twelve or fourteen years, and will yield a crop of well-rooted layers every two years if we manure the ground once every three years. By planting two beds at an interval of twelve months, we may have a yearly crop of layers. It may be added that the mounds between the beds may be utilised for cultivating small vegetables, such as Garlic, Onions, salad, &c., but only during the first two or three years. The plants

we use for layering are sent to market under the name of *chenevottes*, packed in bundles of from 100 to 500, and sold at the price of from 10s. to 16s. per thousand. In the neighbourhood of Paris it is the commune of Fontenay-aux-Roses which has the speciality of this kind of culture. The *chenevottes*, when taken out of the ground, are potted or else placed in a greenhouse. In the first case they are grafted with the scions of new varieties; in the second case, they are planted out in beds of four Roses, at a distance of 1 ft. 2 in. from each other in every direction, after which they are shield-budded and yield dwarf Rose trees, which throw out fewer shoots than those which have been grafted on the Brier.

LAYERING WITH NOTCHED SHOOTS.—This method of layering has been applied with great success to climbing Roses, whose annual shoots are from 3 ft. to 10 ft. in length. When grown on a commercial scale the parent plants are set in beds at a distance of from 4 ft. to 6 ft. 8 in. from each other, according to the variety. In the spring immediately following the plantation the parent plants are pruned down level with the earth, in order to obtain a supply of healthy shoots, which will develop themselves during the summer and autumn. When the cold weather sets in these shoots are covered over with straw to protect them from the frost, not that it will kill them, but it may possibly so alter the condition of the woody fibre as to stop its growth and endanger the success of the layering. In the month of April or May, when the frost is no longer to be feared, and the sap has commenced its upward movement, we proceed as follows: We open round the parent stock a trench about 1 ft. 4 in. wide and 10 in. deep, the depth depending on the quality of the soil. A shoot is then bent down to the bottom of the trench, making it describe a somewhat sharp curve. The shoot must be kept in its proper position by a wooden hooked peg about 8 in. long, and is notched half-way through the wood at the bottom of an eye placed on the under side and on the lowest part of the curve. The hooked peg is driven into the ground over the middle of the curved shoot, far enough to keep the layer firmly in its place, after which the whole is covered up with mould. This operation is repeated all round the Rose tree, as long, in fact, as there are any shoots to layer. In order to avoid the shoots crossing each other and becoming entangled, the shoot which presents itself most naturally to the operator is the one chosen, and a space of from 2 in. to 3 in. should be left between each of the layers. The layering being finished, the trench is filled up either with the earth of the bed itself, if it be sufficiently light and rich for the purpose, or, what is much better, a compost made of equal parts of sand and well-rotted leaves, or equal parts of sand and old night soil well deodorised. When the hole has been filled up to the level of the surrounding soil, a little hillock of earth is formed round the layers so as to keep in the water with which they are watered. At the point where the shoot issues from the earth a stick is thrust in vertically, against which the shoot is trained by being tied with bast, Rush, or Willow. The layers will have become sufficiently rooted by the autumn if during the summer we give them the attention that all plants require to make them grow luxuriantly.

J. LACHAUME.

Crimson and Pink China Roses.—These are, perhaps, the most continuous flowering varieties of the Rose that we possess; for months they are continuously a sheet of bloom. I am well aware that the individual blossoms are not to be compared with those of Hybrid Perpetuals, but for isolated spots in pleasure grounds I feel sure that beds of these old-fashioned Roses will well repay the minimum of attention which they require.—J. GROOM, *Linton Park*.

Roses in Autumn.—The beautiful collection of Roses exhibited by Messrs. Wm. Paul & Sons at the last meeting of the Royal Horticultural Society served to show the advantages gained by planting suitable kinds in every available space close to greenhouse walls and similar places. It was from such positions as these that the blooms alluded to were cut. The plants over the low bare walls during summer, and in autumn yield an abundance of buds. The kinds shown were Safrano, Souvenir de la Malmaison, the beautiful snow-white Niphetos, so much valued in London markets for bouquets, Isabella Sprunt, Marie Van Houtte, and several other good autumn-blooming kinds.—S.

THE FRUIT GARDEN.

POT VINES FOR TABLE DECORATION.

THE Black Hamburg exhibited by Mr. Sage, of Ashridge Park, the other day at South Kensington was admitted to be one of the best fruited and most ornamental of pot Vines—having regard to the small size of the pot in which it was growing—perhaps ever staged. Mr. Sage was kind enough to show me a rough sketch of the iron support which he used in the production of plants of this kind, and from it the accompanying woodcut has been prepared. Ordinary well-ripened pot Vines in 12-in. pots are used, and before they are started the stout iron support seen in the figure, having three stout claws, is firmly fixed into the pot or in the ground on one side of it. On the top of the support is a ring or loop just large enough to grip closely nearly up to the rim an 8-in. pot. I cannot give the height of the support as used at Ashridge, but it is probably about 2½ ft. in height. The bole at the bottom of the upper pot is enlarged, and the top of the Vine is carried through it; then the pot is filled with soil. A small umbrella trellis, about 1½ ft. in height, is then introduced and secured into this upper pot just as the strong support is in the lower one, and the remaining or fruiting portion of the Vine is secured to the trellis upright and trained round beneath the top.

Mode of Preparing Vines for Table Decoration.

The Vine is then ready to be pushed into growth. Above the small pots all shoots are retained and tied up, and every encouragement is given to the production of good fruit and foliage. No doubt it is desirable to have a joint in the soil in the top pot, as rooting may be encouraged more freely. Of course in good short-jointed Vines this would be difficult to avoid. To many there may be nothing new in all this; still, new or old, it is well worth the attention of all interested in Vine culture, especially when such good results can be had as are obtained at Ashridge. It is well known that when Grapes are ripened but a comparatively small amount of root action will suffice to keep them sound and plump for a long time. Thus it is that after the crop on the pot plant is ripened it does not suffer when the necessary severance in the stem beneath the upper pot is effected. Mr. Sage had a plain, useful wooden stand into which to drop these small pots after severance to keep them from toppling over, and thus enable them to be carried about, or be placed on the table or sideboard in perfect safety.

A. M.

Mixed Cropping in Orchards.—In this part of Kent an extensive area is devoted to orchards which are cropped on the mixed plan. In this way the rows of standard Apples and Pears are planted at double the ordinary distances apart, and rows of dwarf spreading bush Apples or Pears are planted alternately; these again have rows of Kentish Cob nuts or Filberts planted between them, and Goose-

berries or Currants in the intervening spaces. Under this system good crops of some of these fruits are ensured in all seasons, and as Gooseberries are mostly gathered green, the shade, while protecting them from frost, does not injuriously affect them. The Black Currant is also in great request for preserving purposes. The bush-trained Apples, Nuts, &c., are kept down quite low, and form open, wide-spreading heads. The centres of the standard trees are well thinned out, but the outer young wood is left tolerably thick, forming a regular umbrella-shaped head, and the crops they bear amply testify to the suitability of the practice. Grafting and double grafting of approved market sorts are largely practised in this district, and on our strong, clayey loam, resting on ragstone foundation, the trees attain large proportions, their stems being more like those of forest trees than of ordinary fruit trees. Cherries thrive best in the lighter soils on the elevated portions of hillsides.—J. GROOM, *Linton, Maidstone*.

THE BLACK HAMBURGH AS A LATE GRAPE.

EVERYBODY admits that the Black Hamburg is the best early spring and summer Grape, but it has more claim to be called a late Grape than many suppose. We have always a supply of good, plump Hamburgs up to the new year, and every one who tastes them during November and December says they are superior in flavour to Lady Downes, Alicante, Gros Colman, or any other Grape, and I am sure that those who are well acquainted with Grapes will readily admit that this must be the case. Some think that thick-skinned Grapes are the best keepers, but I do not find that they resist damp better than thin-skinned ones. I have seen Lady Downes damp or rot as freely as any other Grape, including the Black Hamburg. I am strongly of opinion that it is altogether a mistake to grow such Grapes under the idea that they keep best in winter, and I am sure that those who have tasted a Black Hamburg at Christmas or the new year in as fine a condition as it could be had in August, would, at least, try to obtain a few bunches of it at that season. Black Hamburgs, to come in at all late, may be cultivated with very little expense, as they do not require to be started into growth with much fire-heat in spring, nor do they require much of this at any time throughout the summer season. The bunches should be well thinned out, and the crop must not be an excessively heavy one, unless it be under the care of an experienced cultivator who can bring it to perfection. One of the main points to ensure late keeping in the Hamburg is having the fruit thoroughly well matured, and after that is accomplished little further difficulty need be experienced.

CAMBRIAN.

Dickson's Exquisite Melon.—This Melon was introduced for the first time last autumn with a very high character, which it appears to have well maintained. So distinct is it from other Melons, that it may possibly prove the type of a new and distinct race of this useful fruit. The variety in question has with me proved somewhat small, each fruit averaging about 1½ lb. It is round and handsome in form, very beautifully netted, and in addition to this it has bright green lines extending from the apex to the stalk, dividing, as it were, the fruit into sections, such as may be seen in the Orange when the peel has been removed. The rind is very thin, and the flesh green, juicy, and yet firm; the seeds are comparatively few, and occupy but a very small space, so that there is considerable depth of flesh. The flavour is so exquisite that it well deserves its name, and it has also the very desirable quality of keeping longer in good condition after being cut from the plant than any other variety with which I am acquainted. The habit of the plant is vigorous without being too robust, rendering it very suitable for training on a trellis near the glass. The fruit, as has been already stated, being somewhat small, requires little, if any, support. Indeed, the size of the fruit may by some be considered objectionable, although I am by no means inclined to think so, as one fruit is sufficiently large for a small party; while, for a large one, three or four fruits may be placed upon a dish. This would give variety to the dessert table, and at the same time need not exclude from it a fruit of larger dimensions of some other variety.—P. GRIEVE, *Culford, Bury St. Edmunds*.

Coe's Golden Drop Plum.—This Plum is not half so much grown as it ought to be. When half ripe, if properly preserved and sent whole to table, it makes the choicest of winter dessert, and when ripe nothing is more useful. I am just now (October 20) having glorious dishes daily of it, slightly shrivelled. It is simply a bag of honey. My trees are growing both against west and east walls, and in both places they do well.—R. GILBERT, *Burghley*.

Sweet Chestnuts.—The fruit of the Sweet or Spanish Chestnut is very plentiful hereabouts this autumn, and we find it so useful for dessert that it would well repay anyone to plant and cultivate a few trees to supply fruit for this purpose alone.—CAMBRIAN.

THE HIGH WOODS IN TRINIDAD.

My first feeling on entering the high woods or primæval forest, as it is called here, was (says Canon Kingsley in his "At Last") helplessness, confusion, awe, all but terror. One is afraid at first to venture in fifty yards. Without a compass or the landmark of some opening to or from which he can look, a man must be lost in the first ten minutes, such a sameness is there in the infinite variety. That sameness and variety make it impossible to give any general sketch of a forest. Once inside, "you cannot see the wood for the trees." You can only wander on as far as you dare, letting each object impress itself on your mind as it may, and carrying away a confused recollection of innumerable perpendicular lines, all straining upwards, in fierce competition, towards the light-food far above; and next of a green cloud, or rather mist, which hovers round your head, and rises, thickening and thickening to an unknown height. The upward lines are of every possible thickness, and of almost every possible hue; what leaves they bear, being for most part on the tips of the twigs, give a scattered, mist-like appearance to the under-foliage. For the first

which is sprawling out of the ground and up above your head a few yards off. You cut the leaf-stalk through right and left, and walk on, to be stopped suddenly (for you get so confused by the multitude of objects that you never see anything till you run against it) by a grey Lichen-covered bar, as thick as your ankle. You follow it up with your eye, and find it entwined itself with three or four other bars, and roll over with them in great knots and festoons and loops 20 ft. high, and then go up with them into the green cloud over your head, and vanish, as if a giant had thrown a ship's cables into the tree tops. One of them, so grand that its form strikes even the negro and the Indian, is a Liantasse (*Schnella excisa*). You see that at once by the form of its cable—6 in. or 8 in. across in one direction, and 3 in. or 4 in. in another, furbelowed all down the middle into regular knots, and looking like a chain cable between two flexible iron bars. At another of the loops, about as thick as your arm, your companion, if you have a forester with you, will spring joyfully. With a few blows of his cutlass he will sever it as high up as he can reach, and again below, some 3 ft. down; and, while you are wondering at this seemingly

The High Woods, Trinidad.

moment, therefore, the forest seems more open than an English wood. But try to walk through it, and ten steps undecieve you. Around your knees are probably Mamures (*Carludovica*), with creeping stems and fan-shaped leaves, something like those of a young Cocoa-nut Palm. You try to brush through them, and are caught up instantly by a string or wire belonging to some other plant. You look up and round: and then you find that the air is full of wires—that you are hung up in a network of fine branches belonging to half-a-dozen different sorts of young trees, and intertwined with as many different species of slender creepers. You thought at your first glance among the tree-stems that you were looking through open air; you find that you are looking through a labyrinth of wire, rigging, and must use the cutlass right and left at every five steps. You push on into a bed of strong Sedge-like *Sclerias*, with cutting edges to their leaves. It is well for you if they are only 3 ft. and not 6 ft. high. In the midst of them you run against a horizontal stick, triangular, rounded, smooth green. You take a glance along it right and left, and see no end to it either way, but gradually discover that it is the leaf-stalk of a young Cocorite Palm (*Maximiliana Caribæa*). The leaf is 25 ft. long, and springs from a huge ostrich plume,

wanton destruction, he lefts the bar on high, throws his head back, and pours down his thirsty throat a pint or more of pure cold water. This hidden treasure is, strange has it may seem, the ascending sap, or rather the ascending pure rain-water which has been taken up by the roots, and his hurrying aloft, to be elaborated into sap, and leaf, and flower, and fruit, and fresh tissue for the very stem up which it originally climbed; and therefore it is that the woodman cuts the Water Vine through first at the top of the piece which he wants, and not at the bottom; for so rapid is the ascent of the sap that if he cut the stem below, the water would have all fled upwards before he could cut it off above. Meanwhile, the old story of Jack and the Bean-stalk comes into your mind. In such a forest was the old dame's hut; and up such a Bean-stalk Jack climbed, to find a giant and a castle high above. Why not? What may not be up there? You look up into the green cloud, and long for a moment to be a monkey. There may be monkeys up there over your head, burly red Howler (*Mycetes*), or tiny peevish Sapajou (*Cebus*), peering down at you; but you cannot peer up at them. The monkeys, and the parrots, and the humming-birds, and the flowers, and all the beauty, are upstairs—up above the green cloud. You are in "the

empty nave of the cathedral," and "the service is being celebrated aloft in the blazing roof."

We will hope that as you look up, you have not been careless enough to walk on; for if you have you will be tripped up at once: nor to put your hand out incautiously to rest it against a tree, or what not, for fear of sharp thorns, ants, and wasps' nests. If you are all safe, your next steps, probably, as you struggle through the bush between tree-trunks of every possible size, will bring you face to face with huge upright walls of seeming boards, whose rounded edges slope upward till, as your eye follows them, you find them enter an enormous stem, perhaps round, like one of the Norman pillars of Durham nave, and just as huge; perhaps fluted, like one of William of Wykeham's columns at Winchester. There is the stem; but where is the tree? Above the green cloud. You struggle up to it, between two of the board walls, but find it not so easy to reach. Between you and it are half-a-dozen tough strings which you had not noticed at first—the eye cannot focus itself rapidly enough in this confusion of distances—which have to be cut through ere you can pass. Some of them are rooted in the ground, straight and tense; some of them dangle and wave in the wind at every height. What are they? Air-roots of wild Pines (*Tillandsia*), or of Matapalos, or of Figs, or of Seguines (*Philodendron*, *Anthurium*, &c.), or of some other parasite? Probably; but you cannot see. All you can see is, as you put your chin close against the trunk of the tree and look up, as if you were looking up against the side of a great ship set on end, that some 60 ft. or 80 ft. up in the green cloud, arms as big as English forest trees branch off; and that out of their forks a whole green garden of vegetation has tumbled down 20 ft. or 30 ft., and half climbed up again. You scramble round the tree to find whence this aerial garden has sprung; you cannot tell. The tree-trunk is smooth and free from climbers; and that mass of verdure may belong possibly to the very cables which you met ascending into the green cloud 20 yards or 30 yards back, or to that impenetrable tangle, some 12 yards on, which has climbed a small tree, and then a taller one again, and then a taller still, till it has climbed out of sight and possibly into the lower branches of the big tree. And what are their species? What are their families? Who knows? Not even the most experienced woodman or botanist can tell you the names of plants of which he only sees the stems. The leaves, the flowers, the fruit, can only be examined by felling the tree; and not even always then, for sometimes the tree when cut refuses to fall, linked as it is by chains of *Liane* to all the trees around. Even that wonderful Water Vine which we cut through just now may be one of three or even four different plants.

FOREST WORK FOR NOVEMBER.

OPEN weather still favours the operations of the tree planter, and the fall of rain has enabled holing to be continued in soils where, from the dryness of the autumn, such works had become almost an impossibility. Most deciduous trees are now fit for removal, and no time should be lost before getting them into their new quarters. The gradual hardening or acclimatizing of early-removed trees is highly conducive to their future progress; and this applies more especially to those which have been taken from warm nurseries. Should frosts set in transplanting must be suspended, as all young trees receive a severe check from being removed during frosty weather.

Allotments of coppicing and underwood for sale by public auction should now be made. We have invariably found that small lots, by inviting more competition, command relatively higher prices than larger ones. Without placing any unnecessary restrictions upon the purchaser, the vendor should protect himself by clauses sufficiently stringent to insure good workmanship—early cutting from the stool, and removal from the wood within a reasonable time.

The future crop depends so much upon the time and mode of cutting from the stool, that this is a point deserving especial attention. If cut too early the bark is apt to separate from the wood and admit water during the winter, thus checking the development of adventitious buds. Similar results follow a cutting made during severe frosts. Experiments have shown that the best crop of young shoots follows a cutting made between the middle of February and the latter part of March. Much, however, depends upon the season and the age of the stools. The younger plantations should always be cut first. Felling is generally continued from early in November until the end of March, and by the first week in April it should cease.

Upon all moderately dry soils, which alone are fitted for the growth of the best kinds of underwood, the stools should be cut almost close to the ground. This ensures a good crop of shoots from the dormant buds, and as these spring from near the surface of the soil they are generally erect in their growth, and at the same time they help to extend the stool. All the smaller produce should be cut with a light and keen handbill; poles up to 5 in. or 6 in. diameter with a sharp axe; and all beyond that size with the cross-cut saw. Small stools upon light soils require especial care, as the blows of a heavy, blunt axe sever the fibres of the roots, loosen the entire stool, and destroy the continuity of the dormant buds, which proceed from the medullary rays. All finished stools should be rounded off, that no water can lodge upon them; this may be done with the axe, but it is much better finished with the adze. The bark should adhere firmly all round the edge of the surface.

To insure early removal, mark out good clearance roads. In Kent, we "brush" or bottom these with small faggots tightly bound up, at the rate of about forty to the rod, laid transversely to the line of road. Such roads will carry heavy loads of poles and faggots during the winter, as well as the timber in the spring.

Plantations may now be thinned, and where Birch, Beech, Chestnut, Alder, &c., are laid up for some time to become partly seasoned in the logs, they may at once be stripped of their bark. Ash need not be felled until after the middle of the month. Where it is intended to grow timber of great length, care should be taken not to destroy the leaf-canopy. Where clean-grown timber is also required the branches should always be cleared from the trunks of the standards within two years after the thinning; these rob the crown and produce stag-headedness.

Collect leaves for the nursery; also Ash-keys, Alder seeds, the berries of the Mountain Ash, and such other seeds as ripen during the month; also continue drainage and clear out all watercourses. The seeds of many of our native trees may be sown as they ripen, but the same rule does not apply to exotics.

A. J. BURROWS.

FORMAL OUTLINES TO SHRUBBERIES.

IN the first formation of shrubberies a formal outline may be excusable, but the sooner the shrubs are permitted to grow over and through it, unless it be bonned by a path, the better. I have often thought the common practice of leaving a marginal border round masses of shrubs for flowers a mistaken one; too often, when such is the case, they present but a littery, rubbishy appearance. Can anything add to the beauty of a well-developed shrub springing direct from the fresh green turf? I think not; therefore let the Grass grow close up to the shrubs, without any bare soil intervening, and the different habits and styles of growth of the different shrubs in a well-arranged group will always give that variety of outline which is so pleasing. Of course, a little pruning may be necessary. Art may be permitted to mend Nature, so far as to stop or remove a robber shoot that is likely to destroy the balance of power in the plant. This is requisite in almost every form of tree or shrub growth. In the Grassy glades that intersect masses of shrubs, and which, when well and tastefully arranged, add so much to their picturesque appearance and beauty, groups of the more striking herbaceous plants may be used with good effect. Thus, a group of herbaceous *Pionies* planted out in the Grass a few feet from its margin, in front of a mass of shrubs, has a far better effect than when growing in a crowded condition under or among the shrubs themselves. And the same idea could be worked out with many other plants, such as hardy *Fuchsias*, the autumn-flowering *Anemones*, and notably the *Polygonums*, such as *Sieboldi* and others. This appears to me to be the true way of bringing out the decorative force of any handsome or striking plant, but it must not be overdone. A single group of any suitable subject, well placed, would have a very striking effect; but to overtask the turf in this way would be ruinous. The great evil often noticed in the treatment of any given object is carrying the idea too far. It does not follow because a particular group in a certain position may look well and pleasing, that an increase in the number of such groups would have the same effect.

E. HODDAY.

Acacia Decaisneana.—Of this rosy form of the common *Acacia* there is a specimen in the Imperial private gardens at Vienna about 40 ft. high. It is said to be very beautiful in flower at this size, and is evidently a most vigorous and hardy tree.

Paulownia imperialis as a Fine-foliaged Plant.—This well-known tree is planted singly and in small groups on the Grass about Vienna, cut down every year, and confined to one or two stems when it grows in the summer. The effect is quite as good as the best of the so-called sub-tropical plants with which so much trouble and expense are taken in hot-houses.

ANSWERS TO CORRESPONDENTS.

Alnwick Seedling Grape.—Allow me to say, in reply to Mr. Groom (p. 386) that this Grape possesses excellent qualities, and must occupy a prominent place amongst late varieties. It has fruited for the first time with us in a late house where Lady Downes, Black Alicante, Gros Colman, and Barbarossa are the principal varieties, and in my estimation it far surpasses all of them. In growth, it resembles Lady Downes, growing away freely and clean, and it possesses a strong constitution. If its fruit hangs as long as that of its associates, it must drive them out of the market. Although a thick-skinned Grape, it is thinner than those named. It has berries almost as large as those of Gros Colman, but they are oval in shape. As regards colour and bloom, it has surpassed anything we have had, not even excluding the finest Alicante.—J. HUNTER, *Lambton Castle.*

Planting Box Edgings.—When is the best time to plant Box edgings? and when should existing ones be cut? [Any time between January and March is the best season to plant Box. It should be dug up and pulled into small pieces, each having a few fibrous roots attached to it. All strong roots should be shortened, as should also the tops. Put a little good soil to the roots at planting time. Trim existing edgings after severe frosts are over in spring.—S.]

Medlars.—What is the best method of keeping Medlars? I always find that they get mouldy on the end of the stalk, and the fruit itself turns sour. This occurs before they are really ripe. When ought they to be picked?—F. W. [Let them hang on the trees until sharp frosts are likely to occur, then gather when quite dry, and place them in single layers on wooden shelves in a dry, airy, cool room or loft.]—S.]

Shelves for Fruit Rooms.—What are the best shelves on which to place fruit? I have been informed that they should be strips of wood placed $\frac{1}{2}$ in. or $\frac{3}{4}$ in. apart, and bevelled to an edge, so that very little of the fruit should touch the wood. Should the shelves be painted? If so, is white the best colour?—E. A. [The shelves you name are the best you can employ. They may be made of any kind of hard wood. Do not paint them or put straw on them, as both give an unpleasant taste to the fruit. The latter should be laid on the bare shelves in single layers.]

Sowing Sloes.—When should I sow these to make cover in an Oak wood? and at what depth?—A. [Gather the fruit when ripe, and place them in dry sand in a box or tub till spring, when the flesh can be easily rubbed from the seeds. Sow at a depth of from 3 in. to 4 in. in drills in fine soil.—W.]

Plumbago capensis.—"W." (p. 367) labours under a slight misapprehension, as the climate at Vienna is much more severe than anything we know of in England. The plants in question are, doubtless, taken up for the winter, as the plant is somewhat tender, and suffers at times even at Cannes and Nice.—E. H. W.]

Cracked Pears.—C. H. D.—The peculiar cracking and withering up of your Pears are due to the want of a proper flow or supply of sap in the tree; want of moisture at a certain stage of growth makes the cuticle or skin contract, whilst a flush following makes it crack. Get the tree into proper health, and cracking will not occur.—B.]

Fine Pyramidal Oak (p. 366).—The oldest tree of this Oak with which I am acquainted stands in a forest near Babenhausen, in Bavaria. Its height is about 100 ft., the branches beginning about 30 ft. above the ground. Another, the produce of a graft from it, stands in Wilhelmshöhe Park, near Cassel, in Prussia. Its height is about 100 ft., and its first branches are 6 ft. above the ground.—C. W., *Chester.*

Eucalyptus globulus.—Allow me to say in answer to Mr. Mogridge (p. 366) that we have several examples of this Gum tree planted out here. Some put out four years ago are close upon 30 ft. high, but they are so slender that all of them require supports. Would it be advisable to head them back, in order to make them more bushy, for as they now are it is evident that they will never support themselves.—W. WATSON, *Eaglehurst, Fawley, Hants.*

— In answer to Mr. Mogridge, let me say that the species of Eucalypti that grow at high elevations in Tasmania and Australia (Victoria) that came under my notice were—*E. coriacea*, a comparatively small tree with large and leathery leaves. This grows at an altitude of 4000 ft., and, therefore, should be hardy. *E. Gunni*, also called *montana*, grows at a somewhat lower elevation, and becomes a fine tree 100 ft. high; its leaves are rather small, but the flowers are pretty in a mass. *E. amygdalica* is probably the next hardiest, growing as it does high up on the flanks of Mount Kosciusko, in the Australian Alps, where it has been measured, and found to have exceeded 400 ft. in height. It is a truly magnificent tree, but it must be borne in mind that it is only where shelter can be obtained it can show its columnar trunk towering aloft (perhaps 150 ft. before its first branch) to perfection, and that the peculiar beauty of a well-grown Eucalyptus lies in its smooth dove-coloured, or, as it may be in other kinds, apricot-coloured or black trunk, looking like a column of some vast temple. *E. viminalis* stands wet so well that it is worth a trial; its leaves are Grass-green in autumn, but its growth is angnaly. All these are, to my mind, more really worth growing in England, where we have so many dense-foliaged trees than the famed *E. globulus*, whose virtue consists in having denser foliage than other sorts when young, but when old is so ungainly as to lose all beauty; indeed, I am at a loss to understand its popularity when there are so many other kinds superior in beauty and nearly as quick growing, while, for hardness, it ranks among the lowest, being found only in the richest and

warmest valleys in Tasmania, and it is abundant in Queensland, where the climate becomes tropical. For information on such points Baron Von Mueller, now, I understand, reinstated at the Botanic Gardens, Melbourne, is able to give detailed accounts better than any one else. Seeds of all the best known kinds of Eucalypti can be obtained from Mr. C. F. Creswell, who has establishments at Hobart Town, Melbourne, and Sydney, but I do not know if they can be obtained in England.—E. H. WOODALL.]

Town Gardening.—Would you kindly give me some instructions as to what plants would be most suitable for growing in a small "back green" in Edinburgh which has an open, north exposure. It is bounded by three dead walls and the house wall, which unfortunately shades it from the sun till about noon. Already Ivy has been planted on the walls, and a strip 3 ft. wide could be dug round the walls for herbaceous plants. The soil is rich black loam, and Grass grows quite well in it; would there be any use trying some Roses on the south or west wall?—G. K. [Try *Michselmas* Daisies, such as *Aster Novæ Angliæ*, *Amellus*, *bessarabicus*, and *levis*, *Pompeo Chrysanthemums*, *Geranium sanguineum*, *Christmas* *Roses*, *Senecio pulcher*, *Pyrethrum uliginosum*, *Helianthus multiflorus* fl.-pl., and *Veronica Andersoni*. Certain *Roses* would also probably succeed, such as *Charles Lawson*, *Chenedole*, *Madame Plantier*, and others of the Hybrid China and Bourbon race; also the hardier kinds of *Noisettes*, as well as the *Ayrshire*, *Boursant*, and evergreen varieties.]

Pinus insignis.—In answer to "P.'s" enquiry (p. 366), allow me to say that I have found no *Pinus* nearly so rapid in its growth as *P. insignis*, though I am unable to quote precisely as to its measurements. "P." need not scruple to plant *Pinus insignis* in the open ground in the south of Ireland. I have about 1000 of this *Pinus* of all ages since the date of its introduction, many in the most exposed borders of plantations near the sea, in Mount's Bay, Cornwall. Most of them are seedlings from my own older trees. This species enjoys the moisture of our climate, coming, as it does, from the sea coast of California. I consider it one of the best of nurses, giving better shelter, and growing much faster, than either *P. austriaca* or the *Pinaster*. The severe Atlantic gale of October, 1877, slightly browned the most exposed trees here, but they have already recovered. *P. insignis*, however, suffers severely from snow in a cold winter, losing entire limbs, and often dying from its effects. As to the timber, home-grown samples are not yet old enough to test; but I have planked and used wood of thirty years' growth both for furniture and for wheelbarrows, &c., and find it easily worked, light in weight, tough, and strong, though liable, as might be expected from immature timber, to be wormed. If planted closely, it may be made to produce clean, straight timber.—J. J. R., *Penrose.*

Blanching Endive.—I have some very fine plants of Endive sufficiently large to tie up and blanch for use, but I find if tied up with the least moisture on any part of the leaves they turn rotten and are spoiled for use. I have heard of their being blanched by laying a tile or slate over them, but presume this must be done when they are thoroughly dry. Can you give me directions how to act?—J. Y. [Many ways and means of blanching are resorted to by cultivators, the most common being that of arranging the leaves in the same way as those of Lettuces; if tied in two places instead of one, as is often the case—i.e., one in the middle and one at the top—the blanching will be more complete than if otherwise would be. Some invert flower pots or Seakale pans over the plants, which is, perhaps, the least troublesome method of any. Others cover the heads entirely with dry soil. Straw hurdles, too, put over the plants in such a manner as to exclude light from them, is a very easy and effectual way of blanching, and by continually moving these onward as the heads are cut, a successional supply of well-blanching Endive may be secured. No more than is likely to be used should be blanched at a time, inasmuch as after a certain period flavour and crispness gradually decline. Flat tiles or slates are sometimes used for blanching, first pressing down the hearts of the plants with the hand, and then applying the tile or slate, afterwards covering the whole with earth or dry straw. Whatever process of blanching may be preferred, it should at all times be done when the foliage is dry, otherwise discoloured or rotten hearts will be the result. Taking all things into consideration, there is, perhaps, nothing better for blanching Endive than the common flower-pot, or seed-pans without holes in the bottom.]

Names of Fruits.—*Leigh Holme*.—1, Marie Louise Pear; 2, Pear unknown; 3, Calabasse; 2, Fearn's Pippin Apple; 3, Queening.

Names of Plants.—*J. A.*—*Pyrethrum uliginosum*. *Mrs. G. R.*—1, Canavalia, a large kind of Bean; 2, a Composite, which we do not recognise; 3, *Convolvulus*; 4, 5, 6, 9, varieties of Dwarf Beans; 7, 8, 9, ornamental Gourds. *F. W. G.*—*Rivina humilis*, *Dendrobium palpebre*, *Lastrea glabella*. *Miss A. H.*—The blue flower is *Agatheæ celestis variegata*; the other *Chrysanthemum feniculaceum*.

Laburnum in Flower.—On walking past Salthaire Park, near Shipley, on Saturday last, I noticed that almost every Laburnum was in full bloom, although devoid of leaves. The trees face the north, and are wholly unsheltered.—F. W. J.]

Anemone japonica.—Noting the statement in THE GARDEN (p. 345) respecting the flowering of the Rose-coloured *Anemone japonica*, I may mention that I have between forty and fifty blossoms on my plants at present, and plenty more are coming on.—WM. JOHNSTON, *Ballykilbeg, Co. Down.*

National Rose Society.—The date for this Society's exhibition at Manchester, is Saturday, July 12, not 14, as stated in THE GARDEN (p. 367).

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

LONDON MARKET GARDENING.

THERE are now in England over 161,228 acres of land devoted to orchards, and 33,677 acres to market gardens properly so called. In Middlesex alone there are 4606 acres under market crops, and 3004 acres under fruit trees. In Kent there are 11,589 acres of orchards, and 3466 acres of market gardens, and in Surrey 1669 acres of orchards, and 1654 acres of vegetable ground. In the more immediate neighbourhood of London market gardening is considerably on the decrease, owing to the land being required for building and other purposes. Moreover, land close to London has now become so valuable, that market gardeners are unable to pay the heavy rents required for it; and now when our means of transit are so perfect, goods can be sent to London from twenty miles, or even greater distances off, at very little expense. Hence it is that vegetable and fruit gardens are gradually getting further off every year. A market grower owning from 16 to 20 acres of land, occupied by fruit and vegetable crops within a few miles of London, informed me that he had been offered £5000 per acre for the whole of it on several occasions for building purposes. With florists' establishments the case is wholly different; they may be found by hundreds in the rear of suburban villas, many of them being confined to half-an-acre of ground, which is entirely covered with glass, and from some of these places the amount of plants, fruits, &c., that are sent to market is almost marvellous. The best cultivated market gardens round London are those in the Fulham Fields, the once famous Deptford grounds being now nearly over-run by the builder. From Chelsea to Kew Bridge, on the north bank of the Thames—indeed, almost the whole of the land between the river and the road leading from Hammersmith to Kew is occupied by garden crops. On the other side of the road just alluded to the garden lands extend from Hammersmith to Acton, and from thence between Gunnersbury and Brentford to Richmond, Twickenham, Hounslow, and Feltham. On the south side of the Thames, from Deptford to Woolwich, are vast tracts of land under vegetable crops. From Battersea to Putney are many scattered patches, and from Putney through Barnes to Mortlake are also large areas of market garden ground. In short, nearly the whole of the Thames valley is occupied by fruit trees and vegetable crops.

So much, indeed, has the demand for fruit, and vegetables, and the love for flowers increased in London during the last few years, that market gardening has now become one of the most important of industries; but, whilst thousands are engaged in its pursuit, and fruit, vegetable, and plant growing gardens are being increased in great numbers, the London markets have still to depend in a great measure on foreign produce for a good supply of fruits, early culinary, and salad vegetables. Even plants and cut flowers—large as are the numbers grown within twenty miles of London—are imported in great quantities from France, Holland, Belgium, and other parts of the Continent. This happens especially in early spring when choice flowers are in the greatest demand, and

when such flowers as Lily of the Valley, Lilacs, and Roses can only be produced by English growers by the aid of rapid forcing, which is, on account of the high price of fuel, at all times near London an expensive operation. Foreign growers, on the other hand, can produce them early at little expense; and now that the means of transit are so great, cheap, and rapid, they have little difficulty in competing with English growers, both as regards price and quality of produce. That foreign produce of all kinds interferes seriously with the pecuniary interest of the English grower there can be little doubt, yet there are ample opportunities for men who are well acquainted with their business to start market gardening on a large scale and realise profitable returns. It is, however, a business which fluctuates greatly; and men who commence growing flowers, or fruits for market, and know little of the business at the commencement, unless possessed of a large capital, often fail before they get acquainted with the requirements of the market. The most successful men are generally those who, from long experience, know exactly at what time of the year the demand for each article grown will be the greatest, and when it is likely to yield the largest profits. Whenever a depression of trade occurs, and the demand for market garden produce of any kind is small, it is the beginners in the art who suffer as a rule, and not men who have become established in their business. This year (1878) hundreds of waggon-loads of excellent Cabbages have been sold for a sum little more than that which has to be paid for a load of manure, which market gardeners always contrive to take back with them from London. Broccoli also were so abundant as to be scarcely worth cartage, whilst other kinds of vegetables were only obtainable at high prices. This shows that a great point to be observed with all market gardeners is to avoid, as far as possible, a "glut" in the market. This is sometimes hardly possible, yet I think it might be prevented to some extent if cultivators were to grow such crops as have always paid them best, and which are known to succeed best in their locality, instead of growing on a large scale some kind of produce for which there happens to have been, for the moment, a large demand. Take the Tomato, for instance; when first it found favour with the English public there was a rage for it all at once. Large growers commenced its culture, and the consequence was that the price was so reduced by the quantity brought to market from English and foreign sources, as to make it a by no means profitable crop. Gardenia flowers and Tea Roses, again, were at one time a source of profit to the grower, and the demand being great a few growers produced them in such quantities, that the price obtained for them has become but little remunerative to any one, except those who happen to have a good many blooms just before the "glut" comes. One thing we may remark, that however plentiful any kind of produce may be in the market, the general public derive but comparatively little benefit therefrom, except in the case of common fruits, or vegetables, or flowers, for the retail prices are usually kept up by the middlemen, who require large profits on all their goods; and until there is more direct communication between the grower and consumer, none but those in the most affluent circumstances can hope to obtain an abundance of first-rate English-grown produce, such as Grapes, Peaches, early vegetables, &c. It is a strange fact that people who live near the market gardens where the produce is grown have to pay even higher prices for it than people near the market, which is of course caused by all goods having to be first sent to market.

The rent of garden ground round London varies very much; that nearest to town of course is the highest rented, but, as a rule, land containing no buildings or fruit trees is let at from £6 to £10 per acre; and where good established fruit trees exist, £15, £18, and as much as £20 per acre is often paid for it; and market gardeners inform me that such land is by far the most profitable, inasmuch as should a fair crop of fruit be obtained, it goes far not only to pay the rent, but also to defray labour and other expenses, and the vegetable or other under-crops yield, as a rule, good profits.

To give an estimate of the extent of florists' establishments near London would be almost impossible, so plentiful are they. Barnet, Potter's Bar, Finchley, Enfield, Tottenham, Acton, Ealing, Feltham, Isleworth, Richmond, and many other places abound with plant-producing gardens of every description and size. Although many of our largest fruit growers and florists send large quantities of their produce to Manchester, Liverpool, and other towns, yet the greater portion is grown expressly for Covent Garden market. The hours during which the flower market is open are from 4 to 9 in the morning during the summer, and from 5 to 9 in winter; few persons, therefore, who have not some special interest in flowers and plants are there so early; nevertheless a large amount of business is transacted. The building, which has been erected since 1870, is 200 ft. one way and 76 ft. the other; the central section is 70 ft. high to the ridge, and is efficiently lighted by clerestory windows and a lantern-light, with ample provision for ventilation. The total number of stalls, which consist of two iron shelves or benches one above the other, with a few square yards of frontage, number about 270, each one being capable of holding a large quantity of fair sized market plants in 6-in. pots; the rent of each of these stalls is about £7 10s. per annum. At the entrance to the market, and within the fenced yard, standings are let to people who sell wild Ferns and similar plants.

Everybody in London is, of course, acquainted with the numerous small florists' establishments, with their half-a-dozen or so small houses, in which are grown bedding plants wherewith to deck the gardens of suburban villas, or a few florists' flowers with which to supply a casual customer, as such places usually occupy prominent positions in important thoroughfares where they can be readily seen by passers-by; but comparatively few unconnected with the trade are acquainted with the large plant and indoor fruit depots in which goods are manufactured wholly for Covent Garden and other London markets. Many of these are situated in positions so secluded, that people might easily pass them without observing even their existence. There are no elaborately painted sign-boards, nor direction posts to make known the name of the proprietor, and the character of his stock, for as a rule visitors to such places are a hindrance rather than a help. A very interesting sight in connection with the flower markets in the spring is the thousands of baskets and boxes filled with flower roots of all description, arranged on a sloping bank at the west end of the market. The first kinds of roots to appear are the Christmas Roses and the Winter Aconites; then come Snowdrops and Crocuses, which are succeeded by Daffodils, Lily of the Valley, Squills, various Irises, Tulips, double-flowered Daisies, Primroses, Polyanthus, Sweet Williams, fine blood-red Wallflowers, double-flowered Scotch Daisies, sweet-scented Violets, fine Phloxes, Cloves, Hollyhocks, Rockets, Lavender, and hundreds of other plants. Virginian Creepers, Jessamines, Irish Ivies, Creeping Jenny, and Periwinkles

also find a ready sale for covering balconies, bare walls, and window-sills of London dwellings. Most of these flower roots are brought in small tufts with their roots rudely tied in Moss, Fern, or Grass, and it is astonishing the quantities that are weekly disposed of both by people who stand in the market and by hawkers who take them round on their barrows. They range in price from 1s. 6d. to 3s. 6d. per dozen clumps, according to the variety. Such plants as Ivies are brought in pots and sold at prices varying from 1s. to 3s. each. These kinds of plants are grown in small, out-of-the-way gardens, as well as in large fields; they are generally grown very roughly, the aim being simply to sell them, without any attention being paid to their good or bad qualities. But very often amongst these roots exposed for sale in this rough way we may find some good old English flowers, that it would be difficult to obtain from any other source, or at least under the name they formerly bore, or that given to them by the market dealers. Roots of the red and white Daisy always command a ready sale, and for excellence of strain those found in the market are unsurpassed, the flowers being large and of a fine colour; they are grown on well manured land, and in spring three times a week are sent to market hundreds of dozens packed in shallow boxes, which are readily bought by retail dealers, who display them on their stalls outside the market for sale. Early in spring is also, perhaps, the most interesting time to see the bouquets in Covent Garden, for they are certainly much more beautiful than at any other season of the year. They are then composed of Azaleas, Camellias, Roses, Gardenias, Violets, Spireas, Lily of the Valley, white Lilacs, blue Scillas, Stephanotis, Hyacinth pips, Orchids, and other choice and effective flowers. Sometimes we find them composed of four or five blood-red Roses (General Jacqueminot), each of which are backed up with a few sprays of blue Forget-me-not, several golden yellow Roses (Isabella Sprunt) surrounded with light sprays of Lily of the Valley, and four or five white Roses (Niphotos), backed with plenty of their own foliage. The whole of these, when tastefully combined into a large bouquet, are edged with Maiden-hair Ferns, white Lilacs, and Rose leaves, an arrangement the effect of which is excellent. Button-hole bouquets consist of Gardenias backed with their own foliage. Rosebuds, too, are used in the same way; and when surrounded by fresh and fragrant leaves few button-hole bouquets are equal to them. Some very effective ones, however, may be seen composed of white Hyacinth flowers backed up by a few flowers of the blue Scilla sibirica or the scarlet Euphorbia jacquiniiflora; some are also made of double white Primulas, Neapolitan Violets, Spireas, and Maiden-hair Ferns, with good effect. At whatever time, however, one may visit the Central Arcade of Covent Garden Market, we can always see something beautiful and learn something which we never knew before.

C. W. S.

Calanthes in Flower in Small Pans.—Some time ago we remarked in THE GARDEN that the plan of cultivating Calanthes in small pans, a system practised in Messrs. Veitch's nursery, Chelsea, was likely to prove an excellent one. The plants being now in flower, we can speak of their superiority over those which have been grown in pots or allowed more root room. The pseudo-bulbs are very large, and on account of their confined roots and their having been suspended close to the glass, they have become well matured, and a fine mass of bloom is the result. The pans in which the plants are grown are about 5 in. in diameter and not more than 1½ in. deep, and many of them are furnished with flower-spikes 3 ft. long and as thick as one's thumb at the base. The individual blossoms, too, appear to be larger and of a much better colour than those produced on plants which have had more root room allowed them.

NOTES OF THE WEEK.

The Violet-scented Crowfoot (*Ranunculus bullatus*).—This is one of the very few sweet-scented, winter-flowering plants which we possess. It is now beginning to flower with me, and will continue to produce a succession of blossoms all through the winter. Its flowers are not showy, being about the size and colour of those of the ordinary Buttercup, but they are much more double, and they possess a strong perfume like that of Violets, on account of which they are very desirable. They are borne on single stalks from 6 in. to 9 in. high, and about half-a-dozen rise from each tuft of broad hairy leaves which lie flat on the soil. It thrives vigorously and flowers profusely in a damp and partially-shaded situation. It is very useful for cutting for indoor decoration, as the flowers last long in good condition. It is a native of the Mediterranean region generally, and is the same kind as was imported from Algiers, and sold last year in large quantities at Stevens' Sale Rooms.—W.

Lasiandra macrantha floribunda.—Well-flowered plants of this *Melastomaceae* have a striking effect in a greenhouse in Messrs. Veitch's nursery, Chelsea. The plants of the variety alluded to are dwarf, and yield a large quantity of brilliant violet-purple blossoms, measuring 4 in. across, a result entirely different from that produced by the type, which grows lanky and flowers sparingly. The plants are associated with Begonias, Staticee, *Rhododendron Princess of Wales* (still one of the best and freest-flowering of greenhouse *Rhododendrons*), fine-foliaged plants, Heaths, &c., amongst which they form the most attractive objects.

Oncidium Forbesi.—Amongst *Oncidiums* there are, perhaps, none which surpass this in beauty and usefulness. It will grow and flower freely under cool treatment, and its blossoms furnish a colour which is not frequently found in flowers at this season. In Messrs. Veitch's nursery we noticed the other day plants of it bearing strong, gracefully-arched, branching spikes of rich drab or chocolate-coloured, gold-laced blossoms, which formed a striking contrast to the luxuriant masses of *O. varicosum* and *O. Rogersi*, which were in flower in the same house. Near these, in another house, were also a number of plants of *Odontoglossum Roezli* in bloom, likewise several beautiful hybrid *Cattleyas* and *Indian Crocuses*.

Caladium argyrites.—Few ornamental-leaved stove plants surpass in usefulness this pretty little *Caladium*. It can be grown on and be had in perfection even in the dullest months of winter, when its lively green and white leaves show themselves off conspicuously either on brackets or placed in small vases in the conservatory or dwelling house. Small pots or pans are best adapted for this *Caladium*, as under such conditions the plants may be used for a variety of purposes. We have often grown it in flat boxes and lifted them for placing in vases among cut flowers for decoration at Christmas. In this way the leaves keep fresh for a week or two, and the plants receive little or no injury by being thus transplanted. Quantities of plants of it are grown in small pots in Messrs. Hooper & Co.'s nursery, where they form an effective fringe to shelves and stages furnished with Palms and other green-leaved plants.

Anthurium Scherzerianum in Winter.—A specimen of this plant in Mr. Wills' nursery, Anerley, is at present furnished with a large number of brilliant flower spathes, which appear to be of a much darker and richer colour than any we have before seen. This may possibly be caused by their being produced at this unusual time of the year, a circumstance which greatly increases the value of the plant. The white-flowered form is also in bloom, but as yet it cannot be considered a counterpart of the red kind; by continually raising seedlings, however, and by good cultivation, it may yet be possible to obtain a white-flowered form equal in every way to the crimson kind.

Chrysanthemums in the Temple Gardens.—These are just now at their best. They are arranged in what may be termed a long temporary house, consisting of glass and canvas. The taller plants are grown in pots and arranged to form a bank of judiciously-mixed colours, the pots and bare stems being hidden by a close, low-hedge of *Pompones* planted in the front of the border. The Japanese varieties are this year exhibited here in considerable numbers, and add much to the attractiveness of the collection. Their flowers are much more graceful and less formal than globular or incurved flowers, and ought to be seen at exhibitions as well as elsewhere more frequently than at present. Among the most attractive Japanese kinds we may mention *Elaine*, snowy-white, very large and handsome; *Cry-Kang*, pink and white; *Gloire de Toulouse*, petals long and narrow, and rich magenta in colour splashed with white; *Fair Maid of Guernsey*, white; *Abd-el-Kader*, vivid blood-red and of medium size; *Red*

Dragon, flame coloured; *James Salter*, pink, with broad petals overlapping each other so as to form a ball. Among incurved kinds the most attractive are *Dr. Sharp*, magenta, sweet scented; *Peter the Great*, lemon coloured; *White Globe*; *Triomphe du Nord*, reddish-bronze; *Sparkler*, well named on account of its red flowers, the petals of which are edged with brilliant golden-bronze; *Vesta*, white; *Mrs. George Rundle*, white; and *Mrs. Dixon*, bright lemon. The flowers throughout are very large and fine, and forcibly show what grand displays *Chrysanthemums* may be induced to make during the dullest months of the year even in the centre of London.

— The *Chrysanthemums* at the Crystal Palace are also very fine this year, and very early. Some of the plants measure 7 ft. and 8 ft. in height, and, being arranged in a half circle near the Crystal Fountain, amongst Tree Ferns and statues, they make a grand display.

Two Rare Phalænopeids.—In Messrs. Veitch's nursery, Chelsea, there are now flowering *P. violacea* and *P. Esmeralda*, two rare kinds, which, though chiefly of botanical interest, are well worth adding for the sake of variety to any good collection of *Orchids*.

November Flowers Out of Doors.—Amongst these may be named the delicately-coloured *Iris alata*, blooms of which have been shown us by Mr. Barr. It is the first to flower in the open ground, and when potted early in the season it blooms under glass in October. It is a charming species of a soft purplish-blue colour, both standards and falls.

Dracænas and Crotons at Anerley.—Fine plants of these intermixed judiciously in a large house in the Anerley Nurseries have at this season a striking effect. They consist of well-developed plants remarkable for the rich and varied colours of their leaves, which are brought out in perfection in the light, airy structure in which they are grown. This collection serves to show that fine-foliaged, as well as flowering, plants are always seen to better advantage when arranged in groups and masses than in any other way.

White-flowered Rue (*Ruta albiflora*).—This graceful autumn-flowering plant may probably be known by some under its almost unpronounceable, yet correct, generic name of *Boeninghansenia*. It grows about 2 ft. high, and in foliage somewhat resembles the common Rue, but the leaves are more finely divided and more glaucous. The small, bell-shaped, and pure white blossoms are borne profusely in large, terminal, lax panicles, which droop very gracefully and last until sharp frosts curtail their beauty. In some localities it is quite hardy, but, generally speaking, it should have some slight protection in severe weather, if not planted against a wall. For conservatory decoration it forms a very attractive feature when arranged with bright flowering plants, and for that purpose it well deserves attention. It may be propagated freely by means of cuttings put in in spring, and when grown on with liberal treatment it makes fine flowering specimens for early winter decoration. It is a native of Nepal, and has been in cultivation for many years, but now it is not so frequently met with in gardens as it deserves to be.—W.

Talisia megaphylla.—The stove shrub, the approaching blooming of which, under the name of *Brownea erecta* var. *princeps*, in one of the houses at Lakelands, near Cork, was announced a few weeks ago in THE GARDEN, turns out, now that the blooms are fully expanded, not to be a *Brownea* at all, but *Talisia megaphylla*, a native of British Guiana, where its native name is *Touliohi*, under which, perchance, some readers of THE GARDEN who have seen it in its native country may be glad to recognise it and learn its true botanical name. It is a member of the family of *Sapindaceæ*, or *Soapworts*. The flower-scape is more interesting from its curiosity than from its intrinsic beauty, the centre spike being upwards of 2 ft. in height, and being clothed with branching, candelabra-shaped lateral flower-spikes for about half its height. The individual flower-pips are small and inconspicuous, of a dull woolly, whitish colour, and somewhat resembling in form and appearance those of the Portugal Laurel. The plant was identified and named after a careful comparison of the specimens sent by Mr. Crawford to the Herbarium at the Royal Gardens, Kew.—W. E. G.

Late-flowering Marechal Niel Rose.—Thinking it may interest some of your readers, I write to say that I have this morning (November 5) cut a magnificent bloom of *Marechal Niel* from a standard which has had no artificial protection. The size, colour, and form of the bloom were perfect. Such a Rose so late as November in East Yorkshire is, I think, a rarity.—J. HOLMES, *Beverley, East Yorks*.

MR. LINDEN has opened an establishment in the Rue de la Paix, Paris, for the sale of the horticultural products of his well-known G bent establishment.

NOTES FROM KEW.

Hardy Herbaceous Plants.—Nearly all the hardy herbaceous plants whose blossoms have so far withstood the damp and cold could easily be counted on the fingers. Even the Compositæ, naturally amongst the latest of autumn flowers, now furnish but a few solitary kinds. All the Astera, with the exception of *A. tenuifolia* and *A. miser* var. *pendulus*, noted in last week's GARDEN, are quite gone, and the only plants belonging to that natural order which enliven the (at present) dreary herbaceous ground at Kew are *Neja falcata* and *N. gracilis*, which have before been mentioned in "Notes from Kew," and *Chrysoopsis pilosa*, a North American perennial, growing about 2 ft. high and bearing golden-yellow flower heads. *Nerina flexuosa*, a pleasing Amaryllid of easy culture, from the Cape of Good Hope, has already been noted as a desirable autumn-flowering greenhouse plant. It is, however, doing well in an open border by the side of a wall, and its umbels of charming rose-tinted flowers look doubly pretty in their solitude. A few specimens of *Ipomopsis Beyrichii*, about 18 in. high, have their stems clothed with finely-divided leaves and crowned with pretty flowers which are tubular in shape, the flat, star-like limb being buff, splashed with red.

Greenhouse Plants.—*Viburnum odoratissimum*, a Japanese species, is now gay with its compound umbels of bright coral-red fruits; it is a shrub of neat habit, and is admirably adapted for the decoration of the cool conservatory during the late autumn and winter months; the pretty fruits look well by gaslight, and the plant would, no doubt, if specially grown for the purpose, make a handsome object for table decoration. *Gamolepis europoides*, a shrubby Composite from the Cape of Good Hope, is a neat growing plant, with bright golden-yellow flower heads and out foliage much resembling that of many *Grevilleas*, such as *G. Thelemonniana*. The delicious fragrance of the small, yellowish-white blossoms of the Chinese *Osmanthus fragrans* renders it worthy of cultivation in any collection of choice plants; the flowers are said to be used by the Chinese in scenting high-class Teas. Though known in English gardens for upwards of a century, it is not nearly so frequently seen as its merits deserve. *Acradenia Franklina*, a Tasmanian shrub named after Lady Franklin, belongs to the Rue family, and has opposite, stalked, rigid, fragrant leaves formed of three leaflets, and star-like, white flowers; it forms a dense bush when planted out, as in the Winter Garden at Kew. *Acacia platyptera* is one of the earliest-blooming and, at the same time, one of the most distinct of all the *Acacias*; it flowers most freely in a young state, and specimens in small pots are now gay with thousands of orange-yellow, globular flower heads.

Stove Plants.—*Dombeya Burgessiana*, a very free-flowering shrub or small tree from the Cape of Good Hope, has large, fragrant blossoms, white, veined with red. In general habit it much resembles its relation, *Sparmannia africana*, and is of equally easy cultivation. At present this is one of the principal ornaments in the great Palm stove, but it would probably do well as a greenhouse plant. *Bilbergia macrocalyx*, a beautiful and interesting Bromeliad, is more remarkable for the rich scarlet colouring of the large bracts than for that of the blossoms; the leaves are about 1½ ft. long, and are dark green, with pale spots scattered here and there. In a wild state it is found on the mossy branches of trees in Bahia. *Begonia falcifolia*, a fine sort introduced from Peru by Messrs. Veitch, through their collector, Mr. Pearce, is a distinct and desirable plant, not only on account of its beauty, but by reason of its prolonged flowering season; it grows about 2 ft. high and the stems are more or less branched. The somewhat sickle-shaped leaves are deep green, often bronzed above (spotted with white when young), and deep red-purple beneath; the blossoms are a pleasing rosy-pink colour.—J.

Saving Old Bedding Pelargoniums.—All flower gardens will soon be cleared of their summer occupants, but it is seldom that anyone saves the old Pelargoniums for another year; new sorts and variegated kinds are, however, often worth preserving. We have tried various ways of doing this, one of the best of which is lifting all the plants we are going to save first, cutting them close down to the bottom buds, and then packing them as closely as they will stand in cutting-boxes with a little light soil over the roots. They are then put in a cool glasshouse or room, and by spring every root will be in a growing state, throwing out numbers of shoots and making excellent dwarf plants for planting again the following season.—CAMBRIAN.

Umbilicus Sempervivum.—There is an immense quantity of this bright-flowered and most interesting Lebanon plant in the Belvedere Gardens at Vienna, some of them being in showy bloom recently in the open air. It seems quite hardy, and will prove a welcome addition to the rock garden. The flowers are bright red.—V.

THE FLOWER GARDEN.

PLANTING OUT BOUVARDIAS.

MANY kinds of half-hardy soft-wooded plants, the natural time of flowering of which is during the autumn or winter months, are found to succeed best when planted out in the open air in summer in suitable soil and carefully lifted and potted when about to commence flowering late in autumn. Such is the case with *Bouvardias*. Cuttings of them should be taken off plants growing in the open air about the middle of August, and inserted in well-drained pots filled with a compost formed of finely sifted leaf soil and silver sand in about equal parts. When inserted they should be placed upon cinder ashes in a close frame, where they will soon strike root without the aid of bottom heat. When fairly rooted they should be potted singly into pots some 3 in. in diameter, and placed upon a shelf near the glass in a warm greenhouse or similar structure. About the end of March or early in April they should be shifted into pots some 5 in. in diameter. The soil used may consist of about two parts turfy loam and one part leaf mould with possibly a portion of sand. Peat may be used in place of the leaf mould if desired, but it is not absolutely necessary, as the plants are found to do equally well without it. As the season advances the plants may be placed in cold pits or frames and gradually inured to the open air. They may be planted out about the first week in June.

It is essential that the pots should be well filled with roots when the planting out takes place, and the ball of soil should not be broken with the view of setting the roots at liberty. The roots will be found to strike into the fresh soil readily enough, and keeping the balls entire greatly facilitates the process of lifting and repotting, so as to cause as little check to the plants as possible. If the soil in which they are intended to be planted be of a heavy character, it should be prepared for the purpose by the introduction of a portion of light turfy soil and leaf mould; but in ordinary rich light garden mould they are found to succeed admirably.

When the plants have become fairly established in the soil and are growing freely the stronger shoots should be stopped, and a few stakes may be found necessary in order to induce them to form compact and symmetrical bushes. Towards the end of September most of them will be showing trusses of bloom buds, and before these become further developed the plants should be carefully taken up and potted, using pots of such a size as the plants may require, but avoiding at the same time anything like overpotting. Pots some 8 in. in diameter will generally be found to be the most suitable size, and the soil used may be the same as that which has been already recommended. The plants should now be neatly staked, and should be placed for a time on the north side of a wall, where they should be syringed frequently in order to prevent them from flagging, taking care at the same time to avoid making the soil in which they are potted too wet. In a few days they will generally be found to have recovered from the check caused by removal; and by the 1st of October, not later, they should be placed in the greenhouse, where they will continue to bloom throughout the greater part of the winter, especially if that structure, after the third week in October, be kept somewhat close and warm, and the plants allowed to occupy a position pretty close to the glass. As soon as they have fairly ceased flowering water should be to some extent withheld, and the plants when at rest may be placed in any situation where the temperature does not fall much under 40°. When they again begin to show signs of growing they should be cut well in, and placed in a favourable position as regards light and warmth; and when the young shoots have attained 1 in. or more in length, the old soil should be shaken from the plants, or the ball of earth should be very considerably reduced and the roots cut in, so that the plants may be accommodated in pots of a smaller size. In June they should be again planted out, when they will be found to make better specimens for potting in the autumn than younger plants.

There are now several fine species and varieties amongst *Bouvardias*. One of the very best is *B. Humboldtii* corymbiflora, which comes into flower earlier than the others; and the blooms, which are produced in bunches of twelve or more

together, are of larger size, rivalling in purity of colour, as well as in delicacy of perfume, those of the well-known *Stephanotis*. *B. alba odorata*, also white, has flowers of great substance and highly perfumed. They are shorter in the tube than those of *B. Humboldtii corymbiflora*, and last long in good condition. Among many other free-growing white-flowered kinds may be mentioned *Bridal Wreath*, *Davisoni*, *jasminoides*, *longiflora*, *umbellata alba*, and *Vreelandi*, the last named being a very fine free-flowering kind. The flower tubes of *Maiden's Blush* are of a delicate pink shade; and those of *multiflora*, violet tipped with white. *B. flava* is a very distinct variety with yellow flowers; and *Hogarth*, *leiantha*, *splendens*, and *Van Houttei* are all fine free-flowering scarlet sorts.

Culford, Bury St. Edmunds.

P. GRIEVE.

A PROLIFEROUS ROSE.

THE accompanying figure represents a very complete instance of what is termed median proliferation, a kind of malformation in which the centre of the flower is occupied by a branch bear-

ing normal leaves. Those parts of the flower present are more or less metamorphosed and scattered on the elongated floral axis, whilst stamens and pistils are wholly wanting. I have so recently written something respecting the significance of the singular reversions frequently met with in the organs of plants, that it seems superfluous to enlarge upon the theme again.

W. B. HEMSLEY.

AUTUMN PLANTING GLADIOLI.

SINCE the insertion of my remarks on these beautiful autumn flowers several notices have appeared on the subject of their culture, and more especially with reference to the question of leaving them in the ground during the winter, about which considerable difference of opinion exists. As I have been for perhaps as long a time growing the *Gladiolus* as any other amateur cultivator in a small way, some particulars on the subject of its cultivation may not be out of place; the opportunity of seeing *Gladioli* grown in other places, both in England and France, having been afforded me, my experience is somewhat wider than my own small culture might seem to warrant. That with them, as with many of the *Lily* tribe, a difficulty in their cultivation has been felt by all, except in a few favoured localities, ever since the great improvement of the varieties took place. There was no difficulty in growing *psittacinus*, *gandavensis*, *oppositifolius*, or even *brenchleyensis*, but as soon as the blood (so to speak) became intermixed and increase

in size, texture, and beauty of colouring took place, then delicacy of constitution set in, and nearly all *Gladiolus* growers have more or less complained of the difficulty of keeping new and valuable varieties. There have been two theories as to the loss of bulbs, one which attributes it to a disease analogous to the *Potato* disease and to that which affects sometimes the *Crocus*, and another which says it is owing to exhaustion. Now, although my own opinion as to which is the correct view of these two is very strong, I do not intend to enter upon it, but simply to note the fact, and to see how it has influenced their culture.

We are all aware that certain soils are congenial to some plants, and destructive to others; the whole family of *Rhododendrons* and their allies hate chalk, and only dwindle away and die on it, while the *Fig* and *Apricot* rejoice greatly on it; a heavy soil is death to all the *Lily* tribe, and therefore the *Gladiolus* will not thrive on it. He would be a wizard, indeed, who could get his *Lilies* to thrive on the *London clay*; and, therefore, where there is a heavy retentive soil, it cannot be expected that the *Gladiolus* can be grown with any degree of comfort. A fresh loam, that which is ordinarily called good market garden soil, suits them well; but even where the soil is suitable considerable care is required to obtain success. The plan adopted in France, and almost universally in England, is to plant in the spring (March or April), and to lift the bulbs in November, drying them carefully and keeping them so until planting time. The commoner and hardier sorts have been sometimes left in the ground, but growers have been chary in so treating the choicer varieties. During the last two or three years I have begun to question the wisdom of the plan, and for the following reason: I had about five years ago planted a considerable quantity of spawn in a portion of my garden, now occupied with *Roses*; in taking up the spawn in the autumn it would appear that some of the smaller ones had been overlooked and left in the ground, for each year bulbs have made their appearance; they have flowered well, and when lifted have been large and healthy; and, as since the time I alluded to, we have had winters of varying character—wet and severe—and the bulbs had evidently not suffered, I was led to ask myself whether it might not be, that, although in some cases apparently the bulbs were not injured by being lifted and kept dry, yet that the loss which I so often had to lament might, perhaps, be avoided if I left them in the ground. The result was, as I have already stated, that there were no losses amongst the bulbs, and that the blooms were some of the finest that I have ever had of the varieties so treated.

In adopting this plan somewhat more extensively this autumn I shall not be deterred by the fear of frost, for I do not think that the *Gladiolus*, when planted deep, is likely to be injured by it, except in very severe winters; and should such a winter be before us, it will be easy for those who cultivate on a small scale to put some covering on the beds, such as *Brake* or long litter, removing it when all fear of frost is gone. I did not find that the bulbs left in the ground were one bit earlier in coming up than those planted alongside of them, and they came into flower about the same time. The prevalence of wet is, I think, more to be feared than frost, while wireworm may also in some grounds be troublesome. The depth at which I usually plant is 6 in., but for autumn planting I should be inclined to go deeper still, so as to secure the corms from frost.

Another question connected with this is, Are not English-raised varieties more likely to have vigorous constitutions than those which are raised abroad under more favourable circumstances, but which when coming to our colder and wetter climate suffer? Everything would seem to justify such a conclusion. One great merit attributed, and with justice, to our English-raised *Roses* is, that we can secure that vigour of constitution without which a *Rose*, however beautiful, is comparatively worthless; and Mr. Kelway tells us that he knows little, if anything, of losses in his large experience of the *Gladiolus*, so that a good deal may be urged on behalf of this. The vigour of those exhibited by him cannot be questioned. Whichever plan may be adopted, that of planting them now or in spring, the beds should be prepared now. My own plan is to dig in a quantity of well-decomposed cow manure, and then to turn

it up roughly, to remain so during the winter. I prefer cow manure as being less hot than horse manure, and also less likely to generate fungi. When planting I generally put a little sharp sand round each bulb, and have sometimes used charcoal, although I think this is unnecessary. It was, many years ago, supposed that manure was injurious to them, but it is not, unless it be fresh, in which state no bulbs or corms seem to like it. When the plants have attained the height of 8 in. or 9 in., I generally top-dress with manure, so as to give greater vigour to the plants and keep the ground cool; the rains wash down the salts contained in the manure, while it keeps the surface from drying up by exposure either to sun or drying winds. Mr. Kelway uses a very large quantity of manure in his grounds, and with what success we all know. If the season be dry, the beds must be watered, a thorough good drenching being given to them, so as to wet the soil well.

I have been anxious to revert to this subject of culture because I should like some of those who grow the Gladiolus to give the autumn planting a fair trial and to report the result; it would be such an immense saving of trouble, that it would be hailed as a capital innovation. I shall give it a good trial myself this autumn, and hope to record the results in THE GARDEN. The season has been a favourable one for the ripening off and storing of the bulbs, so that we may hope to hear that they have been lifted well.

DELTA.

ARUM LILIES (CALLAS) IN TRENCHES.

THESE plants are grown largely for market, and they are also used in large quantities for decoration of all descriptions. They succeed well along with scarlet Pelargoniums, the bright glossy leaves and snow-white flowers of the Calla contrasting effectively with the scarlet blossoms of the Pelargoniums, or with any red Chrysanthemum, such as Mr. Gladstone or Julia Lagravère. Quantities of the Calla should be grown in large gardens, to be used for filling up vacancies between tall-growing Chrysanthemums or other plants, positions in which they impart a lively appearance to the whole surroundings. I grow a great many Callas for winter flowering. Before I adopted the plan of growing them in trenches our stock was but limited, but they are so readily increased on the planting-out system, that a small stock may soon be worked into a large one. The planting out in the north of England should be done not later than the end of May if very large plants are required. Trenches should be taken out in a moist situation about 1½ ft. wide and 1 ft. deep, and in the bottom of each should be put a thick layer of well rotted manure, to which should be added a second layer of leaf mould, the whole being pressed firmly down with a rake. The plants should then be turned out of their pots and the balls of soil thoroughly shaken from them, in order to disentangle their roots. We then arrange them according to their different sizes. Their roots are spread out on the bottom of the trench, after which a little leaf soil is scattered over them and worked in amongst the roots. The trenches are then filled in with the ordinary soil to within 2 in. or so of the surface; thus the roots can at all times be abundantly supplied with water. A distance of 1½ ft. asunder will be wide enough apart for large plants, and 1 ft. for smaller ones. It is a mistake to suppose that these plants continue to grow all the year round; their leaves, at least, die gradually down in summer, but the roots are doubtless growing all this time, providing themselves with new fibres, and forming and developing young offsets or bulbs, which swell with great rapidity when the season of growth begins.

If we take, for example, three different sizes of plants and plant them out under exactly the same conditions, it will be found that the strongest offshoots of this year's growth will produce the largest stems, and also the largest flowers, at the end of the second year, of course always assuming that no other growths are encouraged to form themselves round the principal stem during the growing season in the course of the second year, and that the plants are encouraged before and after being planted out. The vigour of old plants is not so easily concentrated in one stem on account of their fertility in forming offshoots, and for this reason they are better adapted

for show plants, or, as before suggested, they make excellent material for forming a groundwork, so to speak, for better plants in a show house or conservatory, to say nothing of their utility in cases of furnishing, a purpose for which they are not easily surpassed. After being planted out, little attention will be necessary beyond that of giving a watering in case the soil should become dry about the roots, which is seldom the case where the soil and trenches have been properly prepared. Our plants are now being lifted, and the opportunity is a favourable one for selecting a quantity of young plants for growing on as single-stemmed specimens next year. An opening is taken out in front and on either side of the plant with a fork, which is then inserted between the plant to be moved and the next plant, and the roots are lifted without the slightest injury. The young plants required for next year are then separated from the parent, and all are potted and taken to a cold frame, which is kept closed and moist for a few days till root action has again commenced. The circumscribed space allotted to the roots and the nature of the soil used induce them to make a thicket of roots, so that it is impossible for them to receive any check in lifting. I have measured four plants grown with single stems, and I found the circumference of each stem to be 9 in., a result which, when it is remembered is attained without much labour or inconvenience, cannot be considered otherwise than satisfactory.

W. HINDS.

Otterspool.

CARNATIONS AND PICOTEES.

PERSONS intending to purchase a selection of Carnations and Picotees or similar plants for which there is a large demand, should now do so without delay, as where there is convenience to keep them over the winter this is a good time to get them. If there be no cold frame or similar structure to keep the plants from wet and frost, it is, however, better not to purchase until the time for planting out in March has arrived. Growers are now removing the layers from the parent plants, and it is much better to send them out now for two reasons; first, they do not receive any check to their growth, even if sent long distances, and secondly, they may be packed in very much smaller compass; a hundred pairs can be packed in a very small box weighing a few pounds. In spring they must be sent long distances in pots, when a hundred pairs would weigh with the packing nearly a hundredweight. This being the time to pot the plants, a few remarks on their culture may be useful. 3-in. pots are the best adapted for them. I pot one large plant or two small ones in each; rich turfy loam with a fourth part of leaf mould and as much sand well mixed together is an excellent compost for them. The pots should be placed in frames, plunged in some light Cocoa-nut fibre refuse, and the lights should be kept rather close at first. During the winter the attention they require is to keep the surfaces of the pots free from green mould or Moss, and all decaying leaves must be picked from the plants; decayed portions of leaves can be cut off with a pair of scissors. The frames must also be carefully attended to during winter, and abundant supplies of fresh air must be admitted; indeed, a constant circulation may be kept up at all times except when the air is heavily charged with moisture. During winter, damp must be carefully excluded from the frames if possible; it is the worst enemy of the Carnation. Clear, frosty weather suits the plants best; the mould in the pots may be frozen and the effect of it not be felt by the plants. It is rather singular that the southern growers are afraid to plant out in the autumn, in case they should lose their valuable plants, and yet as far north as Newcastle-upon-Tyne they plant out in November or early in December, and from these plants produce very large flowers, the plants making most vigorous growth. They trench the ground well, working some rotten stable manure into the soil. Pig manure must not be used, as it produces canker; the sweepings from a cattle market, laid up for a year before using it, is an excellent manure. The plants may be put out 18 in. apart, and it is very desirable to place a few handfuls of rotten, turfy maiden loam round the roots of each plant, but, as turfy loam is seldom free from wire-worm, it must be carefully looked over for that pest. It is a good plan to surface-dress the ground between the plants with rotten manure from an old Mushroom-bed or a spent hotbed. This is excellent to steady the plants, although, as a further precaution, especially in exposed positions, a neat stick should be placed to each plant. The plants are also liable to be thrown out of the ground during alternate frosts and thaws in winter, but, to a large extent, the mulching prevents this. No other attention will be necessary until the plants begin to "spindle," that is, to run up to flower, when a neat stick about 2 ft. out of the ground should be placed to each plant. During

the season of growth the plants must be watered whenever it is necessary, and a good soaking must be given, not watering again until it is actually necessary. If we would take as much pains with these fine hardy flowers when they are planted out in beds as our Newcastle and other northern growers do, perhaps we would also manage them well. Certain it is that they are well worth a little extra trouble, and would form a delightful feature in any garden. When I was an under gardener in Sootland I had to attend to two beds of Carnations in a geometrically laid-out flower garden; each bed would be about 20 ft. long, and as far as I can recollect we scarcely lost a plant during winter. It was necessary to stir the surface of the beds occasionally. The following is a selection of the best florist Carnations for culture in beds in the north; the Picotees are more hardy, and nearly all the varieties may be planted out: Scarlet Bizarres—Admiral Curzon, Lord Napier, Lord Rancliffe, John Barnet, Mercury; Crimson Bizarres—Black Diamond, Rifleman, Isaac Wilkinson, William Murray, John Harland, Albion's Pride; Pink and Purple Bizarres—Sarah Payne, Satisfaction; Purple Flakes—Dr. Foster, Lord Derby, Earl of Stamford, James Douglas; Scarlet Flakes—Mr. Battersby, Sportsman, James Cheetham, Superb, William Harland, and all the Rose Flakes. Those who intend to cultivate their plants in pots must get all preparations completed in good time. It is a good plan to have the manure ready at least six months previously. I use manure from the stables from which most of the litter has been shaken out. It must be laid up in a heap to ferment, and should be turned over frequently to prevent over-heating. Manure prepared in this way is most useful in the potting shed. One barrow-load of it to one of leaf mould and four of turfy loam is the compost I use for Carnations in pots, and it is as well to mix it up at least two months or more before using it. The turfy loam should be pulled to pieces by the hands, a plan preferable to chopping it up, and carefully examine every particle of it for wireworms. Potting is performed about the end of February or early in March, and if the plants can be placed in cold frames for a month before turning them out in the open ground so much the better. Many growers place the plants out-of-doors as they are potted, but if a downpour of cold rain takes place immediately, the plants are very likely to be much injured by it. The plants ought also to be free from green fly before they are placed out-of-doors; this is a very troublesome pest, indeed, to Carnation growers, but I find if the plants are occasionally fumigated with Tobacco smoke during the winter that it can be destroyed. Fumigation is more cleanly and, perhaps, more effectual than dipping the plants in any mixture strong enough to kill them. It is very pleasant work for the ardent cultivator to attend to the plants when they are spindling for bloom, tying the stems to the sticks, and watching the expanding buds. Nearly all the large full flowers have a tendency to split their pods, and the splitting begins sometimes as soon as the colour of the flowers can be discerned. This must be watched for, and the segments on the opposite side must be slit down a little, and the calyx should be tied round with a strip of matting. When the plants come into flower they should be removed to the greenhouse. A few dozen have quite a unique effect amongst other plants. The exhibitor will also place his plants under glass, but he will not arrange them amongst a miscellaneous collection of plants; they must all be placed together, the open flowers in a cool part of the house, and those that are not so far advanced in a part of it where they can get more sun. Many persons have not the convenience of a greenhouse wherein they can place their plants at blooming time. An excellent substitute may be found by utilising any spare lights that are not in use for other purposes; the lights may be fixed high enough to be 1 ft. high above the highest flowers by any plan that may be available at the time. I simply drive two rows of posts into the ground; one row is 6 in. higher than the other, and on the top of each row of posts I nail a slight rail. The rails serve to support the lights and to steady the posts, as they also are of light material. Some light shading nailed on the posts will protect the bloom from high winds. It will also be necessary to shade the glass lights, as Carnation and Picotee blooms speedily shrivel up if exposed to the sun.

J. DOUGLAS.

AMPELOPSIS VEITCHI & OTHER WALL PLANTS.

Nothing is more objectionable than buildings defaced by nail-holes, the result of tacking up climbing plants, unless it be their sprawling about in the wild, uncared-for condition which they too often assume. No wall that has any pretention to neatness and finish should have a plant trained to it without either a trellis or strained wires, unless it be such plants as *Ampelopsis Veitchi* and the different varieties of Ivy, that cling with such tenacity, as not to require any other means of support than that which Nature has given them. A very fine and pleasing effect may be made by using these two kinds of plants alone in alternate divisions of 5 ft. or so wide, accord-

ing to the space to be covered; but when this is done, it should be with the Ivies of neat, close growth, such as *Hedera elegantissima* and *H. aurea*, which, if clipped every spring, make fresh, bright foliage that commands admiration. The contrast between these and the *Ampelopsis* is most striking, and particularly so during the autumn, after the latter becomes a rich claret colour, as it always does in a light, exposed situation. The only drawback which it has is its being deciduous, but by planting it, as above indicated, between ornamental Ivies, its foliage is not so much missed for the short time it is off as it otherwise would be. Those, therefore, who have walls they wish to cover with something really cheerful-looking, that will give them little, if any, further trouble, cannot do better than use these plants for the purpose; and, if the soil before putting them in is well broken up, and a little rotten manure added, they will not be long in running to the top, especially if assisted occasionally during the summer with soap-suds or other similar sewage, as their roots, being so close to the building, are not in a position to be benefited by any rain that may fall. On dwellings, most people have a desire for Roses, and charming wall plants they are, besides which it is the only situation in which some of the best of them can be grown successfully, owing to the shelter and protection they require. Take the *Maréchal Niel*, for instance, the young foliage of which gets pinched and cut about when grown exposed as standards or on trellises, but on walls facing south or south-west they escape and flower profusely. The grandest display of this fine Rose I ever saw was in a position of this kind; but, wherever planted, the thing is to encourage as much young wood of medium size as there is room to lay in, as it is from this that the whole of the flowers are produced. To spur this in or to prune as most other Roses are pruned, is to cut these away, as almost every bud, except those at the base, contains a bloom in embryo, and it is the same with most other climbing Roses, all of which flower with much greater freedom when treated in the above-named way. The best plan for training these is to drive in some studs with holes in the end, through which to run the wires for support, and then get a strain from one end that each may be made tight and fast. If these wires run along every second or third course they will be quite near enough together, and save the introduction of nails and shreds, besides giving greater security. For training Clematises, Honeysuckle, and other similar twining plants, wires strained vertically are best, as then they are in the right direction for the young shoots, which wend their way up them without any assistance. The great improvement that has been made in the first-named of late renders them very desirable as wall plants, a position in which they succeed admirably, and show off their magnificent flowers to great advantage. Jackmanni, and others of similar depth of colour, are most striking on pale walls, the light backing showing up in capital contrast with the blue flowers, and red brick does the same for such delicate shades as *lauginosa* and others of that class. To grow these really well they require great depth of soil, and not only this, but plenty of rotten manure as well, and to be liberally assisted when growing and blooming with water or sewage, which greatly prolongs their beauty. The flowers of these being made on the young growth, the way to treat them is to cut off most of that made the previous year, leaving only a bud or two at the base, each of which will start, and again fill up the space made vacant. Some growers cut them entirely down, but that only answers for certain kinds, and for such as are grown in beds, but even with these it has a weakening effect, as they are so long denuded of foliage. Another strikingly ornamental plant for walls is the old *Bignonia radicans*, a plant that is not nearly so well known as its merits deserve. I well remember how much I was struck with it the first time I saw it in bloom, rivaling, as it did, many of the tender exotics grown with so much care under glass. The flowers of this fine old creeper are about 6 in. long, trumpet-shaped, and are borne in clusters at the ends of the young shoots, and as these are somewhat stiff and stand out from the wall 2 ft. or so, the whole are seen to great advantage. *Bignonia radicans* is a plant that requires a warm aspect and a light, dry soil to grow in, and if these conditions can be secured, it soon covers a large space. Before planting the best way is to drain the border at a good depth by putting in a layer of brickbats, which will quickly carry off surplus water during the winter, and raise the temperature several degrees; and if in addition to this the roots be kept mulched over in frosty weather the plant will be rendered tolerably safe. Many of the supposed tender plants would stand a great degree of cold if protected in the above-named manner, as the collar and the main feeders are the parts first affected, they being very susceptible of injury from rupture of the bark and sap vessels after being frozen through when gorged, as they are then, with moisture. One of the grandest plants for a south wall is the Exmouth variety of *Magnolia grandiflora*, a truly regal plant, having leaves nearly 1 ft. long of a very bright pleasing green colour, and Tulip-shaped flowers as large as a basin, that exhale a strong perfume resembling that of a sweet Lemon. Near the west coast and in

favoured localities this *Magnolia* is sufficiently hardy to stand away from the protection of a building; it then forms large, handsome shrubs on lawns, but inland, and in colder districts, it is needless attempting its culture in this way, as, although it may escape for a time, it is sure to get destroyed in the end. A deep, light, sandy soil suits it best, and in this it ripens its wood and flowers with more freedom than when it grows rampant, with large, pithy shoots. *Lardizabala bitercata*, *Ceanothus azureus*, *Escallonia macrantha*, and *Passiflora corallæa* will succeed in favoured situations, but are not to be depended on as permanent plants, one of the best of which for villa residences is *Crataegus Pyracantha*; that does well on almost any aspect, and is highly ornamental when laden with its coral-red berries. The habit and growth, too, are all that can be desired for a wall, and the branches admit of training horizontally along on wires with the greatest regularity. For the sides of porches, or other low, exposed positions of that kind, *Barberis Darwini* and *stenophylla* come in admirably, as they are very hardy, and have foliage of a bright, shining green; in addition to which, they flower in the most profuse manner possible during the early spring months. The way to treat them is to spar them in immediately their beauty is over, so as to afford time for fresh young growths to form, on which they bloom the following year. S. D.

NOTES AND QUESTIONS ON THE FLOWER GARDEN.

How to make *Tropæolum speciosum* Bloom.—I have had a hint given to me about *Tropæolum speciosum* which I do not remember to have met with in any cultural directions for that most capricious of plants. Mr. Liddell, who resides in St. John's Park, has succeeded in blooming it to his heart's content, and he says that the secret of success with the Scotch weed, as he calls it, consists in gathering up the roots into a small compass every autumn, and in not allowing them to wander over the border just as they like, to the right hand or to the left. This, in fact, appears to be the method usually taken with it in some places in the north, and its efficacy has been proved here in a most conspicuous manner. Three or four plants of it in my garden have done nothing except ramble all over the place, while Mr. Liddell has had a blaze of beauty which has been the admiration of everybody. He attributes the difference to the precaution referred to, though it may be added that he thinks it important that the plant should be grown in the shade.—HY. EW BANK, *St. John's, Ryde.*

Variegated Rock Alyssum.—I find this to be most useful for edging beds, baskets, or vases for winter and spring effect, the variegation being constant. It is a plant of very easy culture; the smallest cuttings inserted under hand-glasses in May make beautiful tufts for autumn planting, and, in addition to the beauty of its foliage, it flowers as freely as the green-leaved variety.—J. GROOM, *Linton Park.*

Dwarf Fuchsias.—It may interest Mr. Cornhill (p. 372) and others to know that there is at least one lovely *Fuchsia* quite suitable for fitting into geometrical designs, namely, *F. pumila*. Its maximum growth here during the season is from 6 in. to 9 in. high, and from 6 in. to 12 in. through, and it has been covered during the summer, and is so still, with pretty crimson flowers. It is used here for lines, and also for what are called dot plants on carpets of various kinds, and, to my mind, it is one of the very best plants which we possess for standing just above the ordinary carpet plants.—T. SMITH, *Newry.*

Fuchsias amongst Ivy.—It is quite true that in many places *Fuchsias* grow into trees and do not get killed down in the winter, but, as a rule, that generally happens in seaside localities. In such cases they commence to flower as soon as they begin to grow, from the fact of all the wood of the previous year being thoroughly ripened; and, as a matter of course, in such situations there can be little need of the Ivy carpet; this would only be required where *Fuchsias* are annually killed to the ground, and where, of course, from having to make new growth quite from the bottom, they come into flower about August; and frequently this only lasts for about a month or six weeks, an early frost in September often spoiling the whole. No doubt those who prefer little trouble to long displays will adopt "A. D.'s" plan (p. 372), but others more industrious, who lift and protect their plants, will reap their reward in the shape of a longer season of bloom. If it were a fact that Ivy roots always travel in a perpendicular direction, there would be some force in "A. D.'s" suggestion to cut away the Ivy round the *Fuchsia* stems in the spring, add manure, and fork up, &c.; but the roots of the Ivy round the sides would run through the new dressing at once, and it is just possible that round the collars, where the coat of leaves

should be thickest, the reverse would be the case. I would recommend "A. D." to try both plans next season, mine and his own, a bed on each side of his door, and give us the benefit of the experience thus gained next autumn.—T. SMITH, *Newry.*

An Alpine Rue (*Ruta patavina*).—This is a most curious little species 4 in. to 6 in. high with gold-yellow flowers, and with the same odour as the common Rue. It is now in the Belvedere Garden at Vienna.—V.

The Rose-tinted Pampas Grass.—Owing to the favourable weather which we have had this autumn this variety of Pampas Grass has developed itself well here, and when associated with the ordinary type has a very pleasing effect, but to those having but limited space I would say do not plant it; coming into flower, as it does, so late in the season, the chances are that four out of five seasons one would be disappointed. Some forty or fifty spikes of bloom might show themselves, but never develop properly.—A. HOSSACK, *Ragley, Alcester.*

Plumbago capensis Out-of-doors at Vienna.—Referring to this subject, allow me to say that this plant is very much used out-of-doors here. We generally have plants of it from 4 ft. to 8 ft. in height, pyramidal in shape, and well furnished with side branches, so that during the flowering season good specimens look not unlike so many blue columns. They are planted out about the end of May or beginning of June, when all danger from frost is over, as the young growths are apt to be injured by late frosts. They begin to flower early in July, and continue in that condition until taken up, which is generally done about the middle of September, as sometimes sharp frosts occur in that month. After shortening in their side branches they are potted and placed in a temperature of 45°, in which they remain till the beginning of March; then they receive a somewhat close pruning in order to induce strong shoots to start for summer flowering, and they are kept rather cool and airy, so as to harden off previously to their being planted out. Groups of them consisting of about ten plants produce a fine mass of flowers, but they have also a fine appearance in the form of good single specimens on the Grass in warm sheltered positions. When in masses we sometimes place common *Heliotropes* amongst them, but one of the best is *H. Anna Farell*; it produces dark blue flowers in abundance, and has a most agreeable perfume. Besides single specimens small groups on the Grass have a fine appearance, flowering profusely, as they do, during the whole summer until they are lifted in autumn. *Lantanas* also do very well with us, and often throw out side shoots that reach a length of more than 2 ft., and that produce flowers in great abundance. These are plants which always produce a striking effect in the gardens at this place and elsewhere about Vienna.—LOUIS KROBATSCH, *Laxenburg.*

Late Pansies.—No doubt this season the frequent and heavy rains that have characterised this autumn have had something—much—to do with the general abundance and excellence of Pansies this autumn and winter, now the last day of October. But late sowing is also a capital receipt for a late harvest of Pansies. April or May are good months for sowing the seed if flowers are wanted right up to Christmas. Sow thinly either out-of-doors or in pans or pots in a cold pit or frame. In either position it is needful to keep a sharp outlook for alga and snails, both of which are particularly fond of Pansies, young or old, root or branch, or flower. A single snail will clear off a pan or plot of seedlings in a single night. Clean light soil should be chosen, a sandy loam with a dash of leaf-mould being the best. It is a good plan to bake or semi-roast all soils for the sowing of these and other small plants at that season. This can generally be managed on the tops of furnaces, but where Cannell's, Wright's, or other boilers of that kind are used, the means of roasting soils, so as to destroy all alga or other insect pests and their larvae, will not be available. A hot plate in such cases would be as useful in the garden as in the kitchen. The seeds are small, and should be sown thinly and covered lightly. As soon as large enough to handle, the Pansies should be pricked out at distances of from 2 in. to 3 in. square. When established and almost meeting in their temporary quarters, plant them out with balls where they are to remain permanently. They should never be allowed to flag for lack of water or to bear seed. The one enfeebles their vigour and shortens their life; the other limits the duration of the flowering period. For every pod of seed ripened there is probably the sacrifice of a score of flowers. The flowers are also smaller and in every way inferior when seed-bearing is allowed. Even the gathering of the flowers assists the plants to produce more and better. Should the plants show any signs of diacrea, a surface-dressing 1 in. or 2 in. thick with spent cow manure or a good soaking of manure water will generally revive and half carry them through the season in full flower. As regards kinds, little need be said, as all are more or less beautiful.—D. T. FISH.

THE FRUIT GARDEN.

NOTES ON PEARS.

ILLUSTRATIONS, like actions, often speak louder than words, and it is certain that, so far as appearance goes, the accompanying representations of Pears verify that proverb, for they are so true to Nature that descriptive notes as to their appearance are unnecessary. I shall therefore only say a word or two as to their quality and season of

green and yellowish-green lines, and sometimes, though seldom, both wood and leaves are similarly marked. The flesh is quite white, buttery, and melting. It ripens about the end of October, and is soon over. *Deux Sœurs* (fig. 3) is one of the best eating and also one of the finest looking Pears in cultivation; in flavour it nearly equals *Doyenné du Comice*, and it is as productive as *Winter Nellis*. Grown on a west wall, the fruit ripens by the end of October, and on standards early in November. The tree is of good, sturdy habit, and makes handsome pyramids. *Vauquelin* (fig. 4), unlike the preceding,

Fig. 1.—Léon Grégoire.

Fig. 2.—Verte Longue Panachée.

Fig. 3.—Deux Sœurs.

Fig. 4.—Vauquelin.

Fig. 8.—Madame Elisa.

Fig. 9.—Glon Morcean.

ripening. *Léon Grégoire* (fig. 1) is usually a moderate-sized Pear, but under good culture it will attain the first rank in this respect. When fully ripe, as it generally is at the end of October and beginning of November, it has the same coloured skin as *Chaumontel*, viz., a deep russety red, and, like that variety, it is also rough to the touch. Its flesh is sweet and juicy, but nearly always gritty at the core. It is a very profuse bearer when grafted on the Quince. *Verte Longue Panachée* (fig. 2) is a novel-looking as well as a very good dessert Pear, but it is a shy bearer, hence its rarity. The skin is distinctly marked, as shown in the annexed illustration, with dark

has size only to recommend it. It is always of large size, but as to quality it should only be used for stewing, a purpose for which it is well suited. It ripens in November, and will keep good for a considerable time. *De la Motte* (fig. 5) is a very fine dessert Pear and a near relative to *Gansel's Bergamot*. It has a rich, buttery, aromatic flesh. Its skin is almost entirely russeted with patches of red on the side next the sun. It is a good grower under all circumstances, and seldom fails to fruit abundantly. *Grand Soleil* (fig. 6) is a medium-sized Pear of but second-rate quality. Its skin is rough and very brown, with a tinge of yellow

When fully ripe the flesh is very white and sweet, but gritty at the core. On the Pear stook it is a shy fruiter, but on the Quince it would doubtless do better. Virgouleuse (fig. 7) is a Pear that is very little grown, though it is one of the best. The fruit is of medium size, and fine in appearance. Its skin is greenish-yellow with dots of russet, changing to a rich yellow when fully ripe. Flesh white and melting, with a delicious aroma. The tree is a good grower and bears moderately well; it deserves a wall and to be included in the most select collections. Madame Elisa (fig. 8) is a very handsome, large Pear, the skin of which is a bright russet with greenish-russet on the shaded side. Its flesh is yellow, moderately rich, and slightly perfumed. It is ripe early in December, and is soon over. Glon Moresau (fig. 9) is one of our standard varieties, and one which is found in almost every garden; it is, therefore, too well known to need description, not the least of its many good qualities being that it will keep for a long period in good condition after it is fully ripe. It ripens in December and will sometimes keep till February.

W. W. H.

PREPARATION FOR THE FORCING SEASON.

VINES which have to be started in November will now be pruned, or should have been a month ago—at least, if they are to escape bleeding after being started—and no time should be lost in pruning such as have to be started between now and Christmas. On the subject of pot Vines I may state that I have this season received from a London firm some of the finest pot Vines I have ever seen, only that they were not quite so ripe as they might have been, but still well finished. My opinion is that many Vine growers in the trade turn their Vines out-of-doors too soon, in the belief that being put out in the cold ripens the wood, which is a great mistake. The wood can only be ripened perfectly in a suitable temperature; in other words, the heat should not be withdrawn till the wood is quite brown and hard, and the laterals also up to the first pinching or joint at least. This ensures well-ripened buds, and is a good guide to go by. While the laterals are green or only half ripened down to the junction with the main rod, the scales of the buds will be green and soft also, and no Vine is fit for forcing in that condition. As to washing and dressing Vines previous to forcing, many cultivators have now given up the practice, without experiencing any extra annoyance from such pests as thrips and red spider, and much labour is saved. Where bug exists upon the Vines it is different, and one cannot be too particular in scouring the Vines and the Vinery, in painting and whitewashing, and cleaning the border. The glass should always be kept clean, so as to let as much light in upon the leaves as possible. I do not think a Vine border should at any time be allowed to get dry, but before the Vines are started it should get a thorough soaking, if with manure water all the better. My plan is to stir the surface of the border slightly, and top-dress liberally with Standen's manure; then mulch 3 in. or 4 in. deep with some rotten manure, and water well with water at a little higher temperature than that of the border, pouring it on till the drains begin to run copiously, which is a guarantee that enough has been supplied. In the case of borders that have become hard and impervious, and do not take the water in readily at first, as is nearly always the case in old borders, the advantage of mulching before watering will soon be made manifest. When the border is forked only, the water is apt to run away through holes and fissures without touching the soil; but the mulching holds it like a sponge until it soaks away gradually. There is little danger of old Vines not breaking away freely at every bud; but young Vines, on which a considerable length of young wood is left, are apt to miss at the lower buds if trained straight up the rafters, but if the rods be temporarily unslung and laid horizontally along above the front pipes, they will break satisfactorily.

PEACHES.—Early houses of these will need to be pruned immediately, though in their case bleeding is not to be apprehended. In pruning the Peach the object should be principally to remove old and bare branches or shoots, and retain those which are young and fruitful, and unless the shoots are imperfectly ripened or weak and spindly towards their extremities, with no fruit buds, they may be left entire. Should it be necessary to cut any back the cut must be made at a leaf bud,

else the shoot will die back to one during the season. I do not think it is an advisable plan to tie the shoots in permanently till the fruit has set, for the reason that the fruit sets better when the branches are free, and when it comes time to look over the trees in spring to see what more shoots may have to be removed, as is often necessary when trees have not been sufficiently thinned out previously, the work can be done more conveniently. It is not necessary to dress Peach trees as a preventive against insects, except scale, and when that is found upon the trees the only plan is to clear them off with a stiff dry brush, taking care always to brush up so as not to rub off the buds, and afterwards the trees should be painted with some insecticide to suffocate those which are left or seal them up; brushing alone does not clear the trees effectually. Far more mishaps occur in the forcing of the Peach than the Vine, and principally because the trees are subjected to a too high or too low a temperature, or an atmosphere that is too dry or too wet. In my own case I may state that I am very particular about my Peach houses during the setting and stoning periods, much more so than with Vines and other plants, neglecting nothing that is likely to contribute to success, and perhaps this may partly account for the fact that during the last twelve years I have never lost a crop of fruit in my early house. The crop has varied once or twice, has been light, but the trees have never failed to produce a crop. My practice from the time the house is started is to run the temperature up in the daytime considerably higher than is usually recommended, perhaps 10° or more, and to drop proportionately at night, never feeling uneasy if the glass does not drop to within a degree or two of the freezing point up to the time the fruit is fairly set. No damping or syriaging is allowed, except once in the afternoons of fine days when, with the aid of hot pipes and sun-heat together, the temperature has been pretty high and dry, and no difference is made when the trees are in flower, except that no favourable opportunity is lost of giving the blossoms a good dewing at shutting-up time. The winter's sun has not power to raise the temperature of a Peach house high enough, and for that reason I fire more on sunny days than on dull ones in order to make the most of these, realising that more progress is made when the trees are in flower, particularly during one good sunny day with a high temperature and ventilation, than during a week of dull weather. Hence, when the flower buds are just on the point of expanding and the weather is dull or wet, keep the trees still, or barely moving, and when the sun shines get up heat with the light and make the most of the opportunity.

STRAWBERRIES.—I like these to stand out-of-doors till they have had a touch of frost, which gives growth a decided check, when they are afterwards stored in cool pits or houses and kept rather drier. After the beginning of December forcing should begin, and the plants may be pushed on under the influence of a day temperature of from 60° to 70°, according to the weather, and a temperature of from 40° to 45° at night, figures which should not be exceeded; in fact, the directions given for the Peach in the matter of forcing apply also to the Strawberry.

J. S.

RIPENING YOUNG WOOD BY ROOT PRUNING.

It has, on the whole, been a rather dripping autumn, more favourable to continuous growth than perfect maturity. Such seasons are rather unfavourable for our fruit prospects next year, for it is generally acknowledged by cultivators that more fruit crops are wrecked through immature wood than by severity of weather. Green wood either flowers imperfectly or not at all, or is injured or killed after or before it flowers; either way there is but small chance of a crop of fruit. Hence the importance of adopting every possible means of completing the ripening of the wood. These means consist mainly of top and root pruning, and the shielding of the late autumnal or winter rains off the roots. In the case of Vines and other fruit trees under glass this is comparatively easy. All laterals and superfluous wood should be removed, so as to admit as much light as possible to the base buds that are to be reserved for fruit bearing. Meanwhile, the borders may also be covered with iron or wooden shutters, or thatched with litter, so as to shed off the rain. An artificial climate of any desired degree of heat and of aridity may also be maintained, so as to force, heighten, or hasten the maturity of the wood. But

out-of-doors the cultivator is more at the mercy of the elements. But, though he may be unable to shed off or check the downfall of the rain he may prevent the roots from absorbing water in excess by the simple expedient of pruning them. Cut off thus from an excess of watery food, the plants, instead of continuing to grow till growth is checked by the frosts, will cease extending themselves at once, and complete the ripening of the wood and buds already formed.

In root-pruning for the special purpose of ripening the wood, it is not needful to carry it to the same extent as when it is done to check growth and force fertility. If only a few of the gourmands or grosser-feeding roots are severed, that will be sufficient. At the same time, all superfluous leaves and shoots should be removed from the tops, so that the light and air may have free access to every bud and branch. By such means the wood will become hard and brown, the buds be filled up into plumpness, and the whole tree the better prepared to withstand the severities of winter and the almost greater rigours of our trying springs.

The plan of laying fruit tree borders on a slope from the wall to the walk, so that the major part of the rain should run off, is also a good one for assisting the maturity of the wood. The super-cropping of fruit tree borders in the autumn should also be avoided. The practice keeps the soil colder and damper than it otherwise would be, and exactly as it does this, in the same ratio does it hinder the maturity of the wood. D. T. FISH.

COE'S GOLDEN DROP & ITALIAN PRUNE PLUMS.

The best autumn Plum in cultivation is Coe's Golden Drop, which will keep good for weeks if gathered before it is over-ripe. We have had good fruit of it for dessert in December by keeping it in a dry room. It grows and fruits freely

Coe's Golden Drop.

Quetsche d'Italie.

on both east and north walls. We have had no experience of it as a standard, but the tree has a good constitution, and would, no doubt, do well in that form. The Italian Prune or Quetsche d'Italie is also another very excellent dessert Plum, having somewhat the same characteristics as the preceding, with the exception of colour, which is a deep purple. The flesh is yellow and very rich and full flavoured, rendering it a most desirable variety to cultivate. W. W. H.

POT VINES FOR TABLE DECORATION.

THOUGH I have objected to table decoration with plants, at least to the extent to which it is carried at present, my objections do not extend to fruiting plants in pots, like the pot Vines grown by Mr. Sage, and figured in THE GARDEN of last week (see p. 405). I have long ago seen Mr. Sage's plan carried out successfully and on an extensive scale, and it answers well enough under some circumstances, as, for example, when the Vines are well grown and the fruit well finished (by no means a common thing with pot Vines), and when the plants could be had ready at the proper season. I am by no means sure, however, that the fruit keeps plump a long time after the cane is severed below the small pot, as "A. M." states. In summer time the plants droop rather badly after a while, and the fruit shrivels. What else could be expected? The plan of placing the plants upon the table in a growing state, or even in an apparently growing state, is a good one, and worth carrying out; and perhaps some of your readers who have not the means of growing the Vines specially for the purpose will find the following plan worth trying, and just about as good as any, and quite practicable with any one who has a Vinery: Get an iron stand, or one consisting of other material, made and coloured in imitation of a Vine stem, hollow inside, in order to hold water, and with half-a-dozen branch-looking projections, 2 in. or 3 in. long, the top of it also being hollow. Set this stand upon the table, fill the hollow tube up with water to the top, and then

out off a few Vine shoots with handsome bunches on them and well furnished with leaves, stick them into the holes and secure them, and you have at once a table pot Vine made to order without the trouble of growing it, and quite as effective as if it had been grown for the purpose. It does no harm whatever to the Vine to cut off the branches with the fruit, and you can have half-a-dozen sorts in the same stand if you like. This is my idea of preparing pot Vines for the table, and it has at least the merit of being cheap and easy, and it is quite as legitimate a way of setting up Grapes for dessert as piling them in a heap on a dish. Pot Vines are not grown for such purposes without considerable trouble and expense. I find, however, that I have been anticipated in my ideas. The practice of sticking the branches of the Vines into vases for table decoration is practised in Paris. Examples were shown at the Exhibition by M. Salomon, of Thoméry. He had a rustic vase stuck full of branches of Chasselas de Fontainebleau, but of a shape to give a bush form to the Vine. At Thoméry I observed also that M. Rose Chameaux was preparing table plants in the same way as Mr. Sage does, only his were grown outdoors against the walls. J. SIMPSON.

Wortley.

—The plan adopted by Mr. Sage for producing elegant pot Vines well fruited for the decoration of the dinner table is not new in conception, but there is some novelty about the way in which it is worked out. Mr. William Cole, of The Grove Vineyard, Feltham, and formerly of Ealing Park, has grown literally hundreds of pot Vines for the same purpose. His practice differs from that in use by Mr. Sage in this respect, that the 7½-in. pot used by him to be the future plant basis is dropped over the Vine rod down to the top of the soil in the large or root pot, so that more of the rod is utilised than is the case in Mr. Sage's plan. The stem of the Vine is also kept free from laterals, all the fruiting wood being trained to the flat wire top, which is from 18 in. to 24 in. in diameter. The uprights consist of stout iron rods, having at the base three claws, which fit into the small pot, and when this is filled with soil and well pressed keeps the plant secure. From Vines grown in this way Mr. Cole has taken bunches weighing 1½ lb. and 2 lb. each, and he has also found that plants would keep fresh and the berries plump two months after the rod had been severed from the old roots. This I have learned from himself, and I have in years past often seen the results of his experience. Whilst at Ealing Park it was also his custom to train a couple of pot Vines over an arched wire trellis some 12 in. wide, and having a span of about 5 ft. across; this, when well fruited, formed an elegant adjunct to the sideboard of the dining room. A. D.

NOTES AND QUESTIONS ON THE FRUIT GARDEN.

Apples and Pears in Northern Districts.—I was greatly surprised to see (p. 380) such Pears as Duchesse d'Angoulême, Chantmontel, Fasse Colmar, Easter Beurré, Beurré Rance, and Ne Plus Menris recommended for a northern climate, as it is a well-known fact to any one at all acquainted with those varieties that they are about the worst and most uncertain of any Pears that can be grown. Even in warm districts it is seldom they are at all up to the mark, unless grown on sunny walls in dry, congenial soils, and then they are in no way equal to many others that can be depended on to come good in less favoured aspects. Such kinds as the above may do very well in the Channel Islands, but I venture to say your correspondent has never yet tasted a good Chantmontel, Duchesse, Beurré Rance, Easter Beurré, or Ne Plus Menris grown outdoors in Lancashire, unless on a south wall. These three latter are not to be compared with Josephine de Malines and Bergamot Esperen, which are the two best late Pears in cultivation. Again, among the early sorts recommended no one would think of growing Doyenné d'Été and Citron des Carmes who had ever eaten a Beurré Giffard, or a Williams' Bon Chrétien, and those superb autumn Pears Beurré d'Amanlis and Beurré Superfin are far superior to others named that come in at the same season. There is no mention made of Doyenné du Comice, a Pear that should be in every collection, however small, as it is really first-class in every respect. As the present is the season for planting, and as much disappointment necessarily follows getting such as do not ripen properly, the opinion of others of your correspondents would just now be of great value. The list of kinds I would recommend is as follows:—Beurré Giffard, Williams' Bon Chrétien, Beurré d'Amanlis, Beurré Superfin, Louis Bonne, Marie Louise, Doyenné du Comice, Beurré Bachelier, General Todleben, Josephine de Malines, and Bergamot Esperen—to ripen much in the order named.—S. D.

Dessert Pears.—Thompson's Pear we are now using along with Fondante d'Automne, both of which are of great excellence and good bearers.—R. GILBERT, *Burghley*.

PLATE CLIII.

WINTER AND EARLY SPRING CROCUSES.

Drawn by H. NOEL HUMPHREYS.

INCLUDED in the fifty or sixty known Crocuses there are several midwinter-flowering species which keep up an unbroken succession between the autumnal and the late vernal species, though, till within the last four or five years, few of them, since the time of the late Dean Herbert, have been in cultivation. We select for this week's coloured plate four of the earlier vernal species from Mr. G. Maw's collection at Benthall, which now includes, with the exception of five or six species, every known Crocus, mostly obtained from their native habitats by Mr. Elwes and himself.

Crocus chrysanthus (figs. 1, 2, and 3) was known to Dean Herbert, but had been long lost to cultivation till Mr. Elwes in 1874 re-introduced it from the neighbourhood of Smyrna. It appears to be a common species in Bithynia, where Mr. G. Maw, during his recent tour in the Levant, collected bulbs in a number of localities, including Mount Olympus, at an altitude of 3500 ft., the flanks of Olympus east of Broussa, at an altitude of about 1000 ft., on the Taktalie Dagh, the Nymph Dagh, and Yamaulab Dagh, near Smyrna, at a height of from 2500 ft. to 4000 ft., and within a few hundred feet of the sea level between Gemlik and Broussa. It belongs to the annulate section, the corm resembling that of *Crocus biflorus*. The stigmata are entire, trivariating high up in the flower, generally bright scarlet but occasionally pale orange. The species has a great range of variation, both as regards colour and size, also in the length and colour of the stigma, and in the character of the foliage. The typical form has flowers of a clear unstriped orange, but there are also an endless series of varieties, brindled and striped with bronze—some as dark and rich as the Cloth of Gold Crocus, others uniformly freckled with bronze externally on the three outer divisions of the perianth, and the form from Mount Olympus is beautifully variegated with distinct patches of bronze at the throat, and suffused with bronze and purple towards the extremity of the limb.

Crocus Fleischeri (fig. 4) was at one time cultivated at Spofforth by the late Dean Herbert, but had been long lost to English gardens till Mr. Elwes in 1874 re-introduced it from Smyrna. Though delicate and fragile in stature, it appears capable of ready multiplication by the formation of small bulbils round the base of the corm. Mr. G. Maw introduced a further supply of the bulbs in 1876, and in 1877 again collected it largely on the Hippurite limestone plateau of Boujah, near Smyrna, where it is by no means uncommon. It also occurs in Cilicia and in Lycia, where it was collected by Forbes. *Crocus Fleischeri* has no near ally. The dark, brick-red, branching stigma is remarkable, and the corms differ from those of any other species in their golden-yellow colour and singular tunic, which consists of silky fibres arranged in interlacing strands or plaits vertically disposed over the corms.

Crocus reticulatus (M. Bieb.)—*C. variegatus* (Hoppe and Hornsch) (fig. 5)—is remarkable for the densely reticulated corm tunic, consisting of strong wiry fibres, resembling the tunic of the Cloth of Gold Crocus (*C. susianus*), with which Dean Herbert erroneously confounded it as a variety. It is an elegant early vernal species, with entire scarlet or orange stigmas, and a narrow finely-pointed limb, varying in colour from white through shades of lilac to purple; the three outer divisions marked with three distinct dark purple-feathered stripes. The Carse, a great limestone plateau above Trieste, is its most western habitat, where it occurs abundantly, both on Mount Spaccato and in the Lipizza Forest, extending eastward to Odessa, Hungary, Podolia, the Banat, and into Asia Minor and the Caucasus, and perhaps southward into Dalmatia, as Visiani's *Crocus dalmaticus*, with a rather finer corm tunic and self-coloured violet limb, is considered a variety of it.

Crocus Crewei (fig. 6) was discovered in the island of Syra, one of the Cyclades, by Mr. Elwes in 1874, and three bulbs only, which were casually dug up with other species, appear to have been imported. One of these, which was received by the Rev. H. Harpur Crewe, who was one of the first horticultural botanists since Dean Herbert's time to make a speciality of the Croci, flowered at Drayton-Beauchamp in 1875. The other two fell to the lot of Mr. G. Maw, who has been fortunate in preserving and multiplying them. *Crocus Crewei* seems to be nearly allied to *C. biflorus*, but is remarkable as being the only species having dark, chocolate-coloured anthers.

Crocus alaticus (figs. 7 and 12).—For the introduction of this, two varieties of which are included in our plate, English horticulturists are indebted to the liberality of Dr. E. de Regel, director of the

St. Petersburg Botanic Gardens. It has been flowered recently at Kew and by Dr. Wallace and Mr. George Maw. It seems to vary considerably. In one variety, flowered by Dr. Wallace, from which fig. 12 is taken, the exterior limbs are externally freckled with bright claret-purple; another variety occurs without any external markings, and, judging from analogy, it is not improbable that distinctly-striped varieties may also exist. This species is of special interest to Crocologists, as its occurrence in Central Asia carries the distribution of the genus a thousand miles farther to the east than any other known species.

Crocus byzantinus (fig. 8)—*C. iridiflorus* of Henffel.—A native of the Banat and Transylvania, flowering from the end of September to the middle of October, and is remarkable for its dark purple stigma and the small size of the three inner limbs. The corm is very flat in form and covered with a thin delicate fibro-membranous tunic. The leaves, which are exceptionally broad, succeed the flowers, and are not produced till the spring. It was cultivated in this country by Parkinson, and is now to be found in most collections of Croci.

Crocus pulchellus (fig. 9).—An abundant species on the shrub-covered hills bordering the Bosphorus, and found also by Mr. G. Maw on the Bithynian Olympus up to an altitude of nearly 4000 ft. The flowers, which are produced abundantly through September and October, are usually of a pale bluish-lilac veined with thin purple lines internally with a golden-yellow throat; the anthers are white or cream colour and the filaments covered with short hairs. The corm is annulate in structure, resembling those of *biflorus* and *chrysanthus*. A white variety occurs sparingly both on the banks of the Bosphorus and Mount Olympus.

It is probable that the whole of the orange Croci, of which there are ten or twelve known species, vary with bronzed forms. *Crocus stellaris* may possibly be a garden hybrid between *C. aureus* and *C. susianus*, as its corm-coat partakes of the reticulated structure of the latter species, and *C. sulphureus striatus* a garden form of the self-coloured *C. aureus*, as they are not known in the wild state, and it is possible that *Crocus vitellinus* and *C. syriacus* may respectively prove to be the self-coloured and variegated forms of one species; indeed, the colouring of a Crocus flower is the least important distinguishing character. Many of the species, notably in the case of *C. cancellatus*, vary in colour and markings from every separate locality; and widely distinct species growing together often put on identical colouring and markings. In the case of *C. cancellatus* var. *Mazziaricus*, and *C. hadriaticus* var. *chrysobelonicus*, which occur mixed up together in the Island of Santa Maura, both of which varieties differ from the type forms, and though widely separated as species, the two varieties are so precisely identical in their colour and markings as to be scarcely distinguishable without close inspection. In the case of *Crocus vernus*, from which all our large purple, white, and striped varieties have been raised by the Dutch, semial variation seems to be an intrinsic character, as in the wild state almost every individual flower differs somewhat, ranging from deep purple to white, through an endless series of striped forms corresponding with nearly every variety in cultivation.

In a horticultural sense this beautiful genus has not been made the most of; out of between fifty and sixty species, nearly all of which are now in English gardens, only three, viz., *vernus*, *aureus*, and *susianus*, are grown to any extent in Holland, and not more than six or seven have been made use of for horticultural decoration in this country. We would commend this fact to the bulb-growers of Holland, where the soil is so specially suited to the growth and multiplication of Crocus corms. Whether hybridisation would be practicable is open to question, as wild hybrids, if they occur at all, are very rare, but the native species of the genus would afford all-sufficient variety without crossing, and a constant succession of beautiful forms from September to March all through the dull flowerless months of winter.

G. M.

Crocus vitellinus.—This rare and beautiful Crocus we noticed in flower the other day in the Kew collection. It is the only yellow-flowered autumn kind at present in cultivation, and on this account is especially noteworthy. It much resembles the well-known spring-flowering *C. aureus*, having flowers of a rich yellow colour, and the leaves partially developed at the same time. It is a native of Syria, and is one of the numerous introductions to cultivation of Mr. Maw, of Benthall Hall, Broseley.—W.

GARDENING FOR THE WEEK.

Indoor Plant Department.

Plant Stove.—The prevalent idea with many who grow stove plants is, that to give them the necessary rest in winter they must be subjected to a temperature sufficiently low to stop growth, even when the soil in which the roots are placed is kept somewhat moist; but where this course is pursued it reduces the value of the stove in winter nearly one-half through keeping the heat so low that the plants required to be kept moving can make little or no progress. To avoid this proceed as follows: Most stove plants that are of a deciduous, or partly deciduous, character, will bear the soil being kept so dry as to induce a state of rest even when kept in a temperature sufficiently high to excite growth, if there were enough moisture in the soil to admit of their making such. By gradually withholding water from the roots of *Allamandas*, *Clerodendrons*, *Bougainvilleas*, and plants of a similarly vigorous yet partially deciduous nature, they may be subjected to the requisite course of rest in a temperature high enough to keep plants that need more heat growing. The supply of water must not, however, be cut off all at once; first, withhold it until the leaves flag freely for a day or two, then give a little, but only a little, and when the plants flag a second time let them go a little longer before water is given; after a few repetitions of this kind the leaves will turn yellow and fall off, and the plants will subside into a state of complete rest through the perfectly dry conditions of the soil. In the same way *Gloxinias*, *Achimenes*, *Caladiums*, and the tuberous-rooted *Gesneras* can be kept dormant during the required period, at the same time keeping up a heat of 65° in the night with 5° higher in the day, which temperature will be sufficient to preserve many plants in a growing state that with a lower temperature would make no progress at all. In cases where plants at rest, and others making growth, are kept through the winter in the same house, it will be advisable to put those that are dormant at the coolest end, leaving the warmest end for the plants required to be kept growing; at the same time the atmosphere should be more humid than if there were less heat, but this should not be overdone so as to cause a great amount of drip from the condensed moisture on the sash-bars and roof glass, as this, by falling on the soil of the plants at rest, would cause a greater disposition to grow than would be desirable. By adopting the above course such subjects as *Gardenias*, *Ixoras*, *Cochlostemas*, *Dipladenias*, *Eucharis*, *Gesnera zebrina*, *Ipomœa Horsfallia*, *Euphorbia jacquinoifera*, and many others that will not flower well in winter with a lower temperature than 65°, or that will make but indifferent progress in the summer if kept lower than this during the winter, can be managed satisfactorily with the plants at rest. Plants like the hard-wooded, evergreen portion of the above must never be allowed to get too dry at the roots or they will suffer serious injury, being wholly unable to bear the treatment recommended for those subjects that cast all or the greater portion of their leaves in winter. The sweet-scented *Stephanotis floribunda*, in the matter of watering, needs an intermediate treatment from that bestowed upon the above divisions of plants, for to continue it at rest in a house where a temperature such as above indicated is maintained, it must have the coolest place with no more water than will be just sufficient to keep the leaves from shrivelling, as if the drying process be carried too far the foliage will suffer, thereby entailing serious injury on the plant. All the air given should be admitted at the coolest end of the house. This will still further assist the object in view.

Cinerarias.—If, early in the spring, a little *Cineraria* seed was sown to flower during the first months of the year, the plants, if they have been regularly attended, will now be beginning to push up their flower stems. Even should the pots appear small for the size of the plants, do not be tempted to give them larger ones, as no additional pot room now will improve them in the least, for when they have already begun to push up their bloom stems the slightest interference with their roots will seriously detract from their proper development. The strength of the flowers will be increased by giving them regularly weak manure water. Do not attempt to force them into bloom, as such a process will only end in disappointment by inducing a weak, pany condition; a temperature of 45° in the night will be found sufficiently high.

Orchids.—One of the first essentials as regards the healthy development of Orchids is cleanliness. By this I mean not only a freedom from insects, but also a perfectly clean state of the leaves. The moist atmosphere of an Orchid house is at once calculated to cause dust and soot, that are sure to find their way inside when air is given, to adhere to the leaves and pseudo-bulbs. On plants that are little subjected to syringing the dust accumulations have nothing to interfere with them; those who

syringe more freely, especially such genera as *Vandas*, *Aerides*, and *Scolecibiums*, the dirt is washed down into the axils of the leaves, where it gathers to an extent that makes the surface at their juncture with the stem completely coated with a black deposit. This has the effect, even after its removal, of causing the portion so covered to have a pale, sickly look, the result of which is that plants that are allowed to get in this condition shed their lower leaves sooner than others kept in a more cleanly state; the effects of this loss of leaf being not only to give them an unsightly appearance, but to weaken them. Large quantities of Orchids are grown in the immediate neighbourhood of towns, the soot-charged atmosphere of which seriously affects them in this way, and unless repeated sponging is resorted to, it is impossible to keep them as clean as they ought to be; but this work should never be done by careless or inexperienced hands. It is no uncommon occurrence to see the leaves of *Vandas*, *Aerides*, and the like split and cracked through for want of sufficient care in the cleaning operations. Beyond the accumulations of dirt which thus reach the plants there is another cause through which they often suffer in this way, and that is, where the water employed for syringing is impregnated with anything that leaves a dirty deposit on the leaves, as is often shown by the white appearance, as if chalk or lime had been present in the water; the effect of this in clogging up the pores cannot be otherwise than to injure them. Water of this character should never be used; and where it is necessary to obtain it from springs or other sources in which a like condition exists, means should be taken to secure a sufficient quantity of rain water, which, if not enough for all purposes connected with the requirements of the plants, should be reserved for syringing.

Insects on Orchids.—With these it is necessary to keep up a continual warfare, especially where the worst description of insects exists, particularly white and brown scale. Periodical brushing and sponging, which admits of their getting on the plants during the intervals in large quantities, do not free them from the presence of these pests in a way desirable. If, in place of thus treating them such as are affected are repeatedly gone over, and all that could be discovered destroyed, they would in time get exterminated, when not only would the labour be very much reduced, but the health of the plants would be improved. The uninitiated in Orchid culture are frequently tempted to try some of the many insecticides now before the public, but I would particularly recommend care being exercised in the application of these, as I have often seen valuable plants all but ruined by their use. All the dressing that I have ever found safe to apply to Orchids, beyond a sponge and brush, the latter especially used with care, is dusting slightly ordinary Scotch snuff inside the axils of the leaves of such plants as *Vandas* and *Aerides*, where the white scale gets down into a position that renders their removal difficult without injuring the plants; it is, indeed, only on the lower fully-matured leaves that I should recommend the snuff to be used. It should be dusted in from a bit of very fine gauze doubled two or three times and formed into a small bag, and when allowed to remain on the insect-affected places for ten or twelve days it will usually be found to have destroyed them. The plants should then be laid on their sides and syringed freely with tepid water until the snuff is removed; finish by sponging. There is no more fitting time than the present for a thorough cleansing of the interior of Orchid houses, washing the glass so as to admit as much of the diminished sunlight as possible, scrubbing the bars and rafters, and thereby removing the slimy deposit that always more or less accumulates in a comparatively close, moist atmosphere. If requisite, the surface of whatever brickwork exists should be limewashed, which will further increase the light. This, with a thorough cleanly condition of the pots in which the plants are grown, and the stages on which they stand, will place them in the most favourable condition for passing through the winter.

Winter Temperature.—In collections consisting of anything beyond a comparatively few varieties, either of Mexican or East Indian plants, there is no time throughout the year when all are at rest, for even during the last few weeks in the year and a corresponding period at the commencement of the ensuing one there will be some that are making growth, but, as a matter of course, the treatment both as to temperature and atmospheric moisture should be such as to suit the wants of the greater portion which are at rest. To meet this the plants that are growing should be placed at the warmest end of the respective houses which they occupy. Here they must receive enough moisture at the root to supply the requirements of the slower growth which they will at this season make. So far as the atmospheric moisture is concerned, taking into account the necessities of the majority which are at rest, and the now minimised drying influence of the sun, it becomes requisite to keep the atmosphere comparatively dry, yet not so as to cause the plants to shrivel too much, neither should the majority be kept too long with the whole

of the material in which their roots are placed so excessively dry, as is sometimes done under the impression that by such treatment the plants will be brought into what may be termed a condition that will force them to flower. Extreme treatment of this sort may possibly further the production of a few meagre flowers; but the blooming, collectively, will always be indifferent unless the management through the growing season has been such as to favour the requisite solidity and fully developed state of the growth essential to a free production of flowers, and, where the plants are wanting in this condition, it is much better not to attempt, by any undue, severe drying up to make them bloom. I have been led to again speak more fully on this subject through often seeing those inexperienced in the cultivation of these plants adopt the course of treatment here indicated as wrong. The same mistake is frequently committed by young growers in simultaneously withholding water at this season from their plants collectively, by which means all with immature, unfinished growth are soon reduced to a shrivelled up condition, by which much injury is done, as, after water is again applied, it is only in very few instances that the unfinished growths can be induced to make any further progress; but, instead of this they push up from the base, and, as might be supposed from the state of the pseudo-bulb, with its weak, totally unprepared buds at the base, the forthcoming growth is almost certain to be weak and unsatisfactory. In the whole range of plant-growing there is nothing more remarkable than to notice amongst even the best growers how varied in their success with different families or species, some individuals succeeding very much better with one section than others. This I recently alluded to, and, in addition to the cause then assigned, there is no doubt that the winter temperature, or, in other words, the rest that some species of plants get, has much to do with their well-being. I may point to *Phalenopsis* in confirmation of this, one of the most beautiful, at the same time less generally well-grown, families of Orchids ever introduced. It is no uncommon thing to see plants of these for a few years making large, almost too vigorous, growth, and after this become diseased through the leaves spotting and ultimately dwindling away. I have seen *Phalenopsis* go on uninterruptedly for a lengthened period without any check where the night temperature for the next three months would average rather below than above 60°. Under such conditions, when they are also confined to a moderate heat in the growing season, the leaves they form are never so broad and long; but they are considerably thicker and stouter, the plants collectively carrying a greater number consequent upon their lasting much longer than where they were formed, and the plants wintered, under correspondingly higher temperature.—T. BAINES.

Flower Garden.

Wherever a system of spring bedding is intended, the planting of the various species of plants and bulbs should be finished as soon as possible, in order to give the plants used for the purpose time to establish themselves in their new position before severe frost or winterly weather sets in. It is also quite time that all bulbs used for this purpose should be in the ground, in order to induce, as much as possible, early flowering, and the consequent early ripening, of the bulbs, so as to admit of their being taken up by the time that the beds are required for the summer bedding plants. In some instances, where the summer flower garden may not be a conspicuous object from the windows of the residence, or where it may be at a considerable distance from it, or in cases where a garden is laid out in some part of the grounds for the express purpose of growing spring flowering plants and early bulbs—under such circumstances it may possibly be considered unnecessary to plant the beds of the summer flower garden with spring flowering plants, thus compelling them, as it were, to do double duty, and subjecting them to exhausting effects. It is true that much has been said and written against the so-called unsightly masses of bare earth which flower gardens generally present during the ensuing five or six months. In reality, however, there is much less in this than might at first sight appear to be the case; as, taking one season with another, during at least one-half the above-named period the surfaces of all flower beds are either frost-bound or hid from view by their winter mantle of snow, during which time it is quite immaterial as to whether they are furnished or otherwise. After all, too, there is nothing so very unsightly in neatly-formed beds of fresh soil, composing an artistically designed garden surrounded by closely-cut and well-swept green sward; but, wherever it may be intended to forego the use of winter and spring flowers in such gardens, the beds should, nevertheless, be neatly dug over as soon as the summer bedding plants are removed; the Grass should be again mowed, if at all necessary, swept, and well rolled down, and put into the best order possible for the winter; while in the soil yard, or in some other out of the way, but convenient, place, preparations should be made for collecting and preparing the necessary quantity of fertilising materials, with which to enrich the flower beds and borders for the following season. This compost may, of

course, consist of various materials, such as well-rotted stable-yard or hothed manure, well-decayed leaf soil, and, if procurable, a portion of the top spit from an old pasture, or sound maiden loam in any form, which should be well chopped up and mixed with the other ingredients, and should be frequently turned during the winter months, and applied to the beds and borders in spring, in accordance with the probable requirements of the different kinds of plants, which are intended to occupy them. This circumstance should always be kept in view, as for some varieties of bedding plants the soil can, as a rule, hardly be rendered too rich; while for others highly enriched soil is by no means desirable, as it tends to produce an over luxuriance as regards foliage, and a corresponding paucity in flowers. Cut down the decaying flower stems of Hollyhocks and other hardy herbaceous plants, and any very choice or scarce varieties of the former, may for greater safety, and for the purpose of more rapidly increasing them, be lifted and potted. Keep lawns and walks as free as possible from falling leaves, worn casts, and other literary matter. Attend to the stock of bedding plants, giving air in abundance whenever the state of the weather will permit, and water only when it is really required.

Indoor Fruit Department.

Vines.—It may be necessary in certain cases to start a Vinery earlier than usual, but too great a change in this way should not be attempted in any one year. If a period of six weeks or two months earlier be desired, it is best to spread such advancement over two years. This may be effected by starting the Vines three weeks or a month earlier than last season, and the same amount of time earlier next year from the date of starting this season. Where two or three different houses are planted with varieties suitable for early forcing they should be made to come in rotation. In this way the youngest Vines would be allowed a natural midsummer growth for a few years. Young Vines planted during the past summer should be pruned immediately the leaves are down. The principal pruning needed in this case consists in the cutting over of the main stem, which should be shortened to within from 2½ ft. to 3 ft. of the ground. Cut away, too, all small lateral growths which may have pushed underneath where they were stopped. Where supernumeraries are grown for early fruiting, they should be cut 6 ft. or 7 ft. from the base, which length will bear half-a-dozen nice bunches next season. Those planted last year will have made two seasons' growth by this time; consequently, they will now have to be treated for their third and fruiting year. If the wood made this season is very strong and well-ripened, it should be cut at 4 ft. further up the rafter than was directed last year; any weak shoot should be cut at 1 ft. lower down, and if generally small the whole may be cut at that length. Prune all lateral shoots from these also, and the buds on this year's growth will be found to produce strong shoots and fine bunches next year; more than 4 ft. of young wood should never be allowed to remain on any Vines which have not reached the top of the rafter, as rods so treated make a much more substantial growth thus restricted than when left longer. Vines fruiting for the first time this season should have their side shoots cut in to a couple of eyes, as formerly directed in the case of old ones. Where supernumeraries have been fruiting along with these they should be rooted out, if at all likely to overcrowd the permanent Vines next season. Very little loose bark will be found on any of these young Vines to remove before washing, and, as the borders will all have been recently made, and therefore fresh and otherwise in good condition, no top-dressing of any rich substance will be needed. A slight forking should be given to the surface, however, so that water may more readily reach the roots. Remove decaying berries from Grapes still hanging on the Vines, an important matter, requiring an almost daily attention at this season. Black and white Lady Downes and black Alicante are the three kinds most exempt from decay, and they are the best sorts for winter supplies, either for the practical gardener or inexperienced amateur.

Pines.—The present is a very inactive time as regards Pine stove. Where much fire-heat is confined in any house, care must be taken to admit a little air when the sun strikes the house, otherwise the foliage is very liable to get scorched when the temperature rises above 80°. Crowns and any odd suckers of such precious sorts as Smooth Cayennes, Charlotte Rothschild, Prince Albert, and any other favourite kinds may yet be propagated in 5-in. pots, and plunged in a smart bottom-heat of 90°, in order that they may root quickly. The above-named varieties do not produce suckers abundantly; crowns of them are, therefore, generally potted and grown into plants, and very good plants they make, but as it is throughout the winter that the crowns of such are most plentifully obtained, a small corner, with a strong bottom-heat, should be reserved, in which to place them as they are produced. Give the plunging material a liberal watering when it shows any indication of becoming over-dry. This feeds the roots, and keeps the atmosphere in good condition.

Kitchen Garden.

Now, when the principal sowings and plantings for this season have been completed, it is a good time to determine matters respecting next year's campaign. A rough plan should be prepared of the kitchen garden, showing with what each plot of land has been planted during the past year, and indicating the rotation for the coming season. If this is well considered now, manuring and trenching operations can be carried out with a view to the requirements of each particular crop. The plan should be drawn to a scale, in order that there may be no difficulty in determining the exact position of each crop, even though removed. It is necessary not only that plenty of everything should be provided, but that there should be no waste, and there is scarcely anything that better repays a little personal supervision than the gathering of vegetables if a good supply be aimed at. If there is a good supply of manure too much stress need not be laid upon the rigid carrying out of any given rotation; still, it is desirable to avoid, as far as possible, planting the same kind of crop two years in succession on the same land. This is a question, however, which hinges very much upon the manure supply and its intelligent application. When a garden has to be heavily and constantly cropped, deep culture and heavy manuring must make up for any breach in the recognised system of rotation. As a rule, where much has been taken out of the land, much must be returned to it. All land intended for root crops next season should be manured, if it is necessary, and deeply trenched as soon as it can be conveniently done, either throwing the soil up into ridges, or at least leaving the surface as much exposed to the action of the weather as possible. The manuring and digging of fruit-tree quarters and borders will be better delayed till the leaves are down, and the trees pruned, so as to avoid incurring unnecessary labour. In warm situations, if it be desired, one or two of the earliest Peas and Beans may be sown; but, considering the risk they have to run, unless attendant circumstances are favourable, it is a question whether it would not be advisable to delay such sowings till January, especially if they can then be started under glass. However, this is a question that every one must decide for himself. Remove the surface-soil from Asparagus beds; wheel on a good heavy dressing of rich manure, and replace the dormant. Horseradish should be taken up and laid in somewhere thickly, to be always at hand and easily accessible when wanted. Provide a good supply of green Tarragon, Mint, Marjoram, &c. Peas may also be sown in boxes in heat, to provide young green tops for flavouring soups, &c.

Parsley, Endive, and Lettuce.—A plentiful supply of Parsley, which, throughout the winter is very desirable, may yet be secured, if the necessary measures be at once adopted. Weak, poorly-grown plants that have been sown in a bed or in rows, and allowed to remain crowded too closely—an error too frequently committed—can never be depended on to produce much after winter fairly sets in, and when the plants are making the least growth. Subjected to such treatment as this, the roots are often so much affected with canker that they have little vitality in them. If, at the time of sowing the crop of spring Onions, a pinch of Parsley seed was put in at intervals over a portion of the ground occupied, and afterwards thinned out to single plants, they will, at the present time, be stout and strong, probably nearly 1 ft. each in diameter. They should now be planted close together, but without crowding; the leaves of each root ought, in fact, just to meet, as in this way they can be protected. An ordinary garden frame is the best, the lights being taken off, except during severe weather, or when there is a likelihood of snow. If a frame with glazed lights cannot be spared, a temporary one made of boards should be used. It should have strips of wood nailed over it, so as to allow of mats or shutters being placed on in severe weather. In planting in this way, holes should be made that will admit of each root being placed in the soil, with its roots intact, in a spadeful of earth; and, treated in this way, they will not feel the effects of shifting. Endive and Lettuce that have already grown to a usable size should be treated in a similar way. The plants may be placed moderately close one to the other—much nearer than those of Parsley. Here, again, frames with glass lights are the best; but if they are not vacant, recourse may be had to covering with mats and dry Fern. Nothing is so good as the latter, as from its light, open nature, it may, in severe frost, be placed absolutely in contact with whatever it is required to protect; mats, on the other hand, or straw when wet, are heavy and lie so close that when frozen and touching the plants, they often do as much harm as good. A good method of blanching, and at the same time of protecting Endive, is to use boards 10 in. or 1 ft. wide, and $\frac{1}{2}$ in. or $\frac{3}{4}$ in. thick, in lengths of from 6 ft. to 10 ft. or 12 ft., according to the lengths of the rows to be covered. These should be laid flat on the top of the Endive, a dry clay being chosen when the plants are free from wet. Place a couple of bricks on each board to prevent their being moved by strong winds; this will also keep the boards in contact with the plants so

as to exclude light, and hasten the blanching process; it will thus become white in eighteen or twenty days after the boards are put over it. More should not be covered at a time than will be need in a month or five weeks, or it may rot. The boards so placed will exclude a good deal of frost, from which the Endive can be still further protected by a covering of stable litter, Fern, or Asparagus haulm; the latter is very useful for protective purposes of this kind, as it does not lie too close.

Extracts from my Diary.

November 11.—Digging large holes and filling them with maiden loam in which to plant Peaches, Nectarines, and Apricots. Covering a bed of Seekale with leaves and manure previously prepared for it. Cutting down Asparagus stalks and clearing the weeds off the beds. Covering up Endive and Lettuce to blanch. Washing the lights and paint in the early Peach house.

Nov. 12.—Shifting herbaceous Calceolarias. Getting the trees in the early Peach house pruned and painted with the usual composition for keeping off and destroying insects. Giving Cucumbers a little earthing with new loam, adding a little charcoal to keep it open and sweet. Clearing old Raspberry canes off wire trellis. Clearing leaves and rubbish off borders in pleasure grounds and getting them forked over.

Nov. 13.—Earthing up Beans. Turning manure and leaves for hotbeds. Giving Asparagus beds a light forking, and covering them with rotten manure. Making a new Mushroom bed. Tying out the trees in early Peach house, and otherwise getting it ready for starting. Getting all Endive and Lettuce under glass as fast as room can be found for them.

Nov. 14.—Sowing Mustard and Cress. Potting on late Primulas. Getting into the potting shed a good supply of different sorts of mould. Emptying Melon pits and giving the walls a good coating of hot lime. Trenching early Pea border, turning in a good coat of manure that had been previously mixed with salt and soot. Commencing to lay down one-half of the Broccoli heads to the north, and covering up the ground between the rows with half-rotten manure.

Nov. 15.—Potting off Hydrangea cuttings which are rooted. Getting in 100 pots of French Beans. Turning manure for Mushroom beds. Getting Strawberries for forcing into cold pits. Looking over Cauliflowers, turning down leaves to protect the heads where required, and moving the most forward ones into an open shed. Raking up leaves in pleasure grounds and collecting them for hotbeds.

Nov. 16.—Looking over Verbena and other cuttings, removing all dead ones and decayed leaves. Cleaning the walks in the pleasure grounds and getting them all rolled down firmly. Getting all rubbish burnt up. Clearing off late Peas, and storing away the best of the stakes. Getting for fruit trees a quantity of loam from the deer park. Cleaning up the kitchen garden walks. Fruit in use for dessert: Pines, Grapes, Pears, Apples, Medlars, Nuts, &c.—W. G. P., Dorset.

Dell's Black-leaved Beet.—In addition to the fine effect which this plant is capable of making in the flower garden, it is equally useful for culinary purposes. In the kitchen garden it looks well in single lines, as, for instance, behind a row of Parsley and before a row of Carrots, thus forming a good ribbon border, which, if rightly taken advantage of will make the kitchen garden more attractive than it usually is.—J. G.

Autumn-planted Cauliflowers.—I have hitherto had successful results by planting Early London and Walcheren Cauliflowers in autumn in drills from 3 in. to 4 in. deep. Put in the plants the usual width apart. Should the weather keep open before winter sets in, and the plants look over vigorous, we have them all disrooted by passing a garden trowel round them. This I find to be a much better plan than that of coddling them in frames all the winter.—J. MILLER, *Chumber.*

Scarlet Runners Late in the Year.—When we speak of Scarlet Runners existing in autumn, putting usefulness out of the question, we must draw a line somewhere, for Scarlet Runners are not nutritious or pleasant to the palate after the slightest frost; even in the south-west of England they are not good after the end of September. Therefore, to plant them in June would be a waste of seed and labour; for the plants would scarcely be in flower before frost attacked them. Even in our mild climates they should be planted in April or the beginning of May; in fact, as soon as the season permits, forming, as they do, a succession to the French Bean, of which the Canadian Runner is decidedly the best. After September we have

plenty of Brussels Sprouts, Cauliflowers, Savoys, Nonpareil Cabbages, and Spinach, to say nothing of roots and Celery cooked. Therefore what need is there of French Beans?—EUGENE E. LEGGEE.

Ridging Ground in Winter.—There is no method which more effectually brings garden soil into a healthy state than laying it up in ridges during the winter season. This system possesses a two-fold advantage, inasmuch as, when the planting season arrives, it is known to be in a sweet condition; and by readily throwing off the superfluous moisture it is more easily brought into working order. On soils of a stiff, tenacious character, ridging is indispensable, but it may be safely affirmed that all kinds of soils would be much benefited thereby. If a very neat and trim appearance is indispensable, then in most cases I would prefer to merely clear the ground and let it lay untouched until the beginning of March. Freshly dug ground would appear to retain an undue amount of water, which has the effect of rendering it pasty and sour. This more especially applies to rich alluvial soils, and I have often noticed that where the surface has been left untouched, and even covered with weeds, the soil will, when dug in the spring, appear much more mellow and be in far better working order than that which has been carefully dug over. I would therefore recommend either throwing up fallow ground into rough ridges (the rougher the better), or letting it alone altogether. Simply digging I consider a mistake, and whoever desires to ensure neatness thereby must expect that he will experience a great amount of labour to bring the soil into that sweet, friable state which in vegetable culture is the very mainspring of success.—J. CORNILL, *Byfleet*.

Market Crops.—Unless the winter proves to be unusually severe there will be no lack of vegetables for general consumption, as the market gardens and fields are literally green with Cabbages, Cauliflowers, Broccoli, Brussels Sprouts, Savoys, Kales, Turnips, Spinach, and winter Onions, all luxuriant in growth. Turnips are, perhaps, not quite so abundant as last year, as the dry October kept the latest-sown breadths in check, but there is an abundance, whilst the very latest plants will pay if allowed to stand over to the spring to produce sprouts. Brussels Sprouts are exceedingly fine and an extensive crop. They need no immediate marketing, as the crop is progressive rather than simultaneous, and picking will extend over a couple of months, or even longer, if there be even a moderate amount of judgment employed in the gathering. The Sprouts also fetch a good price in the market, and the crop can be cleared off in time for early Peas, Potatoes, &c. Owing to the long continued absence of frost this autumn the Runner Bean crop was later than usual, and as long as these are pretty abundant other vegetables are less in request. Now that these are over, however, market vans may be seen heavily laden with green produce, autumn Cabbages especially; and following are immense quantities of deliciously-succulent Coleworts, one of the quickest and most profitable of all autumn greens. Autumn Cauliflowers have had an excellent time for development, but somehow they are not quite as good as usual; but they are fast disappearing, and the ground will shortly be prepared for early Peas. With all this wealth of green vegetables low prices will prevail for the growers if the winter be mild, but a hard winter would provoke scarcity and send prices up. Any such gain, however, would be but small. Should a hard winter set in fortunately the growers will have something to sell if the frost be not too grasping.—A. D.

Diseased Solanums.—The case mentioned by Mr. Inchbald (p. 399) of the appearance of the *Peronospora infestans* on plants of one of the strong-growing ornamental Solanums used for sub-tropical planting is to me exceedingly interesting, as I have at all times given particular attention to the progress and development of this fungus in its varied forms. That the disease seen by Mr. Inchbald was identical with the Potato disease I think there can be little doubt, inasmuch as it has been equally destructive this year amongst Tomatoes, which also belong to the Solanum family, and these would seem to have encumbered in much the same way as did the Solanum in question. Had the mischief taken place more recently, it would have been easy to say that it was the result of an early frost, but there was no evidence of frost at the time mentioned, whilst it was just then that the Tomatoes were so suddenly and destructively affected. The special interest that attaches to Mr. Inchbald's communication is found, first, in the fact that the Potato disease is extending the range of its victims; and secondly, as showing that plants other than fruit or tuber producers are subject to it. It was long thought that the Potato fungus was stored with and planted with the seed tubers, and that the best remedy was to be found in steeping the tubers before planting in some strong solution. The simple fact that plants such as Potato plants raised from seed, Tomatoes from seed, and some other kinds of Solanums from seed, were alike affected, shows the incorrectness of the conclusion. On the other hand, the fact that plants having no root tubers through which to take the disease, are, nevertheless, affected, conclusively proves that the disease exists in the air, and that it is the product of atmospheric action.—A. D.

ROSES.

PROPAGATION BY LAYERS AND GRAFTING.

(Continued from page 404.)

THE LAYERS AFTER SEPARATION FROM THE PARENT STOCK.—This operation is effected in the usual manner by cutting off each layer close to the spot where it enters the ground. The severed shoot is transplanted at once to a pot of from 4 in. to 6½ in. in diameter, according to the size of the plant. The double operation of cutting off and potting the rooted shoot is performed about the end of October or the beginning of November, according to the locality. As soon as it is finished the young trees are placed in the garden in a part having a

Fig. 1.—Rooted shoot after its separation from the parent stool.

favourable aspect, if possible, but in any case they must be sheltered from the sun and wind. They may be left there till the first frosts are approaching without receiving any other attention than being watered when they require it. At the approach of frost the pots must be housed in an Orangery or some similar place, or they may be laid by the heels in an inclined position, so that they may be easily covered with soil to protect them from the cold. It must not be forgotten that the Rose trees of which we are speaking are by their nature very sensitive to cold, and that the young shoots which have just been cut off from the parent stock are particularly so, seeing that their extremities, which are still tender, are gorged with sap since the beginning of the summer. Such is the operation of layering by notching the shoot. The reader already understands that it is repeated every year with each parent stool, because while the layered shoots are striking the parent stool

is producing new shoots, which in their turn must be layered during the next year. It should also be observed that every one of the shoots should not be layered, but only those which are healthy and vigorous. Amongst the stronger shoots we often meet with some with the wood so well developed that there is danger of its breaking off short at the bent portion; in such cases it is always better to make the slit on the upper side of the shoot, and by gently twisting it bring it round with the notch to the side. The slit should be kept open by the insertion of a wooden peg. When we have to deal with a variety which has very long shoots they may be bent over so as to form a second and even a third layer, so that we may get two or three plants from the same shoot. This method is called serpentine layering, and is often practised by horticulturists for the propagation of all kinds of creeping plants.

LAYERING IN POTS.—This method of layering differs from that already spoken of; it consists in placing pots in the trench round the parent stock, each layer being pegged down in the pot in the way already described. The pots should be 4 in. or 5 in. in diameter. This plan obviates the necessity for

of several generations, graft during flowering time, and never lose more than 10 per cent. of these grafts. On the table land of Villejuif a horticulturist grafted a number of ornamental shrubs in the month of February, but not a single one of them succeeded. Another grafted a bed containing 2000 Plum trees, but the whole of the 2000 grafts died, while most of the stocks had to be pruned down.

FORCED GRAFTING.—This method of grafting is practised in winter while the sap would, under ordinary circumstances, be at rest. The sap of plants in propagating houses is always in motion, owing to the artificial heat which is kept up in them. The stocks for grafting on are grown in the propagating house in pots, and after having been grafted they are placed under a bell-glass in the tan of a frame, the temperature of the house being kept at from 50° to 56° Fahr., or more economically they may be placed in a frame in the open air, laid on their sides, and completely buried, the temperature of the frame being kept to 50° Fahr. by its being surrounded by stable manure. Grafts forced by either method may be planted out in the open air in March or April.

Fig. 12.—Layering in Pots.

repotting, and the layers consequently suffer much less. Fig. 11 shows the rooted shoot after its separation from the parent stool, and fig. 12 the method of layering in pots.

Grafting.

CLEFT-GRAFTING.—There are two methods of cleft grafting; first, by grafting in the open air, and secondly, by forced grafting. These two methods are similar in principle, and only differ in the time of year at which they are performed. Open-air grafting is practised from March to April. In spite of the opinion of one of our most learned colleagues, we persist in thinking that a graft that is made just as the sap begins to rise has a much greater chance of succeeding than one which is made when the sap is in a state of absolute rest. One of the conditions of successful grafting is that there must be absolute contact, if not interpenetration, between the cambium of the stock and that of the graft. It seems plain, therefore, that this contact or interpenetration will take place much more easily when the approaching warm weather sets the sap in circulation. The nurserymen at Vitry, who hold to the practice

PRACTICAL DETAILS OF GRAFTING.—Fig. 13 shows a Brier stock cleft-grafted. *A* is the shoot called the graft or scion, and has four eyes; the top of the stock *C* is cut off slanting with a stroke of the pruning-knife at *B*; a vertical slit from 1½ in. to 1¾ in. is made in the stock *C*; the graft or scion is cut to a wedge-like form just under the lowest eye for the space of 4-10ths of an inch, the slope beginning at *D* at 9-10ths of an inch above the eye on the other side, the thickness at the height of the eye from 1½ in. to 2 in. This graft being cut it is held in the left hand, while with the right we open the edges of the cleft with the top of the blade of the pruning-knife and insert the graft in the opening, taking care that the inner bark of the graft and of the stock are in close contact. The junction is bound round with thread at *E*, and the whole of the joint, the cleft, and the head of the stock is covered with grafting wax. When the subject is strong we graft two scions on the same stock. In this case the stock is cut with a small hand-saw, trimmed smooth with the pruning-knife, and, at the time of grafting, the cleft is kept open by means of a little wedge of wood, which is driven into the middle and taken out again when the scions are in their places. Grafting with two scions

has the advantage of keeping up the regular division of the sap, thereby making the head of the future Rose tree more regular than it would otherwise. The freshly-grafted scions should be sheltered from the sun and wind by means of little paper caps. Cleft-grafting is used for all kinds of Roses, whether standards, half-standards, or dwarfs. By placing the latter so deeply in the soil that the graft is covered, we may form Rose trees, as it were, on their own roots. It has been asserted that standard and half-standard Rose trees, when cleft-grafted, do not last long, but we think this is unfounded, for we have seen cleft-grafted Roses fifteen years old in full vigour. Fig. 14 represents a Cabbage Rose stock bearing a scion of a Moss Rose five years old. At *A* we see the point where the scion was grafted; *B* is the stock which was only 2 ft. high at the time of grafting. The graft was made in the spring, and in the summer of the same year the tree bore such

Fig. 13.—Cleft-grafting.

an immense number of blooms that their weight would have broken down the graft if the branches had not been kept up by a stick.

CHOOSING THE SCIONS FOR CLEFT-GRAFTING.—It is of the utmost consequence for the final result that we should exercise great judgment in selecting our grafts. They ought to be healthy, mature, and properly formed, and should be cut in January or February. They are tied into little bundles, according to their varieties, and should be laid by the heels in a

border at the foot of a north wall. The best part of a shoot for grafting is the first third, counting from below, then comes the second third, and lastly the upper third, which should not be used, as the wood of it is never thoroughly ripe. The most convenient thickness for the scions is from 1-6th in. to

Fig. 14.—Cabbage Rose stock, grafted with a scion of a Moss Rose.

$\frac{1}{4}$ in. For thicker grafts we are obliged to use stocks of 1 in. or more in thickness, and the cleft being a wide one, the raw surfaces unite only with great difficulty, besides which there are open spaces in the inner portion of the stock, which lead to the drying up of the graft.

J. LACHAUME.

Marechal Niel Rose on the Banksian.—About fourteen months ago I budded a Marechal Niel on a young branch of the Banksian Rose which started from the roots. The shoot from this is now 7 yds. long, and it has, moreover, thrown out eleven more, each from 6 in. to 36 in. in length. It is in a warm corner, well sheltered from the north and east winds, and we hope that it will yield us many flowers next spring.—W. H.

Perpetual Flowering Roses.—At this season of the year, while the so-called Perpetual Roses are destitute of flowers, Tens, Chinas, and Bourbons are supplying the flower basket plentifully. Growers for exhibition may rely upon sorts that attain the end which they have in view, but private growers want Roses and Rosebuds during as many months as possible, and anyone expecting to have a perpetual supply had better not rely too exclusively on the lengthy list of so-called Hybrid Perpetuals.—J. GROOM.

TREES, SHRUBS, & WOODLANDS.

SEASIDE PLANTATIONS.

ONE of the principal difficulties with which the planter has to contend is the raising of trees upon our coasts, where, from the poverty of the soil or great exposure, or from both causes combined, his most strenuous efforts are often frustrated. Less difficulty, however, seems to be experienced upon the western than on the eastern coast; and this may be due to the fact that in the former case the air is warmed and softened by the action of the Atlantic; while in the latter the winds which assail us cross the northern part of the Continent of Europe. Thus it is found that the Myrtle and many other shrubs which stand the winter well on the west coast of Scotland, and attain a considerable size there, are cut down or dwarfed when allowed to remain unprotected through the winter upon the east coast of England, and this in much lower latitudes. Before commencing the formation of a plantation of trees very near the sea, it will be necessary to erect some mound or barrier, which shall at once break the violence of the winds and intercept the saline particles with which they are loaded. For this purpose a wall of stone or a good mound of turf and soil will be found serviceable, and in most situations the latter is to be preferred, as upon its summit may be planted the White Hawthorn (*Cratægus Oxyacantha*) which will soon spring up and add to the height of the low or screen. Such a wall or mound should not be less than 6 ft. high, and wide enough to take two or three rows of Hawthorns. As soon as this is formed, open ditches should be cut to carry off all superfluous water. Immediately behind this barrier may be planted, in pits which have been thrown out some time before for the soil to meliorate, short but strong plants of Sycamore, Dutch Willow, Norway Maple, and Scotch Elm. The broad leaf and strong branches of the Sycamore and the upright habit of growth of the Dutch Willow particularly adapt them to such situations. The Norway Maple, too, is very hardy, and in its own native habitat grows close down to the sea. These may be looked upon as the standard trees, and they may be placed at distances of about 12 ft. The intermediate spaces may then be filled up with the Scotch Pine and Pinus Pinaster, or Cluster Pine. The former will flourish upon the more elevated site; and though the latter is not well adapted for high ground, still it will grow freely upon most parts of our coast. It will also succeed in a pure sand, and in close vicinity with the sea. By the aid of the nurses, the whole area should be filled up to distances of 3 ft.

In forming such plantations it is not desirable to use trees of more than from 18 in. to 2 ft. in height, which should be well furnished and strong in proportion to their height. The Pinasters may, if reared upon soil of ordinary quality, be about three years old. It should be remarked that the Sycamore and Maple do not flourish upon very poor, thin, or Mossy soils, and, if after two years' planting these and the Elms are not found to be making satisfactory progress, they should be cut off at the ground. April will be found a good time for commencing seaside plantations, as from the great exposure, autumn transplants often suffer considerably. The growth of the Pinasters may be slow at first, but after about twelve years' they will shoot up rapidly. As soon as the plants begin to crowd one another they should be at once thinned out to prevent their being drawn up and weakened. One great cause of failure is the use of tall plants placed at intervals too far apart for mutual protection. A sprinkling of Elder may be found useful, as it proves a good nurse and is very hardy.

At the commencement the planter should confine himself to the level ground, near the water, and the lower part of the slopes, and afterwards push forward his work in zones. As soon as the first belt is well established, and its progress will be in a direct proportion to its depth, he may follow up with the Beech, the Turkey and evergreen Oaks, Corsican Pines, Mountain Ash, Service Tree, the Abele and Ontario Poplars, and the Huntingdon and Bedford Willows; while as an undergrowth to thicken the front lines he may make use of the Mahonia, Gorse, Broom, Barberry, Privet, and Sea Buckthorn. The last will grow upon almost any exposure, sometimes attain-

ing the height of 12 ft., and as its young shoots are thickly set and the shrub is armed with strong spines, it makes a formidable fence; by plashing or layering its branches it will also soon form a dense cover. Its suckers often shoot up at a considerable distance from the parent stock. The plants used should decrease in size in proportion to the elevation, and every succeeding zone should have its strongest plants immediately behind the last of the former belt. The Scotch Fir is particularly useful on account of its retaining its foliage throughout the winter. The Larch in such situations seldom proves very serviceable, unless it is planted in large masses.

The value of the Pinaster as a nurse is mainly owing to its bushy habit of growth, and its thriving on apparently barren sands. The latter property is mainly owing to its sending down a strong tap root, and being at the same time furnished with abundant lateral roots, which, in their turn, are well supplied with numerous small rootlets. Its cones hang in clusters of sometimes not less than eight, hence the name of Cluster Pine. Its bark is deeply furrowed, and the stem very rugged. Its adaptability to exposed places may be seen by its growth in Wigtonshire and upon the island of Bute, where it attains 60 ft. and upwards. It is not suited to chalky or calcareous soils. This tree is extensively used in the south of France for fixing the dunes or moving sandbanks along the coast, and especially between the estuaries of the Gironde and Adour, where there is what is locally named a littoral dune of over 120 miles in length. To stop the progress of the blowing sands the inhabitants begin by erecting a continuous line of fencing about 325 ft. from high water mark. Stout planks are put in, standing about 3 ft. 3 in. above the ground, with intervals between them, through which the sand drifts and serves as a backing. As the sandbank rises the planks are lifted up by means of levers and hooks. A rough, wattled fence is also run along behind the line of paling, and as this cannot be raised it has to be renewed from time to time. The paling is estimated to cost about 2s. per lineal yard, and the annual cost of repairs and raising 3½d. per yard. The wattled fence costs 2d. per yard. As soon as the littoral dune is formed the land immediately behind it is sown down with a mixture of Pinaster, Furze, and Broom seeds, and a layer of Brushwood or Furze is spread over the whole to keep the seeds from blowing away. A few shovels of sand fix the Brushwood. Furze for cover is preferred wherever it can be obtained, on account of its manurial value to the young crop. This light covering has to be maintained for about four years, when the plants will have risen sufficiently high to protect themselves. A strong-growing Grass (*Psamma arenaria*) is also sometimes sown between the plants, and the stalks of this push upwards as the sand rises. The wood of the Pinaster is extensively used in the south of France and in Spain for railway sleepers, and in its own native habitat, in warm latitudes, the Pinaster is tapped for its resin. The tree is first prepared by being exposed as much as possible to the action of the sun.

A. J. BURROWS.

NOTES & QUESTIONS ON TREES, SHRUBS, & WOODLANDS.

The Fever Gum Tree (*Eucalyptus globulus*) about London.—The late Mr. Standish, of Bagshot and Ascot Nurseries, made experiments on the growth of this tree extending over a series of years. He told me that he found it was invariably killed when the temperature got below 4° Fahr., never standing more than 28° of frost. Thus its average life in the south of England would not be more than about ten years, though we have been free from such severe cold for the last sixteen years.—C. W. Dod. [The truth about the Eucalyptus has long been known to anyone who takes much notice of half-hardy trees in our gardens. This does not prevent people who have not done so writing to the "Times" and other papers, and advising its being planted about London, it being wholly unsuited for the climate. Some guilty of this might be expected to know something of the subject. This tree sometimes grows fairly well in the south of England and Ireland, but I have never seen a tree in any part of the country that seemed really healthy or vigorous, or had any of the peculiar grace that this tree and others of its family show, where the climate is really suited to them. It grows well in Southern France and Europe generally, but not nearly so well, so far as I have seen, as in California, on the plains near the coast. What other Gam trees may do in our climate

remains yet to be proved. There is reason to suppose that other kinds will be more hardy. To ascertain which, if any, of the many species are hardy and suited to the climate of England, is one of the subjects that may, perhaps, be thought worthy the attention of horticultural societies, of botanists, and "scientific" horticulturists, as soon as such important questions as fungi parasitic on the stickleback have had their due share of attention.—W. R.]

Autumn Tints in Hardy Azaleas.—The beauty of the fading foliage in the case of deciduous trees has often been referred to in THE GARDEN, but nothing has hitherto been said about deciduous Azaleas, the leaves of which are now brilliantly coloured. Here they are planted in groups on the outer edges of shrubberies and woodlands in company with Rhododendrons, and their tints are more strikingly conspicuous than those of anything else, not even excluding the Virginian Creeper, and the effect is much more persistent. Rhododendrons, I find, are already full of blossoms in various stages of expansion; some of the trusses, indeed, look more like June than October.—J. GROOM.

Irish Yews when Old.—Although Irish Yews are useful where the strictest formality of growth is desirable as central objects in geometric gardens, for instance, or in scroll work laid in Box, I am by no means captivated with their appearance when left to grow unrestrictedly. The branches, which get too heavy to maintain their erect form without support, spread out when old in anything but an ornamental manner. The Irish Yew is, in fact, one of those trees that do not appear to advantage if its natural mode of growth be left unchecked, and where a pyramidal tree is desired I consider that the Cupressus funebris, or Funereal Cypress, is very superior to it in habit and less sombre in tint.—J. G.

Transplanting Large Trees.—For the last twelve months we have been moving large trees from 10 ft. to 20 ft. in height, and having heavy balls of earth. During the months of July and August we left off, and again set to work, being anxious to get the planting done before winter set in upon us. Those trees which were transplanted in June and the beginning of July look quite as well as those planted earlier in the season. We left off planting all Conifers when their growth was breaking into a shoot. Hollies and the common Yew we followed up the planting of even after they had made 6 in. of young wood, and with no bad result. We have three very useful and handy tree-lifting machines, made on purpose for our improvements. They will lift trees with care from 5 cwt. to 5 tons and upwards. With our trained staff of men we can plant six large trees in the day, besides conveying them a quarter of a mile, which I consider is a gain of twenty years or more in forming shelters and new shrubberies.—J. MILLER, *Clumber*.

— I quite agree with Mr. Gillett (p. 366) with regard to moving trees without balls; to save the roots is of far more importance than to move a mass of soil. In fact, I am of opinion that very often the ball of earth moved with so much trouble and expense secures the destruction of the tree, a circumstance which happens in this way: Newly-moved earth is more readily penetrated by water than more solid soil; the feeding roots, therefore, being all contained within the ball itself, gradually exhaust it of moisture, and, as this becomes drier and drier, any water given runs off as it would off a duck's back; and, although watering is persisted in, the tree or shrub perishes from want of it. In all cases where a tree or shrub is moved with a ball, a rim of soil should be placed upon the surface within the circumference of the ball, so as to form a sort of basin, in which all water should be poured. This ensures the soaking of the ball, which cannot be brought about in any other way.—T. SMITH, *Newry*.

An Elm Tree in Kensington Gardens.—At the end of the Long Water in Kensington Gardens, on the west bank, close to the fountains, and surrounded by a seat, stands a noble and beautiful Elm. There is one of the same sort on the opposite slope, and a few years ago there stood higher up on the same slope a still finer specimen. It was blown off, and the stump which remains has sprouted with vigour. The habit of the tree is not fatiguate, but branching, as the Wych Elm. The trunk, instead of being level in surface, as is the case both with the Wych and field Elm, is broken into grand buttresses by the roots, leaving great hollows between. The twigs feather nearly as lightly as the Birch, and the leaves, which are long-shaped and of a vivid green, clothe the massive limbs as thickly as the delicate twigs, giving the tree the appearance of a vast Fern. What is this tree? By the descriptions in London it might be either *Ulmus effusa* or *Ulmus viminalis*. *Ulmus effusa* I have been unable to get—nobody cultivates Elms now; *Ulmus viminalis* I have only seen in nursery gardens in the shape of a miserable, chilly twig, grafted on a long naked pole of field Elm, a thing neither of use nor beauty. To obtain suckers from the trampled ground of Kensington Gardens is impossible. Can any of your readers tell me, not only what the tree is, but where I can get good specimens, not grafts, for ornamental planting? The tree evidently revels in London climate, and in Kensington Gardens they grow trees for planting out, but I have not seen among them one specimen of this glorious tree.—BERNARD COLERIDGE, in "Gardeners' Chronicle."

GARDEN DESTROYERS.

THE GOLDEN ROSE BEETLE OR ROSE CHAFER.

(*CETONIA AURATA*.)

This handsome insect is one of our most beautiful British beetles, and no one can help feeling sorry when they find one nestling in a Rose to think that such a handsome beetle should be in any way injurious to our gardens; but fine feathers do not always make fine birds, and the same proverb unfortunately applies to insects, for though the damage caused by this insect to our Roses is not very great, as the beetle never appears in great numbers, still it does frequently spoil the blossoms by eating the lower and more juicy portion of the petals; and, as it flies remarkably well, is able very easily to go from one flower to another. It is also very fond of the flowers of the White Thorn, Lilac, Mountain Ash, Elder, Pæony, and Candytuft; and in the kitchen garden is often mischievous amongst the flowers of Strawberries and Turnips which are intended for seed by destroying the stamens, thus rendering the flowers unfruitful. The beetle is easily seen when resting on a flower, and as it generally feigns death when disturbed it can be caught and destroyed without difficulty. It may be well to mention that all insects, grubs, snails, slugs, &c., may be killed easily and quickly by putting them into boiling water, or, which is perhaps better, by placing them in some vessel which will hold water, and then pouring boiling water over them. In either case death is almost instantaneous. The grub, which is very similar to that of the cockchafer, and is often mistaken for it, does much damage by eating the roots of various plants, amongst which the Strawberry may be particularly mentioned. Living entirely underground, as they do, the grubs are very difficult to find, but they generally make their presence known by the plants, on whose

Rose Chafer (*Cetonia aurata*).

roots they are feeding, drooping and withering away without any apparent reason. Where plants are attacked in this manner search should be made at their roots as soon as they show the first signs of flagging; for they leave the plant as soon as it begins to die. Flowers of sulphur strewed on the ground and then dug in is said to be a good preventive against the attacks of the cockchafer grubs, and it would doubtless answer as well in the case of these grubs. Rooks, starlings, black-birds, thrushes, and other birds devour them whenever they can find them. The beetle makes its first appearance in May, and in June digs a hole in some light soil in which it lays its eggs. The young grubs when hatched commence feeding upon the roots of almost any plants they meet with. They do not attain their full size for two or three years, during which time they remain underground feeding upon various roots. Curiously enough these grubs are frequently found in ant nests, and in consequence are sometimes called the king of the ants. Their connection with the ants is not at present understood. They do not seem to be molested in any way by the ants, nor to disturb them, nor do either seem to derive any benefit from the other. Curtis, in his "British Entomology," states that in Germany some cattle dealers attach supernatural powers to these grubs, and feed them in boxes, believing that if they thrive so will their cattle. When full grown they descend some depth into the ground, and form rough oval cases, about the size of Walnuts, composed of earth and covered outside with pellets of earth and their own droppings. In these chambers they change into chrysalides, appearing as perfect insects in May. The Rose beetle is about $\frac{3}{4}$ in. long, and of a very brilliant shining green colour, often with a golden or rosy tinge; on the wing cases are various spots and streaks of a yellowish-white colour. The wings are very long and powerful, but when the insect is at rest they are completely covered by the wing cases. The antennæ are short, the last three joints, which are much produced at one side, forming a club when closed, but opening

like a fan at the will of the insect; the legs are strong, the front pair bearing three strong spines, which enable the female to make the holes in the ground for the reception of her eggs. The grub, when fully grown, is about $1\frac{1}{2}$ in. long and about 4-10ths of an inch in diameter, being somewhat thicker towards the tail; it is whitish, fat, much wrinkled, and has three pairs of reddish-brown legs, one being placed on each of the first three joints of the body, which is sparingly clothed with fine reddish hairs. The head is brownish-yellow, furnished with a strong pair of jaws. Though it very much resembles the grub of the cockchafer, it may be distinguished from the latter by its having a hard, rusty-coloured spot on either side of the first joint of the body, and by its body being covered with hairs.

S. G. S.

ANSWERS TO CORRESPONDENTS.

Ants in Vineries.—We are infested with black ants, which came with a quantity of Orchids three or four years ago. This year they have got into the Vinery, and are eating the Grapes. In the early house they destroyed a good many bunches, and they are now attacking those in the late house. Boiling water is thrown down their runs every day, but it does not appear to lessen them. How can we get rid of them?—T. [I have occasionally been much troubled with these pests, more especially among ripe Peaches, and the best remedy yet tried has been the placing of moist sugar and saucers of syrup near their runs. This they have preferred to the Peaches, and whilst they were feeding off the sugar we destroyed them wholesale. Another good plan is to sprinkle about their runs fresh guano, and though apparently it does not destroy them, they soon shift their quarters.—W. W. H.]

Hypericum Coria.—I regret not being able to assist "W." in obtaining the true plant bearing this name, as I know it to exist only in one or two collections in this country, and in those in but small specimens; but probably it is procurable in some of the Continental nurseries; for instance, at Fröbel & Co., Zurich. As to the *H. tennicaule*, from the Himalayas, I am very pleased to hear that the name is in gardens, as it is very rare, even in its native habitat; but if by chance it should not be true to name, and is the same species as there is in quantity at Chiswick, it is no desideratum with me; however, I should very much like to see it when "W." has it in flower. *H. virginicum*, I fear, has quite disappeared from English gardens, and for some unaccountable reason it has not been re-introduced in quantity.—W.

Forcing the Canadian Wonder Bean.—"J. G." (p. 307) may obtain this Bean in quantity by forcing it in pots like any other variety, and supporting it well with stakes before the length of the stem or weight of the crop bears the stems down.—CAMBRIAN.

I have for three years generally sown about two-thirds of this variety, and the other part of Osborn's Forcing, which is a good Bean, but not nearly so large and hardly so prolific as the Canadian Wonder. The latter has one drawback: in May and June it grows much too strongly, and consequently does not show much flower; therefore, at that particular season I always grow Osborn's Forcing.—A. HOSSACK, *Ragley, Alcester*.

Fruit Trees on Walls.—Oblige me by some instruction as to the treatment of a few wall trees in a suburban garden. The aspect is on three sides—south, west, and north; the soil, stiff clay. This latter has been rather deeply dug out, and good mould and stable manure substituted. Is anything else desirable in the way of guano or other artificial appliances? The trees consist of Peaches, Apricots, Nectarines, Cherries, Plums, and Pears, the last on the north wall.—C. E. S., *Willesden*. [Pruning and training the shoots are all that is necessary until midsummer, when a good mulching of manure may be placed over the roots. This being done, guano or other artificial manures will be unnecessary. As regards pruning and the general treatment of fruit trees, exhaustive articles have been frequently given in THE GARDEN, and the weekly calendar always contains information on the subject.—S.]

Asparagus Beds.—Can you furnish me with instructions for making a new bed? I have directed the making of two beds in my lifetime, the last about fifteen years ago, but I gather that there are improved methods now extant. The depths and distances of the plants I particularly desire.—AN ELDERLY AMATEUR. [The ground should, in the first place, be bastard trenched; a depth of 24 in. of soil will be sufficient if well enriched with good stable manure, decayed turf, and a liberal sprinkling of crushed bones in each trench. Our method of bastard trenching, which we prefer to bringing the poor subsoil to the surface, is, to commence with a trench 2 ft. wide, taken out to a depth of 12 in., and wheeled to the end of the ground to fill in the last trench, the manure being first placed on the ground in heaps at convenient distances apart. In the bottom of the first trench the workmen put in a good coat of manure and dig it well down, sprinkling more manure on the fresh-turned soil before the top spit from the second trench is put on it. After removing the top spit from the second trench, the loose soil left by the spade comes to the surface of the first trench; this method brings the middle soil to the surface, the surface soil to the middle, and the subsoil remains at the bottom, having been well broken up and enriched with manure. Towards the end of March or beginning of April the ground will have subsided and be ready for

planting. The Asparagus may be planted in shallow trenches if intended to be grown on the French system, or on the surface if it be grown in the usual way, simply spreading out the roots, and covering them with 5 in. of light, rich soil; place each plant $2\frac{1}{2}$ ft. apart in the row, the rows being 4 ft. asunder; good strong one-year-old plants may be planted as soon as they have started into growth 2 in. or 3 in. long, planting those which have the strongest shoots and discarding those with weak ones. At the commencement of the third year after planting (provided the plants have grown well) some Asparagus may be cut, but the cutting must not be severe, and ought to cease early if a strong and permanent bed be desired. A full supply should not be cut until it is four years planted. We use one-year-old plants, and wait until the commencement of the fourth season before cutting. A good dressing of manure in the autumn applied to the crowns of the plants, with a sprinkling of salt in the latter part of March, and the same of nitrate of soda a month later, which may be repeated again in May, gives the best results.—W. ALLAN, *Gunton Park, Norwich*]

Large Specimen of Pinus insignis.—Allow me to inform "P." (p. 366) that there was a fine specimen of *Pinus insignis* at Castle Lesley, Co. Monaghan. It was killed in one night during the severe frost of 1866. It was allowed to remain for a considerable period in hopes of recovery, but without success. Smaller specimens were also killed at the same time.—P.

Grafting Hollies.—Is this a good time of the year for performing this operation? I have heard that *Rhododendrons* do well grafted in autumn, and so probably I have thought would Hollies.—M. C. D., *Tralee*. [If the stocks are established in pots, Hollies will do well grafted in autumn if protected in frames. April and May are the best months for grafting Hollies in the open ground.—E. F.]

Red-berried Elder (p. 363).—In Peebles-shire the Red-berried Elder when in fruit forms quite a striking plant. I have seen it at Daru Hall (Lord Elibank's, between 550 ft. and 600 ft. above the sea), Portmore (Mr. Mackenzie's, 700 ft.), Dalwick (Sir J. Nasmyth's), and at Stobo Castle (Sir Graham Montgomerie's). These two last places are close to the Tweed, and 600 ft. above the sea level. I can only compare the look of the bushes to that of *Pyrus japonica* in full flower. Along the coast here this Elder always flowers and sets its fruit, but in many seasons the berries drop when only half-coloured, and the bunches have never the luxuriant look of those on the Peebles-shire trees, which also are very superior, on account of their freshness and freedom from dust, to the fruit which I have happened to see on the Continent. I may be wrong, but my belief is, that, in order to appear in its true character and perfection, this shrub, like many other plants, depends more on altitude than on either soil or exposure. I should add that the Elder grows most luxuriantly in marshy ground, a fact exemplified by the burnside at Dalwick, and by the pond at Portmore. I am told that both sheep and rabbits injure Elders.—F. J. HOPE, *Wardie Lodge, Edinburgh*.

Orchard-house Vines.—I have a lean-to Vinery 24 ft. by 12 ft. wide. Instead of planting the Vines to cover the roof I wish to plant them in rows to upright stakes. How far should the rows be apart, 4 ft. or 5 ft.? I propose planting them 4 ft. and 3 ft. apart in the rows, to cross at the top to the next stake, so as to form an arch. If I plant them 4 ft. apart in the rows I shall only then have three rows, but at 3 ft. four rows. But perhaps 3 ft. will be too close. Also, will you kindly say which is the best Muscat Grape to plant in a Vinery not to be heated—Muscat Hamburg grafted on the Hamburg, or the Madresfield Court Muscat, or Cannon Hall Muscat? and will the White Frontignan do?—VINE [Four ft. apart will not be too much between the rows, and 3 ft. between the plants in the rows would do. If the rows run from the back of the house to the front you will, of course, have the longest stakes at the back, diminishing them in height in accordance with the slope of the roof down to the front. Madresfield Court would be better than Muscat Hamburg, but it is not a Muscat. Black and Early White Frontignan would do; also, Black Hamburg, Mrs. Pince's Black Muscat, Black Prince, Royal Muscadine, and Graham's Muscat Muscadine.—S.]

Sparaxis and Crocosmia.—I have lately bought some bulbs of Sparaxis, but cannot find any directions for cultivating them. Will you kindly help me in this matter? I have also some bulbs of *Crocosmia aurea*. As these bloom in autumn, I presume they should not be planted until spring. As I am desirous to place my plants in the border according to their relative height, perhaps you will be good enough to name the height to which Sparaxis usually grow. It is stated by some that they grow 2 ft.; by others that they are more dwarf in growth than *Ixia*.—E. H., *Tavistock*. [Good directions for the culture of these are given in Messrs. Barr & Sugden's catalogue, from which we extract the following: For indoors.—Plant from September to December five or six bulbs in a 5-in. pot, using a compost of turfy loam, leaf soil, and silver sand. Make the soil firm about the bulbs, then place the pots in a cold pit or frame, plunging them in ashes, and withhold water till the plants appear, then give sparingly at first. The lights should be left off except during wet or frosty weather. Early in February, if the plants are sufficiently advanced, remove them to the greenhouse, or where there is a very gentle warmth, and place the pots on a shelf close to the glass, and attend to the plants with water till they are in bloom. For outdoors.—Choose, if possible, a light loamy soil, thoroughly drained, and with a due south aspect; if backed by a wall or greenhouse all the better. Plant the bulbs from September to January, at a depth of from 3 in. to 4 in. and from 1 in. to 3 in. apart. As the early plantings make foliage during the autumn, it is necessary to give protection during severe frost, and this may be best accomplished by hooping the beds over and covering when necessary with

mats; or if tiffany is used it may be allowed to remain till all danger from severe frost has ceased. The plantings made in December and January require no protection in winter, but as they will flower later in the summer than the early plantings, an aspect should be selected where the sun's rays will be somewhat broken; attention to this will prolong the blooming period. On stiff soil, or soils which are rather wet in winter, the beds should be raised, and the bulbs surrounded with sand, taking care that they are planted an inch or two above the level of the path, and where protection cannot conveniently be given, planting should not be done till December or January. Some of our late-planted bulbs were this year in flower in August. Our finest effect, however, was from beds which had been two years planted, and protected simply with straw mats such as the Dutch use for their frames in winter. On one occasion we made up a temporary pit against an old shed, placed 1 ft. of good soil in it, and protected during the winter with shutters, and we had a fine display of flowers. These directions are applicable to other Cape bulbs, such as *Ixias*, *Tritomas*, and *Babianas*, besides *Sparaxis*. The latter attains a height of about 1 ft. *Crococinia aurea* grows about 3 ft., and should remain out of the ground till spring.]

Mushroom Culture.—Will some fortunate grower of Mushrooms kindly inform me how to grow them? do they require heat? what is the best manure for them? and how can one destroy woodlice which eat up the spawn as soon as it begins to spread? should the bed be watered frequently?—E. [Provided that the materials are at command, nothing can be simpler than Mushroom culture. The best and most lasting material is two-thirds horse droppings and one-third of light loam. The manure should be had fresh from the stable, be thrown together to heat, and the soil spread over and intermixed with it. Turn it over each day for a week to allow the obnoxious gases to escape, and the soil to get thoroughly incorporated with it. At the end of that time it may be formed into a bed, which should be as firm as possible by treading or beating as the work proceeds, and it should be at least 2 ft. in depth. Bottom-heat thermometers or test sticks should now be put into the manure, and when the heat has declined to 75° the bed may be spawned by dibbling into it, 2 in. deep and 9 in. apart, pieces of spawn the size of a bantam's egg; then beat down the surface and cover the whole with good light loam to a depth of 2 in. If however, there be any danger of the bed re-heating above the 75° named, the soiling had better be deferred till that danger is past. The bed should now be covered up with a thin layer of straw or long litter, over which lay mats; and no watering will be requisite till the Mushrooms make their appearance. Provided the temperature of the house does not go lower than 45°, fire-heat should not be applied; should it get lower than that, employ slight fires, and neutralise their drying effect by occasionally damping the floors and walls. To prevent the depredations of woodlice, procure a couple of toads and encourage them to stay in their lodgings by furnishing them with a saucer of water at which they can drink. Under the above treatment Mushrooms should make their appearance in about six weeks; and if the weather be bright and drying, water may be required, but, as a rule, unless the bed seems very dry, it is best not to water till the Mushrooms appear. An arid atmosphere and over-watering of the beds are fatal errors in Mushroom culture.—W. W.]

Cherry Plum as a Hedge Plant.—Can you give me any information about this Plum (*Myrobella*), which is advertised as a good hedge plant? Does it answer well for that purpose? and will it grow under timber?—J. S. [That which makes the *Myrobella* Plum especially valuable as a hedge plant is the vigour with which it grows in all kinds of soil, even in the poorest and most exhausted, its hard, unyielding wood, its long, sharp spines, and its great hardiness and non-liability to disease. It grows fairly well under trees, but, of course, not so well as in more open positions. It comes into leaf much earlier in spring, and retains its foliage much later in the autumn than *White Thorn*. At the present time (Nov. 5) it is as green as *White Thorn* in June. Not a leaf as yet shows any symptoms of decay, although we have had some severe frosts. This adds greatly to its value for ornamental purposes. It may be treated, in planting fences, in all respects like *White Thorn*, except that it is not necessary to plant it quite so closely; from four to six plants per yard are sufficient for ordinary purposes. If a strong fence be required very quickly the plants should not be cut at all during the summer. They should be shortened to about one-third of their height at planting time, and each succeeding winter, or time when they are devoid of leaves, they should be shortened to within about 9 in. of the height to which they were cut the previous season till the height which it is desired that the fence should ultimately attain is reached. It may then either be clipped in the ordinary way as appearances require, or the superfluous shoots may be trimmed off every winter. This Plum is also valuable as an ornamental shrub or small tree, and as a stock for the *Apricot* and Plum it is invaluable, succeeding so well as it does on poor soils.—J. E. EWING, *Norwich*.]

Methods of Preparing Green Corn for the Table.—Allow me to inform "*Derwent*" (p. 275) that we do not use the common field Corn, from which meal is made, but a variety called *Sweet Corn*, which is more succulent, sweeter, and of better flavour. The best varieties are the *Early Minnesota*, *Early Concord*, and *Late Evergreen*, and by planting at intervals, Corn may be had for the table until early frosts set in. *Sweet Corn* is ready for use when in the milky state. If, on pressing the thumbnail upon a grain, it yields readily and the milky juice flows, it is in the right condition for use. Now take the ears, strip off the husk, pick off the silky, adhering filaments, boil the ears about thirty minutes, and serve hot; eat with a little salt and butter. It is not considered improper to eat Corn from the ear, taking the end of the

cob in the fingers, or it may be cut off on the plate. Sometimes the ears are roasted before a fire and served in the same way. Another way is to take a knife and cut the Corn from the cob. Cook it in a saucepan, with a very little water, about twenty minutes; then add a little butter, salt, and milk, and cook for ten minutes longer. A third plan consists in taking *Lima Beans* when fresh and tender, cook them about half-an-hour, and then add an equal measurement of Corn cut from the cob, as directed in the previous receipt; boil the whole twenty minutes more, and season with salt and butter. This is called *Succotash*, and it is said to have originated with the Indians in New England. A fourth method, which is considered to be very satisfactory, is to take the ears of Corn, and with a sharp knife cut a thin slice from the tips of the grains; then with a dull knife scrape the Corn from the cob in a pulpy mass. It will probably take a dozen ears of Corn to furnish sufficient for the purpose. Add half a pint rich, sweet cream and a little salt; put it in a shallow pan over the fire, stir often, lest it adhere to the bottom of the vessel, and cook for about twenty minutes. Sweet milk and butter may be used instead of cream if more convenient. Any one who uses *American Sweet Corn* in any one of these ways, during a single season, will hardly be willing to be without that luxury afterwards.—C. H. S., *Niles, Alameda Co., California, U.S.A.*

White Azaleas in the Open Air.—Did you ever know the white *Azalea* being grown in this country out in the open garden? A friend of ours says that he has seen "hedges of them in England," and we doubt this fact. [The white *Azalea* thrives well out-of-doors in various parts of the southern counties both of England and Ireland.—V.]

Eradicating Bindweed.—How can I eradicate *Bindweed*, which grows very thickly in my garden?—O. S. W. [If as many of the roots as can be found are removed, and the land afterwards planted with crops which will admit of the easy and frequent use of the hoe between them, you will master the *Bindweeds* in time, as they will die from want of that support which foliage alone can supply. But hoeing must be done well and often.—S.]

***Erodium pelargoniflorum*.**—Allow me to inform Mr. J. Sisley that the specific name of this *Erodium* should have been as here written, and not *pelargonifolium* (p. 363). As to the adaptability of its name, it should be observed that its flowers resemble those of a *Pelargonium* (notably those of *P. bicolor*) more so than the majority of *Erodiums*, which usually are regular and nearly circular in outline; hence I consider it as being very aptly named.—W.

Names of Plants—*J. R.*—*Dendrobium palpebræ* or *bicolor*. *A. H.*—*Viburnum Opulus*.

***Aralia Sieboldi*.**—This is just coming into flower with me in the open air. Is not this rather unusual?—*J. K., Eastcott Cottage, Pinner.*

Scottish Horticultural Association (Nov. 5).—Mr. C. S. France read a paper on this occasion on "*Ornamental Planting*." Kent, he said, in the beginning of the last century was among the first to lay down principles for the guidance of the planter for landscape effect. He also spoke of the proper distribution of trees, and referred to the particular schools of landscape planting and their various peculiarities. The principle underlying the styles of different nations was found in the outward features of each country. The primary rule to follow by all planters for effect was to imitate Nature. To have unbroken plantations and at other points vistas so as to make the ground appear as large as possible was an important principle to be borne in mind by all who plant to improve the beauty of the landscape. Mr. Alex. Mackenzie read a paper on "*Early-flowering Pelargoniums*." He described the mode of propagation from cuttings and from roots which he adopts in the Warriston Nursery, and explained the treatment followed by him in every particular, from the cutting-pot to the flowering specimen plant. He put in his cuttings principally from March to November, but the operation for the most part might be performed all the year round. The temperature, airing, and staking were explained. The result of Mr. Mackenzie's culture of this plant was that he had a houseful of them in excellent health bearing a profusion of bloom for twelve or thirteen months, a result which he could not produce with any other plant. The principal sorts in his collection were the following: *Madame Tonlegeon*, *Digby Grand*, *Mdme. Lemoine*, *Triomphe de St. Mandé*, *Bridal Bouquet*, *Annie*, *Fire King*, *Mrs. Bradshaw*, *Magnet* or *Marchioness of Lothian*, *grande floribundum*, and *Red Gauntlet*. Mr. James Gordon also read a paper on the "*Osmunda regalis*" in its native habitat at Camstradden, where acres of this much-prized Fern were to be found. He stated the different conditions under which it luxuriated on the banks of Loch Lomond, the frosts attaining the height of 6 ft. Messrs. Dickson & Co. exhibited flowers of the *Schizostylis coccinea* from the open air; also blooms of *Veronica speciosa* and *Violas Golden Gem* and *Lilacina*. Messrs. Todd & Co. showed flowers of the crimson *East Lothian Stock*. Mr. Henry Kinton sent blooms of *Vallota purpurea* in great beauty at this season. Mr. George Donaldson, sent a new seedling late *Kidney Potato*, which was highly commended by the new Vegetables Committee.

Potatoes at the Paris Exhibition.—In reply to Messrs. Carter & Co.'s correction (p. 402) I have to say that when I inspected the collections of Potatoes no awards had been announced, but no one acquainted with Potatoes could overlook the fact that Mr. Porter's exhibits in the classes of twelve and twenty-five dishes were a long way ahead of Messrs. Carter's in the same classes. Of course, the blending of the entire collection in one would easily give Messrs. Carter the victory; but, surely, this was not in accordance with the schedule, which distinctly names the three classes.—W. W. H.

"This is an art
Which does mend Nature: change it rather: but
THE ART ITSELF IS NATURE."—*Shakespeare.*

THE FLOWER GARDEN.

AN "ALPINE GARDEN" IN VIENNA.

NOTWITHSTANDING the healthy change witnessed in our gardens in recent years, it is so seldom that one meets with an interesting collection of Alpine plants on a rock garden presenting any fresh points of interest, that it is desirable to notice such when they are met with.

In an obscure corner of the Belvedere Gardens at Vienna there is an Alpine garden meriting attention. By the way, why is it that an Alpine garden is considered by amateur landscape gardeners and others as only fit for obscure corners? Because hitherto the attempts in this direction have been, as a rule, nearly always ridiculous—a good reason for their usual site. But a properly formed rock garden would be an object to charm the eye in many an open position, and the more open and exposed the better. It does not follow from this that it should be placed in the middle of a level lawn; but neither should it be an object to place in the shade of trees or hid by a hedge, or hid away in any obscure corner, or protected by a piece of canvas on rollers. This Vienna garden is in a nook surrounded by walls, and the surroundings "take away" from the well-formed rock garden, where a great number of rare plants are extremely well grown, and not a few Tyrolese and Balkan plants which are seldom or never seen in our gardens. The general principle in making the garden has been to secure a series of compartments of various sizes with the view of growing a species in each—in fact, the "pocket" system so much and so well used by Mr. McNab in the Edinburgh Botanic Garden. But this system of compartments, instead of being square, as is mostly the case at Edinburgh, is carried out in an irregular and more natural way, so to say, and is so far an improvement; for it need hardly be said that the variety in form and in wants of Alpine plants allow of great variety and naturalness being followed in forming homes for them, so to say. In fact, it is quite easy to do all that is required without allowing the square form to obtrude itself, and any kind of formal receptable must prove detrimental to the effect of the Alpine garden. In addition to these divisions here, there are level and sloping portions in imitation of "moraines," on which, as is well known, numbers of Alpine flowers grow as well as on the rocky portions, or far better. This system might be carried out with advantage to a much larger extent; as what the plants want, as a rule, is a deep, firm rooting-ground, and not always to be transfixed on or against rocks or stones. These are often more serviceable in preventing evaporation and securing drainage and a deep, not over rich, medium for the roots below ground than above it. Many rare species, some of which are spoken of in notes in *THE GARDEN*, grow on these little "moraines" and among the rocks in this garden. But the most novel point in the culture of Alpine plants illustrated here was the establishment of various kinds on the face of rugged stones; that is to say, a variety of species grew from small interstices, cracks, and holes in the stones themselves. This is a most important advance in the culture of Alpine flowers, because it secures a greater vitality in the plants,

though this is accompanied by a much diminished growth; a Saxifrage or an Androsace rooted in the face of a rock or stone, and with no soil but what its roots can trace out in interstices, which cannot, perhaps, be entered by a pen-knife, must necessarily be smaller than the same species grown in the "moraine," but it is none the less beautiful. In fact, to many these brilliant flowering plants reduced in such positions to the size of Mosses have a peculiar charm; and, as mankind exposed to hardships and scant rations are usually less in need of the doctor than those who fare sumptuously every day, so these Alpine plants, living almost on the air, have the endurance, the longevity, and the fecundity of the "oppressed." And although the great majority of Alpine flowers thrive perfectly in rocky or gritty soil, there are some species which one never sees in a good state, except on the face of arid rocks. *Phytocoma comosum*, for example, on the face of the vertical rocks about Lecco, is one of the most beautiful objects seen by those who seek Alpine flowers in their native places. One plant, however, of all others that grow one would least expect to be treated in this way is so grown here, and that is the well-known *Campanula pyramidalis*, which well grown in gardens is often 5 ft. high. But in some of its native localities, at all events, it grows on rocks without soil, and in imitation thereof some seeds were sown in little crevices here, and they gave rise to a group of plants which are almost amusing in their gouty deformity at 2 in. and 3 in. high after several years' growth.

Growers of Alpine flowers know too well the ravages of slugs among them. They are probably not equally alive to the destructive doings of various grubs among them. Here whenever a withered patch is seen among the Saxifrages or Androsaces, a grub of *Pachyrhina imperialis* is found below it. Among other rare and curious plants growing here was a small shrubby *Viola delphinantha*, of Mount Athos, said to be beautiful in flower.

TRITONIA AUREA OUT-DOORS AND UNDER GLASS.

HAVING lately seen several inquiries about *Tritonia aurea* (now often called in catalogues *Crococsmia aurea*), I send a few notes on the treatment and habits of this handsome and curious autumn-flowering bulb. Few bulbs are more easily managed, or more easily lost by mismanagement, than this. The bulbs should be bought as soon as they can be got, and should be out of the ground as short a time as possible. They may be planted 3 in. or 4 in. deep, in pots or boxes, in any soil, a mixture of sandy peat and light, fibrous loam suiting them best. They may be placed anywhere out of the reach of frost, but the less they grow during winter the better. They must, however, be watered at once, and the soil must never be allowed to get dry. This is the most important point in their treatment. They succeed well as border plants in any soil except clay, but seem to like moist beds of peat soil best; they may be planted out in April or May. I have had the shoots killed to the ground by frost in May without injury to the bulb, though of course the growth was weakened and retarded. Treated as a cold frame bulb, and planted out, they will flower in the south in August, but in the north of England a month later, and in cold places it is better to bring them on for a longer time under glass and plant them out later, or to treat them altogether as greenhouse bulbs, for which they are well suited. Though tolerably hardy, there are two objections, besides the lateness of their flowering, to leaving them out all winter in the open ground—one, that they are liable to be killed in severe winters unless well protected with litter; the other, that owing to their habit of straying, in which they much resemble Lilies of the Valley, they are apt to leave the place in which they were planted, and come up where they are not wanted. It is better, therefore, to lift the whole stock in autumn; and as they may, if necessary, be potted many together, and separated when planting-out time comes, this

takes little trouble or room. I lift mine about the beginning of November. This must be done carefully; for, although the tops are not yet dead, the shoots which form the new bulbs next year are already several inches long, sometimes even more than 1 ft. These shoots are jointed suckers, not unlike those of *Triticum repens* (Couch Grass), and as soon as they have completed their horizontal growth, the nucleus of a new bulb is formed on the last joint. This young bulb then makes roots, and sends a shoot perpendicularly upwards to become the flowering stalk of next year. I have not ascertained the exact time at which the parent bulb ceases to be necessary or useful to its offspring, but I believe it to be soon after the young shoot appears above ground. The sucker connecting the new bulb with the old gradually dries up into a hard, wiry thread. When the bulbs are lifted in November for replanting, if sufficient care be taken, the last year's bulbs will be found—to outward appearance, alive and sound, like the old corms of *Gladioli*—connected with the new bulbs by these threads. If the shoots of the bulb have once been made, and been broken off, or allowed to dry up, no treatment will make it produce another shoot. I am at a loss to discover any external test by which these old bulbs can be distinguished from the new ones before the shoots are formed on the latter, unless the flower-stalk is left adhering to it. Having often found a proportion of the imported bulbs barren, I cannot help suspecting that the old bulbs are often mixed with and sold as new bulbs. But to proceed with the treatment of the bulbs when lifted: The old bulbs can now readily be distinguished by having no stalks or shoots, and may be pulled off and thrown away. It will be understood after what has been written above that anything like drying off or storing the roots in a dry place is fatal. They had better not be left uncovered for a single day. When the suckers dry up they die, and the bulb, though continuing sound in appearance, dies with them. Care must also be taken in potting to keep the long suckers at the same depth as the bulb, turning them round the inside of the pot, for if the points are brought above ground before they have completed their horizontal growth and commenced the formation of a bulb, the suckers die. When planted they must be carefully and repeatedly watered. The shoots on appearing above ground will probably all be found to touch the edge of the pot; hence, if you can spare say a 4½-in. pot for every two or three bulbs, they are in the most convenient condition for planting out again with a ball of soil when the time comes. A few years ago I lost my whole stock of *Tritonia anrea*, because my gardener, contrary to instructions, kept them without water during my Christmas holidays. *Tritonia aurea* when grown as a greenhouse plant is liable to wither just before flowering, the leaves becoming brown and drying up prematurely without any apparent cause. I suspect that this is due to deficiency of moisture at some period of their growth, but I want further information about it. The average annual increase of *Tritonia aurea* is about two and a half. I do not know how our neighbours who supply the market contrive to ripen the bulbs before the young shoots start, as in my garden these always start before the flowers are over.

ARUM LILIES (CALLAS) OUT-OF-DOORS IN WATER.

MR. HINDS' remarks on growing Callas in trenches remind me of a system which I once adopted of growing this plant as an aquatic in the open air. When well grown, this Arum is a grand plant whether in flower or not, its fine leathery leaves giving it a truly tropical appearance, but as generally grown it gets drawn or leggy, and, except when placed amongst other plants, it is not always what would be called a good habited plant. It is truly noble when grown in groups or masses, a condition, however, in which it is seldom or never seen. To accomplish this the following plan may be adopted: This Arum is well known to be half-hardy and semi-aquatic; therefore, select some sheltered nook on the lawn for it; if near a shrubbery in a recess, so much the better. Towards the middle of May collect your plants, twelve, twenty, or thirty, as the case may be, go to the brewhouse and procure one of those large, shallow vessels, known as coolers. These are either round or oval, and would hold, according to size, from twelve to thirty of

the plants. Carry the cooler to the spot selected, and place it in such a position as when filled with plants it would appear to the best advantage. When *in situ*, mark out on the Grass the space occupied by the cooler, remove it, and then remove the soil from the inside of the marked space to such a depth that when the vessel is placed in it its rim shall be about 6 in. below the surface; clear all your excavated material away. Group your plants in the cooler as you would arrange a bed of shrubs, the strongest and tallest being in the centre; fill the cooler so that the pots may stand in about half their depths in water. If the cooler should be old and leaky puddle it outside with clay. Procure some thin strips of wood (stout wire will do as well), and introduce them between the plants tolerably close together, crossing them if necessary; tack down these strips to the edge of the extemporised tank. The plants will now appear to be growing in water through a trellis. Procure a quantity of Moss, in as large pieces as possible; lay this evenly on the wire or strips of wood all over among the plants, bringing it out so that it may appear part of the natural turf. You will now have a group of Arums growing in water, but apparently growing out of the turf, and the proximity of the Moss to the water will keep it always fresh and green. Plants thus treated will present a grandeur rarely seen when grown in the usual way, and it is highly probable that treated in this manner in many localities they would survive the winter.

Ormskirk.

NOTES ON BEDDING PLANTS.

THERE has been such an increase amongst plants suitable for bedding purposes during these last few years, that some remarks on what have done well here this season may help those who intend trying new varieties. Amongst Pelargoniums, *Denil de la Lorraine* is a very fine scarlet, becoming darker towards the centre; in form it is perfect, and good in habit. *A. F. Barron*, scarlet, is also excellent in habit, and will probably supersede *Vesuvius* with us. *Comte de Gomez* is very similar to the preceding, and well worth a place in the most select collections. *Louis Veullott*, scarlet, shaded with purple, is pleasing in colour and its habit is good, but it is rather difficult to winter, and ought to be potted singly. *Rosy Morn*, a soft, rose-shaded purple, forms a good companion to the last-named variety. *Vesuvius*, one of the best of scarlets, flowered well, but its trusses with us were small. These have been our best scarlets. In the pink section, *Edith* proved to be one of the best; it is a kind which throws its flowers well up above the foliage, and which produces large trusses that stand rain well. It has, moreover, none of the seedy look which *Christine* used to assume late in the season. *Lady Emily*, a much deeper pink, has flowers perfect in form, and its growth is much dwarfer than that of *Edith*; altogether, it is a very promising variety. *Amaranth*, purplish-pink, is good early in the season, but rain is ruinous to it, especially if the nights be foggy still, in this variety we have a shade of colour which is most desirable. *La Vestale* bears very good pure white flowers, and is a more upright grower than others of the section to which it belongs. It is preferable to *Mdme. Vaucher*. Amongst *Calceolarias*, *amplexicanlis* is the best yellow for large beds, and it has been exceptionally good this season, flowering continuously. *Aurea floribunda* is very good, but rain greatly injures it. *Prince of Orange* has done well with us, and flowered for a long time. *Sparkler* is a distinct variety, with a good habit; and *Ambassador* is the best dark kind, and one which has been very attractive. *Verbena venosa* has been so good this season, that in comparison with it *Purple King* has looked weedy. The plants were raised from seed sown in January. *Crimson King* has been very good. *White Perfection* made too much growth, but flowered well. *Ageratum mexicanum*, still the best of its section for a large bed, has flowered abundantly. Of edging plants, *Pelargonium Willsi roseum*, *L'Elegante*, and *König Albert* have been very good. *Alyssum variegatum*, *Gnaphalium lanatum*, *Viola cornuta Perfection*, and *Perilla nankinensis* have all been good. *Zinnias* have been really grand, and *Phlox Drummondii* has proved itself to be one of the best and most continuous flowering annuals for mixed beds. Our principal flower beds take, on an average, about 1400 plants each, and

when in full beauty they are, as may be imagined, very attractive; all contained self-coloured plants with an edging of double rows.

Ragley, Alcester.

A. HOSSACK.

LILY GROWING.

Mr. C. W. Dod (p. 393) says: "I confess I am puzzled by much that 'Dunedin' writes." How can it be otherwise? Mr. Dod is apparently a believer in the perennial theory, that is, he believes, with Mr. Baker, "that the same bulb goes on living for an indefinite period, sending out each year a flower stem from its centre." So widespread is the belief in this theory, that some Lily growers have attempted to prove its correctness by experimental investigation, but the result has been complete failure. I write in accordance with the system which experimental facts have placed before my eyes, namely, "that the bulb that has bloomed once will never bloom again, and that the parent bulb dies each year after having bloomed." No wonder, then, that some things that I write should puzzle Mr. Dod. He says: "Does he ('Dunedin') mean to say that the stem roots are of no service to the growth and development of the flower stem?" I have said nothing of the kind. I have said that the stem roots are a fruitful source of injury to the successional bulbs, and that some (not knowing this) actually encourage them by top-dressing and heaping up the soil around the lower part of the stem. I have said this, and more on the subject (p. 371), and I have added that the cultivator who can recommend such a thing to be done could not give worse advice. *Lilium candidum*, or the White Lily, has no tendency to throw out stem roots; and yet, when it is properly cultivated, we have not a more stately or a more free-blooming Lily among the whole tribe. Mr. Dod asks: "If the stem roots are of no service to the growth, what do they feed?" I tell him, if he desires to cultivate offsets at the expense of the successional, or next year's blooming bulbs, by all means let him encourage the growth of stem roots, but not otherwise. Mr. Dod also says: "I cannot agree (with 'Dunedin') that a large Lily bulb is no better than a small one." I did not say so. I said (p. 352): "I would never think of choosing a large bulb because it was a large one. I would sooner have a medium-sized bulb of a certain character." He then says: "If to obtain a single flower stem is the object, I grant that he ('Dunedin') may be right, but experience shows me that a large Lily bulb, if planted in a healthy condition, will produce three or four stems, and if lifted next year will have divided into three or four bulbs; a small bulb will produce one stem, and will have grown at the same time into one larger bulb. In this way we gain a year's growth by buying a large bulb." Now, in all this Mr. Dod is entirely mistaken, his experience having led him astray through his misdirected views. In the first place, a large Lily bulb will not produce more than one stem, unless Nature had assigned to it, twelve months before, the office of liberating two or more germs or seed-buds emanating from the same centre. Further, if Nature had done this, it would not have been the bulbs from which the stems had sprung that would be divided into three or four, but it would be their successors (or successional bulbs) that would have been growing up within the parent bulbs at the time they were blooming. Further still, a small flowering bulb is just as likely to produce twin bulbs or triplets (two or three stems) as a large one; but a small blooming bulb will never grow into a larger bulb, for Nature has ordained that after blooming, whatever its size may be, that bulb must die. In saying that he gains a year's growth by buying a large bulb, Mr. Dod is simply deceiving himself and, possibly, others. Mr. Dod further says: "I am at a loss to know how the reproduction of Lily bulbs, on which 'Dunedin' lays so much stress, differs in its main facts from the reproduction of all other bulbs." As true Lily bulbs stand distinctly apart from all other bulbs, and as I have already said so much on this part of the subject in former papers, I shall, at present, confine myself to a few general remarks on points of some importance to Lily growers, and from which Mr. Dod himself may possibly learn something.

In some of my previous papers I have shown that the very best time for transplanting Lilies both in pots and in the open ground is when the bloom is just over. At this time the flowers of the parent bulb have faded, the roots of the parent bulb are dead, and the scales of the bulb itself are dead or dying, though they may not disappear entirely for some months to come. The new bulb and its roots are, therefore, now the only objects we have to care for; and in caring for them we should not overlook the fact that they are in this country under artificial cultivation; that they are not under the protection or the climatic and atmospheric influences of their native habitats; and that leaving the bulbs in the ground for several years in this country without being attended to is not cultivation. The roots do not grow like the stem, but are lengthened by what is termed cell-multiplica-

tion, that is, the parts once formed scarcely if at all elongate afterwards, as the growth takes place continuously at the tips alone; or in other words, the root grows in length by continued additions of new fabric to its lower extremity, elongating from that part only, or chiefly so that the tip of a growing root always consists of the most newly-formed and active tissue. If a bulb of *L. auratum* be planted in congenial soil, it will prolong its roots to a great depth, and these roots will branch out into numerous rootlets, and these rootlets will be covered with innumerable root-hairs which increase to a great extent the absorbing surface, especially if the soil be deep, free, and friable. Hence the danger of disturbing active roots, for the newer the root and the more numerous the fibres the more actively does it absorb nourishment from the soil. Previous to the plant beginning to bloom there are two sets of bottom roots distinctly visible, namely, the roots of the bulb about to bloom, and the young roots of the new or successional bulb destined to bloom next season; both taken, unfortunately, by a great many Lily growers to be one and the same set. The new bulb at this time is provided with all its organs, though not full grown, that is, it has not yet attained its full bulk. At this time the young roots are only about 2 in. or 3 in. long, but they go on lengthening, with less or more activity, during the winter months (if not disturbed), drawing nourishment from the soil and storing it up in the cells of the bulb, where it is elaborated into organic or nourishing matter, the bulb enlarging and becoming more fleshy as this nourishment accumulates. Mr. Dod asks: What do the stem roots feed? It would have been more to the point if he had asked: What do the bulbs feed? He might also have asked: What is the organised fabric of the plant? and how is its growth effected? The stem, leaves, and flowers appear to ordinary inspection to be formed of smaller parts, which are themselves capable of division into still smaller portions. Of what are these composed? To obtain an answer we examine, by the aid of a microscope, thin slices or sections of any part of the bulb. A magnified view will present on the cross section the appearance of a network, the meshes of which divide the whole space into more or less regular cavities. In whatever direction the sections are made the cavities are seen to be equally circumscribed, although the outlines may vary in shape. Hence we arrive at the conclusion that the fabric consists of a multitude of separate cavities with closed partitions, forming a structure not unlike a honeycomb. These cavities are the cells, and they form in the scales of the bulb what we may call the store rooms, full of sap, and so infinitesimally minute are these cells that it has been calculated that in a fresh, healthy, medium-sized bulb of *L. auratum* there are not less than 300,000,000 of them! By cutting across a scale in spring when full of sap, and placing it under the microscope, it will be seen that the cells are of a somewhat polygonal form, leaving no spaces between them, save that which is occupied by the walls of the cells, these being composed of what is termed cellular tissue. If the same experiment be tried after the bloom is over it will be found that the cells, which were full of nourishing sap in the spring, are now completely emptied of their contents and dying, thus verifying what I have often said, namely, "that the bulb that has bloomed once, will never bloom again, and that the parent bulb dies each year after having bloomed."

DUNEDIN.

TRANSPLANTING LILIES.

In what has been written within the last year or two upon the natural growth and cultural requirements of Lilies, there have been several matters adduced previously well known to all observant cultivators of these plants, but still well worth the circulation they have had, inasmuch as they are facts that cannot be too much impressed upon those who know little of the nature of these plants, and who, without care or through ignorance, treat them and other deciduous bulbs much in the way in which they would deciduous or evergreen fibrous-rooted plants, and yet wonder why they do not succeed. The decay of the old bulbs and formation of new ones internally is nothing more or less than what takes place in all bulbous-rooted subjects. In the case of all the scale-formed ones Nature effects her work much in the same manner—that is, a greater or less gradual throwing off and decay of the outer portion. That any one could have disputed this is simply an evidence of how little attention is frequently paid to the natural economy of vegetable life. In what has been adduced, theory and practice kept for a time pretty well abreast—a very desirable consummation. But "Dunedin's" recent teaching has the misfortune of neither according with theory nor practice. If I understand him correctly, he would have us believe that the right time to move Lilies, such as *L. speciosum* and *L. auratum*, is whilst the leaves are yet fresh and green. Now, I will deal with the theory first, looking at it upon the broad principle as affecting plant life generally of a nature

such as these bulbs are that do not form so much as a single leaf more than is necessary to keep up the reciprocal action or natural balance that is required between the roots and the leaves. If you do anything to any plant of these, or such as are of a like nature, that shortens the duration or hastens the decay of the leaves before their allotted time, you inevitably weaken the plants. So certain and universally admitted is this that it seems unnecessary to mention it. Bearing directly upon these Lilies, I may mention that some years ago whilst three or four large pots of *L. speciosum* with their flowers half expanded were being carried on a hand-barrow to one of the houses, the barrow gave way and the pots were broken, the balls of earth being more or less broken also. Having plenty to take their places, and as there were too many bulbs to keep longer together, I at once divided them, doing it as carefully and with as little disturbance of the roots as I could. The remaining flowers opened, but the leaves died much sooner than those of the rest of the stock not moved, and the effects were apparent for two years afterwards in the much fewer flowers which they bore, notwithstanding the increased room which the bulbs had in their new pots. Once or twice after this, when both this kind and *L. auratum* were moved at a similar stage of growth to the extent of a single pot or two, in each case I found that they were much weaker the year following. I have not grown nearly all the Lilies now in cultivation, nor have I any desire to do so, as a good many now cultivated have little to recommend them except it be to exemplify their worthlessness as compared with the best; therefore, I am not in a position to speak of the treatment under which all succeed, but with all I ever grow, so far as removal went, they were treated uniformly in regard to carrying out the operation as soon as ever the leaves had decayed and fallen off naturally, and I may say that thus treated I have had *L. speciosum* that has produced from twenty to twenty-five flowers on a single stem, and *L. auratum* with thirty-seven fully-developed blooms on one stem, and these not the small blossoms one often meets with in a fasciated state. I am always willing to learn, and when I see better results, than the above, traceable either to removal before the leaves had ripened off, or any other course of treatment, I shall be most ready to acknowledge the superiority of the system of cultivation followed. T. BAINES.

FUCHSIAS ON BOTTOM-HEAT OUT-OF-DOORS.

I HAVE grown Fuchsias well for some years in the open air against a south wall in front of a pit which runs parallel to another. The boiler being sunk 6 ft. below the ground at one end of the front pit, which is shorter than the other, and the hot-water pipes crossing to the back pit in a brick chamber about 2 ft. below the walk, I took out a good-sized trench about 2 ft. deep and 3 ft. wide, and at the bottom laid a 4-in. tile drain right and left of the hot-water pipe chamber the whole length of the pit, and rising to the surface at each end. The drain tiles were covered with rubble and filled up with a good, rich mixture of light loam, leaf mould, &c. The hot-water chamber opening into the stove-hole, a continual circulation of warm air goes on, and in cold weather the steam may be plainly seen rising from the end pipes when uncovered, the covering being a small piece of slate laid on, to prevent the heat from escaping and being wasted. Under such conditions the Fuchsias grow so rapidly as to afford an abundant supply of flowers until out down by a sharp frost. They are as yet uninjured, although Dahlias, French Beans, &c., were destroyed on the morning of the 3rd inst.; sometimes the Fuchsias escape, while in other winters they are killed to the ground, but the border having become sunk and been made up, their roots are now too deep to be ever killed by frost. Some of this year's shoots of Madame Cornéliassen are fully 5 ft. long, and it is one of the most showy varieties with which I am acquainted. The drooping kinds are not so good for open-air culture. I have many sorts, but one of the very best is Rose of Castile, as it is so very self-supporting, being an erect grower. I have out spikes of it 18 in. long, which are excellent for cutting and furnishing large vases. I always plant out my old plants in some sheltered place in well-prepared ground, light and rich, and they thrive beautifully. We have a bed of standard Roses at Strydoncote with an undergrowth of Fuchsias, now in its third year, and the Roses being past the Fuchsias have for some time been quite a "sight." A little bottom-heat for plants of a half-hardy character is a great advantage.

Killerton, Exeter.

JOHN GARLAND.

Stem Roots of Lilies.—Having read with surprise the statement of "Dunedin" (p. 371) as to the prejudicial influence of stem roots on Lily bulbs, I have turned out some plants of *L. auratum* which I had planted in boxes, and I find that on the stems of some of them there is a mass of roots, that certainly equal in weight the

bulb, which they, from their mop-like growth, so admirably protect; in fact, a better thatch to shield the bulb could hardly be devised, and I must certainly think that "Dunedin's" views on this point are erroneous. The bulbs were large, imported ones, planted early in spring in boxes 15 in. deep, filled two-thirds with strong garden soil; the bulbs were then carefully planted, covered with sand, and the boxes were filled up with nearly pure leaf-mould. They grew and blossomed exceedingly well, and at very different dates. The stems are dying down very slowly indeed, a circumstance which I attribute to the fact that, as the leaf-mould sunk, I kept adding fresh quantities and watering well. Some of the blooms I fertilised from one very strongly marked bloom, and the pods of seed are still ripening on the stem. How "Dunedin" would increase his Lilies when he does not allow them to seed, and scrapes the stem in addition, I do not know, as I have often found good bulbs formed on the base of the stem; and with greenhouse treatment I think that *L. auratum* would increase as much as the common white does in the open air. Some plants of *L. Szovitzianum* under the same treatment have not done well.—LONDON STONE.

NOTES AND QUESTIONS ON THE FLOWER GARDEN:

The Virginian Creeper Scrambling over Holly and other Shrubs.—The effect of allowing this beautiful creeper to ramble in this way is rich and striking. At a distance it looks as if the shrubs were clothed with glowing red fruit of enormous size. Looked through the rays of the setting sun, nothing can be more rich and beautiful; the leaves seem aglow with crimson and gold, as if the rays of sunlight were passed through as well as reflected from them. As these plants seem to do little or no injury to the shrubs, they ought to be more frequently mixed among them and allowed to ramble at will for effect. They are far more beautiful than against walls. The colours may be equally or more brilliant on the latter, but the free growth and drooping branchlets give a grace and elegance unattainable on walls. I had written thus far when I noticed your remarks about the masses of Virginian Creeper in the gardens near the Palace of Schönbrunn. No doubt such masses as those described are magnificent; but climbing up trees, or running at will over shrubs, this Virginian Creeper perhaps reaches its highest possible beauty. Home plantations, as well as shrubberies, might often be draped with this charming plant. Its chief fault is the fugitive character of its brilliant colouring; hardly does it reach its best than the leaves begin to fall, but as a free, rambling plant, the Virginian Creeper is interesting and beautiful at all stages of its growth. The ample size and verdant colour of its leaves, the drooping beauty of its shoots, and the interesting character of its clinging stems and tendrils, have been too much lost sight of while impatiently waiting for the fiery colour which heralds the fall of its leaves.—D. T. FISH.

A Few Good Autumn Border Plants:—

Anemone japonica	Helianthus multiflorus	Sedum ibericum
" alba	fl.-pl.	" spectabile
Asclepias tuberosa	Hypericum calycinum	" kamtschaticum
Aster longifolius formosus	" patulum	Senecio pulcher
Chelone barbata	Oenothera macrocarpa	Stevia ovata
" Foxi	" taraxacifolia	Tritoma Uvaria
Chrysocoma Linosyris	" Lamarekiana	" grandis
Eryngium bromeliæfolium	Pascalia glauca	Veronica corymbosa
	Rudbeckia speciosa	Zephyranthes candida
	Sedum Ewersi	J. G.

Alpine Flowers.—Hermann Muller writes to "Nature" to say that in the Alps he has found some instances of different forms of flowers in plants of the same species, which, as far as he knows, have been hitherto undescribed, of which he gives a short notice as follows: *Pelargonium sylvaticum* is in one locality near the Albulas Pass gynodioecious, with large-flowered hermaphrodite, and small-flowered female stems *Veratrum album*, *Dryas octopetala*, and *Genm reptans* are in all the localities where he has examined them androdioecious. *Astrantia minor* offers a quite peculiar sort of androdioecious, some stems bearing, as in other umbellifera, in the same umbel hermaphrodite flowers and male ones, other stems producing solely male flowers. *Dianthus superbus* seems at first sight to exist in three forms: (1) Stems with hermaphrodite flowers, being perfectly protandrous and producing a moderate quantity of whitish pollen; (2) stems with female flowers containing very conspicuous rudiments of stamens, but pollenless anthers; (3) stems with pistils remaining imperfectly developed, and with anthers containing abundance of a brown powder. At first sight M. Muller thought their flowers to be male, and the brown powder to be pollen grains; but under the microscope the latter proved to consist of grains, the diameter of which is only about one-eighth of that of the pollen grains of the hermaphrodite flowers. He supposes, therefore, these grains to be the spores of some species of fungus, and *Dianthus superbus* to be gynodioecious.

THE FRUIT GARDEN.

A PROLIFIC BULLACE.

A FEW weeks ago, Mr. Harwood, of Colchester, sent us examples of a kind of Bullace which is grown to a considerable extent in that part of Essex. Its fruiting properties are remarkable, shoots 6 in. or a little more in length being so loaded with fruit as to represent clusters of Black Grapes rather than Plums, and, indeed, a little way off they were undistinguishable from bunches of Black Hamburgh with berries a little larger than usual. Being so fruitful, the trees make little wood, and on that account seldom get beyond the

A Prolific Bullace (half natural size).

size of small, bushy pyramids. When fully ripe the fruit is of good flavour, and excellent for culinary purposes.

CRANBERRY CULTURE IN ENGLAND.

THERE is no fruit so acceptable at this season for tarts as Cranberries, yet how seldom do we see them grown, a circumstance which may arise from a mistaken notion that they are difficult to cultivate, or from an idea that building tanks in which to grow them is expensive. The finest Cranberry beds in the kingdom, perhaps, are at Ashburnham, in Sussex; yet their construction is most simple. They were formerly fish stews, originally about 12 ft. wide; some Oak stakes 3 in. square were driven into the ground 2 ft. from the side, and on these were nailed 1-in. Oak boards to the depth of 16 in. The bottoms of the beds were formed of brick-bats, in order to allow the water free access to the roots. The best soil for Cranberries is peat and leaf mould with a good supply of sand; rough peat ought to be put over the bricks to keep the soil from getting amongst them. During the early stages of growth Cranberries require flooding, but more especially should this be done when they are coming into flower; the water should never be allowed to get below the side board. These beds were so arranged that the water from one pipe served the whole by allowing it to pass from one to the other, there being only a Grass walk of 6 ft. wide intervening. It is astonishing how long Cranberries will keep on bearing without any additional outlay. Some of these beds which I renewed had been fifty years under constant cropping, and Cranberries are very profitable, realising readily 5s. per gallon. Those who contemplate forming beds ought first to consider where a good supply of water can be had from; then, selecting a light airy position, but still not too exposed, have a bed of the required width excavated to the depth of 5 ft., and

puddled with clay sufficiently to hold water; secure a waste pipe, say 3 in. below the top of the bed; when you require the water higher this may be easily done by placing some clay around the pipe to the required height. It is most essential not to allow the water to become stagnant. Do not plant too thickly, because for a few years they grow rapidly, and if crowded do not bear freely. The variety most suitable to grow is the American Cranberry (*Oxycoccus macrocarpus*). Several of our nurserymen offer plants for sale, or they may be had direct from America by the barrel at a very reasonable price.

Ragley.

A. HOSSACK.

PEARS FOR NORTHERN DISTRICTS.

THE recommendation (p. 380) of such Pears as Duchesse d'Angouleme and Beurré Rance, &c., for planting in the "north of England generally," has surprised more readers of THE GARDEN than "S. D." (p. 419). Nearly one-half of the number recommended are, to say the least, exceedingly doubtful sorts for northern districts, let alone recommending them specially for the purpose, while I doubt if any cultivator at all familiar with Pears would think of recommending the Duchesse and Beurré Rance, except for south walls. Both will fruit, but the fruit is unfit to eat and only good for some cooking purposes. Both are delicious Pears when well ripened, but even on south walls they do not always attain high quality in the north. We are using Duchesse Pears here now that have been ripened on a south wall, thanks to the six weeks of fine, warm weather which we had about midsummer, but the quality is by no means first-rate. On the other hand, the sorts recommended by "S. D." are, in the main, trust-worthy for northern districts, particularly Williams' Bon Chrétien, Louisa Bonne, Marie Louise, General Todleben, and Beurré d'Amanlie. The last is not sufficiently known as a hardy sort. It ripens on pyramids here in the open ground, and is a fine-looking and deliciously-flavoured Pear. The tree is also a strong grower, but not very prolific. Though good with us, considering our climate and situation, it appears to attain a far greater degree of perfection in the south, as regards size and appearance at least. I was very much struck with its appearance at the Paris Fruit Exhibition on the 16th of August last, where it was shown in fine condition and of a size and colour such as I never saw it possess before. It was the finest Pear in the show. As to the Chaumontel, also recommended for northern districts, I do not think I ever saw a really good example of it anywhere in the north. The samples which come to market are all from Jersey, where, I am told, it is grown very extensively, as it fetches a good price in the English markets. That some of the more tender sorts of Pears come to tolerable perfection in a few exceptionally favoured localities in the north of England, and even in the Lothians of Scotland, I do not doubt, but recommending such for general culture is another thing. As fine fruit-growing districts are to be found in Lancashire and Yorkshire as anywhere in the north of England, especially near the coast, on the east and west respectively, but in both counties there are also large tracts where only the hardiest Apples and Pears are worth planting, while nowhere does one find the finer sorts such as we have been speaking of grown extensively or recommended. Beurré Clairgean is a very hardy sort and fruits freely in cold districts on the Quince, and the fruit is large and fine in appearance, but it is worse than third-rate in flavour, for which reason I threw several trees of it away here. It is not worth growing as a dessert Pear.

J. S. W.

— With regard to the remarks of "S. D." (p. 419) respecting the selection of Apples and Pears for northern districts, I have to state that the omission of Williams' Bon Chrétien from the list (p. 380) was a mistake. It is an indispensable variety in this neighbourhood, and cannot be too highly recommended. I thought from the opening remarks of "S. D." that my list was to be annihilated altogether, but I am glad to find that we agree as to some varieties. As to some of the sorts condemned by "S. D." the following are their positions: Passe Colmar, west wall; Easter Beurré, laden to the ground with large, handsome-shaped fruits, standard; Ne Plus Meuris, standard; Beurré Rance, standard; and perhaps it may further surprise your correspondent to hear that Ganeau's Bergamot does well as an espalier. If "S. D." be in our neighbourhood at the forthcoming horticultural gathering at Liverpool I will be pleased to show him not only the trees but their produce also.

W. HINDS.

Pearson's Golden Queen Grape.—We have a two-year-old case of this Vine bearing some very fine bunches, and, taking all its merits into consideration, I think it is not only the best new Grape that has been introduced for many years, but one of the finest white Grapes in cultivation. In growth it is free and robust, the bunches handsome in shape and size, and the berries fine in colour and excellent in flavour.—CAMBRIAN.

THE INDOOR GARDEN.

CHRYSANTHEMUMS AT ISLEWORTH.

SELDOM have we seen the Chrysanthemum represented (in exhibition style) in such perfection as we saw it the other day in Mr. Levesley's nursery, Isleworth. Beginning with the Pomonas, we found some dozens of plants growing in cold frames or in low houses close to the glass. Though necessarily trained somewhat formally for exhibition, these plants are much more natural-looking than those generally found at Chrysanthemum shows. They were struck from cuttings in February last and potted on into 8-in. pots, in which they are now flowering. Stopping the shoots was practised four times. When the cuttings had made about 9 in. of growth, the lower 6 in. were stripped of leaves, in order to form clean stems. This stopping resulted in the plants making four strong shoots, which were trained downwards over stout Hazel sticks bent in an arch-like manner over the plant and fastened to a wire ring placed on a level with the bottom of the pot. As the shoots proceeded downwards, they were again stopped at intervals, which resulted in the plants forming complete mounds of fine, strong, healthy shoots and large, dark green, leathery foliage; and at the present time they are literally covered with well-formed blossoms unusually bright in colour. Measuring from the surface of the soil, the plants are about 9 in. high, and in diameter from 4 ft. to 4½ ft. The pots are raised on other inverted pots, which are completely hidden by the plants. The chief features of these Chrysanthemums are their fine form, size, health, and profusion of bloom. Unlike most Chrysanthemums grown for exhibition, these have not been disbudded to such an extent as is generally practised; hence, instead of one flower on a shoot, they have from four to five quite as large and good in every way as single blooms. The kinds consist of the best known old varieties and several well-tried new ones, the aim being to grow the best and those with flowers of the most distinct colours. Among the most noticeable now in bloom may be mentioned Fanny, rich magenta, one of the best dark-flowered kinds in cultivation; Figaro, a scarce sort, with large Anemone-centred flowers of a rich golden-bronze colour, very striking; Antonius, yellow, a hybrid, Anemone-flowered sort; excellent plants of the lilac and yellow-flowered varieties of Cedo Nulli; Andromeda, creamy-white, edged with carmine; Prince Victor (new), dark crimson, a free bloomer and useful for purposes of exhibition. White Trevena is also a fine grower and capable of being trained to any form. Though old, it is still perhaps the best white Pomponé in cultivation. For bouquets its blossoms are invaluable, and small plants of it are excellent for window decoration. Princess Meletia is a fine new kind, not yet distributed; its flowers are of good size and of snowy whiteness, the petals being beautifully frimbriated or feathery. Ernest Benary, a new kind, having pink violet-shaded flowers, is represented by a finely-developed specimen, as is also the well-known kind called Bob, a variety very seldom seen in such good condition as it is here. A noticeable feature in these plants is that not a stake is used in them, excepting two or three bent across the pot, as before stated, by which to support the wire, and to form a foundation on which to build the superstructure, and yet they are as perfect in form as could be desired. Standard plants, grown in 8-in. pots, are also remarkable examples of good culture, whilst in form they are somewhat different from those usually seen. The plants themselves, including pots, are about 6 ft. in height, 2 ft. of the stem at the bottom consisting of clean wood, whilst the head, which is 3 ft. through, is tied in the form of a modified pyramid. No stakes or wires are used beyond one stake to keep the plants steady. Chrysanthemums thus managed are literally masses of blossoms, and for furnishing the conservatory are, perhaps, the best kind of plant that could be employed. Although no roots are allowed to go through the bottoms of the pots, the plants are one and all well furnished with large leaves down to the bottom. The kinds chiefly grown as standards are Mdle. Marthe, white; St. Michael's, bright gold-yellow; White Trevena, and a new unnamed kind with bright mauve-coloured flowers. Large-flowered kinds are represented by dwarf, healthy-looking, naturally-grown specimens, each fur-

nished with upwards of 100 perfectly-formed blossoms, and amongst them may be found such kinds as White Empress of India; the yellow and bronze varieties of Jardin des Plantes; Mr. George Glenny, a rich cream-coloured kind; Mrs. George Rundle and Mrs. Dixon. Altogether, the plants, which number over 100 fine specimens, are among the best examples of Chrysanthemum culture we have hitherto seen, and such results are attributed in no slight degree to the use of Clay's artificial manure, which has a good reputation among growers of plants for market. The plants will be in flower for some weeks yet to come, and are well worth a visit. S.

NOTES AND QUESTIONS ON THE INDOOR GARDEN.

Dracæna Frederici.—This is one of the best of the recently-raised coloured-leaved Dracænas. It has a compact, yet graceful, habit of growth. It can be grown into large plants in very small pots. Its leaves assume a rich rosy-crimson colour, and, altogether, it is one of the best plants for table or vase decoration with which I am acquainted.—S.

Echeveria De Smetiana.—This is a great improvement on *E. secunda glauca*, of which it is evidently a variety. Its leaves being close together, form a compact rosette of a bright, silvery character, which is enhanced by a narrow edge of rose round the fully-developed leaves. Where a dry place in the conservatory can be secured, this *Echeveria* would form a neat and lively edging during winter, and in spring the plants would be available for carpet gardening.—S. C.

New Hybrid Begonias.—By crossing varieties of *Begonia Rex* and *B. discolor*, a new race of Begonias has been obtained in Messrs. Henderson's nursery. The plants are intermediate in foliage, whilst the flowers are like those of *B. discolor*. For room decoration, as well as for other purposes, these Begonias will be found invaluable.

Geonoma gracilis.—The true form of this Palm is equal in gracefulness and beauty to the much-esteemed *Cocco Weddelliana*; indeed, by many it is considered superior, on account of its pinnae being a little broader and of a fresher green colour than those of the *Cocco* in question. We lately saw neat little plants of it in Messrs. Hooper & Co.'s nursery, Twickenham.

A Good Table Plant.—One of the most graceful, as well as easily cultivated, plants which can be employed for table decoration in winter is *Beaucarnea recurvifolia* (*Pincenectitia tuberculata*) grown by Messrs. Hooper & Co. Plants of it in 6-in. pots are placed out-of-doors in summer, and brought into a cool greenhouse in winter, where they throw up heads of gracefully recurved, narrow, green and bronze leaves, and, being of a hardy character, they withstand the heat and dust of rooms, as well as a little rough usage, without being seriously injured.—C. W. S.

Begonia Roezli.—This valuable Mexican species has seeded freely this year for the first time with Herr Ernest Benary at Erfurt, and should prove a useful plant for winter blooming. The flower buds appear about the end of October, and resemble those of an opening Pæony. They are enveloped in a dark red spathe, and rapidly expand into a beautiful umbel of large size, composed of luminous, deep red flowers. In a temperate house the plants of this fine species bloom freely in uninterrupted succession until March, a fact which speaks at once for its great value for conservatory decoration. The flowers being firmly attached to the pedicels, will be found of great utility for bouquets.—G.

Warm Treatment of Bouvardias Best.—Bouvardias, like many other plants, can be flowered in different temperatures. Twenty-five years ago I had two of the then species in cultivation, and grew them, as was at that time customary, in a warm greenhouse. At the time required (through the winter) they produced a fair quantity of flowers from the shoots formed in the autumn, but, owing to the absence of more heat, when the first crop of bloom was cut, they made slow progress in the formation of fresh growth and the production of more flowers. As soon as I commenced to grow them in stove-heat, similar to the treatment which the best of the London market growers give them, I found that in the course of the winter I could cut from a given number of plants three times the quantity of flowers that it was possible to do under the cool treatment. These Bouvardias admit of "cut and come again" to an extent possible with very few plants. Every bit of fresh growth which they make produces flowers when well managed, but the growth must be in existence, or the bloom will not be forthcoming. It was for this reason, and after fully testing both the cool and warm treatment, that I recommended their being treated as stove subjects through the winter.—T. BAINEs.

TREES, SHRUBS, & WOODLANDS.

THE ALDERS.

FRINGING the banks of the rivers and brooks, and growing in marshes throughout the whole of Europe, Asia northward from the Himalayas, and North America, as well as on the Chilian Andes, the Alders are often the most frequent of trees, and contribute in no slight degree to the beauty of the landscape. According to the ideas of the individual botanist as regards specific rank, the genus contains from about fifteen to more than double that number of species, many of them furnishing well-marked varieties, and most of them being known in cultivation. A glance at the woodcuts illustrating this paper will show how wide are the differences in form and size of leaf exhibited by many of them. The habit, too, varies considerably, some of the kinds never getting to be more than bushes, others often attaining a height of 70 ft. or 80 ft.; indeed, under different circumstances the same sort will often run through all the intermediates between a small bush and a large tree, as, for instance, our native Alder, which, on high hills, does not reach a quarter the height it attains in the richer soil of the more sheltered valleys. In some places this is largely grown to produce charcoal for the manufacture of gunpowder. The timber is soft and of no great value, but it is

Alnus glutinosa.

extremely durable when buried under ground or immersed in water. In Holland it is extensively used for forming piles, and its adaptability for this purpose has been acknowledged from a very early period, Pliny calling it "eternal." According to Vitruvius, the city of Ravenna was built upon it, and Evelyn states that the celebrated bridge of the Rialto at Venice was built on Alder piles. About a century and a half ago enormous numbers of plants were imported from Holland to Scotland at a considerable price and planted in large tracts of moist land. Butcher, who records the fact, informs us, however, that no returns suitable to the labour and expense incurred were received. The common Alder does not seem to have been regarded with much favour by many writers as an ornamental tree, although it is one of the finest of aquatic trees; indeed, Gilpin places it, after the Weeping Willow, as the most picturesque of all. With Gilpin, Sir Thomas Dick Lauder fully agrees. He says, "It is always associated in our minds with river scenery, both of that tranquil description which is most frequently to be met with in the vales of England, and with that of a wilder and more stirring character, which is to be found among the glens and ravines of Scotland. In very many instances we have seen it put on so much of the bold, resolute character of the Oak, that it might have been mistaken for that tree but for the depth of its green hue. The river Mole may, doubtless, furnish the traveller with very beautiful specimens of the Alder; as it may also furnish an example of that species

of quiet English scenery we have alluded to, but we venture to assert that nowhere will the tree be found in greater perfection than on the banks of the river Findhorn and its tributary streams, where scenery of the most romantic description everywhere occurs." An advantage the tree undoubtedly possesses over many deciduous ones, which affect drier situations, is its tendency to retain its foliage after they have shed theirs. There

Alnus glutinosa var. oxyacanthifolia. Alnus glutinosa var. quercifolia.

is, however, a great deal of difference in this respect among the numerous species and varieties, several of the varieties of the common Alder being in good foliage after that of the type has fallen. Although in a state of Nature, most of the Alders are found where their roots can obtain at all times an abundant supply of moisture (and under such conditions they reach their fullest degree of development) they will grow well in all but the lightest and driest soils. I believe that all the species known already in cultivation fruit freely in this country, and can be most readily propagated by means of seeds. The numerous, very strange, and ornamental varieties require to be reproduced by layers—a very easy process—or propagated by grafts, using the common Alder or other vigorous kinds as stocks.

Common Alder (*Alnus glutinosa*) has a wide geographical range, being found wild throughout Europe, North Africa, West and North Asia to Japan. It has black bark and rounded, somewhat wedge-

Alnus glutinosa rubrozervia.

shaped leaves, wavy and serrulate at the margins, and deep green both above and below; these, when young, are, as well as the young shoots, covered with a glutinous substance, whence the specific name.

The following are the most striking varieties of this species

HAWTHORN-LEAVED COMMON ALDER (*Alnus glutinosa* var. *oxyacanthifolia*) is a dense-habited bush or small tree with leaves much

smaller than those of the preceding, sinuate and lobed so as to resemble in a marked degree those of the common Hawthorn.

OAK-LEAVED COMMON ALDER (*Alnus glutinosa* var. *quercifolia*) is a distinct and handsome variety, with fine, bold foliage, similar in outline to that of our British Oak. This grows freely and retains its leaves longer than the type.

GOLDEN-LEAVED COMMON ALDER (*Alnus glutinosa* var. *anrea*) has leaves exactly the size and shape of those of the species, but of a fine golden-yellow colour. In suitable situations it does not scorch, and,

Alnus glutinosa var. *imperialis*.

Alnus glutinosa var. *laciniata*.

although it is of somewhat slow growth, it is a most effective ornamental shrub, and one decidedly worth growing in the choicest collections. This does best grafted on a stronger-growing soil.

RED-VEINED COMMON ALDER (*Alnus glutinosa* var. *rubronervia*) is a vigorous grower, with the habit and leaves of the type, the leaf stalks and midribs being, however, a bright red.

LARGE-FRUITED COMMON ALDER (*Alnus glutinosa* var. *macrocarpa*) differs from typical *A. glutinosa* principally in its larger fruiting catkins and bolder leaves, and also in its more vigorous mode of growth.

Alnus glutinosa var. *barbata*.

Alnus cordifolia.

FERN-LEAVED COMMON ALDER (*Alnus glutinosa* var. *imperialis*) is a distinct and handsome tree with elegant, drooping branches and Fern-like leaves, which are more deeply cut than those of the next variety. In some nursery catalogues it goes under the name of *Asplenifolia nova*.

Cut-leaved Common Alder (*Alnus glutinosa* var. *laciniata*) has deeply-pinnatifid leaves which, from their tendency to open out quite flat, give to the tree a totally different aspect from that possessed by the last-named variety, in which the leaves are often very

concave, and the lobes always longer and narrower. As to the origin of this, Loudon quotes Thoin, who, in the year 1819, in the "Nouveau Cours d'Agriculture" states that the cut-leaved Alder was first found by Trochereau de la Berlière, and planted by him in his garden near St. Germain, where the stool still remains, from which all the nurseries of Paris have been supplied with plants, and probably all Europe.

There are also a variety with variegated foliage, and another, *Alnus emarginata* (Willd.), with nearly round, wedge-shaped leaves, dark green, with an edging of light green.

Bearded Alder (*Alnus barbata*) is by some regarded as a variety of *A. glutinosa*. It is a native of the Caucasus, being found on the western side of the Caspian Sea. It differs widely in its foliage from the common Alder, its leaves being pointed, having more or less doubly serrated margins, and often attaining a length of 6 in. or more by a breadth of 4 in. or 4½ in.; on the upper surface they are dark green. The most striking characteristic of the plant is furnished by the bright red-brown hairs which clothe the midrib and principal veins on both surfaces of the leaf, and are so marked as readily to catch the eye.

Oblong-leaved Alder (*Alnus oblongata*) is a large shrub or low tree from South Europe and North Asia, introduced by Miller in 1749. It has obtuse, somewhat egg-shaped, glutinous leaves, the

Alnus cordifolia nervosa.

axils of the veins being naked on the underside. Loudon says the finest tree of this sort of which he has knowledge was one in the Glasnevin Botanic Gardens, which, in 1834, was 30 ft. high.

Heart-leaved Alder (*Alnus cordifolia*), sometimes also called the Napolitan Alder, is a very distinct and handsome South European tree; its leaves, being nearly or quite smooth and of a glossy green, a shade or two lighter than those of the common Alder, give it almost the aspect of a Poplar. It is a fast-growing tree with light-coloured bark, and, from its fine pyramidal habit, it is very effective either in groups or as a single specimen. It remains in good foliage some time after most Alders are leafless, and is perfectly hardy in this country. The flowers are produced in March and April before the development of the leaves. The date of its introduction to this country is 1820.

ALNUS NERVOSA differs from this in its more rounded leaves, which are not so decidedly heart-shaped at the base; it, however, seems to grow quite as quickly as *A. cordifolia*, and to resemble it considerably in other respects.

A. SUBCORDATA is another Alder, a native of the Caucasus, which is also referred as a variety to this species; its foliage is, however, very much larger and bolder, darker green, and its general aspect is widely different both from *A. cordifolia* and *A. nervosa*. Its leaves measure about 6 in. long by 4 in. wide, whilst those of the two others

Alnus cordifolia sub-cordata.

Alnus serrulata.

Alnus incana.

Alnus serrulata rugosa.

Alnus incana var. laciniata.

Alnus serrulata latifolia.

just mentioned are about 3 in. long by 3 in. wide; the relative length of the leaf-stalks, too, is different, those of *A. sub-cordata* being much shorter than the others.

Hoary-leaved Alder (*Alnus incana*) is one which will attain a good size even in dry localities, and which, as an ornamental tree, is well worth growing; it, as well as its varieties, is easily recognised by the smooth, greyish bark of the stem and twigs, and by the grey-green under surface of the leaves. In shape the leaves are ovate, pointed, with margins primarily divided into coarse teeth, which are themselves serrulate. In size they are about 4 in. long by 2 in. wide. It is found wild in North America (where it is known as the Speckled Alder), and is pretty widely distributed throughout the North Temperate Zone. The best of the varieties, which have at various times received names in different nurseries, &c., are as follows:—

A. LACINIATA, a noble tree, with handsome foliage, somewhat like that of *A. glutinosa* var. *imperialis*; the leaves are often from 6 in. to 7 in. long.

A. SUB-LACINIATA has smaller leaves with deeper primary divisions than *A. incana*, the secondary teeth, too, being much more evident.

A. PINNATIFIDA, when casually examined, seems to come extremely near the last-named, but for gardening purposes it is quite distinct; it is of slightly different habit, and the form, size, and serration of the leaves render it well worthy a varietal name.

A. GLAUCA has prettily-serrated leaves (the petioles of which are reddish), deep green above and glaucous beneath. This, one of the most beautiful kinds of the genus (according to Michaux), forms a tree in the United States from 18 ft. to 20 ft. high.

A. ANGULATA differs from *A. glauca* in its leaves being green underneath, and in its having green, not red, leaf-stalks.

Saw-leaved Alder (*Alnus serrulata*), a shrub from 6 ft. to 10 ft. high and a native of North America, makes a very pretty bush with its deep green foliage. The three following, which in the Kew collection are classed as varieties of *A. serrulata*, nevertheless differ from that very considerably.

Alnus Aenobetula.

Alnus japonica.

A. AUTUMNALIS has handsome leaves 6 in. long by about half that width, doubly serrated at the margins.

A. RUGOSA has leaves rather smaller than the last and more rugose.

A. LATIFOLIA has large rounded leaves, sometimes sub-cordate at the base, and with crenulate, weakly-serrated, decidedly wavy margins. They measure about 5 in. or 6 in. in length by 3 in. or 4 in. in breadth.

Curly-leaved Alder (*Alnus undulata*), a native of North America, was introduced in 1782 by the Hudson's Bay Company. It is a small shrub, not growing more than 3 ft. or 4 ft. high in the swamps of the mountainous regions where it is found wild, though Willdenow states that in 1811 a tree in the Berlin Botanic Garden had reached the height of 15 ft.

Birch Alder (*Alnus Alnobetula*) is a handsome bush found wild in the Mid-European and Italian mountains. It flowers in April

(often in March) and produces a plentiful crop of very pretty catkins. The leaves are egg-shaped, pointed, and the same deep colour on both surfaces. In a state of Nature it only grows about 5 ft. or 6 ft. high, but in cultivation makes an elegant little tree about double that height.

Oriental Alder (*Alnus orientalis*) is a quick-growing tree with noble leaves measuring often 9 in. or 10 in. long by about 5 in. broad. This, a native of North and East Asia, is still a rare tree in collections, but it deserves to be much more generally known, its pyramidal habit and enormous ovate, acuminate leaves giving it quite a character of its own.

Japanese Alder (*Alnus japonica*) is a most distinct shrub with lance-shaped leaves 4 in. or 5 in. in length by 1 in. or 1½ in. broad, the margins of which are slightly serrulate. In colour the upper

Alnus orientalis.

glossy surface of the leaves of this pretty sort is a shade or two lighter than in most other Alders, the whitish veins being very conspicuous on the light-coloured under surface. G.

WOODLAND WORK FOR THE END OF NOVEMBER

IN situations where holing was carried out early in autumn good work will have been done in planting, which in many localities has already made considerable progress. Very wet situations, if not filled up by the end of this month or early in December, should be left until spring, for, as it is not advisable to tread in retentive soils around the plants during wet weather, they do not become sufficiently close and consolidated to keep out frosts. The holes also become filled with water, so that transplanting, if continued, must take place under the most unfavourable circumstances. But whenever the hands are driven from planting, trenching, draining, fencing, or road-making may be proceeded with. Every opportunity should be seized to cart heavy materials and remove timber during frosty weather. Timber so carted and stacked near the saw mill is in a much better state for conversion than when covered with grit and dirt, which soon take the edge off the saw. Where coppice felling proceeds on an extensive scale, the work should be so arranged as to cut from the stub during open weather, laying the produce in drifts for trimming up and stacking on frosty days, if such occur. Early felling ensures chances of quick removal, and gives a great choice of customers by bringing the produce sooner into the market.

In open weather continue planting Acorns and Chestnuts; also collect cones of Scotch Pine, Larch, Silver, Norway, and Spruce Fir

in localities where these ripen fit for use. Unless these are gathered in very dry weather, they should for some time be spread thinly in an open and airy loft before being stored in heaps for spring use. When required for planting, place the cones upon the hair of a kiln or Hop-oast, about 6 in. or 8 in. thick, and subject them to a heat of about 110° Fahr. for ten or eleven hours. They may afterwards be removed to the threshing-floor and beaten out with a light flail.

The felling of all kinds of deciduous trees, the Oak excepted, may now be proceeded with. Those trees which have a resinous sap may be cut down at any season of the year, as, on account of such sap being less fugitive than that of other trees, the timber does not open or rend in seasoning. Some old writers on forestry maintain that the Ash can be properly seasoned only when felled after the middle of November. Montesth says, "Ash should always be felled from after the 15th of November till the last week in January, and never before nor after that time to have good timber, and to do it justice; nor is it at all easy to season Ash timber properly when cut down at any other time." Where the bark of a tree contains a conservative quality, as in the case of the Larch, it should not be stripped off at the time of felling. The durability of posts formed of whole Larch, and let into the ground with the bark on, is much greater than that of equal-sized posts of the same material when squared or deprived of their bark. As long as the bark of a fallen tree remains sound, it defends the wood from the influences of sun and air; but rotten bark, by retaining moisture, hastens decay, and it also often harbours injurious insects. Cut down Elm, Poplar, Sycamore, Lime, and Plane trees where necessary. As the last two are largely employed for the manufacture of articles in which the whiteness of the wood is a principal consideration, they should be sawn up and the timber stowed away at once in a dry, but airy place.

Where such old trees as it may be considered desirable to retain show signs of languishing, they may sometimes be renovated by carefully pruning off all dead and decaying branches, and afterwards opening out a good trench round them at some distance from the stem, cutting off the ends of the larger roots, laying a drain so as to carry away superfluous water, and afterwards refilling with a good compost. The turf between the trench and the stem may then be removed and the soil well loosened, at the same time that a liberal dressing of the compost or fresh, rich soil is forked in. In trenching recently-cleared spaces which may require to be refilled with plants in the spring, all remains of roots and fibres should be carefully removed, and the ground thrown up as rough as possible. Only a small portion of the subsoil, say 3 in. or 4 in., should be brought to the surface at each trenching.

A. J. BURROWS.

in high sites stood the severest frost with impunity. Large trees also retain their fine rich green colour much better when in dry, sheltered situations than in low, wet ones. In the "Forester" it is called "the remarkable Pine," and from its growth and beauty it well deserves the name, but the quality of the timber is not described. Probably some of your correspondents may have seen some of the earlier planted trees out up, and can report on the quality of the timber.—JOHN GARLAND, Killerton, Exeter.

Elms in Kensington Gardens.—Mr. Bernard Coleridge asks (p. 428), What is the species of the handsome Elm on the west side of the Long Water, and of its neighbor on the opposite bank? They are very old friends of mine, though I have not seen them for many years. I believe the species to be *Ulmus glabra*. It cannot be *U. viminalis*, of London, because that species was raised in 1817, and these are very much older than that date. There were several of the same species, noticeable by the peculiar striation of the bark when out of leaf, standing in a row immediately within the northern fence of the Gardens, west of Lancaster Gate; but the situation was always unfavourable to the development of their beauty. The species is the most graceful of all Elms with which I am familiar; and I endeavoured, some twenty years ago, to procure plants of it; but those sent me, though procured from a well-known nursery, were a different species, and I have been unable to secure it. It is certainly worth perpetuating. I cannot find these trees recorded in London's "Arboretum," nor does his description of *U. glabra* indicate his knowledge of the variety, which may have been accidental. I never saw it elsewhere. These two trees and the forked Plane tree in the Green Park, once in Lord Coventry's garden, before it was absorbed by the Park, are, or were, the noblest specimens of forest trees in London.—J. J. ROGERS, Penrose.

Autumn Tints in Hardy Azaleas.—The remarks under this heading (p. 428) are in every particular correct. During October and November the hardy Azaleas are the finest tinted leaved shrubs which we possess. Plants growing here and there amongst dark green-leaved Bays have a striking effect, and groups contrasting with fine, healthy *Camellia* trees have a still finer appearance.—CAMBRIAN.

Eucalyptus globulus.—When lately at Fota, near Cork, my attention was directed to some very scraggy specimens of this Gum tree planted in a swampy place, and I was given to understand that it was a mistake to put them in such positions, for although the practice may answer very well in warm countries it will not do here, our winters being too long and cold for them; therefore, if we wish to grow these Eucalypti we must always plant them in the driest and warmest spots which we can find, a practice that holds good in the case of many other introduced trees and shrubs besides the Eucalyptus. I think, too, that they like a site somewhat exposed. A specimen of *E. globulus* is planted in one of the school gardens in Dundalk, and from the position being surrounded on several sides by buildings, and from other causes not readily explained, there is a constant swirl of wind, so much so, that scarcely anything will grow. No Conifer will live there, and even Hollies drag out a miserable existence, but this Eucalyptus planted three years ago is now a symmetrical, leafy, healthy specimen, 20 ft. high, a rich mass of foliage and a striking contrast to its surroundings.—T. SMITH, Newry.

Variations in Coniferae.—It is only when Conifers of the same variety are grouped together that one is able to fully appreciate the variety of form and colour that exists amongst them. The different gradations between young and old foliage is remarkable, a fact fully exemplified in *Cupressus Lawsoniana* and its varieties. We have here a long avenue of *Wellingtonia gigantea*, nearly every tree in which exhibits a different habit and shade of colour. As regards the beauty of Conifers as garden ornaments, they mostly appear to the best advantage when young.—J. GROOM.

Trichostema lanatum.—This rare and handsome plant of Northern Mexico I have found, growing out of its usual range, in the central mountainous portion of San Luis Obispo County, California. It is figured and described in a Smithsonian report some years ago. It forms a very picturesque small shrub, with contorted branches, and twisted, narrow leaves of grey, veined with green. A bank of gravel, or a crevice in the face of a rock, exposed to the full blaze of the sun, is its favourite location. When the flower-spikes, which are very numerous, begin to show themselves, they are almost hidden in a white pubescence, which gives the name *lanatum* to the plant. The flower-spikes are like those of a drooping *Salvia*, from 6 in. to 9 in. in length, and of a reddish-purple colour, changing to a dark purple, and keeping in bloom a long time. The stamens, which are indefinite, form the marked feature of the inflorescence, for they extend over 2 in. out of the flower in a drooping, brilliant mass of rosy-red colour; so that this, relieved against the white, woolly stalk, makes a striking object.—C. H. S., Niles, California, U.S.A.

NOTES & QUESTIONS ON TREES, SHRUBS, & WOODLANDS.

Pinus insignis.—This is deserving of all "J. J. R." (p. 408) says of it, and even more, so far as appearance goes, in places in which it will thrive, for amongst the whole of the Coniferae there is nothing to approach its beautiful green colour. There are many situations, however, in which it will not grow at all beyond the condition of a stunted bush, and, before planting it in quantity, it would be well to see if it does fairly well anywhere in the neighbourhood where soil and climate are similar. *P. astrisica*, on the contrary, will do well in most places, and for effect is second to none, except *P. insignis*.—T. BAINES.

—Three years ago I planted at Sprydoncote several plants of *P. insignis* as well as a great number of other sorts, and the growth of *P. insignis* this year has been astonishing. The leading shoot of one I measured was 5 ft. 6 in. and that of another 4 ft. 11 in. The soil in which they are growing is deep loam and the situation high, but partly sheltered. Others near, but fully exposed, have also made very good growth. I consider this Pine eminently fit for general planting as a hardy ornamental tree, but I cannot speak as to the quality of its timber. From a packet of seed sown in the spring of 1877 I have raised 500 or 600 plants, the average height of which is 18 in., some of them being 2 ft. high. The seed was sown in boxes of light, rich loam, in which the young plants remained until this spring, having grown from 6 in. to 8 in. high. They were then potted in 4½-in. pots and plunged in an open quarter of the kitchen garden in rows 18 in. apart, surrounded with wire netting to protect them from hares or rabbits. I intend this season to have some thick turves of good loam cut about 9 in. square, turn the plants out of their pots, and plant them in the centre of each inverted sod, and again place each a good distance apart to allow them to make plants large enough for finally planting out twelve months hence. It thrives best in a well-drained soil. In the winters of 1860 and 1866 we lost many of our young stock in a small nursery in a low situation, while that planted

PLATE CLIV.

THE DAPHNES OF CHINA AND JAPAN.

(WITH A COLOURED PLATE OF DAPHNE ODORA VAR. MAZELI.)

THERE is a considerable number of quite distinct Daphnes in cultivation which have been imported from time to time from China or Japan, but their nomenclature is exceedingly confused. The confusion was caused by an error in naming the variety first introduced into this country. This Daphne was *D. odora alba*, introduced in 1771, by B. Torin, Esq., and originally cultivated under the name of *D. indica*. The Daphne *indica* of Linnaeus is a totally different plant; nevertheless, the name is still retained in many gardens and in some catalogues for varieties of *D. odora*. In course of time the names *sinensis* and *japonica*, coupled with varietal names, were employed to designate some of the Daphnes received from the same region. From a horticultural point of view, several of these Daphnes are very different from each other, but it is a rule with botanists to regard all the plants which are known or believed to have descended from the same parent as belonging to the same species. This rule is a very good one in theory, though in practice it leads to curious results. For instance, many garden varieties would rank as species had they originated in a wild state and their parentage remained unknown. But although it is easy to criticise and expose the weak points of this rule, it is difficult to devise a more convenient and less objectionable system of nomenclature. Even gardeners, who distinguish and cultivate a multitude of varieties of some plants, find it necessary to classify them and associate each variety with a type under some trivial name. With an abundance of material before us, both in specimens and literature, we are unable to refer the Daphnes under the names cited above to more than one common type. This has been the opinion of several writers, but as their material was insufficient to determine the question, they have been content to record their opinions and leave the limitation of the species to others. The name *odora* is the oldest and most appropriate name, having been published by Thunberg in his "*Flora Japonica*," 1784; hence we adopt it.

Varieties of Daphne odora.

D. odora alba.—As already mentioned, this was the first of this group introduced. Sir J. E. Smith figured it in 1801 in his "*Exotic Botany*," plate 47, but his specimen was very poor, and the flowers are represented of a yellowish tinge. There is, however, a much better figure of it in Jacquin's "*Hortus Schœnbrunnensis*," iii., p. 351 (1798), which exactly represents what is now known as *D. odora alba* or *D. indica alba*. It is unnecessary to describe this favourite winter-flowering shrub, whose glossy leaves and fragrant white flowers must be familiar to most persons. Like all the rest of the group, it is hardy in the south and west of the British Islands, while it is also indispensable as a greenhouse plant.

D. odora punctata.—This is figured in the "*Botanical Magazine*," plate 1587 (1813) as typical *D. odora*, and as the same as the variety *alba*, but improved by cultivation. Like that, it has usually dense terminal clusters of flowers, sometimes supplemented by lateral ones, the outside of the perianth being spotted and bordered with red. The origin of this is not recorded, except that it was received from Messrs. Loddiges. Occasionally in this and other varieties the axis of the inflorescence elongates, and the flowers then, instead of being crowded together, are distributed on short branchlets somewhat as they are in *D. odora Mazeli*.

D. odora rubra.—Generally speaking, we believe this is a more vigorous grower than the white-flowered variety, and succeeds better outdoors, producing its rosy-red flowers in profusion. There is a fine specimen in Kew Herbarium taken by the late Dr. Bromfield from a garden at Ryde, in the Isle of Wight, and in the note accompanying it he says that it was from a fine standard bush about 4 ft. high, which had been out several years unprotected, and flowered freely during the winter and spring months, and was apparently not in the least injured by the long and severe winter of 1845. A good figure of this is given in Sweet's "*British Flower Garden*," series 2 (plate 320). The drawing, it is stated, was made from a plant that flowered in the collection of Mr. George Smith, Islington, in 1836, and which had been imported from China about four years previously. A Daphne allied to this, and said to be a hybrid between it and the European *D. collina*, is figured in the "*Botanical Register*," 1838 (plate 56), and in the "*British Flower Garden*," 1827 (plate 200),

under the name of *D. hybrida*. It has the more hairy leaves of the European species, and flowers intermediate between the two. Under the name of *D. japonica*, Paxton ("*Magazine of Botany*," viii., plate 175) figures a Daphne which is neither more nor less than *D. odora rubra*, having the leaves bordered with yellow. It is described as differing from *odora* in the yellow bordering of the leaves, and in the much richer fragrance of the flowers; but, like Roses, the varieties of Daphne *odora* vary in the quality and intensity of their perfume, and as to the variegation that may happen to any of them.

D. odora Mazeli.—This differs essentially from all the preceding varieties in the flowers being borne on short, lateral branchlets all along the branches, instead of being, as usual, in dense clusters, and almost confined to the ends of the branches. It is possible that it may belong to a different species, perhaps to the true *D. japonica*, which is described as having lateral flowers, but this is very uncertain. The native *D. Laureola* varies with mostly terminal flowers, or scattered along the branches, according to the vigour and situation in which it is growing; but, whatever its origin, its horticultural value remains the same. It was named by M. Carrière ("*Revue Horticole*," 1872, p. 392) after Mr. Mazel, who received it direct from Japan in 1866. It has the character of being extremely hardy and succeeding in almost any soil or situation. The flowers are produced in midwinter, and are consequently often injured by frost, except in very mild situations; but it is equally deserving, with the others, of a place in the cold greenhouse.

Two other species of Daphne have been introduced from China and Japan, namely:—

D. Genkwa.—This beautiful shrub was introduced by Mr. Fortune, who found it in a nursery garden near Shanghai, in the winter of 1843, and it was described by Dr. Lindley as a new species under the name of *D. Fortunei*. It subsequently flowered at Chiswick, and a coloured plate of it was published in the "*Journal of the Royal Horticultural Society*," vol. ii., p. 34. Although a very pretty and very floriferous plant, it does not appear to have spread much in gardens. Mr. Fortune wrote very highly of it in 1847. He met with it in 1841 growing wild on the hills in the province of Che-kiang. It is a deciduous species, and Mr. Fortune remarks, like the English *Mezereon*, it is the harbinger of spring. In March and April the flower buds expand, and then the whole of the hillsides are tinged with its beautiful lilac-coloured blossoms, and have a very gay appearance. Siebold, who gave it the above name, saw it in gardens only in Japan.

D. jezoensis.—A pretty, yellow-flowered, Japanese species of which we have only seen dried specimens, and a coloured figure in the "*Gartenflora*" (plate 496). It has rich green foliage, and the fragrant flowers are borne in terminal clusters. Introduced into Russian gardens by Maximowicz.

W. B. HEMSLEY.

Messrs. Rodger, McClelland & Co., of Newry, who furnished the specimen from which our figure of *D. odora Mazeli* was prepared, writes as follows concerning it: This is undoubtedly one of the handsomest of all the Daphnes. Its robust and leafy character, and also its habit of producing axillary heads of flowers for long distances along its branches make it as charming as it is useful, because its flowers are very similar, both in appearance and fragrance, to those of *D. indica rubra*, and the axillary branchlets are long enough for cutting purposes. The annexed figure is a representation of one of the strong shoots; on the smaller branches the flower heads are terminal. It has proved quite hardy in the north part of Ireland, both on walls and also in open quarters. Like most of its congeners, it prefers a partially-shaded position, although it will succeed remarkably well in a full south aspect, a situation in which it is at the present time (middle of November), just on the point of opening its first flowers. Its very hardy character will render it a most useful plant for many purposes, as, for instance, for the decoration of cool greenhouses, in which it will fill the air with delicious perfume; for window gardens, and, in fact, for all and every purpose where a sweet-scented plant is required during winter and early spring.

Rhodochiton volubile.—A plant of this old and useful greenhouse climber is now finely in flower in Mr. Joad's garden at Wimbledon. It is trained under the roof of a cool greenhouse, and is literally covered with drooping, bell-like, curiously-formed, violet-purple blossoms. It lasts in flower for a long time, and is well worth extensive culture in small houses. It would also make an attractive plant grown in the form of a standard trained over an umbrella-shaped trellis.—S.

PROPAGATING.

ZONAL PELARGONIUMS.—Pelargoniums for bedding during the following season may be increased by means of cuttings made, as shown in fig. 1, in August or September, either in the open ground or in pots in the greenhouse. A bed or border should be dug; and if light and sandy, so much the better. Rake the surface level, press down the soil lightly, and insert the cuttings in rows, leaving a little space between them for clearing out the leaves that will fall from them. In about a fortnight loosen the soil between them a little with a small stick, and if dry give it a moderate watering. The gold and silver tricolors and the white-edged varieties can all be prepared in this way. In regard to these, it is a good plan to have a box or pot of dry sand, and to drop a little of it in each hole along with the cutting. All of them, especially the green-leaved kinds, will be ready for potting in about three or four weeks. In the case of new or scarce sorts, cuttings may be put in at any time of the year. Single eyes, as shown in fig. 2, must be supported by means of a small stick or wire, and they must be set on a slight bottom-heat, on which all the variegated sorts do best placed singly in 2½-in. pots. When struck they should be moved to the shelves. Some of the weaker and finer sorts do best grafted on strong-growing seedling plants of green zonals, which must be raised from seed for that purpose. The stock, which should be about the same size as that of the graft, should

Fig. 1.—Cutting of Zonal Pelargonium. Fig. 3. Fig. 4. Fig. 2.
Grafting Zonal Pelargoniums.

be cut as shown in fig. 3, and on that should be fixed the graft (fig. 4). The two should then be tied firmly together with worsted or matting, when they will unite in about six weeks. They must not be covered up, but should stand exposed in the propagating house shaded from full sunshine. The best months for grafting Pelargoniums are July and August, when the wood has partly ripened.

H. H.

Wire-layering of Plants.—Much has recently been written in THE GARDEN on layering; but I have not seen as yet any allusion made to a system which has been adopted by me, more or less, for these last forty years, viz., the twisting of a piece of fine copper wire tightly round the branch to be layered, and sufficiently tight to indent the bark. I never found this practice to fail even with the hardest of layering wood. The first plant operated on was *Berberis dulcis*, when that Berberry was rare in this country, and owing to the hard, wiry character of its stems it was impossible to get them to root by the ordinary method of layering, while under the wiring process they readily submitted. The other plants operated on were the *Andromeda floribunda*, *Abies Pattoniana*, *A. Hookeriana*, *Azalea*, *Rhododendrons*, *Roses*, and many others. After preparing the shoots by trimming them up, particularly when leafy or branchy, the copper wire is twisted round the branch. If short and springy, they are pegged down and covered with soil; if the soil be dry, a little Sphagnum Moss and a few stones are laid over the surface. Soon after layering a swelling of the bark will take place immediately above the ligature. During the following year it will be found that roots are freely produced from the swollen portion, particularly round the under part of the swelling. When rooted the layers can be detached immediately below the wire. By this method all the kinds tried made excellent plants.—JAMES McNAB, *Royal Botanic Garden, Edinburgh.*

GARDENING FOR THE WEEK.

Flower Garden.

Auriculas.—This is a very trying month for these, especially if the weather be close and fogs prevalent. The decaying leaves are very numerous, and, if not constantly removed, are apt to canso mould near the stem, which may spread to the stem itself, and ultimately cause the death of the plant. If it be necessary to water the plants, as it is occasionally, for the soil must not be quite dried up, do it in the morning before midday; and it should also be done on a sunny day to allow the water to get dried up before night; just fill the pots with water, and neither wet the leaves nor run the water over. Fumigate with Tobacco smoke if there be any trace of green fly on the plants, and continue to do so until that pest is quite destroyed. Many are now raising seedlings. If the seeds were sown as soon as they were ripe in July or August, there will still be small plants appearing above ground. In favourable weather slugs will be in the outlook for these, and must be watched for and destroyed. Ventilate the frames as much as possible, removing the light entirely during fine weather. Dry frosts do good, and it is not at all necessary to shelter the plants from them at present. The lights should be placed over the plants at night, as a matter of course.

Carnations and Picotees.—These have now all been potted and the pots have been placed in cold frames for the winter. I plunge the pots in Cocoa-nut fibre, which answers the purpose perfectly, but any other light, dryish material will do. Some growers do not plunge the pots during winter, as, owing to Carnations and Picotees being like the Auriculas regards hardiness, frosts do no harm to them. A plan adopted by Mr. Dodwell is certainly worth attention in large towns where the plants are much under the influence of smoke and a damp heavy atmosphere. His frames are raised from the ground so that air can circulate freely underneath the plants, which are on a raised stage or platform of wood. Some of the northern growers plant out about this time their Carnations and Picotees in the open ground. My own experience would suggest that only the strong-growing varieties should be tried in this way. If any of the more weakly ones be planted out, I would plant them in pure turfy loam, and over the plants place a bell-glass, which should be raised on stones 3 in. above the ground. The principal use of the bell-glass is to keep off rain, snow, and hoar frosts during winter. Picotees are rather more hardy than Carnations, and would be better able to withstand wet.

Gladioli.—These have not yet been taken out of the ground, but we will probably lift them before long; while the weather is dry it is best to leave them in the ground. Cold rain is most disastrous in its effects upon the roots. Directions were given a few weeks ago as to the way in which the roots should be taken up. Seedlings that have been growing all the summer in pots should now be shaken out of them, because when the leaves decay the bulbs start into growth immediately. If any of them have done this the best way is to pot such bulbs at once; a dozen or more may be potted in a 6-in. pot, and the pots may be plunged to their rims in some Cocoa-nut fibre refuse.

Tulips.—No time should now be lost in getting these planted out in beds. Old growers of them in the neighbourhood of London used to be very particular as regards the time for planting them out. This was generally Nov. 9, but they will do just as well if they are planted a little before that date, or even a week or two after it. An old writer has said, "The Tulip asketh a rich soil and the careful hand of the gardener." The Tulip beds should be deeply trenched and plenty of rich manure should be worked in near the bottom of the trench, and some of it about 6 in. under the surface. Spread 3 in. of good, rotten, turfy loam over the surface of the beds, and in this plant the roots. The crown of the bulbs may be about 2 in. below the surface of the ground, and some sharp river sand may be placed under and over the bulbs. Show Tulips are divided into three classes—Bizarres, Byblomens, and Roses. These should be mixed together in equal proportions. There are usually seven rows in a bed, and the bulbs should be planted about 9 in. apart. The principal growers plant two beds parallel to each other, with a narrow path down the centre. A span-roofed framework, covered with movable canvas, must be erected to shelter the flowers from the sun when they are expanded, and in cold, wet districts the plants must also be protected from severe frosts.

Pyrethrums.—Where it is intended to increase the stock of these it is a good plan to lift the roots now and divide them, potting each division into 5-in. or 6-in. pots, according to their strength. Place the pots in a cold frame, which should be freely ventilated, and attend to watering the plants as they require it; replant in beds in spring. If the beds be not disturbed, it is a good plan to place 2 in.

of rotten manure on the surface of the ground between the plants. Phloxes, Pentstemons, Antirrhinums, Delphiniums, and other plants of a similar character should be treated in the same way, and any of these growing in pots should have the protection of a cold frame.

Hollyhocks in frames must be looked over occasionally, and any decaying material should be promptly removed. Ventilate freely, and in fine weather remove the lights entirely.

Dahlias must also be seen to; the old stems of some of them may have been accidentally stored in a damp state; if so, they will become covered with white mould, which goes down to the crown, and sometimes destroys the incipient growths.—J. DOUGLAS.

Hardy Fernery.

Here many plants are generally used that require some artificial means of protection, and nothing answers the purpose better than a few dry leaves. With a covering of this kind in sheltered situations many half-hardy plants may be wintered with safety, and be made to add much to the charm and interest such places usually afford. Where bulbous-rooted subjects have been recently planted, much watchfulness will be required to see that they do not get disturbed by rats or mice, which soon discover them and often cause damage before it is observed.

Indoor Plant Department.

Conservatory.—In order to insure thorough rest to roof climbers, they should now be kept as dry at the root as the nature of the various plants with which they are associated will admit without causing them to flag or shed their leaves prematurely. In the case of such as are still growing and blooming, which some of them do more or less all the year round, as, for instance, the beautiful *Tacsonias* Van Volxemi and exoniensis, the *Habrothamnus elegans*, and a few others of that character, it will be necessary to maintain the soil in a moderately moist condition, but not to the extent usual earlier in the season when growth is more active. The mildness of the autumn has tempted many to leave some of the more hardy stove or intermediate-house plants in the conservatory much beyond the usual time, and where any of these are still standing they should at once be removed to warmer quarters, for although they may not show immediate signs of suffering, they are sure to do so later on, unless such a temperature can be maintained as to suit their requirements. In no case, however, where there is a mixed collection of plants to be treated, and more especially if *Camellias* form a part, should the temperature of the conservatory range higher than 40° to 45° till after the latter have done blooming, as a very little excitement at this season will cause them to cast their buds; or should they remain on and expand, the flowers are never anything like so fine, either in size or texture, as when they are allowed to come on naturally. Forcing *Camellias* now with a view to bring them on early is quite a mistake, and invariably ends in disappointment, as no plants are so impatient of artificial heat during the winter as they are; what forcing they are subjected to should always be given after they have shed their blooms—a time when they will bear and enjoy almost as much heat as any stove plant, if accompanied with a proportion amount of atmospheric moisture. Another frequent cause of these shedding their buds is dryness at the roots, and should this occur often, it is as fatal as too much heat. The buds may remain on and appear all right till they ought to begin to swell rapidly, when, instead of that taking place, they shell out like ripe Filberts, to the surprise of those in charge of them. Where any doubt exists respecting the soil being in proper condition, an examination should at once be made by carefully breaking it up with a trowel or other implement as deep down as the roots are supposed to have penetrated. Borders in conservatories are often very deceptive from the frequent surface dampings they receive in order to maintain a sufficiently humid atmosphere during the summer and early autumn months, a course which makes the top appear quite moist, while the bottom portion where the roots are may be dust-dry; a mere superficial examination never reveals this, so that plants frequently languish from a cause little suspected. It often occurs, too, that the air of the house in which *Camellias* are standing is drier than they like, and especially is this the case when the conservatory adjoins the mansion; or there is a continuance of frosty weather, necessitating the use of much fire-heat to keep up the proper temperature. A gentle bedewing over the heads of the plants will do much to counteract this without in any way overcharging the atmosphere of the house or rendering it too damp for any other subject that may be in bloom. *Chrysanthemums* will now be the principal flowers for the decoration of the conservatory, and in order to prolong their beauty, they should be placed where they can get plenty of air and be well supplied with water at the roots, taking care never at any time to allow them to approach anything like dryness, or the duration of the blooms will be very short. Late-flowering

kinds should be kept retarded as long as possible by giving them full exposure whenever the weather is favourable, by which means they may be had as late as Christmas, or even into the new year. *Sericographis Ghiesbreghtii* will now be coming in, and if used in the conservatory should be placed at the warmest and driest end, where if not over-watered they will stand well and last in beauty for several months to come. For associating with the *Sericographis* to form groups, *Lihonia floribunda* and *L. penrhosiensis* are admirably adapted, and being of an entirely distinct colour, and resembling each other so closely in the form of their flowers and general habit, they afford a most pleasing contrast. The trio are most charming plants for winter blooming, and well adapted for conservatory decoration. They all succeed and expand their flowers freely in a night temperature of about 45°, with a slight rise during the day, if the air of the house in which they are placed be kept moderately dry.

Forcing Houses.—In order to keep up a good supply of flowering plants, it will now be necessary to get in heat the first lot of *Azaleas*, making choice of those which are known to be early bloomers, such as *Fielder's White*, *Pauline Mardner*, and among the latter of which, from its bright colour and free-flowering habit, is one of the most valuable for forcing. In selecting any of the above-named sorts, pick out those having the most prominent buds, and that were brought early into bloom last season, as they can be got in in much less time than others that were allowed to come on naturally. Plants that have once been forced acquire the habit of flowering early if properly treated after by giving the requisite heat and moisture to complete their growth, and get it properly matured before they are subjected to any exposure or suffer a check. Ghent *Azaleas*, *Lilacs*, *Lily of the Valley*, *Spiraea*, *Solomon's Seal*, *Dicentras*, and similar subjects may be considerably forwarded by placing them in the Mushroom house or any close shed where a little fermenting material can be introduced to afford the necessary warmth. Plants like the above may be forced much more economically in places of that kind during the first stage of their growth than they can in any glass structures, where there is a constant, rapid escape of heat through the laps of the glass and other crevices. In the Mushroom house or ceiled shed, the temperature seldom varies more than a degree or two, and the atmosphere can always be kept regularly charged with moisture, so that forcing can go on without interference from any changes that may take place in the weather. Where there is a large demand for forced flowers, a close, ceiled shed, with a hot-water pipe running through it, and a bed of leaves and tan on the floor in which to plunge the pots, would form one of the most valuable places a cultivator could have, as all things of an herbaceous or deciduous nature might be helped forward by being placed therein till they pierced the soil or began to expand their buds so as to require light. The first-potted *Hyacinths* should now be examined, and if found to have pushed a little top-growth, and to have well filled their pots with roots, may now be got into heat; but, before doing so, place a tuft of Moss over each crown, or cover the same with a small flower-pot for a few days, that the sudden transition from dark to extreme light may be avoided, or the tips of the blanched leaves may suffer injury.

Lilies.—These plants, many of which have for years been comparatively neglected, are now much sought after, the usual mistake, when there exists a mania for any particular family of plants, being committed of attempting to grow all kinds, whether good or indifferent. Numbers have been sorely disappointed by purchasing quantities of Lilies by the description given of them, and that really are not worth growing by any but those who intend forming complete collections. We should advise amateurs to aim rather at selections of the handsomest and most distinct varieties, and, in the case of those that are not certain of succeeding planted out in any locality, to first grow them in pots. When well managed in this way there is a better chance of them doing satisfactorily than by planting out, except where the soil and climate suit them. Numbers who have attempted the cultivation of Lilies have only succeeded indifferently, although they are plants of very easy culture provided the peculiarities of their nature are studied. For example, they should never be potted or have their roots disturbed when they are in active growth; they should never be allowed to suffer for want of water from the time their tops have appeared above ground and have attained considerable size, and all through the growing season, when they have a good amount of leaf surface, they require plenty of water. Another point of equal importance in pot culture is that from the time the tops have died down in the autumn the soil should never be allowed to get too wet or too dry. The present, when the tops of almost all are dead, is the best time for repotting, in which operation disturb the roots as little as possible. Good moderately sandy loam, with one-sixth well rotten manure and leaf mould in equal proportions, thoroughly mixed with the soil, will grow them well. In potting

cover the bulbs with about 4 in. of soil, and stand the plants through the winter in a house, pit, or frame, from which frost can be excluded.

Carnations in Pots.—A few more of these useful plants may be placed in a house or pit where a night temperature of 50° can be maintained; elevate them as near the roof as possible, and do not allow them to become dry at the roots so as to injure them, it being necessary to guard against this defect, particularly in the treatment of plants that are ranged on shelves over the paths where they are not immediately under the eye, and consequently their requirements are less likely to be noticed. Plants of these required for flowering later during the winter should have their pots plunged up to their rims in coal ashes, in a frame or shallow pit, where they can be protected from frost.

Indoor Fruit Department.

Peaches and Nectarines.—Where fruit is required early in May, a house in which the wood had ripened early may now be closed; but to be successful it must be forced very gradually, for to attempt brisk forcing would defeat the object in view. If the border has been renewed, and both trees and structures cleared, it may be necessary to give a moderate supply of tepid water at the roots, but if it be found that the soil is in a healthy, moist condition, it is better to omit watering for some time. Outside borders should be covered with dry litter, leaves, or Fern, and wooden shutters, tarpaulin, or house tiles, should be placed over the whole to throw off wet. Some have strong faith in thick coatings of manure and other fermenting material, for heat being applied over the roots; but, after trying numerous experiments, I am of opinion nothing is gained by this practice. The active roots which draw up nutriment to support the trees and fruit are either at the front of the border, or far beyond it, and the covering in this case is often the means of doing more harm than good by directing the wet to the feeders, keeping them cold and sodden. To be safe it is necessary to be certain how far these roots extend, and let them be protected their whole length. When the roots are wholly inside this difficulty does not exist. Trees always do best when their roots have filled the inside border, and have their full liberty to grow onwards afterwards. Syringe the whole surface of the house, allowing every branch to be well moistened, but the paint need on the trees against insects need not be washed off by applying the water against it with the syringe too forcibly. The floors and inside borders may be frequently moistened with a rosed watering-pot, but a stagnant atmosphere must be avoided. The temperature need not be more than from 40° to 45° for the first few weeks, that is, supposing the weather should be cold; on sunny days give plenty of air, but, at the same time, use the syringe after. It is much better to begin forcing in good time than late and have to drive the trees on quickly. On mild nights it is well to leave on a chink of air. If the fruit-bearing wood be soft and badly ripened, forcing should be proportionately delayed. Figs are more easily forced than Peaches and Nectarines; dryness at the roots or cold and wet soil often causes the soil to drop when about to swell off towards the ripening estate. Brown Turkey and White Marseilles are the most early forced. A good enfacing, as for Peach borders, is advantageous, and preparations in other respects most not be neglected. For trees grown in pots a fresh surfacing of loam, rotten manure, and bone meal is desirable, and they must have good drainage. The pots should be plunged in a bed of leaves giving out a mild heat, say 75°, laying a turf or two at the bottom of the holes in which the pots are to be placed. When the roots grow through the pots and into the earth, giving the latter a good soaking of tepid manure water assists greatly to swell off the crop to a great bulk; 45° at night is a sufficiently high temperature.

Kitchen Garden.

Celery.—We often hear complaints of Celery decaying prematurely through the winter, which is traceable to two causes—either the sorts grown are inferior, spongy, or hollow in the stalks, or the earthing-up and protection during frost has not been well managed. The last crop of all, intended to come in for use after that which we have already spoken of, should only be about half earthed-up—that is, the ridge ought not to be brought higher than the centre leaves, leaving those exposed to the light until later on, to protect which and the general crop from severe frost, sufficient material should be in readiness, in the shape of stable litter, Asparagus, or dried Pea haulm, dried leaves, or, best of all, Fern. Where possible, secure a good supply of this useful material, which, for all purposes of protection from frost, is superior to all others. It must, however, be kept under cover, for, if it is allowed to lie in masses and get wet, it will rot. It is now dead and in right order for gathering. A dry day may be chosen for cutting it, and it may be stowed until required under a temporary covering of any kind, or placed a couple of yards thick over Potatoes, Carrots, or Beet, in the root-shed, and here kept until

wanted. Not only is this Fern (the common Bracken) good for the purposes mentioned, but it is also invaluable for laying over beds of Hyacinths, or for placing round crowns of tender herbaceous plants, the collars of Tea Roses on their own roots, or for putting around the heads of standard Teas. It may be added that there is nothing objectionable or untidy in its appearance when thus used.

Potatoes.—It will be well to again turn over the crop of Potatoes and remove any diseased ones that may have escaped detection previously, as, if allowed to remain, they affect all they come in contact with. Even if there is a total absence of disease they are very much improved by turning over in this way if at all damp. To have Potatoes in the best condition they should be quite dry for a considerable time before using, for this reason—the quality of Potatoes kept in clamps is never to be compared with such as are stored in a dry shed. When the camping system has to be resorted to for wintering Potatoes, they should always be taken out and placed for a month or six weeks before being in a place where they will get dry.

Hardy Fruit.

Preparation for Fruit Trees.—A short time ago I urged the necessity for preparing land for fruit trees of all kinds, including bush fruits, and for completing the planting as soon as the season would permit it. Whatever preparation of the ground yet remains to be done should at once be carried out and the planting pushed on. All the advantages are on the side of completing this work without delay; later on, short days, and the condition of the soil, prevent the possibility of its being done so well or expeditiously. There is another matter connected with early planting that amateurs who have trees to purchase will do well to bear in mind. Those who procure trees early have the pick, which are very often worth double that of the plants sent out subsequently. Trees of any considerable size that are removed should, as soon as planted, be secured from injury from wind by stakes, for, if allowed to be shaken about so as to disturb their roots, it will do them serious injury; trees that require support after planting should have three stout stakes, each about 5 ft. in length. These ought to be driven into the ground about 2 ft. from the trees in a slanting position, so that the tops of the stakes will meet together a yard or so up the stems, at which point they should be secured with strong tarred twine, lapping the stems of the trees with a straw rope, so as to keep them from injury by the stakes.

Extracts from my Diary.

November 25.—Getting in another lot of Ashleaf Kidney Potatoes⁶ in pots. Making up a hotbed for Asparagus with manure and leaves that had been previously well turned and mixed. Planting out the last batch of Coleworts, and stirring the soil amongst those previously planted.

Nov. 26.—Potting herbaceous Calceolarias, and fumigating Cyclamens to kill green fly. Cutting down Jerusalem Artichoke stems and clearing them away, and covering up a portion of the roots with long litter to keep the frost from them. Adding to late Celery a little more earth whilst the soil is dry and in workable condition.

Nov. 27.—Sowing a three-light frame with Radishes. Potting a quantity of Echeverias, and filling a number of boxes with them. Covering up Endive and Lettuce to blanch. Getting all Peach and Nectarine trees unnailed. Finishing tying Raspberry canes and giving a good coat of well-rotted manure between the rows.

Nov. 28.—Sowing 100 pots of French Beans and earthing up those previously started. Clearing out decayed vegetables and dead leaves amongst growing crops. Making up a new hotbed for forcing Asparagus. Rolling lawn tennis ground and other turfed surfaces. Pruning third Black Hamburgh house.

Nov. 29.—Getting a few more Cinerarias and Primulas into gentle heat to bring them forward. Giving second early Vinery a top-dressing inside, and afterwards a good watering. Looking over Cauliflowers, turning down leaves where required, and removing those that are most forward to an open shed.

Nov. 30.—Clearing up leaves and otherwise putting the pleasure grounds in order. Rolling down all gravel walks firmly. Looking over fruit-room, and clearing away fruits that are beginning to rot. Looking over Pines, and watering such as require it; tying up fruit where necessary. Fruit in use for dessert: Pines, Grapes, Apples, Pears, Medlars, and Nuts.—W. G. P., Dorset.

Autumn Broccoli.—I am still cutting Veitch's Self-protecting Broccoli, of which I was curious to weigh two or three heads. They averaged 4½ lb., and not a particle of the flower was to be seen, the foliage covering it in the most perfect manner. I shall make this a standard variety in future.—R. GILBERT, Burghley.

THE LIBRARY.

HEREFORDSHIRE POMONA.*

It is a pleasure to see the handsome first part of this which we hope will make a noble book. The day of books of this sort had appeared to be past, though at one time they were more common, especially of the large form of the one before us. The first things that strike attention in such a work are naturally the plates, and these are exceedingly good. Such woodcuts as are used are not at all equal to the plates, but then they are of much less importance. The book seems exceedingly well done in all respects, except as regards its form, which is, perhaps, cumbersome. The work is produced by the Woolhope Naturalists' Field Club, and was originally intended to form a work of local character, as its title indicates, but the great and widespread interest with which the announcement of its publication had been received has induced the Woolhope Club to believe that it will be more useful if its scope be made more general. It is intended, therefore—subject to the favour and support it may meet with—to make this Pomona a thoroughly English work. Its local name will still be retained, but it will embrace all Apples and Pears of established merit cultivated in Great Britain, even though some of the new or special varieties may not, as yet, be grown in Herefordshire. The coloured drawings, the woodcut outlines and sections, and the greater part of the letterpress are original, and their production very expensive. The Woolhope Club, however, has neither the intention nor the desire to make any profit from the publication of the work; and, beyond the copies supplied to its members, the number offered for sale to the public is very limited, and only sufficient to meet the great expenditure of a work of this character. The first part, now published, comprises the early history of the Apple and Pear. Thomas Andrew Knight (president of the London Horticultural Society from 1811 to 1838) and his work in the orchard; the Fox-whelp Apple, Pomeroy, miscellaneous dessert Apples, viz., Joanneting, Summer Golden Pippin, Court of Wick, Devonshire Quarrenden, Borsdorffer, Worcester Pearmain, Kerry Pippin, and Herefordshire Spice Apple; the Monarch and Althorpe Crasane Pears; new Northern Greening Apple, Spring Grove Codlin, Stirling Castle, Wormsley Pippin, Keswick Codlin, Manks Codlin, Lord Suffield, Hawthornden, and Tom Putt. The second part is announced for publication in 1879, and will contain, in continuation of the introductory matter, a paper on "Modern Apple Lore;" "A Sketch of the Life of Lord Scudamore," by Dr. Bull, with a full-page portrait of his lordship; and a paper on "The Cordon System of Growing Pears," by Sir Henry E. C. Scudamore Stanhope, Bart., with a full-page woodcut of the cordon wall at Holme Lacy. These will be followed by six coloured plates of such different varieties of fruit as may be procured in perfection during the ensuing season.

Meehan's Flowers and Ferns of the United States.—In the recently-arrived numbers of this book we notice especially *Gerardia pedicularis*, a member of a beautiful family not in cultivation; the singular little Snake-mouth Orchid *Pogonia*; the spring beauty *Claytonia virginica* (this plate does not show the delicate beauty of the plant; a purplish variety of the *Anemone caroliniana*, a plant which we do not remember to have seen in flower in our gardens; the Swamp Rose (*Rosa carolina*) and the old Phlox reptans, long known under the name of verna in English gardens. The plates, the letterpress, and, above all, the printing and paper are excellent.

The publication is announced (Ch. Stahl's Verlag in Neu-Ulm) of a "Grasses Illustrirtes Kräuterbuch," containing a complete description of all plants and herbs in reference to their uses, their effects and application, their culture, collection, and preservation. It contains instructions for the preparation of all kinds of medicines, juices, syrups, conserves, essences, powders, &c. The work contains coloured illustrations, and is published in fifteen parts.—"Natore."

Messrs. W. B. WHITTINGHAM & CO., of Gracechurch Street, announce a third edition of Col. Money's treatise on "Tea Cultiva-

* "The Herefordshire Pomona," with the most esteemed kinds of Apples and Pears. Edited by Robert Hogg. London: Hardwicke & Bogue; Hereford: Jakeman & Carver.

tion and Manufacture." The entire work has been revised and much extended, and now makes an important demy octavo volume of 200 pages.

ROSES.

DIFFERENT MODES OF GRAFTING.

(Continued from page 426.)

DOUBLE CLEFT OR CROWN-GRAFTING.—When the diameter of the stock will allow of it, we may put on two scions opposite each other, as shown in fig. 15. The scions are, as in single cleft-grafting, placed at the extreme outer edge of the cleft, so that the bark of each of the grafts is in contact with that of the stock. At C is the eye whose growth will favour the union of the scion and stock. At B is shown the head of the stock, which, in this instance, is cut at right angles to the axis

Fig. 15.—Double cleft, or crown grafting.

Fig. 16.—Chinese, or tongue grafting.

of the stem. This mode of grafting facilitates the ascent of the sap by equalising its flow all round the head of the stock, besides which the head of the resulting Rose bush is much more regular.

CHINESE OR TONGUE-GRAFTING.—Fig. 16 represents a very solid kind of graft, which does not produce a swelling, and which allows the Rose grower to use a stock of very slender dimensions. It should always be well covered up with grafting-wax.

B is a notched slice which is cut through the bark of the stock ending at A, and about $\frac{3}{4}$ in. in length, against which the cut portion of the graft C is pressed. E is the shoot of the graft, and F the ligature.

DOUBLE TONGUE, SHOULDER, OR CHINK-GRAFTING.—This method of grafting, which is shown in fig. 17, succeeds well with either the Rose or the Apple. The graft is slit up through the middle to the depth of 1 in., half of the cut portion is

Fig. 17.—Double-tongue shoulder, or chink-grafting.

Fig. 18.—Cleft-grafting.

sliced off, and the free end cut to the shape of a wedge, a wedge-shaped notch being made on the other side, as shown at B and C in fig. 17. The head of the stock is cut in the same way, but of course in the opposite direction, so that all the parts fit together exactly. The graft is bound up and covered with grafting wax in the usual way. This kind of graft is very solid. It does not form a swelling, and as the line of the scion and the stock are in the same direction, the resulting bush is of regular form.

CLEFT-GRAFTING.—This mode of grafting, which is shown in fig. 18, is greatly patronised by French Rose growers. M. Lévêque, jua., of Ivry-sur-Seine, grafts from 15,000 to 20,000 stocks by this method every winter, which enables him to deliver thousands of new varieties in the spring. The stocks best adapted for this kind of grafting are the Manetti, the de la Grifferaie varieties, and young seedling Briers. In the course of the month of November the stocks are prepared by pruning the roots and the stems, the latter being cut down to the length of about 4 in. They are then planted in 4-in. pots in light, rather than heavy, earth. The best mixture for the purpose is one-third of dry mould, one-third of well-rotted night-soil, and one-third of heath mould or fine sand, the whole being well mixed up together. The soil is pressed well down round each stock, and the pots are placed in a cold house or under a frame, so that the roots may develop themselves.

During the first half of January we begin grafting, continuing our operations through February, and using the young, tender shoots taken from the first grafts or from other Rose trees which have been previously placed in the greenhouse. In performing this operation, first cut the stock in a slanting direction at the top; then insert the point of the knife, as shown at A A on the right side of the figure (fig. 18), and draw it downwards on the right side towards the root in an oblique direction. Make a corresponding cut on the other side, so that the two cuts end in a point. The notch or cleft should be about $\frac{1}{2}$ in. in length, and ought to be made opposite to a bud, which is to be allowed to grow so as to draw up the sap to the top of the stock. The depth of the cut should be such as to allow the bark of the scion to come into contact with that of the stock. It should in no case penetrate as deep as the pith of the shoot, and should be begun level with the lowest bud. The scion itself should be cut so as to exactly fill up the cleft in the stock A A. It is a good plan to cut the scion so that the bud may be at about the middle of the length of the cleft. The eye will thus be out of the reach of accidents, and will, at the same time, promote the union of the graft and the stock. In order that the operation may succeed, it is necessary that the internal portions of the bark and alburnum of the graft should be in contact with those of the stock; if they be not so, the stock and graft must be cut even. The graft being in its place, it is kept in its proper position by the thumb and forefinger of the left hand, while the right is used to bind up the junction with coarse thread, as shown at D, fig. 18. The top of the stock, the head of the graft, and the junction are then covered with grafting-wax. These grafts are then placed under bell-glasses in the propagating house, or in small boxes fitted into the frames of the house and covered with lights, the temperature being kept at from 60° to 68° Fahr. by means of hot-water pipes. If a propagating house be not available, a bed should be prepared from 1 ft. 4 in. to 1 ft. 2 in. in thickness, and composed of one-half of stable litter and the rest of well-rotted loam and leaf-mould, which must be well mixed together as the bed is being made. When the operation is completed, the surface of the bed is trodden down; and if the stable manure be too dry, the whole must be watered after the frames are put in their places, the surface of the soil being covered over with a layer of old tan or light earth about 4 in. in thickness. At the end of five or six days, as soon as the material has become sufficiently heated, the frames are filled, the pots being placed very close together, but without being plunged in the tan.

HERBACEOUS GRAFTING.—Grafting is carried on in the same way during the second year, the only difference being in the choice of the cutting, which is either taken from the grafts made the season before or from plants grown in pots and previously placed in the propagating house in the month of November. During the latter half of the month of January we use shoots which have already somewhat advanced towards maturity. The slips are cut so as to have three buds on each, as well as two or three leaves on each petiole. These herbaceous cuttings are grafted on stocks which have been kept in reserve in the propagating house or under frames, and which should be in full vigour. The mode of grafting adopted during the first year is carried out in all its details, the only difference being that the graft is herbaceous, whence the name. It is necessary to keep these winter grafts in a damp atmosphere so as to favour their development. The suckers which grow up from the roots of the stocks must in all cases be removed, but the shoots thrown off by the body of the stem should be pinched off gradually, beginning at the bottom and working upwards towards the graft, and completing the operation when this latter is in full growth, when they may be pruned away, the intention being to promote the upward current and retention of the sap. Care must also be taken to prevent the grafts from being injured by frost by surrounding the frames with dry stable manure, and covering them on cold nights with straw mats, taking advantage of the middle of the day to give them a little air so as to prevent them from becoming too damp. The frames should also be protected with stable litter when the sun is too hot, or the glass of the frames may be painted over with limewash, and the watering should be moderate. When the grafts have struck well, and have shoots of 8 in. in length,

they are transferred to a cool house or frame, where they are left to develop themselves until such time as a favourable moment for planting them out has arrived.

GRAFTING ON CUTTINGS.—This method of grafting is carried out on the same principle as that described above, differing only in the fact of the stocks being unrooted cuttings. For this purpose we choose cuttings of those Roses which root easily and quickly, such as Jules Margottin, La Rosière, Jacques Lafitte, Pio IX., De la Grifferaie, and Manetti. The cuttings should be from $\frac{1}{4}$ in. to $\frac{1}{2}$ in. in diameter, and cut slantwise into slips $2\frac{1}{2}$ in. to $3\frac{1}{2}$ in. in length. The others must be cut horizontally under the bottom eye, taking care to preserve the swellings or calluses of those which have any. It is on the upper portion of these cuttings that the scions are grafted, as shown in fig. 19. The scions, of course, are always thinner than the cuttings upon which they are grafted, and are generally cut from choice varieties of the Tea Rose, the grafting of which necessitates great care and much heat. An excellent way is to shield-bud the most vigorous branches of these Roses during the months of April and September, placing them sufficiently close to allow of their being cut as soon as possible, so that every shield-bud will yield a cutting that is less inclined to throw out shoots. The most favourable time for grafting on this plan begins in the middle of September and ends towards the middle of December. For the later operations it is as well to keep a reserve of cuttings, so that they may not be attacked by the frost. These operations have the advantage of being able to be carried out in a room or house during the frost, so that large numbers may be prepared in what would be otherwise a slack time. Before transplanting them definitely, they must be placed in sand or heath mould at the rate of eighty under each bell-glass, each frame holding ten bell-glasses. They must be attended to just in the same way as has been recommended for cutting scions planted elsewhere. When once the scions begin to grow we must give them air by raising the frames or bell-glasses, taking them away entirely when there is no longer any danger of frost, that is to say, about the middle of March, so as to accustom the young shoots to the air. This greatly facilitates the planting out of the grafted cuttings, which should take place about the middle of May.

Fig. 19. Graft with out callus. Graft with callus.

J. LACHAUME.

Autumn-blooming Roses.—A great deal has lately been written about autumn-blooming Roses. I doubt if any are superior, after frost has put in one or two rather severe appearances, to John Hopper and Duke of Edinburgh. In an open and exposed position here the Teas, although (Nov. 3) still covered with blooms, have none left that do not show the effects of last week's frosts in rotten outside petals and damp, sodden, rotting buds, while the two varieties just named are still producing buds and blooms of good quality which have not suffered from the excessive wet and frosts. Of course, however, no Roses are equal to Teas for autumn blooming so long as frosts and a superabundance of damp can be avoided.—J. E. EWING, *Norwich*.

Rose Culture.—Being uninitiated in the art of Rose growing, it was with some misgivings that I procured last autumn about thirty half-standard trees, chiefly Hybrid Perpetuals, and planted them in my little garden. I dug holes about $1\frac{1}{2}$ ft. deep, put a bucket of stable manure in the bottom of each, planted the trees, staked them, and (regarding the culture of Roses as a mysterious affair, not to be rashly undertaken) waited anxiously for the result. I have been, however, rewarded for the little trouble I took with a good display of Roses, both as regards quantity and quality, without a single failure. Either, therefore, my experience is exceptional, or nothing is easier than to grow Roses. One of my trees, Madame Bérard, a Tea Rose, deserves special remark; it was one of the first to bloom, has kept up all the summer a continuous display of exquisitely-tinted flowers, and has at this moment about fifteen plump and healthy-looking buds, some of them half expanded. Certainly no Rose in my limited experience can compete with this one.—S. CHAMP, *Bridport, Dorset*.

LONDON MARKET GARDENING.

Plants and Flowers for Market.

The houses in which growers for market cultivate their plants and flowers are generally span-roofed; light and airy, with a path running through the centre; as a rule, little attention is paid to painting and glazing in such places, what is done being performed when work is slack by men employed on the place. One grower never paints his houses after they are built. They are put up by his own workmen, painted two or three coats and in this state they remain, nothing afterwards being done, except putting in a few squares of glass when necessary. When worn out such houses are taken down and new ones built in their places. The best examples of plant houses I have seen in market gardens are those belonging to Messrs. Beckwith & Son, of Tottenham; they are span-roofed without rafters, the sashes in which the glass is fixed being of iron and placed at such distances apart as to admit a pane of glass 2 ft. wide. By being thus constructed every possible ray of light is taken advantage of, and to this may be attributed in a great measure the almost marvellous results in the way of culture obtained there. The heating apparatus in this place consists of seven powerful horizontal tubular boilers, each of which measures from 10 ft. to 12 ft. in length and 6 ft. to 8 ft. in width, and weighs nearly 9 tons. They were prepared from plans furnished by the proprietor, and are found to be more economical, powerful, and durable than those of more complicated construction. To these boilers are attached upwards of seven miles of 4-in. piping, and in ordinarily mild seasons they consume 600 chaldrons of coke and 250 tons of coal, besides an enormous quantity of breeze, small coal, cinders, &c. Here, as elsewhere, no provision is made to have gravel walks or paved floors; these consist simply of the hard ground, upon which now and then a barrow-load of broken clinkers is thrown down to fill up holes where water might stand. There are between thirty and forty hands employed in this, one of the largest plant growing establishments near London, and each of these has, as a rule, his work regularly allotted to him, so that he knows exactly what to do and when to do it. Market gardeners always endeavour to secure good workmen, and keep them as long in their service as possible, frequent changes in such establishments being very inconvenient, as new hands require a long time to become acquainted with the work. Propagating is carried on with wonderful skill and rapidity, and a man well versed in such work is seldom out of employment. Everything done in such establishments is done at high pressure, everybody is in a hurry, and the work performed in one day in such places would surprise many a young gardener in a private establishment who thinks himself overworked. Some market florists have a few kinds of plants of which they make a specialty, and to these they devote the greater part of their time, which in a great measure accounts for the superiority of different market plants grown in such places over those produced where mixed collections are grown; some, however, whose ground is but of limited extent cover it with glass, and produce healthy marketable plants of various descriptions at all seasons of the year. The advantage gained by growing a variety of plants is, that a few van-loads fit for market can at all times be made up; whereas where only a few kinds are grown, blanks in the supply and consequently in the incomes often occur. In some of these places there are about twenty houses ranging from 60 ft. to 150 ft. in length, and every inch of space is utilised in the most

profitable manner. I have known from a comparatively small place upwards of 100 dozen plants to have been sent to market weekly throughout the year. During the summer, when Heaths, Cytisus, and the more hardy kinds of plants can be placed out of doors, their places in the houses are occupied by Bouvardias, Ferns, Lycopods, and such plants as are disposed of in time to make room for the young plants in spring to come indoors. Bedding plants of different kinds are grown to fill up any vacant space that may occur in the houses, and these, being but a very short time on hand, add greatly to the profits of the place. One good illustration of a small market garden that requires but a comparatively small capital to start with, but from which a large profit may be made, I saw some time since at Tottenham. Indeed, it is almost astonishing how a man can meet the expenses attending the culture of fruits and plants for market and yet realise a fair livelihood by the proceeds from so small a place. The ground is attached to a small villa residence, and is not an acre in extent, but nearly the whole of the space is covered with glass. The houses are principally span-roofed, arranged side by side, thus saving the necessity and consequently the expense of building side walls to each house; only the houses at each end of the block have brick sides, the roofs of those houses in the middle of the block being supported by stout wooden planks from 12 in. to 15 in. wide laid on brick piers built at a distance of from 10 ft. to 12 ft. apart. Into these planks or wall plates the rafters of the houses are fixed. The eaves of the roofs are within 6 in. of each other, and by hollowing out this vacant space in the planks, an excellent and cheap trough is made for carrying off the water from the roofs into an adjoining tank prepared for the purpose. These span-roofed houses are about 60 ft. in length, 20 ft. wide, and sufficiently lofty to allow of a person working comfortably in them. A narrow path runs through the centre, and on either side, a few feet from the glass, are erected stout but rough wooden stages, on the top of which are laid a few inches thick of ashes. One doorway only is allowed to these houses, the space being far too valuable to leave more than one end of the house unoccupied. The wooden rafters in which the glass is laid are light, but of fair strength, and being from 18 in. to 20 in. apart, admit of large panes of glass, and thereby all the light possible. All building, glazing, painting, and, in fact, all the labour connected with the place, is performed by members of the family, and to this fact may be attributed to some extent the satisfactory results that are obtained, each having personal interest in the business.

Roses.

In the London markets, as in every town and village in England, the Rose, to whatever section it may belong, is considered the queen of flowers; even when there is not a great demand for other flowers. Roses can always be disposed of in large quantities. At Christmas and for several months afterwards if we want a Rose we get a Tea, and have to pay from 1s. to 2s. 6d. for it, but during June we get a beautiful Moss, Provence, or a Damask for 1d. Tea Roses of course yield the best returns to the grower, but there are near London men who, out of a very limited space of ground, grow sufficient Hybrid Perpetual Roses to gain for them a fair livelihood; whilst Moss Roses are considered one of the most profitable of outdoor crops.

TEA ROSES.—During winter and early spring the blooms of Tea Roses always find a ready sale at good prices in the market, and although large quantities are imported

from France, English growers, by aid of cheap glass, &c., and improved kinds, are beginning to compete on favourable terms with the foreigner. Whilst it is true that Continental growers have the advantage of a warmer climate, which enables them to produce Roses early at little expense, yet they have the disadvantage of losing a day or two in transit, which, even in cool weather, takes some of the freshness off the blooms. The Covent Garden florists, moreover, want flowers at given dates, and these they can only procure at short notice from English growers who are within an hour's ride of the market. One of the largest growers of Tea Roses near London is Mr. Ladds, of Bexley Heath, who has several span-roofed houses 300 ft. long and from 35 ft. to 40 ft. wide filled with them during winter and spring. The plants are grown in good, sound, sandy loam in pots varying in size from 8 in. to 10 in. in diameter, the plants being trained in the form of pyramids by tying the main shoots to an upright stake inserted in the centre of each pot; in this way the plants have a neat uniform appearance, and do not take up so much space as if trained in any other form. Potting is usually performed in spring after the plants have ceased blooming, but very often they remain in the same pots for several years, unless their drainage becomes defective. If the houses are not required for other purposes during the summer, the Roses are allowed to remain in them, otherwise they are removed and arranged closely together in beds in the open air, kept well supplied with water at the roots; and in this way they succeed almost as well as when left under glass. One house of Tea Roses is, however, always retained for furnishing a supply of bloom during the summer and autumn. The principal varieties grown are Niphetos (pure white) and Isabella Sprunt (golden-yellow); these kinds are profuse bloomers; the flower-buds are large and perfect in shape; and as fully expanded blooms are never needed in the market, only kinds that will produce a large quantity of well-shaped buds are cultivated. From the middle of September till the end of May, the quantity of Rosebuds sent to market from this place averages from 70 dozen to 200 dozen every market morning. These are eagerly purchased by the bouquet makers, who pay from 3s. to 9s. per dozen for them according to the season and the supply in the market. Every afternoon preceding the market days a man goes over all the plants and cuts every bloom that is fit, placing them as he does so on a large shallow tray carried by a boy on his head. When all are gathered each bud has a piece of soft matting tied round its middle to prevent the petals from expanding and becoming injured. They are then carefully packed in boxes ready to be sent to market early the next morning. Some florists near London grow Tea Roses into enormous specimens in tubs or large pots, and others plant them out and train them over the roofs of houses; little pruning in any case is done to Tea Roses. Some growers have houses planted with them in which they are allowed to grow nearly wild, and the crops of flowers which they produce is marvellous. The greatest enemies Rose growers have to contend with are mildew and green fly; the former is only kept in check by precautionary measures, such as dusting the hot-water pipes with sulphur when the plants are started into growth, and the latter by frequent fumigation, a healthy airy atmosphere, free growth in the plants, and frequent syringings overhead. In most nurseries Tea Roses are grown in some way or other, the plants themselves being often trained under the roofs of the houses in such a manner as to obstruct as little light as possible

from the other kinds of plants which are grown beneath them. In other cases the plants are grown in large pots and trained up a series of trellises about 6 ft. or 8 ft. in height and from 3 ft. to 4 ft. apart. A pathway along one side of the houses admits of the blooms being easily gathered or the plants attended to. By this means the whole of the space is utilised most profitably, and the plants receive abundance of light and sunshine on all sides. Examples of Marechal Niel and Gloire de Dijon are the kinds usually found planted out in large houses, the branches being trained, as before stated, in lines along the roof. I have seen plants thus circumstanced that had been planted only two years which have made over 35 ft. of growth each, some of the shoots being as thick as a good sized walking-stick, and bearing hundreds of blooms. Such kinds as Mrs. Bosanquet, Devoniensis, Madame Falcot, and Lamarque are highly esteemed by some growers; they are all excellent kinds in the bud state, but for general purposes there are no Tea Roses at present grown for market which equal Niphotos and Isabella Sprunt. Mr. Ladds, to whom reference has already been made, used formerly to grow large quantities of Marechal Niel, but he now scarcely grows it at all.

GARDEN DESTROYERS.

THE WOOD LEOPARD MOTH.

(ZEUZERA ÆSCULI)

This beautiful and delicately-coloured moth is fortunately not very common in this country, as its caterpillar is very destructive to many cultivated trees and shrubs by boring into their stems and branches, and making in them long galleries in which they live, feeding upon the wood of the tree. In time the branch so bored dies, or is so weakened that it is easily broken off by the wind. As the caterpillars frequently do not attain their full size until the third year, they have plenty of time in which to do considerable mischief. The trees which are particularly liable to the attacks of these insects are the Apple, Pear, Quince, Holly, Lilac, Privet, Ash, Mountain Ash, Elm, &c. As the caterpillar spends the whole of its existence within the branches, it is very difficult in any way to reduce

Caterpillar of Wood Leopard Moth (*Zeuzera aesculi*).

their numbers. When a branch begins to wither it should be carefully examined, and if a hole is found in the bark round which there are small, sawdust-like particles of wood, and some of their droppings, the branch should at once be cut off to prevent the caterpillar doing any further mischief; care must be taken, however, that the branch should be cut back far enough to render it quite certain that the caterpillar is not left behind in the tree. The portion cut off should then be split open and the caterpillar found and destroyed. If the caterpillar is in the stem of a tree, or in such a position as to make it impossible to cut the bough off without injuring the tree, its hole may be somewhat enlarged with a knife; and if it cannot be reached in this way, a wire may be introduced into the hole, a good thrust from which would kill the caterpillar. The perfect insect should of course be killed whenever it may be found. The female moth is furnished with a very strong ovipositor, with which she deposits her eggs in the bark of the various trees. The eggs are round and orange coloured, and are laid at the end of July or beginning of August; the caterpillars are soon hatched, and live at first between the outer and inner bark; as they grow stronger they work their way into the wood of the tree. They do not increase much in size until the following spring, when they begin to grow rapidly and increase in size until May in the next year, when they are generally

full grown; they then leave the woody part of the branch, and form a thick web under the bark, in which they assume the chrysalis state, and from which they appear as perfect insects in July or August. The moths are particularly elegant insects; the females, which are considerably larger than the males, are about $1\frac{1}{2}$ in. in length, and measure about $2\frac{1}{2}$ in. across the wings. The markings of both sexes are alike, but the males may easily be distinguished from the females by their antennæ, which are black and deeply pectinated or toothed, like a comb, on both sides in a most beautiful manner for half their length from their base, and the upper half deeply notched; whilst those of the females are slender, clothed with a whitish down towards their base, and to the naked eye appear quite smooth. The females are also provided with a projecting, brown ovipositor. The head and thorax are covered with a very thick white pile, the latter having three black spots on either side of its centre; the body is thickly clothed with a black down, each joint being fringed with white. The wings are long and narrow, and are white and almost transparent, with

Wood Leopard Moth (*Zeuzera aesculi*).
