(LATE T. DAVISON.)

INTRODUCTION.

NATURE is the general name for all that exists, so as to be perceptible by the human senses, without being planned by human contrivance, or executed by human labour; and in this, its general meaning, NATURE stands opposed to ART. But the line of distinction between the two is by no means precise, inasmuch as all the materials of art are natural substances, and all the processes of art are applications of natural principles.

Hence, although practice may render the hand more dexterous in execution, yet before art can be in the least extended—before one addition can be made to the accommodation and comfort of mankind—we must go to nature for the materials, and to a knowledge of nature for the method of using them.

Nature, then, is all to us both for knowing and for doing—our life, our means of living, our enjoyment; and when our knowledge of it becomes so extended as to enable us to see that it is *one whole*, the countless parts of which work together with incalculably more nicety than any machine which the most skilful of us can put together, that these parts have within themselves a power of repair and reproduction which we are unable to imitate even in the slightest degree—when we carry our contemplation thus far (and if we think for ourselves, the distance is not a long one) the conclusion is irresistibly forced upon us,—that subjects so many, so varied, so beautiful, so exquisite in their structures, so perfect in their adaptations—principles so simple yet so powerful, operating at all distances, efficient alike upon the atom and upon the mass,—now determining the orbits of comets, and the career of planets, through space to which we can assign no bounds; and again, bringing back the green mould on the bark of the tree, or peopling the waters with myriads of living creatures,—that this majestic structure must have had a Maker; and that those laws which congregated worlds obey as easily as the thistle-down yields to the wing of the tempest, must have emanated from One, compared with whom, human strength, and human wisdom, nay, all that is material, must be as nothing.

It is this vast extension, this endless application of natural history, and its tendency to promote a more perfect knowledge of the works of creation, which raises it so high in the scale of human inquiry and pursuit, and which renders every attempt to impart it in more accessible, more easy, or more persuasive forms, one of the most praiseworthy services that can be rendered.

No doubt the lessons of nature abound everywhere. They come to us in the beams of the sun, producing days and seasons, clothing the earth with plants, peopling it with animals, and making it gay with flowers, tuneful with songs, lovely to every sense, and abundant to every wish. Those beams command the winds of heaven, sending them to one place with drought, to another with rain,—making the calm to glitter, the breeze to rustle, the gale to sweep,—gleaming the lightning here, and volleying the thunder there,—and producing, by the variety of their own action and that of the surfaces and substances on which they act, all those phenomena of the weather and what the weather brings, about which we speak so much and know so little. Air and sea too, in their own properties are volumes teeming with instruction, if we could read them; and we soon could if we would. Of the solid matters which compose the earth, of its plants and its animals, whether on the land or in the sea, it is unnecessary to speak, because man has no wealth but from them, and no means of acquiring it but by the knowledge of their properties. It is indeed the very extent of nature which deters us from the study of it; and when we do attempt that study, after knowing by report how extended it is, we do not find the same assistance as in those secondary applications of it which are more immediately accordant with our daily pursuits, or more immediately within the grasp of common minds.

This is not to be wondered at: Nature being the source of all the sciences, and the most successful observers having extended only a little way in their knowledge of it, it is utterly impossible that any man can come so prepared as to understand it all, or even live so long as to acquire a thorough knowledge of any one division. But still there are many labourers in the field, their numbers are increasing every day, and it is one in which all may labour without slackening their hand in any other pursuit; though it is not one the whole of the acquired knowledge of which can be generalised into a single science.

The principles, and the practical observation or knowledge of facts, must be taken apart from each other; the former constituting what may be generally termed The Physical Sciences, which more immediately connect the observed facts with, and render them useful in, the arts; and the latter constituting the science of Natural History, or the appearances of nature in all its departments, as they present themselves to the senses.

But Natural History must not be confounded with *history*, in the common application of the term, as recording the succession of actions in time merely; for it includes, also, the knowledge of all natural subjects *as they exist in space*, and not only in their single characters, but in their relations to each other, to the proximate subjects among which they are found, and to nature generally in its co-existence, and in as far as is possible in its succession.

These considerations will readily be admitted, when it is borne in mind that nature furnishes us with powers and instruments, as well as with materials; and that, though it is chiefly as materials that we ultimately apply nature to use, the abundance and quality of these depend upon the efficiency with which we can make the powers of nature work for us; and that of course depends upon our knowledge of those powers. The truth of this stands in need of no argument or illustration; we have only to direct our attention to the garden, the field, the meadow, and the forest, and consider where would be our food and our clothing, and even the possibility of our existence, if the natural powers which are daily and hourly at work for us there were to cease for one season or one month.

PLAN OF THE WORK.

Regarding Natural History as we have attempted to define it, without even implying disparagement to any of the existing publications, it may be said, that a work which shall place the whole subject before ordinary readers, in an accessible, easy, and ample manner, brought down to the present advanced state of science in all its departments, and yet freed from the technicalities of science, which are perplexing to ordinary readers, is still a desideratum. To supply that desideratum is the purpose of the present work; and that purpose is sought to be accomplished, by avoiding the granderror into which the projectors of most works of a similar nature have fallen, that of making a collection of detached articles, not only without connexion in themselves, but scattered through many volumes, filled with other matters, which destroy the usefulness of each other by the confusion; and, by rendering frequent repetition unavoidable, greatly reduce the value of the work as a book of reference.

The plan which has been adopted for avoiding these faults, and ensuring the opposite advantages, has been to combine the two principles of a complete and connected SYSTEM OF NATURAL HISTORY, with an ALPHABETICAL DICTIONARY; and it is confidently hoped that the success and the advantages of this compound plan will be equally apparent. The complete system will ensure the same connexion, and the same freedom from repetition, as if the work were performed by one author and published at one time; while the alphabetical arrangement will enable the reader at once to turn to any single point upon which he may wish to be informed.

The systematic arrangement of the productions of nature, in the divisions and subdivisions into which they have been distributed by the best authors, furnish at once the plan, which has only to be properly executed in alphabetical order; and then, the purpose is attained, and the work rendered equally available and equally useful for systematic study and for consultation upon any single point that may be required. A short account of the manner in which this is to be accomplished will serve at once as a key to the work and an introduction to the study of Natural History.

One principle will run through the whole: that of giving under each article all that properly belongs to it, giving that clearly, and as fully as appears to be consistent with the interest of the reader and the extent of the work, but giving no more.

In following up this plan, the various classes into which animals, plants, and minerals have been divided by naturalists will be given in their alphabetical order, with the characters on which the class is formed; to this will be appended the orders into which the class is divided, and which will be found also in the order of the alphabet. From these again the reader will be referred to the family, and from the family to the minor groups or genera.

It is evident that reference can be made from particular articles to general ones as readily as the other way; and that, therefore, not a single line of repetition will be necessary in any of the articles, because each article will explain all that relates to its own subject; and if the reader wishes to turn to any thing more general, he will have only to look at the commencement of the article, to see from what articles that one subdivides or branches, and he can easily turn to these.

The same method will be followed through all the steps from the class down to the species, in every instance in which it can further the purposes of information to descend so far; and where that is unnecessary, the more important species will be found described under the genus or other final group, which appears to favour the grand object of furnishing the most abundant and accurate information, in the most accessible form and in the smallest compass.

In the references, the common English name (when there is one), and the systematic name will be given together; and where it suits equally well for other purposes, the alphabetical arrangement will follow the English names. This will prevent waste of space, make the work at once adapted for popular reading, without the labour of acquiring learned names, and occasion no difficulty to those who follow the systematic arrangement from the more general articles to the more particular, because if they do not find the next stage of the description under the one of the two names which are in juxta-position, they may make sure of finding it under the other.

NATURE is usually considered as divided into three KINGDOMS, of which short explanations are given in the following sections.

THE ANIMAL KINGDOM.

These words are expressive of one of the three great divisions of material substances; namely, all those that are possessed of *animal life,* as distinguished from plants, which have *vegetable life,* and from minerals, which are understood to have no life of any kind. In what we are accustomed to call the more perfect instances of them, the distinguishing characters of all the three are so clear and explicit, that nobody has the least hesitation or difficulty in discriminating them; and thus they neither need nor admit of explanation. They belong to that department of knowledge in which words can add nothing to the information derived immediately from the senses; and, therefore, in proportion as attempted definition becomes more elaborate, it also becomes more inapplicable. When, however, the characters have a certain degree of obscurity, and one part of the subject belongs, or appears to belong, more to one division, and another part more to another division, it then becomes rather puzzling to decide, and popular judgment assigns the subject to that division of which it has the external characteristics most conspicuously. With the products of the land there is little difficulty; for though the forms of some plants, or parts of plants, have a slight resemblance in shape, and occasionally in colour, to animals—as, for instance, the flowers of some species of *orchis* to insects, and the fruit of some cucumbers to snakes, yet in these as in all other cases of land plants, there are always accompanying parts or circumstances, which prevent the possibility of mistake; and the observer can admire the resemblance, just as he would admire a picture, without any danger of confounding the identity. Farther, as the food of animals does not come regularly in the air, all land animals are, to some extent or other, locomotive, and none of them are rooted. We know less of the food of plants than of that of animals; but it is probable that all plants feed in part upon air, or, which amounts to the same, upon air-borne substances; and, therefore, though all plants are not rooted in the earth, none of them are locomotive. The common sensitive plant, and the various other plants, the leaves and other parts of which move when touched, do not indicate the least approach to the animal character. Growth from the end, drooping in the heat, erection of the leaves during a shower, are motions common to most plants; and the plants alluded to are merely instances of some of the more singular modifications of the common vegetable motion.

In the waters it is different; and though, even there, there is no danger that a plant shall be mistaken for an animal, or that the whole of an animal (when known) shall be mistaken for a plant, yet there are cases, in which, from our ignorance of the whole, we are in some danger of mistaking part of an animal for a vegetable, or even for a mineral. The water, by its natural currents, and also by the smaller currents, which many of its inhabitants are capable of producing, brings their food to many of those inhabitants, just as the air does to plants upon land. And of the species which are fed in this way, which are often very minute, there are many that are elevated upon stems or pedicles, and these are so plant-like in their forms, that they have sometimes been regarded as plants; and writers on vegetables have claimed the sponges, corals, and corallines, as members of the vegetable kingdom. On the other hand, the supports of some of these aquatic animals take so much the form, and acquire so much the consistency, of rocks, (as in the small animals which form coral reefs with such wonderful rapidity in some seas,) that they have sometimes been considered as minerals. But a very little observation enables us to make the distinction, even in those cases in which it appears to be most obscure. The hard parts of animals generally burn into lime (though in some of the obscurer aquatic ones there is silex), or we can detect lime in them by chemical tests; and in the progress of burning, they all, more or less, give out an ammoniacal smell,—that smell which is so powerfully given out in burning feathers; and they give out that smell the more strongly, the less proportion the lime which remains bears to the whole substance. Only a few aquatic plants contain lime, while several of them contain silex, but that is in the bark, rather than the inner parts; as, in those animals which contain it, it is in the case rather than the animal itself. Burn a bit of sponge or of coralline, and then a bit of the sea-weed or other vegetable which resembles it the most, and the smell will at once point out which is the animal substance, and which the vegetable.

It is not by any essential difference in the matter of which they are composed, that we are enabled to ascertain to which of the three kingdoms of nature any substance belongs, for all matter, considered in its mechanical and chemical properties only, is mineral, even when it forms part of the organisation or structure of a vegetable or of an animal. The kingdom must be determined from the combination and arrangement of the parts. If these are everywhere the same, and the whole dependent upon those general laws of mechanics and chemistry,—which hold in like manner, though not to like extent, between particle and particle, as between mass and mass, so that the larger mass may be considered merely as a multiple of the smaller,—then the substance is a mineral one; and it is a solid, a liquid, or an air, or *gas*, according to the state, which state depends upon the great modifying principle, or principle of *action*, in matter, which we know only in its effects, and which we call magnetism, electricity, light, heat, vegetable life, animal life, according as it appears in different modifications, rather than from any knowledge that we have of it in itself, either as essentially the same, or essentially different, in those several modifications, and the almost endless diversities in which they appear in nature, or in the operations of art.

When the parts of a subject, whether formed of the same combination of matter, or of different ones, have a local distribution, and a difference of function, so that the whole subject is not a multiple of any one of them, but the aggregate of the whole, and has its properties as a compound being, depending upon the form and arrangement of those parts, rather than upon their mere chemical or mechanical properties as matter, then we call it an *organic* or *organised* being, the production, not of the common principles of chemical and mechanical action, but of *life:* which life, in fact, acts in opposition to the common laws of mechanics and chemistry; and when from any cause it can so act no longer, the organic being *dies*, ceases to display any of the functions of organic life, and becomes an *organic remain;* and though, as such, some parts of it, as for instance, the bones and shells are found, not merely in accumulations of mud and rubbish in a loose state but after they have been consolidated into rocks, there are always some parts of the organic structure which yield to the common laws of matter so soon after the life is extinct that we can have no interval of time between them. The hard timber of the oak or the cypress may remain for centuries; but the sapwood, and especially the living body, intermediate between the bark and the wood, speedily perishes. The bones take some time to moulder in the earth, and they remain even longer bleaching upon its surface, especially if the climate is uniformly cold; but the most anxious watchfulness can hardly determine whether the breath in the nostril, or the beam of life in the eye, is the first to vanish.

The distinctions of the three kingdoms of nature are thus not absolute and essential, but relative. The matter which is now in one of them may have formerly been in another; and may be in another again. But the relative difference is generally obvious enough; and we can not only, in most instances, easily draw the line between what is living and what is not, but in dead matter we can distinguish the organic remain from that which either never has been organised, or has so far yielded to the laws of inorganic matter as to have had all its organic characters; and of organic substances, whether living or dead, we can generally distinguish between the animal and the vegetable.

These preliminary considerations are necessary in order to have a clear understanding of the extent and limits of the *Animal Kingdom,* but they do not fall within those limits; and will not therefore have to be reverted to in the sequel of this article. The animal kingdom comprises animals only in their living state; and, as such, the knowledge of it is ZOOLOGY, or "The Science of Life." Zoology admits of ready and obvious division into three parts. First, the structure of the organs of animals,—the science of ANIMAL ANATOMY, or, as the general science was first appropriated to the structure of men, COMPARATIVE ANATOMY. Secondly, the uses, functions, and actions of the organs in their combination, with the differences of form and habit thence arising, and also the relations of the several animals to each other and to the rest of the material creation, the knowledge of which constitutes the science of ANIMAL PHYSIOLOGY. Thirdly, the external appearances of animals—their habits, general economy, haunts, numbers, and distribution over the earth or in the waters. This is the portion of the general knowledge of animals, which is open and inviting to the knowledge of all mankind, and which, though it cannot be intimately and thoroughly understood without a knowledge of the other branches, is yet so extensive and so inviting, that there are few who do not more or less attend to and understand it. There is no name except the general one of ZOOLOGY which properly applies to the whole of it; for NATURAL HISTORY, as being equally applicable to all nature, is less precise. It is subdivided into various sciences according to the forms, characters, and habits of the different animals; and it is the arrangement of those branches of the description of animals, so as to accord as accurately as possible with the differences and agreements that are actually to be found in nature, which constitutes the value and advantage of a system of *animated nature,* or a statistical table of "the *animal kingdom,*" by means of which the various classes or subdivisions may be more easily known and more clearly understood, in themselves singly, and in their relations to each other and to the whole. There are, indeed, two other divisions of the science of animals, which are highly interesting; but which perhaps require to be treated separately,—DOMESTICATION OF ANIMALS, AND PROGRESSIVE ZOOLOGY. The first of these is a branch of popular and practical knowledge, and probably the most useful in the whole range of zoological science. The other is of a more speculative character; and our information on it is exceedingly vague and imperfect, especially upon the very points upon which it would be most desirable to be informed. It relates to the changes that have, in the lapse of years, taken place in the numbers, the localities, and the species of animals; which races of them have become extinct, and when, and by what means; and whether any new ones have come in their place, and if any, which, and by what means. To assist us in the first branch of that inquiry, the data are obscure and few. The remains of the lost animals which appear to have inhabited the land, are deep in the earth, and those of some of the former tenants of the waters (if analogy of structure is to be any guide, and other than that we have none) are often found on the mountains at miles above the present level of the sea. On the other branch of the subject, we are without any guide, and all that we can say is, that, as far as our observation goes, there is not in the productive powers of existing animals any means of producing a new species; and we know of no source whence any animal can be produced, but by parent animals of the same species. The species is, indeed, somewhat plastic under the hand of natural circumstances, or the resources of art; and may be broken into varieties differing much from each other in external appearance and in disposition; but still there appear to be specific bounds which no art, and not even nature itself, can pass.

ARRANGEMENT OF ANIMALS.

No arrangement of animals can be perfect; first, because we do not know that we are acquainted with all the species; secondly, because there are many species of which we know very little; and thirdly, because of those which we know best, the greater part are known as more or less domesticated; and we are consequently unable to separate the natural parts of their characters from the artificial. The system of the late Baron Cuvier possesses simplicity as well as some other advantages, and therefore, in brief outline, we shall nearly follow it, though in different language, and with such alterations as may seem more suited for ordinary readers. The fundamental principle of that system may be said to be the greater or less development of the principle of life, as indicated by the brain or central part of the cerebral or nervous mass being both more produced and more localised, or, if the expression may be allowed, more or less concentrated; and in proportion as life is thus more developed, and, according to our ordinary mode of expression, more complex, or has a higher degree of organisation, it is also more easily deranged by mechanical injuries, and parts that are mutilated or destroyed, are not so easily restored or replaced. A wound in the human body always leaves a scar, unless where healed by what is called "the first intention," or without inflaming or granulating: and though so healed, it leaves a raphe or seam if it be large. When a nail is torn off the human finger, it is not often replaced by one equally perfect; and if even the tip of a finger is cut off, it does not grow again. The parts, within certain limits, have the power of preservation and repair; but the production of that which we call the more perfect animal appears to be the effect of one united and concentrated energy, which cannot be made to act again in the reproduction of a single organ. As we descend in the scale, and the energy of life is less concentrated, the power of reproduction increases. The leg of a frog, or the claw of a crab, will grow again; and when we descend still lower, to some of the small formless animals which inhabit the water, we find that almost any part can be reproduced; and that the species may be multiplied by mechanical division, as the segments grow to perfect animals. There is not, however, any gradual chain traceable from the one to the other; all species are distinct, and we can only form larger groups by means of some general characters, and leave the particular characters to the smaller subdivisions.

The most important and general, as well as the most obvious distinction, is that of *Vertebrated* and *Invertebrated* animals; or, animals which have spinal columns or back-bones, and animals which have not. To avoid repetition, and insure brevity, we shall take these in their order, without contrasting the one with the other.

VERTEBRATED ANIMALS.

These have the central mass of the nervous system inclosed in a case of bone, commencing anteriorly in the skull, and continued through the spinal column, which consists of a greater or smaller number of pieces or vertebræ, (but always of the same number in the same species,) variously articulated, or jointed together, according to the strain that they have to bear, and the motions they have to perform; but always well secured against dislocation, and so formed that the nervous mass which passes through them can sustain no injury in their ordinary and natural motions. This column may be considered as the centre or basis of the organisation to which all the other bones which support the softer parts are articulated. To the anterior extremity of the column are united the bones of the face and mouth, the latter consisting of two jaws, placed the one above the other, and having their principal motion in the elevation and depression of the under jaw, and the jaws variously furnished with teeth according to the habits of the species and the nature of their food. The other extremities, or limbs, never exceed four, are sometimes only two, and sometimes wholly wanting. They are more or less intimately articulated to the vertebral column, according as they support that column; and their forms and relative developments, like those of all the other parts, depend on the habits of the animal.

The muscles, or organs of motion, in those animals, are, with the exception of some that answer particular purposes in the economy, and are mostly styled *involuntary,* inserted in the bones, one on each side of a joint, and they pull the *distal* bone, or bone farthest from the spine, into a new position by their contraction.

The skin, or external covering, is flexible, and consists of an epidermis or cuticle, a mucous tissue, and a corium or true skin. The appendages to it are fur, hair, feathers, or scales; and while the animal is in health it is capable of resisting both air and water at the ordinary temperatures.

The brain, or cerebral mass, with its continuation in the spinal column, and the prolongation in various nerves or chords, forms the system of sensation. The other systems are the nourishing, the circulating, the respiratory, and the productive.

The nourishing system consists of the mouth, the stomach, and the intestinal canal, by which the food is received and assimilated so as to render it fit for being mixed with the blood.

The circulating system consists of a heart, arteries, and veins. The heart, even for one system, consists of two cavities, a ventricle, or more muscular one, which propels the blood through the arteries, and an auricle, or weaker one, which receives it on its return through the veins. But in most animals of this division there are two systems, one of them pulmonic, or receiving the blood from the body, and sending it to the lungs or other organisation that answers a similar purpose and the other systematic, receiving the blood from the lungs, and circulating it over the body. By the systematic arteries the waste of the body is supplied; and by the returning blood through the systematic veins, the matter which has ceased to be fit for the purposes of life is taken up. The blood, thus loaded with the waste of the system, is sent to the lungs, or other respiratory organs, where the refuse, which appears to consist principally of charcoal, unites with the oxygen of the air, in the case of lungs, or with oxygen separated from water in the case of gills; and these combined are given out in the state of carbonic acid gas, and in very nearly the same volume as the oxygen required.

The respiratory system is for the supply of the oxygen, to accomplish which air is taken into the cells of the lungs, or water made to pass between the fibres of the gills, the blood being in the mean time exposed to it, not naked, but in minute vessels, of which the coats are exceeding delicate. The details of these systems, further than they are connected with the external appearances and characters of animals, belong to physiology rather than to this branch of the science.

In the productive system the males and females are, in most instances, different individuals, and they are viviparous, oviparous, or ovoviviparous. The first, which bring forth their young alive, are either *placental* or *marsupial,* the former bringing forward their young in an internal uterus; the latter bringing them forward in a marsupium, or pouch on the abdomen, which also serves as a bag for carrying them in while they are very young. The oviparous produce eggs, which are hatched externally, with or without the heat of the parent, according to the species; and the ovoviviparous produce eggs which are hatched internally, and the young brought forth alive. The last of these bear some slight resemblance to the marsupial animals; and it is said that the young, in the very early state, sometimes take refuge in the envelope in which they were hatched; but this fact is not very clearly ascertained.

In all cases, however, the young is, from the very beginning, that is, from the first rudimental state in which it can be traced, a being distinct and separate from the mother;

and whether it is in the womb, the marsupium, or the egg, its circulation, as soon as it has one, as an entire system, is its own, and not part of that of the mother. The umbilical cord is a substitute for feeding and breathing only; and the pulse of the fœtus is not connected with, and does not beat at the same rate with that of the mother, and either may survive the other, though the young in the early stages can do so only for a very short time. Here, again, the details, interesting as they are, properly belong to physiology.

The gradation of vertebrated animals may be considered as ranging from man to the fishes; and in the range there are four distinct classes very well defined, both by their structure and their habits. Beasts, Birds, Reptiles, and Fishes, are the common English names of these four classes. The first of these is neither very descriptive nor very precise in its meaning, as it is originally co-extensive with animal, or even with being; and therefore it is advisable to substitute for it the term Mammalia, which is strictly descriptive of the most peculiar and distinguishing character of the class.

INVERTEBRATED OR SPINELESS ANIMALS.

Though these animals are all much smaller in size, and possess the principle of life in what we are accustomed to call an inferior degree, their inferiority is of course merely relative; because the structures of all animals, when considered with reference to the functions which they perform, are equally perfect. But still, there is a very marked difference between the two grand divisions of animals; and, if the terms can be admitted, it may be said, that while vertebrated animals are organised upon the brain and its spinal prolongation, as a basis, the invertebrated animals are organised upon the stomach, or the alimentary system. Not that it by any means follows that these animals feed either more frequently or more abundantly than the vertebrated races; for many of them, in certain stages of their being, do not eat at all, and in several, the functions of life, and feeding among the others, can be suspended for years—in all probability for ages—without death ensuing. The resemblance which these suspensions of the functions of life in the invertebrated animals bears to hybernation in the other classes has not been traced, and is, perhaps, not traceable; but it may be stated as a general fact, though one to which there are no doubt exceptions, that they obey the common physical laws of matter much more readily than the vertebrated animals, being strongly influenced, not only by climate and season generally, but by the slightest changes of the weather, and even by the times of the day.

It accords with general principles, that this greater obedience in the animal to the common laws of matter should be the result of an inferior development of the principles of animalisation; for, in all the races with which we are most conversant, we invariably find that the more sluggish life naturally is, it is the less easily extinguished. It must not, however, be understood that this inferred or presumed inferiority in the invertebrated animals is accompanied by a diminished intensity of any particular function. Indeed, it is rather the reverse; for the very same principle which enables the animal to yield more readily to external circumstances must also enable the whole of its energy, so to speak, to go more readily and completely to the performing of any one function. Accordingly, we find muscular action and the endurance of mechanical injury so great in some invertebrated animals, that we can hardly institute any comparison between them and the vertebrated ones. Comparing the size, the grass upon the most finely mown lawn is apparently more formidable to many insects than the closest jungle or forest would be to us. But the insect makes its way easily and without fatigue; and not only that, but it pushes aside substances as large in comparison with its own bulk as if a man were to push the carts and waggons, nay almost even the houses, out of his way as he walks the streets. If the spring of the lion, or the bound of the antelope, were to bear the same proportion to the size of those animals as that of the common flea or the lobster, the last of which has to leap against the reaction of water, it would be almost from jungle to jungle, or from mountain to mountain; and if the strongest-shelled tortoise were to fall from a height proportional to that from which many of the invertebrated animals can fall with perfect impunity, it would be dashed to pieces.

From all that we can observe, we have reason to conclude that the nervous or sensatory system admits of the highest degree of animal organisation, the one which is the farthest removed from the common properties of dead matter; and in proportion as that system is more developed and predominant, the functions of the animal become more varied, but individually less capable of effort, and altogether less capable of endurance. A very slight wound causes death in the mammalia and birds; and though the reptiles and fishes can recover from severe lacerations, they are all suceptible of being wounded to death; but when we come to what may be considered the inferior tribes of the invertebrated animals, where there are few functions, few organs, and nothing which can be positively pronounced to be a distinct nervous system—the entire animal being little else than a skin which can feel—we find that no cutting, and hardly even pounding in a mortar, can put the creature wholly to death. Still we do not know enough of the functions of those animals, or of the developments of the different systems in the different races of animals, to enable us to arrive at any certain conclusions with regard to the relations which the intensities of actions in those several systems have to each other, or to the power of endurance or of action in the animal generally, or the other systems which make up its organisation.

Hence it is necessary to observe great caution in assigning the energy of one part of the organisation to another part, or of pronouncing any one of the systems of which the organisation is made up as being the sole, or even the chief, seat of animal life. Even from ourselves, where, as we have feeling added to observation, our knowledge should be most perfect, we can conclude nothing without a stretch of theory which does violence to the truth. The circulating, the nervous, and the alimentary systems have at times been each regarded as the seat of animal life in man, (not as the locality of the mind, for that mind can have physical locality, while from its very nature it can have no physical extension, involves a contradiction in terms,) but of our animal life without any reference whatever to the mind. In fact, those principal systems seem to be all pretty equally the seats of life, as there are peculiar injuries which, if done to any of the three, will extinguish it with equal rapidity.

Indeed, the safest conclusion is that the life is in the organisation rather than in the organs; and as we cannot subject that to experiment, we can safely carry our theories no farther than the facts which actually come under our observation. Of this much we are certain, both from what has been mentioned of the invertebrated animals, and from what we observe in the vertebrated ones, that the perfection of the nervous system is not in proportion to the motive one, and, perhaps, sometimes not even to perception itself, in at least some of its forms, whatever it may be in others. The nervous system in the eagle and the vulture is much less perfect than in the mammalia; and yet the vision of the one, and the means, whatever they may be, by which the other finds out its food at very long distances, are far more acute than any similar capacity in the more perfect class. The return of bees to their hives and other resting places, and countless other habits of invertebrated animals, which cannot depend upon any thing at all analogous to the operation of our senses, are well calculated to teach us caution in coming to those conclusions, respecting the animals that differ greatly from ourselves in their organisation, to which we are too apt to be betrayed when we begin the study of zoology.

The fact of being invertebrated serves to separate this division of the animal kingdom from the former, but as it is a negative, it cannot be made the foundation of a positive definition; and the animals differ so much from each other, that it is not easy to write any thing general respecting them. If the nervous system be taken as the foundation, there is tolerably distinct subdivision; but it is an internal one, often not very easily ascertained, and still more generally hidden from popular observations, so that it is of little use to common readers.

The first of these subdivisions has what may be considered, perhaps, as the principal brain in the form of a sort of collar surrounding the gullet. From this collar nervous filaments proceed, which thicken into knots or ganglions in the course of their length, and the animals which have them have thence been denoted Gangliata, or ganglionic animals; but the term does not carry much information. Of these ganglioned animals there is another division, which, if the structure of the nervous system is to be taken as the foundation of arrangement, is of considerable importance; namely, that of those which have something analogous to a spinal cord, though not supported by a spinal column, unless we are to consider the external covering which invests the whole body as having that character, and those which have the nervous filaments diffused from the originating collar in such form that no one of them predominates very much over the rest. The first of these have the principal nervous elongation in the form of a cord, extending longitudinally backwards, and enlarged into a greater or smaller number of knots or ganglions; and as the body is often formed into joints or segments, having some slight resemblance to rings, these have been called Annelides, or ringed animals. There are so many diversities of appearance, habit, and the structures of the other systems, that no very precise or satisfactory information can be grounded upon these characters. There are, however, some external characters accompanying this knotted nervous cord. The animals have a head, though, in the common meaning of the word, a brainless one; and they have detached or articulated feet, or some sort of substitutes for them. They have also, in some instances, internal cartilaginous substitutes for bones; their external hard coverings, when they have them, are intermediate in their composition between bones and shells; and they have at least some of the organs of sensation belonging to the vertebrated animals, or at least bearing some analogy to them. They have also this farther in common with the vertebrated animals, that if their bodies are supposed to be divided vertically by a mesial plane passing from the anterior to the posterior extremity, the external parts are symmetrical, that is, the one half corresponds with the other, only the one is turned to the right, and the other to the left. Those animals are, therefore, to be considered as making nearer approximations to the vertebrated animals in some of their characters, both external and internal, than any others of the invertebrated ones.

The second subdivision of gangliated animals have no resemblance to the vertebrated animals in their structure; and they vary so much from each other, that no very precise general account of them can be given. They are termed mollusca, or soft-bodied animals, from the circumstance of none of them having any internal bones, though many of them have shells which entirely cover them, and others have portions of shell, more or less produced, concealed under the skin or in its folds or duplicatures.

The second principal division of invertebrated animals have been called Radiata, or rayed animals; because many of them, in some part of their structure at least, have a radiated form something resembling the rays of a star. That does not, however, so well point out the nature of the nervous system as the epithet *gangliata,* in the former division; because in many of them it is difficult to trace the nervous ramifications to any definite centre.

THE VEGETABLE KINGDOM.

Vegetables, like animals, do not admit of general definition. The name signifies "that which grows;" but though growth is common to all vegetables, it is also common to all animals; and there are some minerals that have a sort of growth. Diamonds, for instance, are tolerably well ascertained to grow in some soils, and rock crystals on some rocks. The growth in each of the three kingdoms of nature is, however, a different operation, acting upon different principles, and producing different results; and, for that reason, growth can form no part of the general definition of any of the kingdoms of nature; though the particular mode of growth is an important character.

A vegetable is, like an animal, a whole, and cannot be divided without mutilation; though the vegetables which admit of being multiplied by dividing the existing ones are much more numerous than the animals that can be so multiplied. The production, growth, and general functions of vegetables, form the subject of VEGETABLE PHYSIOLOGY.

Though some vegetables float in the water, and others hang suspended in the air, yet their general habit is to be rooted in the ground; and no vegetable, whether rooted or not, changes its place, unless removed by some external cause. But this negative quality of the want of locomotion cannot be made part of an exact general definition of vegetables, any more than the active quality of growing; for it is a general property of matter, whether organised or not; and it is also a property of some species of animals.

But though this want of locomotion cannot enter into the definition of vegetables, it is a very important point in natural history, and renders the vegetable tribes far better indications of climates and seasons than the animals are. All animals can, to a certain extent, avoid circumstances and occurrences which are disagreeable to their nature; and though plants can do the same in a very slight degree, more especially in those parts of their organisation which are the most delicate, and, as one would say, the most immediately alive, yet it may in general be said that the vegetable must stand exposed and abide whatever happens. No doubt the power of endurance in them is much greater than it is in animals; and as we have already seen that those animals which have the principle of life the least developed, or have their organisation the most simple, are the most capable of enduring; so we find that vegetables are generally more capable of enduring than animals, and that the more simple the organisation of the vegetable, the more enduring it will be. By endurance is not meant the resistance of external causes and circumstances generally; but rather the obedience to these, or the resistance of destruction, which is really a yielding to the course and operations of nature.

The circumstances now mentioned give a very peculiar interest to the natural history of vegetables. No plant, taken simply in itself, is perhaps so interesting as some animals, as it wants the charms of perceptible activity and affection; but it is in vegetables far more than in animals that we trace the variations of different regions of the earth, and those of the same region in the different seasons of the year. All that we can perceive of the action of the sun, the atmosphere, and atmospheric humidity, upon the inorganic and dead matter of the earth, is illuminating or darkening, heating or cooling, drying or moistening, softening or hardening, or, even in the extreme cases, mechanical division or chemical solution. But vegetables bring into play the principle of growth (at least their own form of it); and the operation of that principle, or, which amounts to the same thing, the operation of climate or season upon it, evolves all those curious forms which every where compose the carpet or clothing of the earth, where its mineral surface is not permanently too cold, too dry, or too shifting, for allowing the principle to act.

The natural history of the vegetable kingdom thus admits more readily and more distinctly of division into three parts than that of the animal kingdom. First, the descriptive history of the species, singly, but in their classification; and that constitutes the science of BOTANY, a word which originally meant *grass*, the grasses being, in the pastoral times, as they are still, the most important vegetables of temperate climates. Secondly, the species of plants which are, generally speaking, best adapted to the different latitudes of the globe, grow most abundantly and readily, and are most characteristic of the scenery there.

This forms what may very properly be termed Vegetable Geography, a very interesting and important department of natural history, but one which has not hitherto been treated of separately to the extent which its importance requires. Thirdly, the seasonal changes which take place in the appearance of plants, and which, as has been remarked, constitute the grand index to the revolving year, and which has not yet received a name as a distinct branch of science.

The two last-mentioned divisions are intimately connected with each other; because plants are influenced by climate only so far as that climate produces season; and if they had the same season, or the same succession of seasons, all climates would be alike.

The general circumstances, whether we call them of a climatal or a seasonal nature, by which plants are influenced, are humidity, heat, and light; wherever these occur to the same extent the action of any one vegetable may be presumed to be the same. It is usual to refer the origin of heat generally to the sun; and though that body is not the source of all heat, and perhaps would not be the source of any without something upon which its beams could act, yet the heat of the sun is that by which vegetables in a state of nature, and even as cultivated, are the most generally influenced. The light of the sun is also the principal and perhaps the only light which has a general influence on vegetable action. No satisfactory experiments have been made to show what might be the effect of artificial lights on vegetables; and though moonlight produces some effects, they appear to tend to ripening rather than to growth. That might be expected, as the light of the moon wants the extreme rays of the solar spectrum, and especially those chemical rays which lie invisibly beyond each extremity of the colours, and which so curiously link together the polarities of atoms, the phenomena of magnetism, galvanism, electricity, vegetable action,—and probably all the phenomena of matter to which the name of action can be applied.

As, however, separate treatises on the various branches of physical science would be out of place in a work expressly devoted to the study and illustration of natural history, the reader will, in every instance, be referred to those articles in the first division of the Cyclopædia, where they are fully examined. The classification of plants as much as possible according to their organisation, will be found in the general article Botany; and the process of vegetation, its nature, and its results, as forming both the component and the constituent parts of plants, will be treated of under the various articles belonging to Vegetable Physiology.

THE MINERAL KINGDOM.

This division, or kingdom, of nature, comprehends all the unorganised parts of the earth: but it may be advantageously subdivided; for, without any reference to their chemical properties, which are fully illustrated in the *First Division* of this work, mineral substances may be viewed in two distinctly different lights,—first, in themselves considered individually; and, secondly, in their relations to each other and to the whole earth, both in its present state and its past history.

Both of these are parts of natural history; but the first of them belongs more to descriptive detail, and the second more to theoretical conjecture. The knowledge of the first is the science of Mineralogy, and that of the second is the science of Geology.

Geology, though of late years it has made rapid progress, is still only in its infancy, so that, though there are many interesting facts, there can be said to be no general system. The general purpose of the science is to examine the whole surface of the earth, and as far below that surface, whether dry land or water, as observation can go; to ascertain the form, nature, and arrangement of the several parts; and to point out, if possible, by what agents and in what manner, they were brought into their present state and situation. Climates and seasons, plants and animals, are all greatly influenced by the substance of which the earth is composed; and therefore, besides that, its more speculative range, there is a great deal of practical usefulness in Geology.

Mineralogy, the other division of the science of the mineral kingdom, admits of being viewed in various lights; the chief of which are, the natural appearances of minerals, and the actions which they are capable of exerting upon each other, or upon other substances. It is the first of these which strictly belongs to natural history; and the general arrangement of it will be found under the article MINERALOGY.

From these short notices of the three kingdoms of nature (which may be considered as a brief summary of the matter of this division of the British Cyclopædia, as the preceding remarks were of its plan) it will be apparent that the science which treats of any one branch becomes the more clear and distinct the more that its characters are peculiarly its own, and the further that they are removed from those general properties and laws of matter which form the subject of the physical sciences. All the parts of Zoology may be rendered intelligible without much reference to the rest of nature; while Botany must either be, in a great measure, confined to description, or reference must be made to the seasons and the weather; and if we do not take into account all the productions and operations of nature, the science of Minerals must be simply descriptive.

CONCLUSION.

THOUGH, as has been stated in the preceding part of this article, there are no external or popular characters by which the three kingdoms of nature can, on their confines (where all their characters are faint and obscure,) be distinguished from each other; yet there are distinctions of a physiological character which are in themselves clear and specific; and to bear this in mind is of the utmost importance to all who study Natural History.

Natural History has a tendency to produce in the mind certain effects which are not produced by the other sciences. These sciences are simple in their principles; and how far soever the investigation of them may be carried, or how valuable soever may be their applications, they address themselves to the understanding only. But there can be small progress in Natural History without bringing the feelings into operation; and when these are excited, the result may be good, or it may be evil. In the mechanical and chemical sciences, we can always see, and generally express, the relation between the cause or power and the consequence or effect; and when we have discovered the relation, or ratio, in one instance, we at once conclude that it will be the same in all similar ones, so that the terms of all are merely multiples, or submultiples, of each other; and the law, when once investigated, has much of the clearness and simplicity of a geometrical proposition, or may be stated numerically and made the subject of arithmetical computation. But it is far different when we come to study nature. Many phenomena, whether locomotive, of growth, or otherwise, take place there, in which we can trace no measurable relation between the apparent cause and the effect. There is, for instance, no relation between the size of seeds and that of the plants which they produce; neither can we tell, from all our experience of the germination of known seeds, whether an unknown one will grow slowly or rapidly. In the animal kingdom, there is still more uncertainty—more to perplex our reasoning and veil itself from our scrutiny. We find, in animated nature, strength where we would be apt to look for weakness, daring where we would predicate timidity, and, in an endless variety of cases, the reverse of what we, reasoning as mechanical philosophers, would infer.

Now, it is an acknowledged law of human nature, that where the understanding is unable to reach the whole of any subject, the feelings invariably take up the remainder; and as that portion by which they are excited is without the guide which accompanies the understanding, there is always some danger that the feelings may lead us into error.

It is impossible to study even the most limited portion of nature without feeling that there is some sort of connexion between that and other parts. The opening of the bud and the song of the bird are, for instance, in some way dependent on the return of the spring; yet we cannot call the spring the *cause* of the one or the other, though it certainly is an element in that cause. The instance adduced is a simple one; and yet the relation is of so complex a nature that we cannot analyse it. When we make the attempt, we are sent far and wide: the sun, the atmosphere, the locality on the earth, the rain which has fallen, surrounding objects, the observed properties of the immediate subject of our inquiry, and that mighty mystery, life, which is felt to be something more than all that we can name as matter, but of which we can know nothing farther than the beings in the production and economy of which it is so indispensable an element. All, whether of plants or of animals, which the season produces, are formed of materials that seem to us to come from the remains of the former season; but besides the materials, there are modes of working, which impart to the species all those characters by means of which they are distinguished from each other, and which preserve those specific characters, amid all the varieties to which they are subject from other causes. In one place, the oak lifts its top high in air, and spreads its boughs so that a multitude may be covered by its shade; and in another place, it is gnarled and stunted. It is still the oak, however, and no soil, situation, or treatment, can change it to another tree. It is the same with all: we find every thing which lives or grows in so far obeying the circumstances under which it is placed; but there is always one part of its character, in which it remains proof against all the viscissitudes of nature, and all the contrivances of art.

That portion we, if we think at all (and who that looks upon even the simplest production of nature can refrain from thinking?) cannot resist tracing backward in time, and inquiring into its origin. Is it of matter? Assuredly not: it is "the workman" by whom matter is moulded into all those forms which we see; and it would not be more absurd to consider the potter identical with the clay out of which he forms his vessels, than it would to confound that which makes a specific plant or animal with the mere matter of which the plant or animal is composed. Is it of the circumstances in which matter is placed? It cannot be; for the sun may warm and illuminate, the rain may distil, and the breeze may play, for ever; but if the germ be not there, there will be no living thing. It appears too that, in all cases, the primary action of the germ is in the dark, and excluded from the atmosphere; yet, even then, it is an independent being, nourished by the parent, no doubt, but forming no part of that parent.

Thus, even the little bud upon the tree, carries us wide over all space, and backward into all time, still leaving something to be added, which the senses cannot discover, and in the investigation of which those instruments which have done so much in the philosophy of mere matter give us no aid. When we point the telescope to the distant, or bring the most minute object under the microscope, we find much that is new, wonderful, and delightful; but the grand discovery is, that we are no nearer the ultimate bourne of knowledge than the dimmest eye in its unassisted glimmerings. It expands to infinitude, it stretches back to eternity; and yet, in all its boundless magnitude and countless duration, it is *one system*. The sun is as much adapted to the planet, and the planet to the sun, as the shell and the kernel of the nut, or any two of the most simple and clearly connected natural productions with which we can meet. Not one single production (no, not one atom) of the whole wonderful structure works alone. Bring the mind to bear on what point soever we may, we are guided toward the whole; so that we dare not deny that the smallest atom in the deepest mine is influenced by the minutest starry speck which the telescope discovers in the depth of heaven's azure.

This is the matter of feeling which Natural History draws forth in a manner different from any other science; and in which truth and error are the very extremes of mental happiness and mental misery. The system has no assignable bounds, yet it is one; the parts are countless, yet they are all in concert; they are ever perishing, yet they are ever renewing; they are ever changing, yet they are still the same. Can we, therefore, believe that a system so vast yet so united, so changeful yet so constant, can be without a Maker and Governor more mighty than it all? Can we by possibility doubt that there is ONE who "sitteth upon the zone" of this mighty structure, and to whom, infinite space is the same as a mere point, and eternal duration as a single moment?

The proofs do not require to be reiterated, or even stated; they are felt irresistibly by all who enter upon the study of nature without prejudice or bias. But the distinction of species, which holds against all circumstances, is an irresistible demonstration that matter is under the government of that which is not material. Were that not the case, we should have those deviations, which may be called circumstantial, taking place as readily in the one direction as in the other; because, if the inherent properties of mere matter did it, there is no reason why a deviation to superiority should not take place as well as one to inferiority. But all the instances of deviation from the specific models with which we meet, are stoppages on the way to the perfect form, and not efforts beyond it. The animal never becomes in any degree a plant, or the plant an animal; neither does one of the more simply organised become one of the more complex, though the complex organisation is often so imperfect in some of its parts as to have a considerable resemblance to the more simple. Thus it appears, that all which the direct interference of the common laws of matter can do for an organic being is to injure or destroy it; and that, though all are flexible to those interferences for a certain length, there is, in all cases, a point at which destruction is the result. But if the organised and living being—the plant or the animal, were produced by the mere properties of that matter of which its body is composed, it is not easy, nay, it is not possible, to see how the same laws that gave it organisation could disorganise it; for that would be making the same principle both itself and its opposite!

There are many instances in which we are not able to trace the law; and in all cases it is a nice and difficult point; but though we cannot always obtain knowledge so complete as to make it a perfectly satisfactory ground of argument, surely we should not better ourselves by grounding argument upon our utter ignorance? It has been already mentioned that the three kingdoms of nature are a little obscure upon their confines; but that very obscurity is sufficient reason why we should draw no conclusion from what we may half discern, half imagine there. Whenever there is light enough, the distinctions are plain; and sound philosophy merely demands, that where we must grope, we ought to grope according to our knowledge, and not in opposition to it. We never find the mould of our gardens changed into roses without the vegetable action of the rose-tree; or the leaves of our trees changed into caterpillars without the action of animal life in the insects; and as little do we find the caterpillars changed into warbling songsters without the specific action of animal life in the birds. But, till one or other of these occur in some one instance, we have no right to presume, as some have unguidedly presumed, that, in those obscure cases where we have little or no knowledge, the very same matter may, according to circumstances, become either animal or vegetable, without the parent and the germ.

THE

BRITISH CYCLOPÆDIA.

NATURAL HISTORY.

AARD-WOLF, *aerd-ouf*, or earth wolf (*proteles cristata.*) A carnivorous animal of Southern Africa, bearing some resemblance both to the hyæna and the fox, but still so different from both, and also from every other known species, as to warrant its being classed as a separate genus. Its size is about the same as that of the fox, but it is shorter and thicker in the body, and the legs are a little longer in proportion. The nose is somewhat produced, pointed, and without hair; the ears moderately long, slender, and nearly naked; the body is covered with woolly

Aard-Wolf.

fur of a yellowish ash colour, brindled with darker brown and black in transverse bands; there is a stiff bristly mane along the whole back from the nape to the tail, which is highest in the middle, and gives the animal a "pig-backed" outline; the tail is covered with hair nearly of the same texture, but not quite so long; and the mane is brindled and the tail slightly marked with rings.

There are four walking toes upon each foot, and a small thumb on each of the fore ones, articulated higher than the others, and not coming into use in walking. The claws are rather long and strong, but they are digging claws rather than prehensile ones. Indeed, though in structure this animal is carnivorous, it appears to be a mild and timid creature, living rather socially with its species, in burrows under ground, and not coming much to the surface during the day, at least at certain seaons. It is a curious feature in the natural history both of Southern Africa and the southern plains of South America, that there should be in them races of animals intermediate between the *insectivora* and *carnivora* properly so called, which dwell and feed under the surface at those times of the year when that surface is little else than an arid waste.

ABDOMEN. This term is generally understood by naturalists as descriptive of a portion of the animal structure somewhat analogous to the third and last great division of the human frame, though, in some cases, a similarity of form and situation has alone occasioned the adoption of that name. So long, however, as we confine the name of abdomen, as above described, to animals of the class Mammalia, it is perfectly correct. As the Mammalia and Birds, in the principles of their formation, require a provision to be made for an extraordinary exercise of bodily activity, and particularly of rapid circulation and respiration, they are furnished with an apparatus capable of powerfully inflating the interior of their lungs; at the same time, the thoracic organs are found insulated from the abdominal viscera, and the cavity of the latter is perfectly circumscribed and well defined. But with reptiles and fishes (still speaking of vertebrated animals), the arrangement of the organ is found to be changed, according to the different conditions of their existence. In the first, one simple cavity encloses the respiratory, circulatory, and digestive organs. If from the vertebrated, we pass to the invertebrated animals, we shall not find in them any cavity to which the name of abdomen can properly apply, as being receptacles formed of the same elements and inclosing the same viscera. With these the organs of circulation, respiration, and digestion, no longer occupy distinct cavities; to neither molluscous animals, worms or annelides, can we properly attach the terms thorax and abdomen, as they are defined in the human anatomy.

In the Arachnidæ the continuation of the thorax is called the abdomen; and no doubt has arisen as to its analogy with the abdomen of insects. It may, however, be observed, that the resemblance only holds good, inasmuch as it forms a continuation of the thorax and contains a portion of the intestinal canal; but not because it is formed of the same rings, or because it encloses, without exception, the same viscera possessing similar functions: observation proving that it is not the same under every circumstance.

In the hexapodal insects the abdomen is well developed, perfectly distinct from the thorax, particularly when that part supports the wings, for in the apterous individuals, that difference is, in default of these organs, rather less marked; the same may be said of the greater number of larvæ, all of which, having the rings of the body equally developed, cannot be divided into abdomen and thorax, if the existence of feet to the three first rings did not sufficiently indicate the respective limits of each of them. It is, nevertheless, impossible to establish this distinction in the apodal larvæ; and if we admit in them a thorax and abdomen, that distinction rests on analogy only. We may then assimilate that provisional state of the insect to the permanent condition of the annelidon, and employ the term body to designate the whole animal, without seeking to establish divisions which cannot fall within our view.

ABDOMINALES. A very numerous and interesting order of MALACOPTERYGEOUS, or soft finned-fishes, and the second in Cuvier's arrangement of the animal kingdom. Their general external character as an order is that of having the ventral fins attached to the abdomen, behind the pectoral ones, and without being attached to the bone of the shoulder.

Though fishes, at least those of the soft-finned division, are classed from the position of their fins, the influence of the differences of position, either upon the character or the habits of the animal, is not very well known. It may, however, be mentioned that the abdominal fishes swim in shallower water than those which have their fins in a more forward position or wanting. Many of them inhabit the fresh waters; and those which are found in the sea avoid the deep waters. The abdominal fins appear to keep the body more steady in troubled waters than is done by those which are situated anterior to the pectorals. The order comprises many genera and species, which may be arranged into the following families :—

CYPRINIDÆ, the *Carp* family,—ESOCÆDÆ, the *Pike* family,—SILURIDÆ, the *Silure* family,—SALMONIDÆ, the *Salmon* family; and CLUPEADÆ, the *Herring* family.

With the exception of the last family, these are almost wholly fresh-water fishes; and they are, generally speaking, wholesome and valuable as food.

ABELE TREE (*Populus alba*, Linnæus). A large deciduous forest tree, indigenous to Britain,

Abele Tree.

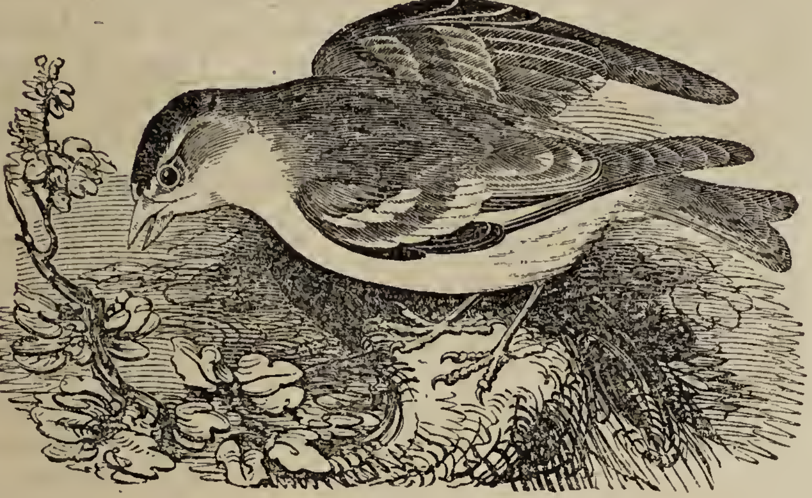
belonging to the Linnæan class and order, *Diœcia Octandria.* Generic character: Calyx one-leaved, five-toothed, bellying; corolla five-petaled, irregularly coloured, inserted into the calyx; capsule three-celled: seeds two, sub-globular, enclosed in a roundish-shaped capsule, opening with three valves. Natural order, *Amentaceæ* (male flowers like catkins) of Jussieu. The height varying from 60 to 100 feet.

This is one of our largest British trees when on its favourite soil, which is a deep bog or peat earth, or a calcareous gravel near the bank of a river or pond. It luxuriates in a superstratum of porous decayed vegetable matter. The roots send up numerous suckers; on which account the tree is injurious near gardens; and on pleasure grounds they are unsuitable, as well on account of their suckers as for the labour they occasion by the fall of their catkins in spring, and the early fall of their leaves in autumn. Its growth is rapid, but the bole seldom exceeds forty or fifty feet in length. The timber is inferior; being light, mild in grain, yet beautifully white. Though subject to the worm, if kept perfectly dry it lasts many years as beams or rafters. Notwithstanding the butts of aged trees are of large dimensions, they seldom turn out well at the sawpit. The lower branches are liable to be broken off by wind; the stumps soon decay, and become a nest for insects, the larvæ of which are sought and burrowed out by woodpeckers; in the holes thus formed the moisture enters, and a rotting cavity is formed, ever increasing downwards: hence the unsoundness of this kind of timber.

The abele cannot be recommended either as a timber or as an ornamental tree: but there are portions of estates where nothing but alders and some sorts of willows will thrive, which may be finely wooded by planting this kind of poplar. The group represented in the previous column must be familiar to many of our readers, forming a beautiful ornament on the banks of the Thames above Richmond.

ABELMOSCHUS. The old trivial name of a species of Hibiscus, and also the name applied to the sixth section of that genus.

ABERDEVINE, or EUROPEAN SISKIN (*Carduelis spinus*, Cuvier; *Fringilla spinus*, Linnæus). A handsome little green and yellow finch, of the genus or division to which the common goldfinch of this country belongs. It is not quite so large as that bird, and the tail is much shorter; the wings are rather long, and are commonly held drooping. The bill is of a pale brown, tipped with blackish brown; the iris of the eye dark hazel, appearing, unless closely examined, black. The feathers on the crown of the head and throat are, in the male, black; but when first put forth, at the general moult in the autumn, they are edged with a greyish brown fringe, which gradually wears off on the approach of spring. Over each eye is a streak of dingy primrose yellow; the neck, back, wings, and tail, olive-green; paler, and more yellow, on the lower parts of the back, towards the tail. The feathers of the back and wings are marked down the middle with a streak of dark blackish green; the sides of the head, throat, breast, and under parts, pale wax yellow, inclining to sulphur yellow; middle of the parts below the breast very pale yellow colour, passing into white; across each wing are two bands of primrose yellow, and between them one of black; part of the quill and tail feathers are edged with pale gamboge yellow; the legs and feet yellowish brown. The head of the female is of a brownish colour, inclining to grey where the male is black; the cheeks and sides of the neck olive-green; and the rest of her plumage is of a more dingy colour than in the male. Among the females very pale varieties are not uncommon. The young, as in most other birds in which the sexes are dissimilar in plumage, resemble in their nestling feathers the old female; the young males acquiring the adult plumage at the first moult, though they do not then become so bright as the older birds.



Aberdevine.

The whole markings of the plumage in this species considerably resemble those of the common redpole linnet (*Linaria pusilla*); the colours, however, are different. Though by no means remarkable for the melody of its song, it is a species highly prized by bird-fanciers, for the purpose of breeding with canaries, with which it readily pairs. It has even been conjectured by some to be the original wild stock of the domestic canary bird, or at most to be merely a marked variety of that species; this is, however, but a mere fancy: the original wild canary (*Fringilla Canaria*) abounds in the islands from which it takes its name, and is now frequently imported into this country; whilst the species now under consideration is a native only of the more northern parts of Europe, descending southward on the approach of winter. It has generally been described, in this country, as a very uncertain winter visitant, occasionally appearing in vast numbers, but at irregular and often distant periods, many years sometimes elapsing between its visits. In the neighbourhood of London, however, these birds are taken very regularly every autumn by the bird-catchers, though in much greater abundance some seasons than in others. Probably, a considerable number migrate to the south of England every year; but as they have not been observed to visit regularly any particular place, they are doubtless often overlooked. They may generally, however, be found, during the winter, in most situations where the alder grows plentifully.

Whilst in these parts, they commonly associate with the small redpole linnet, subsisting, like that species, on the seeds of various trees, especially on those of the alder and birch; but rarely descending, like the goldfinch, to feed on the seeds of thistles. Like most of the other smaller finches, they are fond of the unopened blossoms of furze and of fruit trees, eating the sexual parts of the flowers. They feed also on the seeds of the hop; and as they mostly congregate in large flocks, they have been known to do much damage to the hop-plantations, the places where they have been being easily known by the number of strobiles found lying on the ground. They assume a variety of curious and constrained attitudes when feeding; and are, in general, so intent, as to suffer themselves to be easily taken with a long fishing-rod, smeared at the end with bird-lime. In confinement, the aberdevine is constantly running along the wires of its cage, and when tame, if any thing it is fond of is held to it, it is taken always with the head downwards. If a privet berry, or a piece of almond, to both of which it is extremely partial, be given, it generally places it between its feet, or holds it with one foot whilst picking it, in the manner of the tit genus (*Parus*). The same habit may also be observed in the goldfinch, and in others of the genus *Carduelis*, but not in the linnets (*Linaria*); even the small redpole linnet, which in many respects so closely resembles the aberdevine, has no notion whatever of holding its food with its foot; but if a piece of almond be given to it, will nibble off a small portion, and lay the remainder carefully on the perch beside it, until it is ready for another mouthful. The aberdevine appears in confinement to be very fond of fruit; it eats the pulp only of the privet berry, leaving the seeds; the bullfinch feeds upon the seeds, and rejects the pulp. Like its compeer, the goldfinch, it is a remarkably healthy, docile, and familiar little bird, and its progeny with the canary generally inherit the same good qualities, for which reason they are highly prized by amateurs. Its docility frequently subjects it to the same kind of education as is bestowed upon the goldfinch and redpole, and like those birds it is often taught to perform a variety of little amusing tricks, such as to open the lid of a box containing its food, to draw up its water by means of a little bucket, and to come when called and perch on the hand to be fed. It rarely sleeps upon a perch, but most commonly clinging by one leg to the wires on the side of its cage. Its treatment in confinement should be similar to that of the goldfinch and linnet.

The song of the aberdevine is very similar to that of the goldfinch, though not quite so musical and sweet; it is sharper and more piercing, and finishes always with a remarkably harsh jarring note, which it would be impossible to express upon paper; its common chirp, and call-note, also, considerably resemble those of the goldfinch. When singing, it will often attempt to peck any other smaller bird that is confined with it; with its wings spread wide, its head low, and bill open, it moves about in a very singular manner, threatening its companions, and exhibiting to advantage the pleasing mixture of yellow and green upon its plumage. It is almost perpetually singing; and though by no means a loud songster, its voice may often be heard over those of much more powerful vocalists, from the peculiar sharpness of its notes. Its musical powers, however, on the whole, are not sufficiently fine to render it a desirable cage bird.

Early in the month of March, though in some seasons not until the middle of April, at which time their plumage has acquired its full summer brightness, the aberdevine leaves the south of England for the pine forests of Scotland, in some of which they have been ascertained to breed. The nest, according to M. Temminck, is built among the higher branches of the pine, which accounts for its having escaped the researches of the earlier naturalists. The eggs, four or five in number, are of a bluish white, speckled with purplish red. They begin to reappear in the south about the middle of September, and a few are occasionally taken near the metropolis in their first nestling feathers, which, as before mentioned, resemble those of the adult female. Like the other smaller finches, they are readily caught by means of a call bird, being so fond of each other's society that a party soaring on the wing will invariably alter their course, and descend to the call of a single one from below. They fly in successive undulating courses, alternately rising and falling, and generally utter a chirp at each propelling motion of the wings ; as may be also observed in the linnet and goldfinch, and in most other birds of this family.

ABIA. A genus of insects belonging to the order *Hymenoptera*, and family *Tenthredinidæ* of Leach. The antennæ are short and elevated ; the third joint very long : superior wings with two marginal and three sub-marginal cells. The abdomen of the male has an elongated silky spot on the posterior part, the eyes nearly joining. Two species only of this genus have yet been found in this country.

Sp. 1. Abia nigricornis. Antennæ black : wings from the middle to the apex, with light brown spots : feet light red : thighs black and shining.

Inhabits the alder, and is found in May and June.

Sp. 2. Abia sericea. Antennæ yellow : thorax black and shining, and slightly hairy : abdomen above green and shining, beneath black, the sides green : feet yellow, the thighs black at their base : wings transparent, brown in the middle.

Inhabits the furze, and is found in May and June.

The genus Abia was established by Dr. Leach, in the third volume of the *Zoological Miscellany* : and has been adopted by most authors.

ABIES (Salisbury). The Fir. A genus of trees belonging to the Linnæan class and order, *Monœcia Monodelphia* ; Natural order, *Coniferæ* (conebearing) of Jussieu.

Abies Excelsa. *a.* Male catkin. *b.* Anther, shedding its pollen. *c.* Female catkin. *d.* Scales of female catkin. *e.* Scale of ripe cone. *f.* Seeds.

Generic Character : Flowers, males and females, separate, the former simple ; single catkins bearing blunt stamens ; the latter being roundish catkins, with many two-flowered scales ; cones of various shapes, more or less cylindrical ; scales woody, regularly laid on each other, enclosing the seeds, which are winged.

This conspicuous and useful tribe of forest trees was formerly associated with the pines, but has been separated by modern botanists. The distinctions are chiefly founded on the manner of foliation ; the pines bearing their leaves in bundles, that is, they issue from a little sheath in pairs, or in threes, fours, or fives together ; the firs, on the contrary, bear the leaves singly, or are said to be solitary. There is, however, great affinity in the manner of growth, quality of their wood, and resinous sap, and in their native habit. The silver fir is one of our most stately and ornamental forest trees, rising to a great height, with a proportionate bulk of bole. This, as well as the different sorts of spruce firs, have always an elegant appearance ; they are graceful in themselves, and wherever they stand they enrich the landscape. The hemlock spruce (*A. Canadensis*), so called from the pensile position and light ramification of its spray, resembling in some degree the foliage of the common poisonous hemlock, is one of the largest trees in North America, but from their recent introduction, there are none in this country that have yet arrived at near the natural stature. All the tall ones are ornamental, as well as fit for timber at every period of their growth ; from the period they are mere poles, suitable for fencing, up to the time when their trunks supply beams of any required length. Planted as screens, for shelter, or for nurses to other trees, no other answer the purposes better. Their favourite soil is a dry gravelly loam ; but they will thrive any where in deep, or on well trenched ground. Some of the firs are of humble growth, as the *dumosa* (bushy), and the *Clanbrasiliana* (Lord Clanbrassel) ; such are valuable in ornamental planting.

All the sorts are raised from seeds sown in the spring, and afterwards transplanted, first into beds, and in a year or two into rows, to gain strength before final transplantation.

For an account of the more useful or ornamental species, and the best mode of culture, see Fir Tree.

ABIETINEÆ (Richard). A subdivision of the Coniferæ or Fir Family, which includes the genera *abies*, the fir or spruce ; *larix*, the larch ; and *pinus*, the pine. For a description of the tribe, see Coniferæ.

ABILGAARDIA (Vahlenberg). A small grassy-looking plant, a native of New Holland. Linnæan class and order, *Triandria Monogynia ;* Natural order *Cyperaceæ*. This species differs from the rushes in having the scales of the flowers placed in two imbricated ranks ; by its pointed seeds and the three-sided base of its style. There are only two species, both greenhouse perennials, viz. *A. Monastachya*, one spiked ; and *A. Tristachya*, three-spiked.

ABRÆUS. A genus of insects of the order *Coleoptera*, and family *Histeridæ*. The antennæ are geniculated, and terminated by a nearly solid club of three articulations ; the basal joint of the antennæ somewhat elongated, second and third nearly cylindrical, straight ; fourth short ; fifth, sixth, and seventh, nearly globose and equal ; eighth, nearly globose, lenticular ; ninth, tenth, and eleventh, forming a short oval club ; elytra shorter than the abdomen, the margin of the sides inflexed : body thick, nearly globose or quadrate ; tibiæ elongated and straight ; tarsi with five joints, long, slender and contractile ; sternum simple.

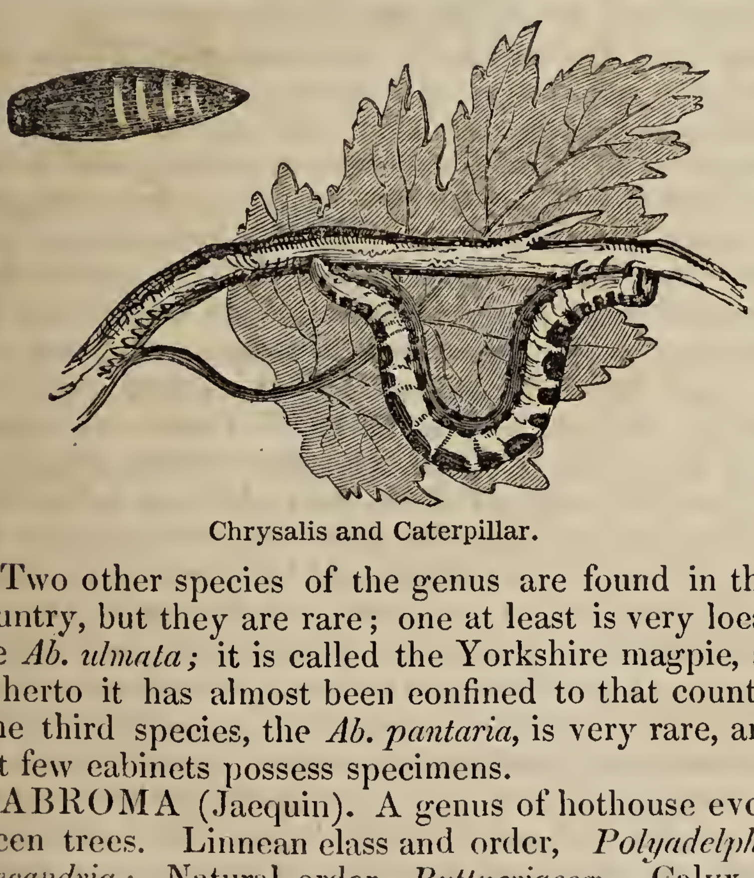
This genus was established and the character laid down by Dr. Leach, in the third volume of the *Zoological Miscellany;* it contains two species, the Ab. globosus, (Hister Perpusillus, Marsham's Coleoptera, and the H. Minertus; they are found in the dung of cattle in the early spring months.

ABRAXAS. A genus of insects of the order *Lepidoptera*, and family *Geometridæ*. The antennæ are simple, not fringed: body slender: palpi scarcely hirsute: wings, when at rest, extended horizontally, neither angulated nor indented. larva or caterpillar with ten feet. This genus was separated from the *Geometria*, and named by Dr. Leach. There are three species found in this country; one of which, the *grossulariata*, is very destructive to the gooseberry plants in our gardens, and begins to consume the leaves and injure the plants almost as soon as the leaves appear. We should recommend, for the destruction of them, that the plants be examined early in the morning, before the dew is off or the sun has much power, to seek for or collect them, as they feed at this time, and may be easily detected: poultry will feed on them with avidity, as indeed they will on most caterpillars.

Ab. grossulariata, common magpie moth. Wings white, the upper or superior with the base, and streak towards the hinder margin yellow, with six rows of round black spots, more or less confluent; lower or inferior wings with a few scattered spots in the middle, and a streak of the same beyond the middle, and a row on the hinder margin; body yellow, with rows of black spots; expansion of the wings one inch eight lines to two inches; appears in the perfect state about the end of July.

Magpie Moth.

Caterpillar, with ten feet, white, with a yellow line down the side, and numerous rows of black and irregular spots and dots. Chrysalis or pupa suspended by a thread, black with yellow bands.



Chrysalis and Caterpillar.

Two other species of the genus are found in this country, but they are rare; one at least is very local, the *Ab. ulmata;* it is called the Yorkshire magpie, as hitherto it has almost been confined to that county. The third species, the *Ab. pantaria,* is very rare, and but few cabinets possess specimens.

ABROMA (Jacquin). A genus of hothouse evergreen trees. Linnean class and order, *Polyadelphia Decandria;* Natural order, *Byttneriaceæ.* Calyx of one sepal, persistent, cut into five deep clefts; corolla pentapetalous, concave, arched; stamina six, united at the base into a globular pitcher; some of them destitute of anthers; styles five; capsule pointed, of five places and five salient angles, opening at the top, with many kidney-shaped seeds. Of this genus two species are described; viz. *A. Augusta,* smooth stalked; and *A. Fastuosa,* prickly stalked. Both very elegant East Indian shrubs.

ABRONIA (Jussieu). A genus of evergreen creeping perennials, natives of California. Linnæan class and order, *Pentandria Monogynia;* Natural order, *Nyctagineæ.* The flowers are borne on the points of the axillary peduncles; calyx tubular, coloured, limb in five divisions, stamens five; ovary of one place, and one-seeded, forming a five-angled fruit, which is covered by the persisting base of the calyx. There are only two species, viz. *Mellifera,* honey-bearing; and *Umbellata,* umbelled.

ABRUS (Wild Liquorice). A genus belonging to the natural order *Leguminosæ,* and to the Linnæan class and order *Diadelphia Decandria.* Generic character: Calyx of two lips, the upper of one lobe, the lower of three; corolla irregularly butterfly-shaped; stamens ten, nine united and one apart; fruit of one place, filled with beautiful pea-shaped scarlet seed, with a black scar. The only known species is the *Abrus precatorius,* or Prayer Liquorice. This is a deciduous climbing plant found in Jamaica, the roots of which are used in the same way as liquorice. It furnishes those scarlet seeds, familiarly known under the name of crabs' eyes, which are worn as necklaces and used as rosaries. From the latter circumstance, the name Precatorius or Prayer has been derived. These seeds are said to be eaten in some countries, but are very indigestible.

ABSINTHIUM. The old trivial and now the specific name of the common wormwood. It is also the name of one of the sections of the genus Artemisia.

ABSORPTION. A species of natural action, the knowledge of which is essential to the understanding of a vast number of natural truths, and the explanation of a still greater number of natural phenomena. It is the power which one substance has to receive another, diffused through its mass, without being thereby decomposed. The substance which receives or imbibes the other is called the *absorbent,* and usually styled the active one; but the action is reciprocal, though different.

Absorption takes place in all the kingdoms of nature, though some of them at least are specifically different in each of the three; and there are many degrees and modifications in each. The action is not very easily defined, but it may be regarded as one between the surfaces of the small parts of the two bodies; and one of the bodies, at least, must be in the fluid state. When the two bodies are in the same state, that is, both liquids or gases, or solids in a minute state of division, there is no absorption, it is mixture; but a liquid may absorb a gas, and a solid may absorb either. When the denser body unites with or disperses itself through the rarer, as when spirit, oil, or water, is dispersed invisibly through the air, the process, though an important one in the economy of all the kingdoms of nature, is usually described as a chemical one. But in the mere act of absorption, or that of evaporation, the nature or composition of the absorbed substance is not understood to be changed. In nature, therefore, absorption is the act of producing a new compound, by bringing one of the parts within the other's range of action.

When the process extends no further than absorption, it belongs to chemistry, and not to natural history, for chemistry holds the same place in the mineral kingdom which physiology does in the animal and the vegetable; and as in these absorption is only one part of the physiological process, and that a preliminary one, which in itself produces no result, the modification of it can be better explained in treating of those ultimate actions to which it is preliminary.

When the absorbed substance is a liquid, it is generally taken up by vessels which are, from the offices which they perform, called *absorbents*, or by apertures in a membrane, which are called *pores*; but there appear also to be absorbing surfaces, in which no pore is discernible either by the eye or the microscope. Plants absorb water by the *spongelets* or little sponges, upon the *rootlets*, or young fibres of their roots; but they also absorb by their leaves, and, in many instances by their whole surface, even though, when examined by the microscope, what appear to be pores on their surface seem rather to be *culs de sac*, or small indentations, lined throughout with the unbroken epidermis of the plant. When a plant thus absorbs, it revives; and the same takes place with animals, and even with man himself. If one who is parched with drought stand over water, and especially with the bare feet immersed in it, thirst is allayed, and the body recovers its tone, in a manner similar to that in which a lopped twig or a pulled flower recovers, when it is sprinkled with or dipped in water, or when the stem of it is placed in that fluid.

There are, in the case of the human body, some other circumstances, which not only prove the existence of an intellectual principle, totally different from the body, but which show that that principle can, of itself, to a certain extent, sustain the body and allay its anguish. When one has been long upon the dry hill, fatigued, exhausted and parched, the sight of a running stream, or even the sound of a waterfall, will revive the spirits, and bring at least a momentary relief, as the author of this article has often experienced. The duration is, no doubt, fleeting; and though the observations of Shakspeare are as philosophic as they are practical, for—

> "Who can hold a fire in his hand,
> By thinking on the frosty Caucasus?
> Or wallow naked in December's snow,
> By thinking on fantastic summer's heat?"

yet still, such is the power of the mind over the body, that both the eye and the ear can absorb relief, in cases where there can be no material contact.

In the action of vegetables, the whole preliminary part of the process appears to be absorption; and, though in many instances the mode eludes our most careful observation, they can, in the greater number of the species, feed at the whole of the active surface when in leaf, they do not in any instance take food into an organ at all analogous to what we call the stomach in animals. From this, it should seem that, with them, nourishment passes more immediately to organisation, without the process of assimilation. Excepting in the case of poisons, which both plants and animals seem capable of absorbing, and which they absorb at different parts, according to their nature, plants do not appear to take into any part of their system substances which are not wholly available for the purposes of vegetable life and growth. They no doubt give out gases, and different ones, according to circumstances; but there is still a difference of opinion even amongst the most eminent botanists as to whether they give out any excrementitious matter, either in a solid or a liquid state; and the gases which they give out bear more resemblance to those given out by animals in respiring, or in some other process posterior to assimilation, than to the matters which are rejected by the animal system in that process.

The power of absorption, in organised substances, increases nearly in the ratio of the complexity of their organisation. Plants absorb less than animals; and among these those of the simplest structure absorb the least. There appears to be, in the living subject, only a very limited power of election of what matter it shall or shall not absorb. Absorption can separate mechanical mixtures; but it is doubtful whether it can effect any chemical solution. Air and water are the substances most generally absorbed by the external surfaces both of plants and of animals; and in the case of water, any foreign substance with which it happens to be mechanically mixed is generally left behind. When sailors are long exposed without water they can quench their thirst by plunging themselves into the sea, or by wetting their clothes with sea water; and if the relief is obtained by so wetting the clothes for a long time, these become impregnated with salt to a much greater extent than if they had been kept the same length of time in salt water, without being in contact with the absorbing surface of the body. If, when one is in a boat at sea in very hot weather, the arm, even the hand only, is placed in the water, an agreeable freshness diffuses itself over the whole body, and the part immersed gradually becomes covered with an incrustation of salt.

The sea fogs, which are evaporated, especially from flat beaches upon which the tide water alternates, in the early part of the season, can hardly be said to be salt; but when they settle upon vegetables, the leaves and other surfaces of these absorb the water, and the salt remains, so that, after a few hours of a thick fog, it is very perceptible to the taste. Up to a certain point, that process is wholesome; and the crops and hedges seem as much revived as if the humidity had descended limpid from the sky; but if it continues long, and the sun breaks out so as to evaporate the remaining moisture quickly, the salt corrodes and destroys the leaves. It appears to do that more readily and completely in proportion as the leaves are of a more absorbent structure; and hence the difficulty of getting many species of plants to grow, if exposed to the sea air. City fogs have even a more pernicious effect upon vegetables than saline fogs from the sea; because the salts with which they are loaded are of a more caustic nature; and because some of them are absorbable by the plants, and thus, though they do not instantly kill them, they injure their qualities. Culinary vegetables which are grown within the reach of those fogs are very inferior in flavour to those grown in pure air, even though the soil and mode of treatment may be very much inferior.

Evaporation, or the taking up of humidity by the atmosphere, is a species of absorption, and follows the same law. Common salt does not rise and mingle with the air in that process; but the more pernicious matters which pass into the state of gas at low temperatures do; and hence the invisible vapour which rises from the sea is usually limpid and wholesome, while the effluvia of marshes and other places, where organic matter is in a state of decomposition, taints the air with poison.

The action of the air upon plants, and upon animals in breathing, appears also to be analogous to absorption—to be, in fact, the identical process; and as the *nitrogen* of the air seems to be only the vehicle in which the oxygen is in these cases conveyed to the plant or the animal, we may thence infer that those two component parts of the atmosphere are merely mechanically mixed, and not chemically united. That holds in the case of animals which breathe water by gills, as well as in that of those which breathe air by lungs; for the fish cannot live in water that has been wholly deprived of air, any more than a land animal can live in an exhausted receiver. It is a general law of nature, to which there are no known exceptions, that combination can be separated but by some action more powerful than that by which it was united. But the formation of water from its elementary gases, oxygen and hydrogen, has not, in any instance with which we are acquainted, taken place without an intensity of action, which no known plant or animal, or any part of the one or the other, could bear; and, therefore, we cannot reasonably believe that any of them can decompose water, so as to avail themselves of either of its elements, by any process at all analogous to absorption, whether by the surface generally, or by any specific surface, such as that of the cells of lungs, or the fibres of gills.

Hence, in what part soever of nature it takes place, we must regard absorption as a merely mechanical process—an action as between surface and surface, in which, how minutely soever the substances may be mixed with each other, there is no chemical action,—no decomposition of an old substance, and no formation of a new one.

In vegetables the process is simple, and it appears to be the only one by which matter is added to the leafy part of the vegetable. They receive their food wholly by absorption; and the process of assimilation takes place afterwards. In animals the case is different; for though the surfaces of most animals are capable of absorbing, and the matter which they thus absorb sometimes, in part at least, serves as food; yet the food, properly so called, of even the most simple animal, is first taken into some sort of a stomach, and there assimilated, before it is absorbed.

There is still this further distinction between absorption in vegetables and in animals, that all which the vegetable absorbs goes to additional growth or increase of substance, either in the structure of the individual plant, or in the formation of seeds, or other germs of new ones of the same species. Plants, no doubt, give out gases; but there is not in any plant a means of taking up the waste of the system, and replacing it by new matter. Plants do, under peculiar circumstances, form accumulations of pulpy or starchy matter, which is sometimes called vegetable ALBUMEN; and the act of cultivating vegetable substances for food chiefly consists in making them produce useful nutriment, rather than stems and leaves; but still, there is no power in the vegetable to absorb that which has once formed part of its original structure, and replace it by new matter, which shall again perform the same function, as is the case in the animal economy. When the sap of the year has once granulated into cambium, and that cambium has ripened in the autumn into wood and bark, there is no return of it to the living action of the tree. It lingers for a longer or shorter time, according to the species, as ALBUMEN, before its final consolidation into "heart wood;" but when its one season is passed over, it buds and blossoms no more; and thus, how long soever the tree may last, it is still but an annual, as a growing vegetable of the same localised matter. Some trees, indeed, have the power of obliterating the remains of small lateral branches, after new layers of wood have grown over them; as we find many trunks of pines and other trees without any appearance of knots in the wood, though we know, from the habits of the species, that they must have at one time been branched at short intervals, all the way from the root upwards. But the obliteration of these and also of the pith in many trees takes place in the wood, where we cannot examine it, and therefore we cannot say whether it is produced by absorption or by simple pressure. Generally speaking, vegetables have not the power of removing any part by absorption, however much that part may disfigure or injure their system; the gnarl upon the bole of the deciduous tree, and the union of shoots which sometimes produces so singular an appearance in pines, are never obliterated. In animals, on the other hand, there appears to be an almost unlimited power of absorption. The waste of all parts of the system is continually taken up; and many unnatural accumulations of matter are absorbed by the action of the system, without the aid of any artificial application.

In many subjects, both animal and vegetable, there are seasonal accumulations of matter, which are again absorbed, as will be explained at length in the article HYBERNATION; and in some animals there are accumulations at certain ages, which are absorbed for the support of the system when the powers of assimilation begin to fail, or when they are weakened by disease. These absorptions extend not merely to the fat of the animal, but to all the soft parts; and it is truly said of certain diseases and conditions of the body, that they "eat the flesh off the bones." Nay, the bones themselves do not escape the ravages either of disease or of time; for that bending of the body and shortening of all its dimensions which take place when, in the extreme of life, man passes into "the sere and yellow leaf," are occasioned by absorption of the bones—not merely of their cartilaginous part, but of the salts of lime; and this absorption is sometimes so excessive, that the lime thus taken into the circulating blood is precipitated upon the coats of the blood vessels, and even upon the heart itself, forming what are termed *ossifications*. There have been instances in which one part of the body has had the blood vessels thus converted into tubes of bone, while the rest retained the power of all its functions; and also instances where, in consequence of ossifications of the heart or the proximate vessels, the system has repeatedly stopped till put in motion by the application of ardent spirits or other strong stimuli; from which it appears that absorption is among those functions of the animal system which last the longest. It is indeed very probable that absorption continues even after life is extinct; for though it takes place largely in the living structure, it cannot be said to be, in itself, a function of life, or a display of the living principle. While the living principle maintains its activity, it controls the power of absorption; and the different tissues with which the several parts of the body are covered have it in different degrees. The coating of the internal parts of an animal absorbs in a manner quite different from that of the external. There are many substances which, taken into the stomach, or exposed to any of the internal surfaces, act as poisons, in which the hands may be washed with perfect impunity; though there are others, the absorption of which by any part of the body is equally deleterious. But as the internal surfaces are the most delicate, it may be presumed that absorption, especially that of noxious gases, takes place most readily at them. In most cases, however, the absorbing surface performs other functions, such as that of secretion; so that it is not very easy to ascertain whether greater injury be done by the mere absorption of the offensive matter, or by the direct action on the surface at which that matter is absorbed.

The readiness with which the surfaces of animals, especially the inner surfaces, absorb different substances, is the means of much good as well as harm; and most medicines which are what is termed alterative, or intended to produce a gradual change in the body, without any violent or specific action of the intestinal canal, produce their effects by being absorbed. It is to be understood, however, that the effect is not in the mere absorption, which is a mechanical process, but in some subsequent action; and that action sometimes very rapidly diffuses itself over the whole body.

ABSTINENCE literally means voluntarily refraining from taking food; but it is often applied to all cases where food is not taken, in what may be considered the average quantity, whether voluntarily or not. This is the sense in which it is used in natural history, and as such it is an important branch of the physiology both of animals and of vegetables. It stands opposed to repletion, or excessive feeding, and the wholesome state for both animals and vegetables lies between the two; but the precise point in any one instance is a matter to be determined by actual observation of that particular instance.

That different plants have different capacities for food, and that these capacities fluctuate with the seasons, and other external circumstances and agencies to which the plants are exposed, must be obvious to every one who has paid the slightest attention to the progress of vegetation. It must also be observed by every one that, in the same species of plant, the quantity and also the quality of the matter elaborated depend very much on the quantity of food. If it is in rich soil and exposed to a damp atmosphere and moderate warmth, the produce is very great; but the parts are soft and spongy; and if any part of the plant be used as human food, that part is crude, tasteless, and does not, in the same weight, furnish so much of even less palatable nourishment as that which is grown with more moderate feeding. This principle is general, and it is a most important one in that first of all arts, the cultivation of vegetables; but it must be received with some explanations. Plants are naturally adapted to different situations; some to the waters over which the air is constantly impregnated with vapour; some to the arid places, where there is little moisture either in the air or the earth; and there are habits intermediate between all these. In every case, however, there may be discovered a medium state, which is better suited to the whole action of the plant, than if it were either more highly fed or subjected to greater abstinence. When we cultivate, either for human food, or for that of domestic animals, it is not the whole plant that is our object so much as some product of it; we seek, for instance, to produce more succulent or farinaceous matter in the seed, the bulb, the tube, the stem, or the leaves; and up to a certain point of forcing, by prepared soils and manures, and by sheltering from the cold and violent currents of the air, we attain our object; but there is always a limit, which if we once pass, we defeat our object; the functions of the plant are impaired, it ceases to be fertile, and it becomes unable to bear even moderate changes of temperature. The ultimate seasonal action of every plant is the ripening of the seed; and before that is perfected the action of growth as increasing the quantity of matter in the plant ought to cease also. Those plants in which several fructifications are in progress at the same time—as the orange among the trees of rich soils in warm climates, and the common juniper among the shrubs of cold and rather sterile places—are exceptions, though in them each succession of fruit obeys the same law as those which bring forward but one crop at a time; and it is found that when planted in a soil too rich and warm, the juniper not only remains sterile, but is difficult to be kept alive.

In annual vegetables, the cultivator can adapt the soil to the plant by experience; and it is there found that change of place will correct the bad habit which the plant in time acquires, either from too rich or too poor a soil. Seed corn from the hill runs less to straw and yields better on the rich and sheltered bottoms; and seed corn from these grows stronger and ripens earlier on the hill. It is the same with bulbs and tubers, and indeed with cultivated plants generally. One cultivation stimulates one part of the system of the plant more than it does the other parts; and as the seed must partake of the artificial qualities (the qualities produced by locality and culture) of the plant upon which it is grown, the change from soil to soil tends to restore it back again, by, on the one hand, repairing the exhaustion which had been produced by abstinence, and on the other correcting the surfeit which had been caused by repletion. Shortening the duration of plants is one of the effects of high culture; and though we have no data for ascertaining the early history of the grain plants and pulses which are now known only as cultivated, it is by no means improbable that they all have at one time been perennials; and the fact of their being capable of multiplying by the roots, is at least a strong presumptive proof that such has been the case; though it appears that now they have lost so much of their original character that they are unable, without the assistance of human art, to bear the common succession of seasons in our climate for longer than a year or two.

In plants of longer duration—trees for instance—whether cultivated for their fruit or their timber, the principle of abstinence cannot be so well applied; and as in both large growth is the main, because the marketable, object, the chief efforts are in the other direction—to produce quantity as rapidly and as abundantly as possible, and let the quality be as it may. In general, however, it is best when the seed is gathered from a plant on average soil, and the nursling reared in the same. But on the whole, *abstinence* has been very partially applied in the cultivation of vegetables; though the general principle of its action be plain enough, the details have not been sufficiently studied.

In animals, especially those species of them which are the most familiar to our observation, the effects of abstinence are better known; though even these are so varied in different species, that it is not easy to generalise them. As an animal, at least one of the warm-blooded classes, is a much more complicated organisation than a vegetable, it follows, as a matter of course, that both abstinence and its opposite must have more effect upon the animal system. Abstinence in the young or growing stage will, as a matter of course, diminish the size of the animal, just as a thin and hungry soil diminishes the size of a plant. But the opposite treatment cannot carry the opposite effect to the same extent in the animal kingdom as in the vegetable. The reason of this will at once become obvious, when it is considered that the food of the plant, whether obtained through the medium of the soil or the air, is taken immediately into the substance of the plant by absorption; while, of the food of the animal, it is the liquid portion only which is absorbed, and that too but in part; and also that the part absorbed, if it exceed a certain limit, injures the power of assimilating the rest of the food, and thus produces some of the effects of unhealthy abstinence. Fat animals are not the most ravenous eaters, whether the eating take place at long or at short intervals.

When the health, comfort, and activity of the individual are the objects, which is the case with men, and with all the working animals, an accurate knowledge and judicious use of the principle of abstinence are of the very first importance; for if the simple organisation of the vegetable can be so acted upon by excess of food as that one part of its system shall get the better of the other parts, and produce one of the natural components or products in much greater abundance than the others, much more must it happen with animals, and especially with those of the more complicated organisations.

The food of the animal, even during the period of its growth, goes to replace the waste of the body as well as to increase its volume. The digestive power consequently requires more frequent supplies during the period of growth than after the body has attained its full dimensions; but though the supplies require to be more frequent, there is even more danger of excess than where the body has attained maturity; because the same degree of gluttony, which emaciates the body and takes the colour of health out of the cheek in after life, as certainly both stunts and deforms the growing subject. Nor is that all; for, from what has been stated of the excessive action of one part of the system diminishing that of all the rest, the pampered youth must, as matter of course, grow up, as one would say, "brainless in science, and handless in art." When young people have free range in the open air, they make solid bones and firm flesh upon even abundant feeding, just as trees on a rich soil make good timber, when the breeze of heaven plays freely around them; but it sometimes happens that the good feeding is purchased by the sacrifice of that exercise which would render it wholesome; and then they necessarily grow up much in the same manner as poles in those thick plantations where they are choaked and etiolated by their own closeness, and will not last for even a year when they are put to the test as timber.

In old age, when the power of assimilating has begun to fail in proportion to that of absorption, and there is a tendency in the body to take up its own matter in the circulation, abstinence has a direct tendency to increase the evil; and it does so the more as, at that period of life, the feeling of hunger is not so vigilant a monitor as when the system is in a more vigorous state. Hunger is the call for assimilation, not for absorption; and as the absorption is the more energetic of the two at that age, a partial inroad may be made upon the system before hunger becomes keen. It has been remarked, that old men who do not eat except at long intervals, sooner become bent in the spine, and stiffened in the joints, than those who do not eat more on the whole, but do it more frequently.

Throughout the whole of animated nature, it is a law that those animals which can bear the most copious feeding at one time, can also bear the longest abstinence; but it is also accompanied by another law, that where there is the most intense action, there must be the greatest supply of food to maintain that action. Something, too, depends on the nature of the food. Animals which feed upon leaves continue eating during the greater part of the day; those that feed upon seeds eat less frequently; those that feed upon other animals less so; and the preyers on warm-blooded animals the least of any. But in all these, the amount of quietude and repose after the meal obtained are always in proportion to the power of abstinence. The more powerful of the predatory animals, whether mammalia or birds, are never found sporting. When their hunger is appeased, they lay themselves down to rest—the lion stretches himself in his den, the eagle squats on her ledge, or rests balanced on her pinnacle, and all the weaker animals are at peace, or at least in freedom and safety, till the lord of the desert or the queen of the cliff again comes forth to feed.

These general observations, which can be much better expanded into their particular details in treating of those animals of which they are characteristic, tend to show how very beautifully all the parts of nature work together. In man, we find that the years of his life, during which he can bear the most hearty meal and the longest abstinence, are also those in which he is called upon to perform the duties of life with the greatest energy and the least interruption; and that as we look nearer either to the commencement of life or its close, we find that this feebleness of the system of the body is indicated by the more frequent calls for nourishment. In the predatory animals again, the repose after they are fed gives peace and safety to the rest of the creatures; and the lion spares the flocks on which he feeds as much, and nearly from a similar cause, as man does,—though in the case of the lion it is merely an instinct of the animal, yet it is as much a law of his nature as his other habits, or even his form; while with man it is matter of reason and experience.

There are many very interesting points in the natural history of particular animals closely connected with the powers which these have of enduring abstinence; but they either belong to the peculiar organisations of the species in which they are manifested, or they are of a climatal or seasonal nature, and as such can be noticed with more advantage in the article Hybernation, and in those on the seasons during which they take place. There are also many singular instances of abstinence in human beings, some of them what are called voluntary and others involuntary, some well authenticated and others doubtful; but though these, to a certain extent, show the flexibility of the human system to circumstances, they do not come within the legitimate province of Natural History.

ABUTA (Aublet). A genus of evergreen climbing plants. Linnæan class and order, *Diœcia Polyandria;* Natural order, *Menispermaceæ*. Of this genus there are only two species described, viz. *A. rufescens*, rufescent; and *A. candicans;* both natives of Cayenne.

ACACIA. An extensive genus of exotic trees and shrubs belonging to the Linnæan class and order *Polygamia Monœcia;* and to the natural order *Leguminosæ*, division *Mimoseæ*, of Jussieu. The name is derived from the Greek word ἀκαζω, to sharpen, in consequence of many of the species being thorny. Generic character: flowers, polygamous; calyx, four or five toothed; the petals of the corolla four or five, at one time free, at another coalescing; stamens varying from ten to 200; pods not jointed, juiceless, and two-valved.

Branch of the Acacia.

The species included under this genus are very numerous, amounting to about 300. They are shrubs and trees, varying in habit and foliage; and while by their beauty and elegance they contribute not a little to adorn the countries in which they grow, they are found to be of essential service in the arts and manufactures by supplying them with a hard and durable wood, which is deservedly much valued. They are found in the tropical regions of Asia, Africa, and America, and also abundantly in New Holland, Van Diemen's Land, and New South Wales. They all bear pods like the pea family, but in their blossoms they have a considerable resemblance to the willow tribe. By their airy foliage and golden flowers they throw a charm even over the sterile deserts of Africa:—

> "Our rocks are rough; but smiling there
> Th' acacia waves her yellow hair;
> Lonely and sweet, nor lov'd the less
> For flow'ring in the wilderness."

The leaves are, as we have already stated, in the greater number of the species, pinnate, that is, having a central stalk and numerous small leaflets on either side of it, as represented in the engraving; in others, however, the leaf-stalks become dilated vertically into hard, leathery expansions, denominated *Phyllodia*, which seem to serve all the purposes of leaves, and which in their young state generally bear leaflets. From this difference in the foliage, the species have been divided into those having pinnate leaves, and those provided with *phyllodia*. The latter are of frequent occurrence in New Holland and the other parts of Australia, and may be said, in some degree, to characterise the vegetation of those countries.

We shall notice a few of the important species. The *Acacia Arabica, vera, Senegalensis,* and *Nilotica,* &c., are interesting in a commercial point of view, as yielding the substance called Gum-Arabic. This exudes either spontaneously or from incisions made into the bark, and subsequently hardens by exposure to the air. When pure it is transparent and colourless, has neither taste nor smell, and is perfectly soluble in water, forming what is called mucilage. Gum Arabic derives its name from having been originally brought from Arabia; subsequently, however, Africa, more especially Senegal, has furnished a considerable quantity. From this circumstance the name of Gum Senegal has been given to some varieties. The Gum Arabic tree is also found in the East Indies. The gum is collected in the months of December and January, and sold in large quantities to French and English merchants. It is capable of being used as an article of food, and is very nutritious. During the time of the gum harvest the collectors subsist upon it entirely, and six ounces are said to be the usual allowance for an adult, in the course of twenty-four hours. Gum is used extensively in medicine, as a bland mucilaginous substance, for the purpose of allaying various irritations. It is made into the form of lozenges and jujubes with several other substances. It is useful in the arts, being employed in calico-printing to give consistency to colours, and to prevent their spreading. For similar reasons it enters into the composition of writing ink, blacking, &c. Botanists employ it to fix the dried specimens of plants upon paper, and it is used in the formation of numerous fancy and ornamental articles, such as seals, rice boxes, &c. The bark of the Gum Arabic tree is employed in India as a tonic for strengthening the stomach, and a decoction of its pods serves for the purpose of washing.

Another species of Acacia, the Acacia Catechu, or Khair tree, a native of the mountainous parts of Hindostan, deserves notice chiefly on account of its yielding a substance which is used in medicine. This substance, which was formerly erroneously denominated Japan Earth, but now receives the name of Catechu, is an extract from the internal part of the wood of this tree prepared in Bengal, and other parts of India, by decoction and evaporation. The extract is also prepared from the pods of the tree, as well as from other plants, such as the Nauclea Gambic and Areca Catechu. It has a reddish brown colour, and its taste is very astringent. On account of its astringent property, it is used in various diseases as a medicinal agent of considerable efficacy.

The Acacia discolor, and several other species known in Van Diemen's Land, under the general name of *Wattle*, furnish much of the timber used in that part of the world.

From the bark of the Acacias, found in Van Diemen's Land, more especially the Acacia decurrens and mollissima, an astringent extract was lately prepared and imported into Britain for the purpose of tanning leather. It was found, however, that the expence of the extract was far too great to render it a marketable commodity, and the bark itself is therefore now substituted. Occasionally a quantity of the Mimosa Bark, as it is termed in commerce, is imported into London. The bark is of little value in Van Diemen's Land ; and although the freight and duty are considerable, still so long as the Acacias continue to be cut down, in that country, for the purpose of clearing the ground for cultivation, the price must remain in some degree moderate. The Mimosa Earth is more astringent, and possesses a more powerful tanning property than the oak bark, but it imparts to the leather a reddish tint, which renders it fit only for sole leather. The Mimosa Bark, however, when mixed with acorns, may be used for the tanning of dressed leather.

The Acacia decipiens, found in New Holland, was formerly mistaken for a fern, and called fern-tree, on account of its long flowerless branches. The Acacia melanoxylon, denominated in Van Diemen's Land, Black-wood, is a beautiful tree, with foliage reaching to the ground. It grows to a considerable height, but does not attain a great diameter. Of late years various new species of acacia have been collected in Australia, by Mr. Allan Cunningham, Mr. Fraser, and Dr. Leber.

The acacias are propagated by seeds, or by cuttings put into sandy soil, under a bell-glass, and kept warm. The flowers of some of the species of acacia are used by the Chinese for dying a yellow colour.

In our shrubberies the Robinia Pseudo-Acacia, or Locust-tree, an elegant shrub, bearing white pea-shaped blossoms, occasionally tinged with pink, is commonly cultivated under the name of Acacia.

For the better distinguishing this numerous family botanists have arranged the species into five divisions, founded on their different modes of foliation, and these divisions have again been subdivided into sections, founded on their manner of flowering, or on the absence or difference of their armature. A few of the species are climbers, and many, indeed a whole division, are marked *dubiæ*, not being sufficiently known to distinguish to which section they belong. The name Acacia has also been given to many other species of plants, viz. to a species of Darlingtonia, to a Gagnebina, and to several of the genus Prosopis.

ACÆNA (Vahlenberg). A genus consisting of ten species of curious evergreen herbaceous exotics, chiefly from South America, towards the Straits of Magellan and New Holland. They belong to the Linnæan class and order *Diandria Digynia*, and to the natural order *Rosaceæ*, tribe *Sanguisorbeæ*.

ACÆNITUS (Latreille). A genus of insects of the order *Hymenoptera*, family *Ichneumonidæ*. Generic character: superior wings, with the first sub-marginal cell very large; the two discoidal cells situated longitudinally, one above the other; mandibles bidentate, or notched at their extremity ; palpi with their joints not very unlike each other; oviduct covered at its base by a large scale.

To this genus belongs the Ichneumon dubitator of Panzer's *Fauna Insectorum Germanica*. It is certainly a rare species in this country; but the insects of this family have been greatly neglected by entomologists. Gravenhorst, in his work on the Ichneumonidæ, has enumerated seven species. Many of the ichneumons may be found on umbelliferous plants, upon which the respective species deposit their eggs ; and it would be highly desirable if we could identify the larvæ, for there is no doubt, from what we have observed, that each caterpillar has its own peculiar parasite, and that nothing is left to chance. The rarity of many of the moths in the larvæ state will also account for the scarcity of certain species of this family of insects.

ACALEPHA. Animals forming the third class of Cuvier's *Zoophytes*. This name is given to them from the faculty several of them have of stinging the hand when touched. Their form is always circular and radiated, and their organisation complex. Their mouth serves also as an anus ; their stomach, being in the form of a sack, is sometimes prolonged in radiated intestines, through different parts of their body. These, probably, replace the vessels they otherwise are deficient of. They are divided into three families. The fixed species include the *Anemonies*, the *Zoanthes*, and the elegant *Lucernaria*, belonging to this class.

The free species float on the sea, and their brilliant legions cover an immense extent with phosphorescent light during the absence of the sun.

Another species is the *Hydrostatic ;* which are so called from having one or more bladders filled with air, by means of which they remain suspended in the water.

Lamarck has separated the Acalepha into the different sections of the two orders, which form his third class of invertebrated animals, called *Radiata*.

ACALLES (Schönherr). A genus of insects of the order *Coleoptera*, family *Curculionidæ*. Antennæ genitucated, twelve jointed, rather stout ; funiculus seven jointed, its two basal joints obconic ; the remainder subrounded, and slightly coarctate ; the club short, ovate, acuminate. Rostrum longer than the thorax, stout, a little bent, inserted during repose in a deep elongate pectoral groove, which is strongly margined: eyes minute: thorax rather long, convex, lobate behind the eyes, narrowed in front, the base truncate: scutellum wanting: elytra connate, subgibbous, embracing the sides of the abdomen : legs rather stout, the intermediate pair shortest ; tibiæ slightly compressed, the apex furnished with a stout tooth within.

Ac. Ptinodes. Piceous ; with scattered cinereous scales above, and erect muricated black spinulose ones : eyes brown : thorax deeply punctate : elytra dilated before the middle, attenuated posteriorly, deeply and coarsely punctate-striate ; variegated with cinereous; beneath rufo-piceus, densely clothed with cinereous scales : legs and rostrum rufo-ferruginous : antennæ pale testaceous.

Curculio Ptinoides *Marsham*, length one line and a quarter.

Inhabits sand pits and gravelly places, at Coombe Wood, Surrey ; Darenth, Bexley and Charlton, in Kent. The above situations may be searched in the months of April, May, and June by the young entomologist, who will be amply repaid by the novelties which he may there obtain.

ACALYPHA. A genus of uninteresting exotic shrubs and annual herbs, belonging to the Linnæan class and order *Monœcia Monadelphia*, and to the natural order *Euphorbiaceæ*. This genus is arranged in four divisions, dependent on the character and situation of the flowers:—viz. 1, male and female flowers on the spike; 2, spikes of distinct sexes, the female ones terminal; 3, spikes of distinct sexes, the upper ones male; 4, flowers on separate plants, or diœcious. The known species are natives of North and South America and the Indies.

ACAMARCHIS (Lamaroux). *A. Dichotomous Polypidom*, of the first class and first order, whose polypi are found in shelly or non-irritable cells, which are united and alternate, terminated by one or two lateral points, with a vesicle at their opening. The vesicles are nearly globular; helmet-shaped, and placed on the borders of the cells, which they appear wholly to close. Various opinions have been formed with regard to their uses; but the most prevailing idea is, that they are ovaria, enclosing the germs of future individuals; for it has been observed, that these vesicular bodies are sometimes whole, in which case they are always found filled with small globular bodies; when these supposed ovaria are found opened by a transversal slit, the cells are empty.

The acamarchis resemble each other in form; they only differ by the number of teeth placed on the external side of the cells, and by the form of the latter, the border being either smooth or toothed; the upper membrane of the cells is frequently wanting, and in this state Ellis figured his first species.

The substance of the acamarchis is more horny than chalky; their colour a dull green or grey, changing by desiccation, or exposure to air and light, to a fawn colour, more or less bright. They attach themselves by numerous fibres to solid marine productions; and are found in the equatorial and temperate seas, seldom exceeding four inches in size.

ACANTHACEÆ. A natural family of plants, allied to the *Scrophularineæ* and *Bignoniaceæ*, belonging to the monopetalous division of *Dicotyledonous* vegetables. It contains about eighteen genera and 168 species, which are herbs or shrubs, chiefly inhabiting tropical regions. Their elastic dehiscent capsules, wingless seeds with hooked dissepiments, and imbricated flowers, are their distinguishing characters. Their leaves are opposite; inflorescence terminal or axillary; flowers in spikes, furnished with bracteas, and of a white, blue, yellow, scarlet, or purple colour. Calyx with four or five divisions, persistent; corolla monopetalous, and generally irregular; stamens two or four, in the latter case didynamous. The fruit is a capsule with two cells, and the seeds are supported on a filiform podosperm. Many of the species are mere weeds, but some of them are showy, and cultivated. Among the genera included under this family are *Acanthus*, *Thunbergia*, *Ruellia*, and *Justicia*. They are generally bitter and tonic, but their properties are scarcely known. The Acanthus (from the Greek word ἀκανθ, a spine) is the genus whence the name of the family is derived. The *Thunbergias* are climbing plants. *Justicia biflora* is used medicinally in Egypt; and the *Justicia pectoralis* boiled in sugar yields a sweet-scented syrup, considered in Jamaica to be a good stomachic. *Justicia paniculata*, called *Creyat* in India, is said by Ainslie to be the basis of the French *Drogue Amère*, famous as a tonic. The plants belonging to this family are propagated by seeds and cuttings.

ACANTHACEÆ; *Acanthus mollis*. *a*. Corolla opened, showing the stamens and pistil. *b*. Stamen. *c*. Pistil. *d*. Ripe seed vessel, covered with its calyx and bracte. *e*. Seed vessel burst previously to shedding its seeds. *f*. Seed opened, showing the radicle and plume.

ACANTHIA. A genus of insects, of the order *Hemoptera*, family *Acanthideæ* (Leach). The antennæ are filiform; labrum very prominent; rostrum straight and long; eyes very large and prominent; feet formed for walking and jumping.

This genus was established by Latreille, and has been adopted by later writers on the subject. To this genus belongs the *maculata;* black spotted with a pale colour; inhabits grassy banks.

ACANTHION. A genus of *Mammalia*, belonging to the order *Rodentia;* resembling the porcupines in many respects, so far as the very vague knowledge which we at present have of the genus extends. All that is at present known of the members of this supposed genus is one skull and one skeleton; the former from the island of Java, and the latter from some unknown place. The Javanese skull has the hinder part of the cranium depressed, the upper part elevated, the muzzle shorter, and the lower jaw shorter in proportion to the upper than the common porcupine which is known in Europe; but the lower jaw does not appear to be fully developed; and as the age of the specimen to which the skull belonged is not known, there may not be character enough in it to warrant the establishment of a genus.

ACANTHOPHIS (Spine-snake). A genus of poisonous serpents classed by baron Cuvier in the natural family of the vipers, but differing from them in many essential characters. They have a single row of plates on the under side of the tail, except sometimes near the extremity, where they are divided into two rows. The tail itself terminates in a small horny spine, which is not, however, peculiar to this genus, or even to poisonous serpents.

The characters of this genus, and even of most reptiles of all orders, are very imperfectly defined; and the species of this particular genus are very little known. The habits of poisonous serpents are in general so obscure, and they are so eagerly destroyed wherever they are found, that accurate accounts and unmutilated specimens are equally difficult to be procured The Acanthophii are cylindrical in their bodies, but tapering to the neck and the tail, and the length is considerable in proportion to the diameter, though the whole animal is of small size. The head is obtuse, covered in part with nine or ten scaly-guard-plates, and the plates round the eyes are partially raised or erected, so as to give a faint resemblance of a crest. The upper part of the body is covered by imbricated scales of a rhomboidal form, and the lower part particularly by simple plates as already mentioned. Besides the poison fangs, the jaws are armed each with a double row of small reserved teeth, to assist in the process of deglutition; and from the extent of the gape it may be at least supposed that the prey which they swallow is large in proportion to their size.

In New Holland, the only country where they have been ascertained to exist, they live in holes at the roots of trees or otherwise in concealment, and kill lizards and other small animals by poisoning. The New Holland species has been designated *Brownii*, after Brown the botanist. The body is coaly black, with some white on the upper lip. The tail is flattened, and its junction with the body is indicated by a diminution of the diameter. It is understood to be the most poisonous serpent in Australia; and as such, we may naturally suppose that exaggerated stories respecting it will be circulated. Another species, of which the native habit is not known, has been called *cerastinus*, from its resemblance to the crested viper, or horned viper of Egypt and Nubia. It is greyish above, and brownish-yellow on the under part, with black spots on the edges of the abdominal plates.

ACANTHOPTERYGII; *Spinous-finned Fishes.* A very numerous order of bony fishes, or of those that have their skeletons with the greatest proportion of earthy salts in their composition, and, therefore, the hardest that are met with among the fishes, though inferior in that respect to the bones of the mammalia and of birds. Their bones are, in the recent state, semi-transparent; they are more or less flexible; and they are without the ordinary cells and tubes in the internal joint, which are filled with marrow or oil in the bones of the mammalia, which answer the purposes of air-tubes in those of birds.

Their skeletons consist of the bones of the head, the spine, and its ribs and branches, and other small bones to which the fins are articulated, and which are either embedded in the muscles, as the shoulder-bones are in the mammalia, or articulated to the processes of the spine by elastic tendons. As the bones are most perfectly developed in the division under consideration, this seems the proper place to notice the difference between them and the bones of the other vertebrated animals. The head consists of a great number of bones, as many as 70 or 80 in some species; but they adhere to each other, and the sutures, or innumerable joinings, become obliterated. The bones of the head are altogether, in general, large in size; but the cavity for the brain is small. The teeth, except in a few species, are instruments of prehension rather than of mastication; they are, in general, very numerous and small, and the palate and partially the tongue are sometimes beset with them as well as the jaw. The head is united to the spinal column by a single tubercle, but the joint admits of little motion. There are never many of the vertebræ of the spinal columns *cervical* or tending to form a neck, and in most of the divisions there are none. The section of the vertebræ is sometimes circular, sometimes angular, and sometimes compressed laterally. The dorsal and caudal parts of the spine consist of a vast number of vertebræ, varying in different species and tapering towards the tail; the last one being always compressed laterally, and generally rounded, particularly where the small bones of the caudal fin are articulated.

The form of the vertebræ and the mode of their articulation, as compared with those of the other three orders of vertebrated animals, are worthy of notice, as indicating a greater simplicity of purpose than in that of the fishes. In them the spine is nothing more than a flexible rod. Each vertebra is a short cylinder or prism, according to the form of the section, terminating in a conical cup at each end. The interior of these cups is marked by concentric rings, said (but not proved) to indicate by their number the years that the fish has lived. The cylinders usually widen a little towards the mouths of the cups, which are slightly turned over or rounded. These cups are, in the living state, completely filled by cartilaginous fibres, softest toward the centre, where, from the form of the cups, they are also largest; they allow of free motion laterally, though not to any great extent in the single articulation; and the whole is at the same time highly elastic. The chief difference between the bony and cartilaginous fishes in this part of their structure is, that in the latter the column has little distinction of vertebræ, but is equally flexible through its whole length.

The dorsal part of the column, or that which answers to the spine of the trunk in the mammalia, is without spinous processes on the under side, but has them on the upper, and also obliquely and laterally, the ribs being articulated to the latter. All the bony fishes have ribs, sometimes forked, sometimes double, sometimes compressed, and sometimes in the shape of bristles; but in the cartilaginous fishes they are wanting. The caudal vertebræ have spinous processes both on the upper and the under side, which become smaller towards the termination, according to the shape of the fish. The clavicles support the sides of the body behind the gill-openings; and the pectoral fins may be considered as having some resemblance to the anterior extremities in the mammalia and the wings of birds; but the bones answering to the pelvis are very obscure.

The principal muscles in the bodies of these, and, indeed, of all fishes, are placed on the sides of the spine, and supported by the processes. They are formed in layers, placed in curves with their convexity toward the head. In this division they appear to contain more albumen and less gelatine than in the cartilaginous fishes, and even less than in those which have soft fins. The spinous fins have also more motion than those with soft rays, and especially than the fleshy ones; but so little is known of the habits of the animals that no very certain conclusion can be arrived at. The muscular action in swimming consists in bending them to each side alternately, accompanied by expansions of the rays of the caudal fin, resembling the opening of a fan; and in those fishes that have large scales, the posterior margins of these hold on upon the convex side when the body is bent, and thus tend to steady the action and prevent recoil.

The brain forms a smaller portion of the whole nervous mass than in the warm-blooded animals; and as the spinal column is in proportion to the body, not to the brain, we may naturally conclude that the energy of the senses, taken on the whole, is inferior to that of motion and digestion. They do not appear to feel much pain from wounds in the flesh; but in some species at least, there is a sense in the skin analogous to what we call touch. That the common trout (*salmo fario*) is pleased by tickling is so familiarly known that it has been made the foundation of a common saying on the effect of flattery :—

> " If you *tickle* the trout,
> You'll soon have him out;
> But handle him rough,
> And he's sure to be off."

The fishes of this division have no external ears, nor, indeed, have any of the osseous fishes ; and in the cartilaginous ones, the external orifices are exceedingly small. In the external ear there are, instead of the lamina and tympanum in the mammalia, certain little balls of porcelain lustre suspended by a nervous plexus ; but how the agitation of the water acts upon them so as to produce sound, or to what depth and in what particular manner sounds are produced in, or affect the water, is very little known, as we cannot bring it to the test of our own ears, and it is not possible to judge accurately of one sense from comparison with another ; that sounds have a considerable effect upon water is, however, clear, from the well-known fact that a cannonade tranquillises the waves for some distance round. Fishes have no voice when in the water ; and those sounds which some of them make when out of it are produced by convulsions of the gills and gill-openings, and not by the mouth. There is not, indeed, any organisation of the mouth or throat by which sound could be produced. Touch, indeed, appears to be their only means of communication with each other ; and that and sight are the senses upon which they chiefly depend. Authors have, indeed, written about the sense of smell in fishes, and pointed out how trouts of taste, differing from our epicures, prefer recent game to that which is high ; but the statements are not very philosophic in themselves, and they are opposed to all the facts of fishing with artificial bait, which no fish refuses if it is skilfully made and well-timed in the offer. The nervous enlargements at the origin of the olfactory nerves are, indeed, in some species, almost as large as the brain, but we know little of their action. Taste there can be little or none, from the readiness with which the same fish catches again and again at the same artificial bait ; and the whole internal surface of the mouth is of a description to which we would not, from the analogy of other animal structures, attribute much sensation of any kind. It is true that fishes are affected by impure water ; but the pain which it gives them appears to be chiefly, if not wholly, felt in the gills. In these cases they come to the surface, and pant and gasp there as if they were anxious wholly or partially to breathe the air. That may be seen in places where flax is much cultivated and prepared. When that plant is macerated, or steeped, in order to make the fibres part from the leaves, it communicates a most offensive intoxicating poison to the water ; and when the pits are allowed to empty themselves into streams, the fish are instantly affected and come to the surface,—come to more speedy and certain death indeed, for the most virulent part of the poison is the lurid scum which floats on the surface.

The eyes of fishes are much more perfectly formed than their other organs of sense, and we are much better acquainted with their action. They even observe a very minute object when the water is dark and the surface ruffled. But in a clear day river fishes can see a shadow passing along the water, and are alarmed by it. Their eyes are admirably formed both for protection and for readiness in the use. The surface is in general flat, and the common integument passes over the eye without any duplicature or eyelid, except in a few very peculiar species; and thus the most violent agitation of the water produces much less effect upon the eye of a fish than a gentle breeze does upon the human eye. Such an eye could not indeed exist exposed to the air, or to any drying element ; and hence in all eyes that are to be used in the air, there are either moveable eyelids, as in the mammalia, or nictitating membranes, as in birds, by the application of which the coat of the eye is kept moist and transparent. But the eye of a fish, from the nature of its element, and the adaptation of the structure to that element, is always ready ; and in all states of the water in which the muscular action of the fish can keep its place, the eye can see the smallest substance. Turbid water, or even rolling pebbles, can do little injury to an eye so flat. But in proportion as the external surface of the eye is flat, the crystalline lens is convex. It is, indeed, nearly a perfect sphere ; and thus the eye has great magnifying power ; although it appears to have considerable range of focal length. The eye of a fish is one of the most curious varieties of that most interesting of organs. See the article Eye.

As this division is considered by Cuvier as containing the most perfect fishes, or the types of the class, the mode of their respiration and the circulation to which it is necessary, must be regarded as that which is most perfectly expressive of an inhabitant of the waters—a breather by means of gills, the fibres of which play freely on that fluid. The structure and form of gills will be found explained in the article Fishes ; so that we have here only to remark that the heart of fishes is small and single. The auricle receives the blood from the body and sends it to the ventricle ; and that propels it through an artery which is finely ramified over the gills. From the gills it returns by veins, small at first, but meeting and emptying themselves into the aorta or large artery, which lies along the under side of the spine; and from that it is sent over the body, returning by veins to the auricle of the heart, but the veins are often much dilated, and the circulation in them very sluggish. The gills and the parts near the spine are the only ones that bleed copiously when wounded.

Such is a very short summary of the general structure of osseous fishes ; and we should now point out the characters of the order. Of these, however, there is hardly one constant, unless it be the spiny rays in the fins, and even that is not absolutely confined to the order, and is very variable in it. The particulars must therefore be reserved to the families or subdivisions, of which Cuvier's list is subjoined ; and the characters and subdivisions will be found noticed under the several titles.

Family I. *Percoideæ*, the perch family. They are numerous, and generally wholesome and rather palatable as food.

Family II. *Enaplœcephaleæ*, armed-headed fishes. These have the head variously furnished with spines, plates, or other appendages.

Family III. *Sciænidæ*.

Family IV. *Sparidæ*, the gilt-head family.

Family V. *Mænidæ*.

Family VI. *Squameptereæ*, scale-finned fishes.

Family VII. *Scomberidæ*, the mackerel family.

Family VIII. *Tænioidæ*, the riband-fish family.

Family IX. *Theucidæ*, the lancet fish family.

Family X. *Pharyngolabyrynthidæ*, labyrinth palated fishes.

Family XI. *Mugilidæ*, the mullet family.

Family XII. *Gobioidæ*, the goby or sea gudgeon family.

Family XIII. *Carpaptereæ*, fishes bearing the pectoral fins attached to an elongated stem like a wrist.

Family XIV. *Labroidæ*, the wrasse family.

Family XV. *Fistulidæ*, the pipe fish family.

ACANTHOSCELIS. A genus of Insects, of the order *Coleoptera*, family *Scarabidæ*. The antennæ are filiform (thread shaped); the first joint very large, the others considerably less, but gradually increasing near the extremity: superior lip very short, and furnished with three teeth: mandibles large, projecting, and toothed internally: labial palpi, with the last joint nearly cylindrical: mentum or chin, articulated and strongly trilobated. Thorax convex, transverse, and almost square. Body short, and convex: elytra short and very convex: anterior legs very strongly palmated: posterior legs short, thick, and covered with spines: trochanters almost as large as the posterior legs.

The Count De Jean observes, that this new genus was formed by Latreille for the *Scarites ruficornis* of Fabricius, and is indicated in his *Familles naturelles du Règne Animal*. This species appears a good genus, as it is easily distinguished from *Scarites* by its short, thick, and very convex form, and the above character.

ACANTHOCINUS (Megerle). A genus of insects of the order *Coleoptera*, family *Cerambycidæ*. Antennæ of the male more than four times the length of the body, those of the female above twice its length; basal joint somewhat robust, second short, third longer than the fourth; the remainder nearly equal in the female, but gradually lengthening in the male to the terminal joint, which is very long and slender: palpi short, the terminal joint fusiform, acute: body rather depressed: thorax transverse, having a spine on each side: legs robust.

Acanthocinus.

Acan. ædilis. Body short and depressed; the colour brownish, and the surface more or less thickly covered with ash-coloured pubescence; head punctured, and having a shallow groove on the forehead; antennæ of the male four or five times the length of the body, those of the female twice its length; the base of the joints brownish, and covered with cinereous pubescence, the apex black; thorax thickly and ruggedly punctured, with a strong spine on each side, and four tufts of yellowish pile placed across the disk before the middle; elytra, with the apex of each rounded, the upper surface unequal, pale brown, with cinereous pubescence and a few scattered tufts of black pile; the base punctate, the apex nearly smooth, having an oblique irregular fuscous fascia anteriorly, and another, somewhat abbreviated, behind; under side ferruginous, clothed with whitish glossy pubescence: legs brownish, pubescent, the tarsi somewhat dusky: length of the body from seven to nine lines.

The abdomen of the male has the anal segment short and emarginate, but in the female it is produced into a long conical tube of a black colour.

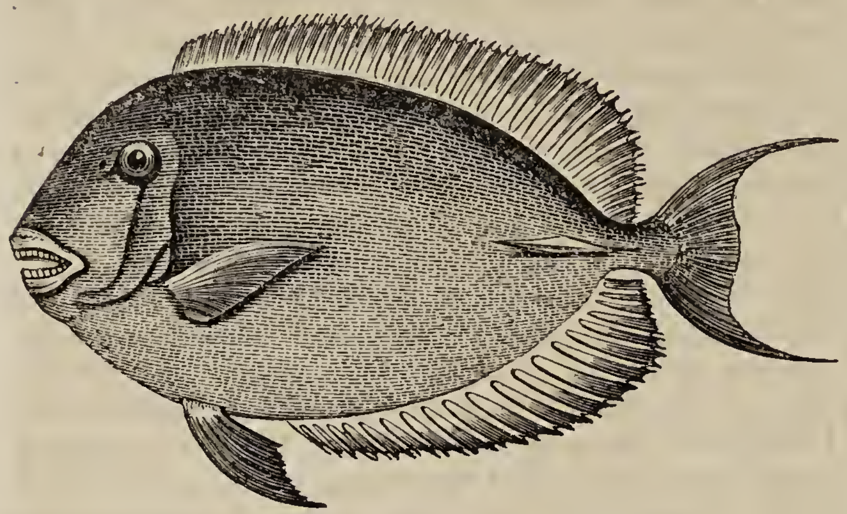
This is a very local insect, but has been found rather plentiful in Worcestershire, and many of the London cabinets have been supplied through the liberality of Mr. Raddon, the eminent engraver; specimens have also occurred in the neighbourhood of Kirkaldy, in Scotland, and are preserved in the cabinet of Sir P. Walker.

Acan. speculifer. Greyish white, with four spines on the elytra and two on the thorax, forming a coronet of spines, in the male, with a burnished spot like talc, on the disk of each elytron. It is figured in the previous column. Length of the body one inch.

This beautifully-formed and extensive genus of insects are found on timber in their adult state, and their larvæ feed on the decayed wood: the feet of these are extremely small, the body soft, and of a whitish colour; the anterior part larger than the posterior, the head scaly, and furnished with powerful jaws: they are very destructive, perforating the interior of the largest trees. Most of the species of this family produce a singular noise, by rubbing the hinder part of the thorax against the base of the abdomen. Lister calls this a querulous sound, though it bears a nearer resemblance to the rubbing together the milled edges of two pieces of coin, and we are not aware that it is confined to either sex. It has been asserted by some authors that some of the species are nocturnal.

In the exserted oviduct of the females of the timber-feeding larvæ, a most beautiful provision of the Creator is shown, the animal being enabled to insert its eggs into the crevices of the bark of trees; thus securing them from the effects of the weather, and protecting them from birds; for as soon as the caterpillar escapes from the egg, it begins to enter the wood, and tends greatly to assist in the destruction of those immense trees which, if left to a casual decay, would prevent the growth of others in those extensive forests of tropical climes, where these wood-feeding, elegant, and singular insects abound. In very few tribes in this portion of the insect creation do we find more to admire or charm the eye,—their beauty of form, variety of colour, length of antennæ, and the clothing with which they are invested, seem to claim the attention of man.

ACANTHURUS. (Lancet Fish). A genus of fishes, belonging to the ninth family of Cuvier's order of fishes, with spinous fins. The characters are, the body and tail compressed; the mouth rather small, and without any teeth on the palate, but furnished with a single row of strong cutting teeth, with jagged points in each jaw; and they have but one dorsal fin, and on each side of the tail there is one or more very sharp moveable spines, with which the fish inflicts severe and deep wounds, if incautiously handled. It is from the depth of the wounds inflicted by these instruments, and their tendency to bleed, that the common name of lancet fish is given; and the generic name "spine tail" is founded on the same. There are about six known species, all inhabitants of the warmer seas, and most, at least, found both in the Atlantic and the other tropical oceans. The particular use of these formidable spines in their economy is not well known; probably they are employed as defensive weapons against larger fishes. The common lancet fish is found chiefly in the West Indian seas, where its flesh is much relished, as being both wholesome and nutritious. The characters, and even the names, of the species are a little confused. Some have the dorsal fin much produced; others have the spines on the tail partially concealed anteriorly by a tuft of bristles; and others again have the teeth so deeply grooved on the one side that their cutting edges resemble the teeth of a comb. They are altogether a very curious genera of fishes, peculiar to the tropical or warm seas, and very characteristic of them, which are the only portions of the sea where animals, whether fishes or reptiles, are understood to graze the vegetable productions of the deep.



Acanthurus nigricans.

The above figure will give some idea of the shape of these singular tenants of the deep, which, notwithstanding their trenchant teeth, and the very formidable weapons with which their tails are armed, cannot be classed among predacious fishes. Their principal food, at least that of most of the species, is not even the small animals of the sea, but marine plants—the more succulent kinds of sea-weed, which grow so abundantly in the shallows of the tropical seas. They thus bear to the rest of the finny tribes a relation somewhat similar to that which the herbaceous mammalia bear to the rest of that class. Not that they ruminate; but their intestinal canals are long, and very much convoluted, as is the case in those of the mammalia which live upon vegetable food; and it is not a little singular that the defensive weapons (for it does not appear that they use the spines or lancets for the purpose of attack) should be placed on nearly the same part of their bodies. In the horse and the ass, and still more remarkably in the giraffe and the kangaroo, the defence is in the heels; and so powerful is the kick in the giraffe, that if it take effect it can fracture the skull of the lion; and the spines upon the acanthuri are so situated that they deliver their blow with the whole muscular power of the fish; and thus render it rather a serious matter for the sharks and other voracious fishes to attack them in the rear.

There is something analogous in another class of the inhabitants of the sea—the whales. The common Greenland whale does not feed upon vegetable matter, but its food consists of such small substances, and is caught by so curious an apparatus—the plates of *baleen*, or whalebone and their fringes, that the animal cannot either attack or defend itself from its enemies by the mouth, or in any way with the forepart of the body. But the blow which the common whale can give with its tail is far more powerful than that even of the largest of the toothed whales; and may be said to bear nearly the same proportion to their bite that the kick of the kangaroo bears to the bite of a dog, or the kick of the giraffe to the bite of a lion.

In these different situations of their weapons, which may be traced through all the classes of animated beings, we can discover a very striking proof of that beautiful adaptation, equally free from redundancy and defect, which makes the study of nature so useful to us in the economy of our artificial contrivances. All the predacious animals have their weapons in front, and conducive to the purposes of feeding; and the more powerful they are in preying, they have their hinder parts weaker than the anterior ones—that is to say, weaker in proportion. Not only so, but their eyes are turned more to the front, and infenced and shaded by the superior parts of the orbits, so that their most effective action is in guiding the animals to their prey. The non-predatory ones, on the other hand, have in general the hinder parts stronger in proportion, so that they may defend the animals while they are feeding; and their eyes stand out, so that in very many instances they can keep guard in the rear, without turning the head. In the horse, the kangaroo, and the giraffe, these adaptations are very striking, and there is an approach to them in the acanthuri. The form of the body, deep at the middle, but compressed laterally, enables it to take a strong hold on the water as a fulcrum; while the comparatively slender portion, near the root of the caudal fin, to which the lancets are attached can move with great rapidity, and the weapons cut right and left with great effect. Their eyes, too, stand out; so that the fish can see its enemy and take aim, instead of striking at random.

ACANTHUS (Bear's Breech). A family of deciduous herbaceous plants, containing seven species, chiefly natives of the south of Europe. They belong to the Linnæan class and order, *Didynamia Angiospermia;* Natural order, *Acanthaceæ.* Generic character: calyx of four unequal divisions, the two outside ones being smallest; the corona is of one lip; stamens four, two being longer than the others; anthers unilocular, and bearded; capsuli oval, of two places, each containing two seeds. The leaves of the A. mollis are remarkably graceful, and are said to have supplied Callimachus with patterns for the foliage of the capital of the Corinthian column. The Arabs have a species, the leaves of which they eat as a salad.

ACARI (Cuvier, Leach). A class of the invertebrate animals established by the late Baron Cuvier of the great type *annulata*, or *annulosa* of Mac Leay, the characters of which are as follows: Tracheæ for respiration; body formed of but one segment: mouth rostriform, in some furnished with maxillæ and mandibles; legs six or eight: the following are the sections and families of these so little understood and less known animals, as but very few of the exotic species have yet reached this country:

Section I. Legs formed for walking.

A. Mouth with mandibles.

Family I. *Trombidiadæ*: Palpi porrect, and furnished at their extremities with a moveable appendage.

Eyes two, placed on a pillar. Body apparently divided into two parts by a transverse line; the anterior division bearing the eyes, mouth, and four anterior legs.

Genus *Trombidium, Ocypete.*

Eyes sessile. Body not divided by a transverse line, palpi with the under part of their last joint furnished with a moveable appendage.

Genus *Erythræus.*

Family II. *Gammasidæ*: Palpi porrect, and simple.

Genus, *Gammasus.*

Family III. *Acaridæ*: Mouth furnished with mandibles, palpi simple, very short, not porrected.

Genera: *Oribita, Notaspis, Ocarus.*

B. Mouth furnished with a rostrum.

Family IV. *Ixodiadæ*: Eyes obscure or concealed.

Palpi and rostrum exserted.

Genus, *Ixodes.*

Palpi and rostrum hidden.

Genus, *Uropoda.*

Family V. Eyes distinct.

Palpi distinct.

Genera, *Cheyletus, Smaris, Bedello.*

Palpi concealed.

Genus, *Sarcoptes.*

Section II. Legs formed for swimming.

Family VI. *Eylaidæ*: Mouth with mandibles.

Genus, *Eylais.*

Family VII. *Hydrachnidæ*: Mouth without mandibles.

Genera, *Hydrachna, Limnochares.*

ACARNA (Linnæus). A genus of herbaceous plants, natives of the south of Europe, belonging to the Linnæan class and order *Syngenesia Æqualis.* Natural order, *Compositæ.* There are only two species, viz. *A. gummifera,* gum-bearing, which is a perennial; and *A. cancellata,* latticed, which is an annual.

ACARUS (Linnæus). A genus of the Annulosa, in the class *Acari,* and family *Acaridæ* (Leach). Body soft; mouth naked, and furnished with mandibles, or jaws; palpi very short, simple, and not porrected: tarsi with a pedunculated vesicle at their extremities.

Sp. 1. *A. domesticus.* White, with two brown spots; body ovate, the middle coarctate, with very long hairs: legs equal. It inhabits houses, living in cheese, flour and meal that have been long kept.

To the naked eye, these minute creatures, the *cheese mites,* appear little more than moving particles of dust; but on the application of the microscope they are found to be perfect animals, performing all the regular functions of life. The head is small in proportion to the rest of the body. Their legs are furnished at the extremities with little claws, by which they are enabled to lay firm hold of the substances they inhabit. The body is furnished with long hairs, which enables them to creep through crevices that would not otherwise admit them.

The females, which are easily distinguished from the males, are oviparous. The eggs are so minute that, on a comparative calculation, it appears that ninety millions of them would not fill the shell of a pigeon's egg. These are hatched, in warm weather, in about twelve days; but during the winter season the time of hatching is much longer. When the young first come forth they are extremely minute; and before they attain their full size they cast their skin several times.

The mites are very quick-sighted; and when once they have been touched with a pin, it is easy to perceive a great degree of cunning exerted to avoid a second touch. They are extremely voracious animals, and are often observed even to devour each other; and so very tenacious are they of life, that they have been kept alive many months between two concave glasses, by which they were applied to a microscope. Leeuwenhoeck placed a female mite on the point of a pin for examination; she remained there ten days, and during the time laid two eggs, which for want of food were devoured.

Acarus Scabiei. The acarus that inhabits the vesicles of the itch.

These insects have also given name to a disease called *Acariasis,* many curious instances of which are given by medical writers; and Mouffet relates the following instance of lady Penruddock, concerning whom he expressly tells us, that acari in every part of her body—her head, eyes, nose, lips, gums, the soles of her feet, &c.—tormented her day and night, till, in spite of every remedy, all the flesh of her body being consumed, she was at length relieved by death from this terrible state of suffering. Mouffet attributes her disease to the acarus scabiei above alluded to; but from the symptoms and fatal result, it seems to have been a different and much more terrific animal. He supposes, in this instance, the insect to have been generated by drinking goat's milk too copiously. This, if correct, would lead to a conjecture that it might have been the *A. lactis* of Linnæus.

Man is not the only animal subjected to the attacks of these little tormentors; from the elephant to the smallest quadruped, from the majestic eagle to the delicate humming bird, from the leviathan of the deep to the smallest fish, all in their turns are annoyed by these minute parasites; and the following well authenticated facts will prove that insects also suffer from them. The common dung beetles may often be met with in the spring of the year, covered on the underside of the body with small mites, which look as if they were engaged in suction—they are often so numerous that no part is uncovered, they also attack other beetles, especially those of the harpalidæ and histipidiæ. They are easily disturbed, run with great swiftness, and may often be seen in hot beds, prowling in search of the stercorarious beetles. But the most remarkable insect of this kind is the *Urapoda vegetans;* it derives its nutriment from the insects it assails, not by its mouth, but by means of a long anal pedicle, by which it is attached to them. De Geer found these in such numbers upon a species of *leptura,* that its whole body was almost covered with them; they hung from the legs and antennæ in bunches, and gave the animal a most hideous and disgusting appearance. Under this load of vermin it could scarcely walk or move, and all its efforts to get rid of them were in vain: many were attached to its body and to each other by their anal pedicles, but others had cast them off, and were walking about. When put into a glass with earth, they began to abandon their prey, so that in a few days it was quite free from its plague. He found that these parasites lived long in alcohol.

The author of the present article can vouch for the following anecdote, communicated to him by Mr. Daniel Bidder, an indefatigable, well-informed, and old collector of insects, as well as a close observer of their proceedings. Many years since when collecting in the new forest of Hampshire, he sat down on a bank to take some refreshment, the sun was obscured by clouds, when presently he saw a specimen of the *apis terrestris,* or humble bee, alight near him, and begin to scratch, and make a disturbance; there being no sun the ants had retired, but it was an ants' nest on which it had taken its station; the ants immediately came out to attack it, and observing the insect covered with acari, soon destroyed or carried them off; when the bee, thus relieved from its enemies, carefully cleansed its body and wings with its feet, and then took flight again, evidently much relieved. There is nothing which more strikingly displays the wisdom and power of the Creator than the faculties with which the small species of animated nature are endowed. In our ordinary estimates we are accustomed to associate grandeur and power with magnitude, and to suppose that the productions of nature become insignificant in proportion as they become small. But, when we go to nature itself, and compare the size of the creature with the functions which it performs, we discover that mere material size is an absolute clog upon the living energy, and that the smaller animals are, in proportion, much more active than the greater.

ACASTA. A genus constituted by Dr. Leach, from the Linnæan genus Balanus. These shells are found enveloped in sponge, and never affixed to hard bodies; the valves are but slightly connected together, particularly those at the lower part; the exterior form is oval subconical, formed of six lateral unequal valves with an orbicular lamina, internally concave (resembling a patella), forming the base; the operculum with four pieces or valves, the exterior of the base being conical or convex, prevents the shell from standing by itself in an erect position, when detached from the substance which envelopes it. There are three species known. Lamarck and modern naturalists continue to place this genus with the Balani, from which there does not appear sufficient reason to separate it.

ACCENTOR. A genus of birds belonging to the insectivorous order, or rather of that intermediate character which connects the insectivorous with the seed-eating birds, as the hedge-accentor, hedge-chanter, commonly but incorrectly styled the "hedge-sparrow," the species with which we are most familiar as a common resident British bird; it feeds upon insects in the summer, and upon seeds and other vegetable matters in the winter.

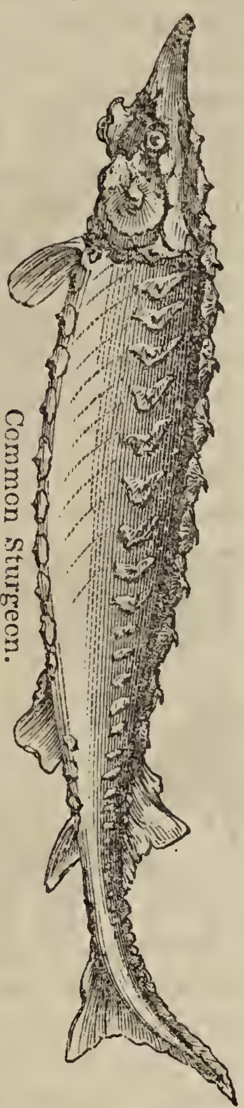
The characters of the genus are: the bill slender and of mean length, conical in its form, much pointed, the *tomia* or cutting edges compressed, and the upper mandible slightly notched towards the tip; the nostrils basal, pierced in a large membrane, and naked; the legs stout, with three toes forwards and one behind, the inner toe free, but the middle and outer ones united at their bases. The wings are wedge-shaped, the first quill being very short, the second half the length of the third, and the third the longest in the wing. They run fleetly upon the ground, and fly with boundings or jerks. They are, as far as is understood, all song birds, with sweet notes, but not very much varied or powerful. There are several species.

A. modularis, the hedge-chanter, is the only British species; it is resident, though it migrates within the country with the seasons, being found in the fields and on the edges of the moors in summer, and resorting to the neighbourhood of farm-houses in the winter, though not in large flocks like the seed-eating birds, properly so called. They hop about in farm-yards and near houses in the winter; but in February, or even in January, if the weather is mild, the male commences his song, which is sweet and plaintive, and always delivered from the perch; for when the bird flies, he merely utters that querulous "tit," which has procured him the name of titling. Soon after the song commences, the birds pair, retire to the fields, copses, or moors, and commence the labour of nest building. The nest is always built in the thick cover of a hedge or bush, constructed of moss and wool, and lined with hair. The eggs are four or five in number, of a clear greenish blue without any markings. The nest is usually completed in March, at least in the southern parts of Britain; but there are probably two broods in the year, as the eggs of the cuckoo are said to be found in the nests of these birds, and the hatching of the first brood must be in progress before the cuckoo arrives. The hedge chanter is an inoffensive little bird, and one of sober appearance; and there is hardly any difference in the plumage of the sexes. The length is about six inches, the extent of the wings about eight, and the weight about six drams. The size is nearly the same as that of the common red-breast, but it is more slender in proportion to its length, does not seem so robust, and has not the pert and pugnacious air of the red-breast. The bill is dusky, and the tarsi and toes yellowish brown. Top of the head grey with brown streaks, throat and breast bluish grey, upper part yellowish brown with the centres of the feathers purplish brown, belly greyish white, and some white on the middle coverts of the wings and the lower ones of the tail.

A. montanellus, the hill-chanter, is a bird of the hilly parts of south-eastern Europe and central Asia; and, like the former, does not migrate far, as it is not found so far south as Naples, even in the winter. During the greater part of the year it inhabits the woods on the hills and dales of the mountains, forming its nest nearly in the same manner as the British species; and, like that, descending to the plains and inhabited places when the severe weather sets in; and it serenades the people with its soft and plaintive song before it departs. The most remarkable external distinction between the two is that the hill species has the cheeks black.

This genus has been confounded with the warblers, and also sometimes with the wagtails; but they are distinct both in their generic characters and their habits.

ACCIPENSER (Sturgeon). A genus of fishes belonging to Cuvier's seventh order, or first order of *Chondropterygii*—the order *Sturionidæ*; that is, cartilaginous fishes, with two gills, and having a gill-lid to the opening, but no gill-flap. Their bodies are long, and not unlike those of the sharks in shape, but they are very different in their covering. Their skins are beset with longitudinal rows of osseous plates, in some instances bearing a considerable resemblance to the shells of limpets, and in others keeled or produced into spines. Their heads are also armed with bony plates; their muzzles more or less produced, and their mouths placed under the muzzle, of small dimensions compared with the size of the animals, and without any teeth. The upper maxillary bones are united to those of the cranium, which form one piece without distinct sutures, as is the case with all the cartilaginous fishes; but the under jaw can be protruded, or projected farther forward than in the sharks, there being three articulations in the intermaxillary bones of the sturgeons, while the under-jaw of the sharks is articulated by a single tubercle. This particular form of articulation, however, enables the jaws of the shark to act with much more power than those of the sturgeons or indeed of almost any other fish, as besides the motion of closing they have a lateral grinding one, and also separate motions of the teeth. The lower jaw of the sturgeon is furnished with a sort of beard of soft fibres. The eyes and nostrils are placed laterally and wide from each other. There are no external ears, but the labyrinth of the ear is much better formed within the bones of the cranium than in the bony fishes; though there is not an external opening of the ear, as in the cartilaginous fishes that have the gills fixed. There is indeed a small hole behind the temple, but it does not lead to the labyrinth of the ear. The dorsal fin is placed behind the ventrals, and the anal fin under it. The caudal fin surrounds the extremity of the tail, but is not much produced, except in a lobe on the under part. The air-bag is very large, and communicates with the gullet by an aperture of considerable magnitude.



Common Sturgeon.

Fishes of this genus are mostly large, and inhabit the great rivers and shores of the temperate latitudes rather than either the torrid or the cold. In Britain they are rare, and they are not very common on the west coast of Europe, or in the rivers which empty themselves into the seas there. In the east of Europe and west of Asia they are much more numerous. The flesh of some of them is highly prized, and more resembles meat than fish, both in texture and in flavour; that of others is unpleasant, and in some instances unwholesome. The fish, and especially their roes, which in a prepared state are called *caviar*, form an important article in eastern commerce, the more so that the species which are most esteemed are found in the more northerly rivers.

The whole body of the sturgeon is very gelatinous; and the air-bag, when freed from fat and oil, is the purest gelatine and therefore the best jelly or glue that is obtained in the animal kingdom. It forms the genuine *isinglass* of commerce. The same substance may, however, be obtained from the fins and other refuse, and indeed from the refuse of any fish; and there is as much of that description of matter not only wasted, but wasted in such a way as to be very offensive, at our fishing villages, and many of our fish-markets, as would supply all the arts abundantly with that very useful, and in the culinary art very wholesome article. There are four European species.

1. *The great sturgeon* (*Accipenser huso*), common in the Danube, the Po, and some other large rivers of south-eastern Europe, and occasionally found in the Atlantic. It has the skin smooth, the plates flattened, and the filaments that form the head short. It is a very large fish, twelve to fifteen feet in length, and weighing from two to three hundred weight. Cuvier mentions that specimens nearly 3000 pounds in weight have been seen. Indeed, as these cartilaginous fishes do not appear ever to "get old," or to cease from growing, it is not possible to fix the maximum dimensions which they shall not exceed. This species is neither palatable nor wholesome.

2. *The Scherg sturgeon* (*Accipenser pelops*) is much smaller, being seldom above four feet in length. It has the osseous plates more produced into spines than any of the others, and the muzzle longer in proportion and more slender. It is very abundant in many of the Russian and German rivers, but its flesh is little esteemed or sought after.

3. *The little sturgeon* (*Accipenser ruthenus*) is the smallest European species, seldom measuring more than two feet in length; but it is the most highly prized of the order, and both the flesh and the roe are accounted delicate food; the plates on it are very numerous, they are keeled on the sides, but flat toward the belly.

4. *The common sturgeon* (*Accipenser sturio*) grows to the length of six or seven feet. The plates are arranged in five longitudinal rows upon each side, very firm in their structure, and sharp and spiny at their points; the muzzle also is pointed, and the filaments of the head are longer than in any of the other European species. This is the species which is best known in domestic economy.

Several species have been mentioned as inhabiting the larger rivers of North America; but our acquaintance with them is still very incomplete. For an account of these fishes as articles of commerce, as well as for any further light that may, in the interim, be thrown upon their history, we must refer to the article Sturgeon.

ACCIPITRES (Takers by Force). Rapacious Birds, or Birds of Prey. A numerous and highly interesting order of birds, displaying the peculiar characters of the class in the very highest perfection, and forming one of the grandest features of animated nature. Their general habit is to feed upon warm-blooded animals, which they overtake by speed of flight and kill by strength; and some of the most bold and daring of them subsist wholly upon this species of food, and will suffer the greatest extreme of hunger before they partake of any other. Some, however, feed more upon carrion and offal; others upon fish, reptiles; and some occasionally upon insects. The characters and the haunts of the different species vary with the nature of their food, and the manner in which that food is obtained. But though they are thus different, and their appearance and conduct strike us as being in some species sublime, and in others the reverse, they are all so admirably adapted to their peculiar modes of life, that it is impossible to say which affords the finest instance of that wonderful coincidence between purpose to be obtained and means of obtaining that purpose, of which creation is so very full, and the contemplation of which is calculated to inspire us with so much veneration for the great Author of nature, and at the same time to afford us models in all our useful arts, which our utmost skill can never excel.

In this order of birds we have the perfect model of strength combined with swiftness; and also of power and energy, when in action, united with calmness and repose when that action ceases to be necessary. The birds are preyers, but they have their appointed prey; and though, of course, they have no design in the matter, they exist for the preservation of the very races upon the surplus of which they feed. The powers of life are everywhere greater than the average need there is for them; and throughout the whole of the organic world, whether vegetable or animal, the surplus of one race feeds another, so that the season provides for itself. When the heat of the sun acts, if the surface be not mere dry sand, the powers both of animal and vegetable life must obey it; hence, in those places the number of mountain birds, mountain hares, and other mountain animals, which are produced in the warm seasons, could not be supported in the cold; and thus, if it were not that the mountain eagle and the mountain hawk thin their numbers, they would be thinned by starvation.

But a thinning of the numbers by starvation would be a very unwholesome thinning. It would come, not like the judicious pruning of the cultivator, who removes a part in order to benefit that which survives, but like the blight which falls upon and withers all indiscriminately, so that the part which remains is of little value. Hence, the provisions which nature makes against redundancy and consequent want and suffering, all come into operation before that which they correct has done mischief. There is one set of regulations (for the predatory animals are, in a natural point of view, regulators and not destroyers) which apply to all indiscriminately, whether disease has begun or not, and to that class the bolder of the rapacious birds may be considered as belonging. There are others which clear off the weakly, for whom there is, in the course of nature, little prospect of recovery; and to that class some of the rapacious birds, and the ravens and others of the omnivorous order, may be assigned. There are others still, which do not attack, but clear the earth of the remains after casualty has done its work. These do not kill, but they, in general, feed ravenously; and they are so furnished that they can scent, or otherwise discern, their peculiar food from afar, and can range far and wide over the country in quest of it. It will be seen that one division of the birds of prey have this character.

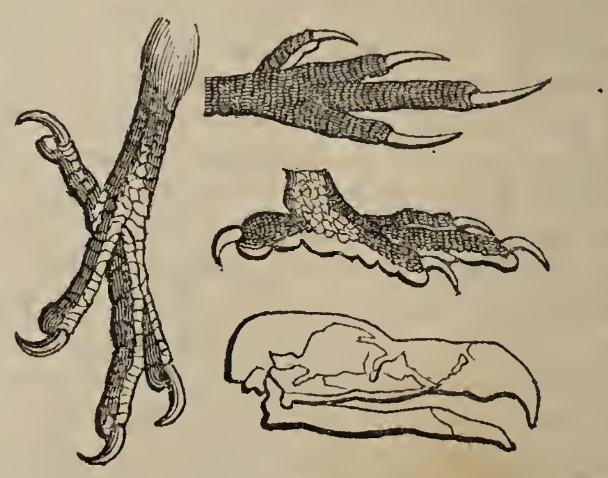
These remarks are general, and apply to rapacious animals of all kinds, as well as to the order Accipitres among birds; and as all animals prey upon organised substances of some kind or other, they might, by the same fastidious spirit of ignorance, be in turn accused of similar cruelty. The lamb nibbles innumerable plants, which, if let alone, would bear seeds, and exhaust the soil till the grass disappeared, and it could bear only sorrel, or moss, or some equally unseemly and unprofitable crop; and the warblers consume myriads of caterpillars, which, but for them, would not leave one green leaf in the grove.

Such are the uses, in wild nature, of the Accipitres; and it is to wild nature only that the more powerful ones belong. When man claims the produce of the flock and the field, as the reward of his care and culture, they retire, and leave him to enjoy the fruits of his labour. In their characters they are well defined; and when one of the order is known, there is little danger of mistaking any of the others; for their form, their air, their flight, and all their appearances and actions harmonise.

Their general characters are:—the bill of moderate length, strongly made, hard, and firm in its texture, sharp in the *tomia*, or cutting edges, very much hooked at the lip, and generally with a tooth in the one mandible and a notch in the other. The feet have four toes, three forward and one behind, but the outer ones are sometimes reversible; the whole armed with very strong, sharp, and crooked claws (usually called talons), those on the hinder toe and interior front toe being generally the largest, and acting most immediately against each other. The tarsi, or lower portions of the legs (of the feet rather), are generally short, very tendinous, and have strong bones; but they are firm rather than large. The bodies are compact, and the feathers generally strong and not easily ruffled. The eyes are keen and piercing, the scent in some of the species very acute, the motion often rapid, and the general expression that of great energy and equally great endurance. There are two tribes very distinct in most of their habits: those that prey by day, and those that prey by night or in the twilight.

TRIBE I. DIURNAL BIRDS OF PREY.—These have the plumage firm and close, the flight rapid, and the whole air and expression energetic. The base of the beak is covered by a naked membrane called a cere, in which the nostrils are pierced. Their eyes are placed in the centre of the head, so that they command nearly the whole horizon. Their sternum or breast bone is very strong, and has a deep keel along the centre, to give motion to the muscles that move the powerful wings. The *furca*, or "merry-thought," the bone which keeps the shoulder-bones apart, is a strong semicircular arch; the bones of their wings are very fully developed, and in some of the more perfect the fingers can be distinctly traced in the terminal bone. All their bones, indeed, are remarkable for firmness and strength; and the hollow ones are powerfully fortified by cross pieces at all parts where they have to bear any great strain. Their wings vary in form according to the habit, but the quills or flying feathers are very strong and stiff, as are also the tail feathers, which are in general capable of being spread out like a fan; and they and the quills are well supported by casements. The whole structure of the bird is a model of the union of the greatest possible strength with the least possible weight. There are two very distinct families, *vultures* and *falcons*, the latter admitting of convenient subdivision into septs or sections.

Vultures (*Vultur*). These birds chiefly inhabit the warmer countries, where, from the violent alternations



of drought and rain, other animals are subject to many casualties. They are found chiefly in wild and mountainous places; but they range far and wide, feeding chiefly upon carrion, and not often attacking living animals. They can endure hunger long, but they feed greedily, even to stupefaction and incapability either of flight or defence. They have a very keen sight. They are uncouth and ragged in their forms, and, in proportion to their strength, cowardly in their dispositions.

Their more obvious characters are—the beak straight at the base, hooked at the tip; part of the head and neck bare of feathers, the eyes close to the head. The tarsi and talons rather feeble, the former covered with a network of small scales; the wings very long, and seldom quite closed when the birds are on the ground. They, however, vary a good deal in their habits. Though cowardly in their nature, and easily put to flight, even by much weaker birds, when these offer to attack them, the vultures are daring enough in the search of their food. They will not only hover around carnivorous mammalia, and attempt to share the carrion or other prey upon which these are feeding; but they approach human habitations, encampments, and even cities, pouncing readily upon animal substances, but preferring those that are in a putrid state. They are the least predaceous birds of the order; and some of them, in a few of their characters, bear a slight resemblance to the poultry tribes. They build their nests generally in rocks, and do not perch on trees. See Vulture.

The Falcon tribe (*Falconidæ*). This family, as has been hinted, admits of convenient subdivision; but the general characters of the whole are striking and well defined. The head and neck are feathered; the eye is shaded by a projection above, which has something of the appearance of an eyebrow, and gives great keenness, as well as intelligence of expression, to the eye, which, in itself, is very bright. The cere of the bill is generally coloured, and the basal portion of it beset with short strong hairs. Both mandibles are, in general, hooked throughout their whole length. They are very strong; the upper one pointed at the tip; the under one obliquely rounded, and the cutting edges are furnished with a tooth, or notch, more or less perfect. The whole instrument indicates a capacity of rending substances in a more recent and consistent state than the carrion beak of the vultures. The nostrils are pierced in the cere, open, and rounded or oval in their outline.

The tarsi are stout and of moderate length, and covered with feathers or with scales; the outer toe is often united to the middle one, with a membrane at its base; but the inner toe is quite free. The claws are very pointed and sharp, capable of much motion when the bird is excited; but retractile, although not into sheaths, when it is in a state of repose. The retraction, which is performed by an elastic tendon, elevates the point of the claw above the plane of the pad on the tip of the toe, so that the claws are not injured when the birds rest upon sharp points. The claws are not used in feeding.

In many of the species, there is considerable difference between the plumage of the young and mature birds, which has sometimes led to the multiplying of one species into two or more. The same mistake has, also, sometimes arisen from the difference between the male and the female. The female is by far the more powerful bird, often a third heavier than the male, and strong, bold, and fierce in proportion. The principal differences in the plumage are, the young have the colours more broken and mottled than the mature birds, have more the tint of the female than that of the male, and the females are more inclined to brown than the males.

They are very strong, and can carry an animal nearly as heavy as themselves through the air for many miles. They prefer the prey which they kill, which are most of them warm-blooded animals, birds, or the smaller quadrupeds; but some of them also eat reptiles, fishes, and even beetles. They are not cruel birds, and do not torture their prey like the vultures. They are quiet birds, and seldom come abroad except to seek their food. They nestle in lofty and inaccessible places, and more rarely in trees or on the ground.

They eject by the mouth the bones and other exuvia of their food which resist the process of digestion; and the ejectment is in the form of balls, which are called "castings," or "quids." They inhabit most parts of the world; but the larger species are found only in wild places, and the more bold and daring ones in the cold latitudes rather than in the warm or even the temperate.

The more obvious subdivisions are, Eagles, Harriers, Hawks, Kites, and Buzzards, under which titles notices of the more remarkable species will be found.

Tribe II. Nocturnal Birds of Prey.—Though the habit of these is predaceous as well as that of the former, they are very different both in their characters and the times of their appearance. The diurnal birds of prey have their plumage compact and firm, and when they dart through the air they ring as though they were clad in armour; and few of them will seize their prey except openly in the free air and the light; and the most daring ones assail it only when on the wing. The nocturnal species, on the other hand, are birds of twilight and gloom; they reside during the day in holes or the thick coverts of trees; and most of them, when they resolve to fly while the sun shines, appear confused and lose their way. Their plumage is "fined off" at its terminations into a very soft and delicate fringe, which enables them to glide noiseless through the air, and even among the leaves and sprays of the thick forests, of which some of them are inhabitants. Their noises even are hollow and dolorous, and have not the stirring and ear-piercing effect of the chirrup of the diurnal accipitres; and hence they have obtained the common name of Owls, or "howlers."

Their most general characters are these: the head large and round, having a slight resemblance to that of a cat; their eyes very large, directed forwards, capable of great dilatation in the pupil, and surrounded more or less with fine downy feathers, which in some of the species form a complete circle, which nearly hides the bill. Their external ears are hidden by feathers, but they have large cavities in the skull, and the sense of hearing is presumed to be very acute. Their bodies, in consequence of their thick and downy plumage, are very small and light in proportion to their apparent size; and their bones have not the general strength of those of the preyers by day: their beaks also, though hooked and very sharp, are much more slender, and without any notch in the mandibles. Their tarsi are weaker; and their claws, though very sharp, are much more slender in proportion to the size of the birds. Their feet have three toes in front and one behind; but the outer toe is generally capable of being reversed, so that the toes act two against two, in clutching. Some of them have erected feathers, or a sort of crests, upon the sides of the head, which have procured them the names of horned owls or sacred owls; and those which are without these crest feathers are called smooth-headed owls.

Though in general timid birds, preying in the dark or the dusk, there are some of them of more bold and powerful character, venturing abroad during the day, especially in gloomy weather, and committing considerable ravages upon birds and the smaller quadrupeds. These are, however, chiefly inhabitants of northern and thinly inhabited or uninhabitable regions; and they rarely approach the dwellings or the possessions of man, and cannot be said to do much or material injury.

From the nature of their food, which is chiefly the different species of mice and other small and destructive quadrupeds, of which they capture vast numbers, owls may be regarded as among the most serviceable of wild birds; and those species which are of the greatest use are so far from timid or retiring in their manners, that they resort to farm-yards, barns, and other places, and perform their services, even in spite of the persecution which they meet with from the thoughtless; and were they encouraged and protected in proportion to the usefulness and the assiduity of their labours, there is no doubt, that they might be made to add both to the value and the interest of most parts of the country. For notices of the species, see Owl.

ACEPHALA (literally "having no head"). The fourth in order of the six classes into which Cuvier divides the Mollusca. (See Mollusca.) The grand character of the class, by which the whole of the numerous orders, families, and genera, which are comprehended under it, are distinguished from all the other mollusca, is that of having no visible head or neck, the mouth being merely an opening in the common integument of the body, without jaws, teeth, or any hard parts whatsoever. They are also without organs of sight or hearing, or indeed any allocated parts which we can pronounce to be organs of any sense; so that we can say nothing about the extent or the kind of their sensations. The mouth is situated under the cloak, or in its duplicature; the cloak being, in the majority of cases, double, and folded over the body, sometimes with the lobes free for their whole length on the under part; at other times united in the posterior part, so as to form a tube; and at others, again, united for the greater part of its length. Their organisation is very simple,—there being, in many of the species, very little distinction of gullet, stomach, and intestinal canal, but merely one continuous tube, which has few convolutions. Their nervous system is equally simple, consisting of one ganglion situated on what may be considered the gullet, and generally two further down; but these last, as well as the cord by which they are united to the first one, are often so obscure that they can hardly be traced. They are all understood to be self-fertilising, as well as bisexual; but still, production is no more spontaneous in them, than in those animals which have the sexes in separate individuals. A single individual can, however, soon stock a considerable space with them, as, under favourable circumstances, they are very prolific. They are all inhabitants of the water; and indeed few or none of them have sufficient powers of locomotion for finding their food upon land. Some adhere to the rocks by peduncles or stalks; others are chained by byssi, or threads; some make use of these threads for motion; others move by means of the foot along the surfaces of rocks and other substances; others effect a leaping motion by suddenly shutting the valves of their shells; and others, again, make their way through the water by compressing their bodies and ejecting a jet against the water in the rear. Many are incapable of quitting the bottom of the water; and others bore into the mud, or rocks.

They are, as has been said, very numerous; and are also exceedingly varied in their sizes, forms, and habits. Some, as the genus *Chama*, are among the largest, if not the very largest, of invertebrated animals; others are very minute. Some, as the oyster family, are much sought after as food; others, as the various species vulgarly called pearl oysters or pearl muscles (the *Avicula margaritifera* of the Indian seas, and the *Unio margaritifera* of many of the British rivers, especially in the northern parts of the country), are much esteemed for the pearls which they afford. Some are equally mischievous, as the *Teredo navalis*, which bores into the timber of ships, perforating it till it has the appearance of a honey-comb.

There is one circumstance attending this class, which is more favourable to a useful knowledge of it than any thing that is to be found in those tribes of aquatic mollusca which have free range of the sea, and can ascend and descend in the waters at their pleasure. Of these, more especially of such as, from the forms and qualities of their shells, we would naturally infer to be the most interesting, hardly any thing is known but the empty shells; and the history of these, however minute or perfect it may be, bears about the same relation to the history of the living animals, as a history of the costumes of different nations would bear to the history of those nations themselves. It so happens too, that the univalve *pelagic* shells, whether unilocular or multilocular, that is, whether they consist of one chamber or of many, which inhabit the depths of the ocean, and, upon the general principle of all sea animals, are not cast upon the shores till they are dead, are the most striking in their forms and the most beautiful in their colours. They are, therefore, those which are most eagerly sought after to stock the cabinets of the curious; and the consequence has been that, in as far as molluscous animals are covered with shells, the science of them has become a science of shells rather than a science of animals—a peculiar department of mineralogy rather than a part of zoology. Now, as the acephala inhabit the banks and bottoms at reachable distances, many of them without low water mark, and none of them beyond the reach of dredging (at least so far as is known), they form a branch of this very interesting department of nature, which can, to a very great extent, at least, be studied zoologically; and the habits of the animals themselves, as well as the mere forms of their encasements, can be made matter of science.

The acephala admit of a very convenient division into two sections—those which have shells, and those which have not. The first of these are usually styled *conchifera*, or shell-bearing; and the second *tunicata*, or cloaked.

Acephala conchifera have the shell in all cases external, and divided into two valves, which vary much in their form, size, and mode of articulation. Cuvier divides them into families, each containing many genera; and the names of these families are as follows: *Ostraceæ* (the oyster family), *Mytilaceæ* (the muscle family), *Camaceæ* (the chama family), *Cardiaceæ* (the cockle family), and *Myeæ* (the family of gapers).

Mollusca tunicata. The members of this section are in all cases without shells, the body being invested with two cloaks or tunics, which are in some instances separated from each other, excepting at the natural openings of the animals; while in others they are united throughout their whole extent. In some the surface is smooth, in others it is rough; and others again have the power of forming to themselves a sort of artificial clothing by soldering or glueing all over their bodies little pieces of sand and shells. Some of them can move through the water by first inflating the body with that liquid, and then forcing it from the posterior aperture, by the contractile force of the muscles of their tunics. The anterior opening in the tunic is usually much larger than the other one; because, while in most, or all of the conchifera, the gills are freely exposed to the water as it passes between the open valves of the shell, the gills of the tunicata are always within the tunics; and the animals either draw in water by the mouth and pass it by the other opening, or inhale and expel it by one and the same opening, in a manner similar to the breathing of the cartilaginous fishes, and not very dissimilar to that of the mammalia.

The genera and species of this section are few, compared with those of the former; the following being the principal:—*Thalia*, *Ascidia*, *Botryllus*, *Pyrosoma*, and *Polyclinum*; the first and second having their tunics separate, and the remaining three having them united.

Further particulars of the families composing the first section, and the genera composing the second, will be found under their respective names.

ACEPHALOPHORA (Blainville). In the modern system of Malacology, an articulated molluscous animal, in which the head is not distinct from the rest of the body. It is without any sensitive apparatus. The body is generally flattened, enveloped in a mantle, divided into two lobes; very rarely naked, and most generally included in a bivalve shell. The mouth large, constantly concealed, without any trace of teeth or organs of mastication. The respiratory organs are always bronchial or aquatic, and hidden.

This class is divided into four orders. The 1st, *Palliobranchiata*; 2d, *Rudista*; 3d, *Lamellibranchiata*; 4th, *Heterobranchiata*; descriptions of which, with their divisions into families and genera, will be given under their respective names, in the alphabetical arrangement of this work. They embrace an extensive and beautiful portion of that part of the invertebrated animal kingdom called Conchology by former naturalists, whose system was founded on the testaceous covering of molluscous animals, which wholly covered, or only partially protected, certain portions of their bodies, without any reference to the structure and habits of the animal itself; the only natural and unerring guide in the study of this, as well as every other work of the great Architect of nature.

All animals of this class are naturally aquatic: a great number of them marine, but a few inhabit lakes and rivers. They all feed on microscopic animals, or animal substances, in nearly a molecular or extremely minute state of division.

ACER (the Maple). A family of hardy trees and shrubs, chiefly natives of Europe and North America; belonging to the Linnæan class and order, *Polygamia Monœcia*; and to the natural order *Acerinæ*. Generic character: Calyx, more or less deeply divided into five parts; petals five; stamens, generally five to nine in number; one style, two stigmas; ovary dedymous; leaves simple, opposite, and generally divided into several distinct lobes; seeds two, each with a wing.

This genus contains about thirty species and varieties, and is arranged by botanists into four divisions, founded on the form of the leaves as entire, and, five-lobed, or cleft. They are all readily raised from seeds, and also by layers, cuttings, and budding; directions for which operations, together with descriptions of the more important species, will be given under the article Maple.

ACERA (Lamarck). Animals belonging to the fourth order, *Gasteropoda*; second class, *Paracephalophora*, of Blainville's system of Malacology, fourth family. The body more or less globose, gasteropod, divided into two parts, the anterior of which is often provided with lateral lobes; the head indistinct, without tentacula, or only with rudimental ones. There is no internal or external shell.

ACERINEÆ (The Maple Family). The forty-fourth order of the natural system of Jussieu, containing two genera and fourteen species of valuable forest-trees. They abound in North America, and all over the North of Europe. The foliage is more beautiful than the flowers, the latter being generally small, and by no means showy. They all receive the common name of maple, except the *Acer pseudoplatanus*, which is called sycamore, and in Scotland the plane-tree. The timber of almost all the species is valuable for very many purposes; especially to the cabinet-maker, the turner, musical instrument-maker, and for the manufacture of alkali, the maples of North America, are of great value. The sap of all yields sugar in considerable quantity; the *A. saccharinum* being the chief rival of the sugar-cane. For obtaining this precious article in North America, Michaux informs us that the following means are had recourse to:—In February or March, while the cold is still intense, the bole of the tree is bored in two places, five inches apart, at about twenty inches from the ground, and on the south side of the tree. The auger used should be somewhat more than half an inch in diameter, and the holes are made in an obliquely ascending direction, and to the depth of half an inch into the alburnum or wood of the tree. Into these holes tubes or fossets are fixed, ten inches in length, to receive and conduct the sap into troughs, placed below. The sap continues to flow pretty copiously for a month or six weeks; after which time the flow declines. Four gallons of sap yield about one pound of sugar, and from two to four pounds is the usual produce of a tree of the average dimensions, and growing upon average soils. During the sugar-making season, sheds are erected in the wood, for carrying on the boiling and other processes connected with the manufacture. Three workmen are allowed to attend 250 trees, which give on an average 1000 pounds of sugar. The United States are said to produce ten million pounds per annum of maple sugar.

It is the old butts of this tree which yield the beautiful veneers called *bird's-eye maple;* but to procure this in its finest shadings of the grain, much skill is required in cutting it up.

The ash-leaved maple, *A. negundo,* was formerly ranked in the Acer family; but has been separated by Moench, a German botanist, and now made a genus of itself under the generic title of *Negundo,* and of which there are two species; viz., *N. fraxinifoliam,* and *N. crispum.*

The generic character of the order is—Flowers polygamous; calyx five-cleft; corolla five-petaled, spreading, or none; germens two or three superior; seed single, roundish, its capsule terminated by a wing.

ACETABULARIA (Lamouroux). A genus of umbel-shaped polypidoms or corallines; the stem branchless, slender, fistular, and terminated by a striated radiated umbel, either flat or slightly funnel-shaped.

The Acetabulariæ partake of the characters of the Tubulariæ and Sertulariæ, by the situation of their polypi, each being placed in a distinct tube, and participating in a common existence by means of the stem, to which the lower part of each animalcule is attached; these tubes, which are very visible and projecting in the lower part of the umbel, blend and disappear when they reach the stem; they form distinct lines on the upper part of the disk.

They are found in thick tufts on rocks and solid marine substances; in the first stage of their development, the tube attains its full size, and the umbel is extremely small in diameter; by slow degrees this enlarges and acquires its full size; when it has attained that point it merely increases in solidity, and soon after perishes; many circumstances inducing a belief that these polypidoms have but a short existence. In the sea the stems are flexible, gelatinous, and of a greenish colour, the disks occasionally displaying a very brilliant shade of green; some of these characteristics disappear by desiccation, and the polypidom becomes nearly white and very fragile.

They are found in the tropical and temperate seas of both hemispheres, seldom attaining more than four inches in height. Two species are described by Lamouroux, one of which is found in great numbers in the Mediterranean, and the other in the Antilles.

ACHATINA (Lamarck; *Bulla,* Linnæus). A class of mollusca belonging to the *Paracephalophora* of Blainville.

The animal inhabiting this shell resembles that of the *Helix,* though modern naturalists have very properly separated this elegant genus from those of Helix and Bulla, with which they were confounded by the Linnæan school. They are an elegant and numerous family of shells, in many respects resembling those of the genus *Bulimus;* but on examination the distinction is manifest. The columella is smooth and truncated, and the margin of the aperture never thickened, which seems to indicate that the animal breathes only air; and though not altogether incapable of existing in an aqueous element, probably derives its sustenance from the vegetation on the banks of rivers or stagnant pools, only occasionally venturing into the water from necessity rather than habit. The shell is oval or oblong, ventricose, striated longitudinally; aperture ovate, never thickened or reflected; a smooth straight columella, truncated at the base, without an operculum. They are oviparous; and one species, the *Achatina zebra,* produces a hard-shelled egg, as large as that of a small bird. Many species are clothed with an epidermis.

A. zebra. Fig. 1.

A. virginea. Fig. 2.

This genus is subdivided into four species. The 1st, oval and subventrical, *A. zebra. fig.* 1. The 2nd species, with the aperture nearly round, rather short, and an internal transverse callosity, *A. virginea.* The 3rd species, subturriculated, and with the last whirl attenuated in front, *A. glans.* The 4th species, distinctly turriculated, *A. columnaris. fig.* 2. This last is a reverse or heterostrophe shell, as are some others of the genus. These shells sometimes attain a very great size, and their inhabitants are said to be voracious eaters; all of them are properly terrestrial shells, and Lamarck enumerates nineteen species. None have ever been found in a fossil state. Their trivial name is *Agate Snails;* only two of the species are European. The others inhabit the warm countries of the two continents, and Africa abounds in some of the larger species. The internal structure of this genus is here represented in a sectional point of view.

ACHILLEA, or YARROW. A natural genus of herbs, belonging to class the *Syngenesia,* order *Polygamia superflua,* of Linnæus; and to the natural family *Compositæ,* order *Corymbiferæ,* of various authors. The name is derived from Achilles, the pupil of Chiron, who is said to have first used some of the species medicinally. There are about eighty known species, some of which are indigenous in Britain. They are bitter, aromatic, and more or less tonic and stimulating. The *Achillea millefolium,* milfoil or common yarrow, is abundant in Britain; and was formerly used in medicine, but it is now almost neglected. The Highlanders, however, still make an ointment of it, which they use for healing wounds. The *Achillea ptarmica,* or sneeze wort, was used to promote sneezing, and to increase the flow of saliva. Its roots were reckoned a substitute for the pellitory of Spain, and hence the plant formerly received the name of *Bastard Pellitory*. The *Achillea nana*, or dwarf yarrow, grows on the Alps, and is employed to flavour vinegar.

ACHILLEUM (Schweigger). A genus of fossil *Zoophytes*, separated from the sponges. The Achilleum was shown to be a distinct genus by Schweigger, and adopted by Goldfuss in his "Petrefacten," in which work he describes it as being polymorphous (many shaped), affixed, and of a reticulate hollow fibrous structure.

ACHIRUS. A genus of *malacopterygeous* fishes, of the flat form, and nearly allied to the sole, only they are wholly without pectoral fins. There are many species of them, and they even admit of division into two sub-genera; the *achiri*, properly so called, which have the caudal fin separated both from the dorsal and the anal by a small rayless space; and the *plagresiæ*, which have them united; the former have also the eyes on the right side of the head, and the latter have them on the left.

There is nothing peculiar in their habits, so far as is known. They are found in the shallows, and near the shores, in all the warmer latitudes; and they furnish an abundant supply of wholesome food to the inhabitants. As is the case with the whole family of the flat fish (*pleuronectes*), they remain generally near the bottom, where they find their food, consisting of the small animals which are deposited on the banks while the water is still; but they do not, as is vulgarly represented, stay there because they have no *air bladder;* for the sinking and swimming of a *living* fish do not depend upon specific gravity; most fishes, if not all, being specifically lighter than water, as is proved by the fact that they all come to the surface when dead, and even when sickly and dying.

The species are very numerous; but wherever they are found they differ but little from each other, or from the common sole of our own shores, either in a popular or an economical point of view. *A. marmoratus*, which is found abundantly on the coasts of the Mauritius, has the fins minutely spotted with black upon a pearl white ground, and the side in which the eyes are marbled with the same colour. Others are marked with smaller spots, and others again are striped; but these are mere distinctions in colour, upon which no character appears to depend. Wherever the water is not too deep for their habit, they are found in all latitudes of the warmer seas, and extend in the Atlantic, till, more northerly, they meet the common sole. None of the family, whether of this genus or of any other, appear to be in any degree migratory or discursive. Their form is not adapted for long voyages, and therefore they remain on their banks; and, wherever there is a bank with deposits of mollusca or other small animals, some of the species are sure to be found. It is probable that the molluscous food is one cause of the superior delicacy and flavour of their flesh.

ACHLAMYDEÆ. A general term, applied to those plants which have neither calyx nor corolla; this is the case with the willows, &c.

ACHNODONTON. An exotic grass. Linnæan class and order, *Triandria Digynia;* Natural order, *Gramineæ*. There are only two species, viz. *A. Bellardi*, Bellard's, which is a perennial; and *A. tenue*, slender, an annual.

ACHRAS. The name of a genus of plants belonging to the natural family *Sapoteæ*, the Sapota or Sapodilla Tribe; and the class *Pentandria*, order *Monogynia*, of the Linnæan system. The term *achras* is properly, the Greek name of the wild pear, and has been applied to this genus on account of some resemblance between the fruit and a pear.

Generic character: Calyx deeply divided into six segments; corolla six-cleft; six barren scale-like stamens, alternating with an equal number of fertile ones; ovary having from twelve to six divisions; fruit, a many-seeded apple, the seeds being enclosed in compressed osseous nuts.

There are two or three species known. The most important is the *Achras Sapota*, the common Lapota, Lapodilla Plum-tree or Bully-tree, a native of America, found near Cumana, the Caraccas, &c., and called by the natives *Nispero*. It is one of the largest trees in the mountainous woods of Jamaica, and attains a height of thirty or forty feet. It is a tree abounding in a milky juice, having entire coriaceous leaves, and axillary one-flowered peduncles. The fruit, when fully ripe, has a sweet, luscious taste, and is considered an excellent article for the dessert. If not completely ripe, and some say almost putrid, it is acrid, and cannot be eaten. The seeds are aperient and diuretic, and have been given in the form of an emulsion in calculous complaints. The bark of this and several other species, more especially the Achras or Lucumus Mammosa, is astringent and febrifuge, and has been used as a substitute for cinchona, under the name of Jamaica bark.

ACHYRONIA (Willdenow). An evergreen shrub, from New Holland. Linnæan class and order, *Diadelphia Decandria*. Natural order, *Leguminosæ*. Only one species has been described, viz. *A. villosa*, villous.

ACHYROPHORUS (Robert Brown). Linnæan class and order, *Syngenesia æqualis*. Natural order, *Compositæ*. Generic character: Receptacle chaffy. Calyx somewhat imbricated. Pappus feathery.

The *A. maculatus*, spotted-leaved, was formerly *Hypochæris maculata*, Linnæus.

ACIANTHUS (Robert Brown). A New Holland genus. Linnæan class and order, *Gynandria Monandria;* Natural order, *Orchideæ*. Generic character: Calyx of six unequal divisions, the three exterior terminating in points, the interior smaller; labellum small, entire, spread out, showing two callosities at the base, but without foliar appendices. There are three herbaceous, tuberous rooted, perennial species.

ACICARPHA (Jussieu). A genus belonging to the class and order *Syngenesia necessaria* of Linnæus. Natural order, *Calycereæ*. Generic character: Flowers capitate, opposite the leaves, having an involucrum of four or five divisions attached to the lower part of the ovarium; the inferior flowers fertile, the superior sterile; ovaries, united in one body. There are three species known, all originally from the continent of America.

ACIDOTON. Linnæan class and order, *Monœcia Polyandria*. Natural order, *Euphorbiaceæ*. Generic character: Calyx of from three to five divisions in the male flowers; females bearing above thirty stamens, having the filaments connected in a cylindrical tube; ovary with three short styles, bearing stigmas; fruit globular, with three places and seeds. A hothouse tree, native of Jamaica; one species only, viz. *A. urens*, stinging.

ACINUS, or GRAIN. A term applied to each of the small granular masses of which a compound berry, such as the raspberry or bramble-berry, is composed.

ACIOTIS (D. Don). Hothouse under shrubs. Linnæan class and order, *Decandria Monogynia*; Natural order, *Melastomaceæ*. Of this genus there are two species, viz. *A. discolor*, various coloured; and, *A. aquatica*, aquatic; both formerly belonged to Melastoma.

ACIS (Salisbury). Bulbous-stemmed perennial plants, from the South of Europe. Linnæan class and order, *Hexandria Monogynia;* Natural order, *Amaryllideæ*. Of this family there are five species.

ACISANTHERA (Jussieu). An evergreen hothouse shrub, a native of Jamaica. Linnæan class and order, *Decandria Monogynia;* Natural order, *Melastomaceæ*. Generic character: Calyx ventricose; corolla of five petals; stamens six, vacillating; capsule crowned by the calyx, many-seeded.

ACMADENIA. (Wendland.) An evergreen green-house shrub, from the Cape of Good Hope. Linnæan class and order, *Pentandria Monogynia;* Natural order, *Rutaceæ*.

ACMELLA (Richards). Biennial and annual hothouse herbs, natives of warm latitudes. Linnæan class and order, *Syngenesia superflua;* Natural order, *Compositæ*. Species, three.

ACMENA (Decandolle). An evergreen ornamental shrub, native of New Holland. Linnæan class and order, *Icosandria Di-Pentagynia;* Natural order, *Myrtaceæ*.

ACNIDA (Linnæus). Virginian hemp; an uncultivated annual herb, native of North America. Linnæan class and order, *Diœcia Hexandria;* Natural order, *Chenopodeæ*. Generic character: Calyx of the male flowers in five deep divisions, from the bottom of which rise five stamens; those of the female flowers are in two divisions, and almost surrounded by an involucrum of several leaflets; ovary crowned by from three to five sessile stigmas.

ACONITUM (Linnæus). An extensive genus of hardy herbaceous plants, natives of Europe. Linnæan class and order, *Polyandria Trigynia;* Natural order, *Ranunculaceæ*. Generic character: Calyxn one; corolla, five-petaled, upper ones arched; nectaria two, peduncled, recurved; pods from three to five. There are above 100 species, arranged into four divisions, founded on the varied structure of the flowers, number of seed vessels, &c. The roots are tuberous; and many of them are very dangerous poisons. The monkshood of our flower borders (*A. napellus*) is one of the most common and showy, and one in which the deleterious principle abounds. The plants of this genus are very generally distributed, being found in North and South America, Siberia, and Japan; Richards divides them into four sections, founded on their mode of flowering, &c.

This poisonous body is of an alkaline character, and we are indebted to Professor Brande for its first discovery. As this vegetable poison is likely to be taken through mistake, it may be advisable to point out the symptoms which rapidly follow its absorption in the stomach. It is usually attended by violent vomiting and diarrhœa, and the best remedy is to evacuate the stomach by large draughts of tepid water, and then to take repeated doses of olive oil and milk.

ACONTIA (Dart Snake). A genus of ophidian reptiles, very judiciously separated by Cuvier from the genus *Anguis*, or the snakes properly so called. In their organisation they are intermediate between the snakes and the true serpents. Like the former, they are perfectly harmless, entirely destitute of poison fangs; have the teeth very minute, and are incapable of either killing a large animal or swallowing any thing of much size; but they want those parts of the skeleton which render the snakes, properly so called, a sort of lizards; without external feet. (See ANGUIS.) They have no scapular bones, not even the rudiment of a pelvis; and, instead of a sternum, or breast bone, their anterior ribs are united by cartilages. The head has the structure of that of the lizards; and, as in them, the whole body is covered with small scales, and without those bony plates which fence the under part, and at the same time serve as organs of locomotion in the true serpents.

This genus are usually of but small size, gentle and timid in their manners; but not destitute of courage when pursued. Their mode of defence is to dart their whole body with considerable force against their assailants; but they do not resort to that if they can conceal themselves, and escape even with wounds. Their mode of progressive motion is a curious one; it is neither, strictly speaking, a crawl, as in the true serpents, nor a walk—even that sort of wriggling walk which snakes use by the help of the scapular bones, the sternum, and the pelvis, though destitute of feet. They carry the head and anterior part of the body erect, and work their way by means of a sort of wriggling motion of the rest of it. That, and their resemblance at a distance to some of the venomous serpents which are found in the same countries, cause them to be disliked and persecuted, just as the common and equally harmless snakes in this country are, because the viper is venomous, and they happen to have something of the same shape.

The species of these harmless reptiles are numerous, and distributed over many of the warmer and especially the more arid parts of Africa and Asia. In the former continent they are met with in most regions suited to their habits, from the shores of the Mediterranean to the Cape of Good Hope; and in the latter, they range from the Isthmus of Suez to China. In no place, and in no species, however, have they any formidable weapons to use, either against man or against any other animal of even moderate size. Their food consists of worms, and insects and their larvæ; and it is understood that they render considerable service to the people of the countries which they inhabit, by destroying noxious species, such as the locust and the white ant.

The accounts of these harmless creatures, which have been handed down in the writings of the poets, the historians, and even the naturalists of antiquity, may serve to teach a little caution in crediting what the same parties have recorded upon other matters. According to some, they could project themselves with so much velocity, as to pierce and transfix those against whom their motion was directed, as if they had been arrows shot from a bow, or javelins launched from the most powerful engines of ancient war; according to others, their bite was the most venomous of all the serpent race, and neither medicine nor *charm* could prevent its fatal effects; and yet these reptiles were then, as they are now, incapable of killing even a small animal. It is, of course, not known to which of the species those accounts allude; and it is evident that they have combined in their descriptions all the species of serpents, whether poisonous or not, of which there was even a rumour. All species that have the structure alluded to are, however, alike harmless; all have the same timid character, and the same disposition to keep out of the way; on that account, the number of species is not known, and of those that have been named the history is imperfect.

ACORN. The fruit of the oak, which grows as represented in the engraving. In times of scarcity

acorns have been used as human food in perhaps every country in Europe—in some parts of Spain even to this day. As the food of swine they constituted in early times a considerable item in the profits of manors, which were usually valued according to the number of swine that could be fatted in the woods. This was more particularly the case with our Saxon ancestors, who had large herds of these animals.

ACORUS (the Sweet Flag). A genus of plants containing three species, one being a British aquatic, and two terrestrial, from China. They belong to the Linnæan class and order, *Hexandria Monogynia*. Natural order, *Aroideæ*. The British sweet flag was formerly used to strew the floors of churches and halls on particular occasions; the bruised leaves yielding a grateful scent.

ACOTYLEDONOUS PLANTS. Are those in which the seed lobes are not present or indistinct. Vascular plants are peculiarly characterised by the presence of a cotyledon or cotyledons and cellular plants by the absence of a cotyledon. The former group corresponds to the phænogamous plants of modern botanists, and is subdivided into monocotyledonous, dicotyledonous, and perhaps polycotyledonous divisions, according to the number of the cotyledons proper to the species. This division has acquired its celebrity chiefly in consequence of its having been adopted by Jussieu as the basis of his natural system.

The latter group—the cellular, or acotyledonous plants—correspond pretty nearly in their extent to the imperfect plants of Ray, the cryptogamous plants of Linnæus, or the agamous plants of Humboldt, amounting, as it is said, to about 6000 species. Hence it will be seen that they embrace merely the lower grades of the vegetable creation—the Filices, the Musci, the Hepatscæ, the Algæ, the Fungi—being placed, as it were, at the bottom of the scale, and exhibiting, in their outward aspect, as well as in their internal structure, nothing of that loveliness of form, and but rarely that brilliancy of colouring, by which some of the other divisions of plants are distinguished. They are the first and rudest types of vegetable life, many of them consisting merely of a cluster of minute cells, or of minute threads, as in the case of *proto-coccus* and *byssus*; and many of them being, in fact, nothing more than a mere slime or mucus, as in the moulds and nostocs. Yet these minute and apparently insignificant tribes of vegetables are by no means useless or superfluous in the scale of nature. They are just what they should be to complete or keep up the integrity of the vegetable kingdom, whether it be by decomposing putrid and fæcal matters, or by preparing a soil fit for vegetables of a higher order. They are scattered over all climates and all quarters of the world, replenishing both earth and sea with vegetable life, and ascending even into the regions of the air, by the very lightness of their seeds or germs, to be wafted on the wind, till drenched with moisture they descend again, ready to cling to the soil that suits them, if it should be even the surface of the flinty rock, or to spread themselves over mountains of eternal snow, or to immerse themselves in the waters of the ocean. Thus many of the algæ, at least, sow their seed and germinate where no other plant could live. They grow up, and come to maturity, and perish where they grow, forming, in the process of years, a soil of some depth. First mosses, and then ferns, are found to follow in their train, leaving a soil deeper and richer still, till at last, in the revolution of ages, the very surface of the barren rock is covered with a soil capable of supporting the loftiest trees.

ACROCEPHALUS. An ornamental annual plant, belonging to the Linnæan class and order, *Didynamia Angiospermia*, and Natural order *Labiatæ*.

ACROCHORDUS (Warty Serpent). A genus of serpents, supposed to be of the innoxious kind, or those which have no poison fangs, found in the island of Java. Only one species has been observed with any degree of attention; and the history of that one is so imperfect, that naturalists are not agreed as to whether it strictly belongs to the serpents destitute of poison, or has a mode of poisoning of its own, by means of a peculiar bone which has been detected in the head, and without the ordinary apparatus of poison fangs.

From the little that is known of the observed species, the *Acrochordus Javanensis* of systematic writers, the *Aular cærrau* of the natives of Java, it should seem that the animal has no need for poisoning apparatus of any kind, which is commonly used by those serpents that have it, not for the purposes of war, but for the capture of prey, as the stomach of the one which was found by the traveller Hornstedt, previous to 1787, contained, not the remains of animal matter of any kind, but those of fruit. The form of the animal is as singular as that species of food is uncommon for a serpent. The head is rather small and depressed, the upper jaw projecting beyond the under one, and each jaw furnished with two rows of small but sharp teeth. The tongue is short, thick, and unlike the tongues of most other serpents. The scales are nearly of uniform size upon all parts of the body; they have three successive keel-shaped elevations. When the animal dilates the skin, which it has the power of doing to a considerable extent, the scales stand up like warts; and it is from that circumstance the animal is named.

The specimen met with by the traveller already alluded to, was a large animal, upwards of eight feet in length; and three inches in diameter at the thickest part. The form of the body is very singular; it gradually increases in thickness from the head to the insertion of the tail; and then becomes suddenly small, the whole tail being of trifling dimensions compared with that of many serpents. In the specimen alluded to, the tail was nowhere more than half an inch in diameter, or only about one-sixth of that of the body near its insertion. Nothing further is known of its habits, than that it was found in a plantation and had been eating fruit. From the number of persons who have visited Java since it was found without meeting with another specimen, it must be rare as well as singular.

ACROCOMIA (Martius). A genus of palms, natives of tropical countries, belonging to the Linnæan class and order, *Monœcia Polyandria;* natural order, *Palmæ.* There are eight species described.

ACROSTICHUM. A genus of plants containing nine species of foreign ferns, in the Linnæan class *Cryptogamia Filices.* There are three divisions of this genus, founded on the forms of the leaves; viz. undivided, divided, and pinnate. All the species of this genus are natives of the warmer parts of both continents, but they are much more abundant in America than in the ancient continent.

ACROTRICHE (Robert Brown). A genus of plants consisting of three species of evergreen, greenhouse, New Holland shrubs. They belong to the Linnæan class and order, *Pentandria Monogynia;* natural order, *Epacrideæ.* Generic character: Calyx having two bracteas attached; corolla funnel-shaped; fruit, a drupe of five cells.

ACTÆA (Baneberry). A genus of plants belonging to the Ranunculus family, comprising only a few species; one of which, the *Actæa Spicata,* Black Baneberry, or Herb Christopher, is a native of Britain. This species has a creeping root, and a triangular, leafy, smooth stem. Its flowers are white, and grown in a dense egg-shaped cluster. Its berries are about the size of currants, and have a purplish-black colour; they are said to be poisonous. The root, given cautiously, has been useful in some nervous diseases. The whole plant yields a fetid odour, which is said to be relished by toads. Sheep and goats eat it; while cows, horses, and swine refuse it.

ACTINIA (Linnæus, Lamarck, Cuvier). The first genus of the class *Acalepha.* These beautiful and wonderfully organised animals, when expanded in search of their food, may be compared to full-blown flowers, elegantly striped, spotted, or variously marked with the most vivid hues; their trivial name is the SEA ANEMONE, which flower they greatly resemble.

The animal possesses a cylindrical, fleshy, simple, and very contractile body, attached by its base to rocks placed within the reach of the flowing tide; they rarely exert any locomotive power, though they certainly possess the faculty of removing from one place to another; their mouth, which is the only opening to the body, is terminal, and furnished with teeth, surrounded by one or more ranges of tubular radiated tentacula, disappearing when the animal contracts its orifice, in which state it is not unlike a ripe fig, or a small closely drawn purse. The coriaceous skin which covers the Actinia enables them to assume various forms, they are sometimes flattened, conical, or cylindrical. The *Actinia verrucosa,* or Great Actinia, inhabits the coasts of Great Britain, and many other northern countries, in some of which they are considered delicacies for the table. In the tropical climates numberless elegant species abound.

They feed on small molluscous insects, shell-fish, shrimps, &c., but principally small sea-crabs, which they draw into their mouths with their tentacula, ejecting the shells or other indigestible portions by the same opening; these tentacula, being tubular, appear to attach themselves by creating a partial vacuum in each of them, as no viscous fluid is absolutely perceptible on touching them, but a gentle suction is distinctly experienced. The whole interior of the body forms but one cavity or sac; and from the great expansibility of the mouth, large shell fish may be swallowed without injury; but when the shell is so situated as not to be readily discharged by the mouth, it is said to be forced through the body, making a wound near the base, which readily heals, without occasioning any apparent inconvenience to the animal.

They possess the power of changing their place; but their locomotion is extremely slow, and performed by the animal detaching itself at the base, reversing its body, and using its tentacula as legs, these being probably furnished with a viscous exudation, and a roughness well calculated to effect the office.

The Abbé Dicquemarre details some curious experiments on the extraordinary reproductive powers of these animals, in the Phil. Tran., vol. 63, p. 361.

He, in the first instance, cut off the tentacula, which were again produced in about a month, repeating this a second and third time with the same result. The upper part of one of the animals being also cut off, the base was found a few days afterwards to have fallen from its place, but it soon recovered its limbs.

After cutting one of them in two, the abbé presented a piece of a muscle to the detached part, and the limbs seemed eager to take it; they drew it into the mouth, and it was swallowed; but as the body was wanting to receive it, the piece came out at the opposite end, just (says the abbé) as a man's head, being cut off, might be supposed to let out at the neck whatever was taken in at the mouth: it was offered a second time, and again received and retained till the following day, when it was thrown out. In this manner it was fed for some time, the pieces, when they did not pass through, appearing considerably altered on their reappearance at the mouth. If the base itself of any of these anemonies be injured by an incision, the wound generally proves fatal to the animal.

On being put under an exhausted receiver, these animals did not seem to experience any ill effects, or to exhibit any inconvenience from being deprived of atmospheric air; if their tentacula were expanded when thus placed in an air pump, they remained so, and not the least contraction could be perceived on withdrawing the air.

Some of these actinia lived upwards of a year without any other food than the animalcula afforded them from the sea-water.

When shell-fish, pieces of fish, or raw meat, were offered, if not too large, they were always swallowed. The shells, even if closed, they ejected in the course of a day or two, but perfectly cleared of their contents.

The animals are all of them viviparous, and bring forth their young alive at the mouth, and the abbé states that he witnessed their production several times; they were generally from eight to twelve in number. Though at this age some of them were nearly imperceptible, they immediately attached themselves to the nearest object, and expanded their tentacula in search of food.

These animals, though destitute of eyes, were evidently affected by light. When a candle was placed near the vessels containing them, at such a distance as not to impart any heat, they regularly closed, and did not again expand till after the light was removed. When, however, they had been plentifully fed, they contracted more slowly, and sometimes even remained open.

The abbé, among other experiments, placed a narrow slip of meat in such a position as to enable two of these animals to seize either end—an animated contest commenced between them to gain possession of this piece, each in turn drawing in the greater portion; this lasted about three hours, at the end of which, one of them having lost its hold, its antagonist gained the prize.

In Hughes's History of Barbadoes a minute account is given of one species of actinia, which he considered *a sensitive plant, having animal properties.*

The actiniæ are incapable of supporting a strong light or great degree of cold; loud sounds affect them, and fresh water kills them; when they are seen expanded, they indicate fine weather with greater certainty than the barometer; when left by the tide for any length of time they contract themselves, remaining filled with water, which they eject with great violence when irritated.

These animals, like the polypi, have prodigious powers of reproduction; they may be separated transversely or vertically, and each foliated tube becomes a distinct animal; and some time after perfectly formed small actiniæ issue from the mouth.

When forcibly detached from their base, the lacerated portions, which remain attached to the rock, continue to live; their volume increases; the form swells; its mouth, stomach, and tentacula become developed, and a perfect actinia is re-produced. These again produce from the latter part of their base globules, buds or shoots, which are detached by themselves, and, fixing in their turn to the neighbouring rocks, produce fresh colonies.

About thirty species are known. only one of which, the *actinia viridis*, possesses the property of stinging the hand when touched, a circumstance almost constantly observable with the medusæ. Some species of actinia are eaten, principally in the hot climates, where they are far more numerous and infinitely more beautiful than in the northern latitudes. They are found in all seas, lining the vaulted caverns of rocks, below high water mark, or attached to the surrounding masses; and, in general, each species selects its particular habitat. The term Zoophyte, or animal plant, has, by many naturalists, been applied to these animals in common with the corals, corallines, and other polypidoms, equally improperly so named, as it merely arises from a singular coincidence of external resemblance without being founded on any physiological affinity. In proof of which one fact alone will be conclusive, that of their having one or many mouths, leading to an alimentary cavity, or organ of digestion, which does not exist in any vegetable.

ACTINOCAMAX (Miller). A genus of fossil *Cephalopodous Mollusca*, established by Mr. T. S. Miller, who describes it to be closely related to the Belemnites.

Generic character: "A club-shaped spathose concretion, consisting of two nearly equal longitudinal adhering portions. Apex pointed; base, a convex but obtuse cone. The whole formed of a series of enveloping fibrous laminæ."

For a considerable time these fossils were supposed to be either spines of echinites or belemnites, to the latter of which they have a very close affinity. From the first they may very readily be distinguished by their retaining their original laminated fibrous structure; whereas fossil echinital spines, when broken, always exhibit the uniform substance of crystalline carbonate of lime, with the constant fracture of the primitive rhomboid.

From the belemnites they may at once be separated by their not possessing the conical cavity or alveolus for the reception of the chambered shell; but are terminated by a protruding cone similar to the spines of cidarites.

With regard to the precise situation which this genus holds in the system of nature, together with many others, it is only possible to reason from analogy; and the tendency of that evidence is, that it belongs to the class *Cephalopoda*. In following out these views, it appears that actinocamax is the bone or *sepiostarium* of an animal belonging to Lamarck's division of the *cephalopodes*, the *sepiaria;* while the belemnites arrange among his *polythalamia.*

These views, first promulgated by Mr. Miller, have since received particular elucidation from the pens of M. H. Ducrotay De Blainville (Mémoire sur les Bélemnites, Paris, 1827), and P. L. Voltz (Observations sur les Bélemnites, Paris, 1830), &c.

This genus as yet appears to be geologically peculiar to the chalk formations of England and Normandy.

ACTINOCRINITES (Miller). A genus of fossil animals of the class *Radiata*, forming a distinct family, first established by Mr. Miller, under the name of *Crinoidea*, or lily-shaped animals (particulars of which family will be given under that head).

Portions of these fossil remains have been long known under the ambiguous names of wheel stones, fairy stones, rosary beads, trochites, entrochites, &c.; but it is to Mr. Parkinson we are indebted for the true nature of these singular and interesting remains, who described a species of this genus under the name of the *Nave Encrinite*, from its resemblance to the nave of a wheel. The characters of this genus are thus defined:—

"Animal having a round column composed of numerous joints, perforated by a round alimentary canal. At the summit of the column is placed a pelvis, formed of three plates, on which five first costals and one irregular costal adhere, which are succeeded by the second costals and intercostals and scapulæ; from whence five arms proceed, forming two hands, with several tentaculated fingers. Round side arms proceed at unequal distances from the column, which terminates at the base in a fascicular bundle or root of fibres."

The remains of this genus pervade the transition and carboniferous limestone series of this country.

ACTINOLITE. A mineral of a green colour, forming an interesting variety of hornblende. It is divided into Asbestos Actinolite, Common Actinolite, and Glassy Actinolite. The first of these appears massive, in distinct concretions, and internally the lustre is remarkably brilliant. It is found in gneiss, mica-slate, and granular limestone. Berzelius, on exposing this mineral to the action of a blow-pipe, found that it was not altered by moderate ignition; in a brighter heat it whitened, and was then converted into a yellowish brown opake glass. Vauquelin thus describes its chemical constitution:—

Silica	47·0
Lime	11·3
Magnesia	7·3
Oxide of iron	20·0
Oxide of manganese	10·0
Loss	4·4

Mr. Children, in his valuable notes to Berzelius, describes a specimen from Taberg, near Philipstadt, as consisting of one atom of trisilicate of lime, and three compound atoms of bisilicate of magnesia and protoxide of iron.

The common actinolite occurs in a variety of forms, and is found in great beauty at Loch Eil in Inverness, and in the neighbourhood of Redruth, Cornwall; it is also common in the northern parts of Europe.

The glassy actinolite is usually of a mountain green colour. It occurs in primitive rock in the Isle of Skye, and in various parts of Europe and Asia.

ACTION OF ANIMALS. The action of animals is a subject of the greatest interest, not only as displaying that beautiful harmony of organisation and purpose which is conspicuous throughout the whole of living nature; but because, in the organs of animals, and the actions which they perform, we find the most perfect models for the various species of machinery employed by human ingenuity. Their actions must be considered as threefold, or depending upon three distinct sets or systems of principles or laws. In the first place, as the body of the animal is matter, it must obey the mechanical laws of matter; so that neither the whole, nor any part of it, can move without the exertion of a force sufficiently powerful to overcome the resistance of inertia and gravitation. A finger cannot be stretched or bent, an eye cannot twinkle, or adapt its focus to an object at a different distance, without an effort as much greater than the result as is sufficient to overcome the inertia of the organ. This effort must have a certain magnitude before we can feel it, just as all objects of the senses must have a certain magnitude before we can perceive them; but as we can virtually analyse the object of sense down to the ultimate atom which cannot be supposed to become less, so can we analyse the effort down to its minimum. But in many cases we feel fatigue, either from the intensity of the effort or from its continuance; so that standing with the feet close, the body erect, and one arm down by the side, we feel the keeping of the other arm horizontally stretched, for even ten minutes, more fatiguing than if we allowed the body its natural play and carried a hundred weight for the same time. It cannot be the *matter* in the body which thus becomes fatigued? The stone never tires in lying on the ground; the planet in its orbit (though the motion, in the case of the earth, is more than sixty thousand miles in the hour) is never fatigued, or requires rest. That which gives the effort is fatigued and exhausted by giving it, and fails in being able to give it beyond a certain limit; it is not matter, but something which, to a certain extent, controuls and overcomes the ordinary properties of matter, whether that matter be in the body of an animal, or in something external of it. This power of overcoming the laws of inanimate matter is what we properly term *animal power;* and the result of it, the only means that we have of judging of the power, or knowing of its existence, is *animal action.*

But, secondly, the animal power ceases to act, if it is not accompanied by certain chemical changes, the occurrence of which, in opposition to the ordinary chemical action of inanimate matter, proves that it too is the result of *animal* power. The chemical combination of the food, be that food what it may, must be wholly changed by the process of digestion; new matter must be added to all the parts of the body, and that which is no longer fit for the purposes of life (the waste and rubbish as it were) must be removed out of the system, by various external avenues, and generally from the internal and more delicate parts, by the action of the air upon the blood and of the blood upon the air, in the operation of breathing. It has often been poetically as well as popularly said, that the air in this operation is the life; and even those who might have been expected to write *advisedly* at least on the subject have gone into arguments to prove that the air is really a vital fluid, that it is the source of *animal heat,* and the preserver if not the fountain of animal life; but truly there is no vitality in the air, or in any component part of it, neither is there in *any one substance* a store of *heat,* or of any other energy, *substantively* accumulated, and producible without the action of something else. The breeze would play long enough over the pasture, ere it awakened the most kindly herbage into sheep; and the storm might rage for ever among the mountain crags, without animating these crags into eagles. The natural action of the air is to *cool* that against which it beats; the air which is discharged from the lungs is warmed as well as changed; and if that which is received into the lungs is so nearly of the same temperature with the body as to exert no cooling influence there, the breathing of it is always unwholesome and laborious. The heat and the chemical changes which take place in the living body, like the mechanical action of that body, take place in opposition to what would be the state of things around if life were not there; and when life is extinct, the matter over which it held controul is yielded up to the common laws of matter: the body falls prone on the ground in obedience to the law of gravitation, and it decomposes and moulders in obedience to the laws of chemistry, with a rapidity proportional to the intensity of their action.

The power which the animal has of controling the mechanical and the chemical laws of matter begin, increase, fade, and cease together; and while they remain in action, every effort of the one is followed, or rather we may say, contemporaneously accompanied by a similar effort of the other. The power in the one animal is therefore *one* power—the physiologic power —the power of life, of which, from the very nature of things, we can know nothing further than we are able to infer from the results of its action, which is, indeed, all that we can know about power of any kind.

Of the chemical actions of animals we can know but little, or rather nothing; for chemical action is between particle and particle, even in dead matter, and the result even there is always mechanical before we can observe it; therefore, in speaking of the action of animals as a subject of rational and useful, and even of entertaining knowledge, (for that which has no meaning cannot entertain much or long,) we must confine ourselves to their mechanical action. Even there, we must exercise some caution in order to see clearly the beauty of the subject, and to learn successfully those practical lessons which it can so abundantly furnish.

When it is said that the power of life in an animal opposes or counteracts the common laws of mechanics and chemistry in matter not animated, it must not be understood that these laws are violated, or that the properties of matter are, in the least, either changed or destroyed. If creation were thus unstable, it could not endure: if the properties of matter, which belong to it simply as such, and without any reference to composition or combination, were not co-existent with matter, inseparable from it for an instant, and capable of perishing only with its final destruction, there would be an end not only of all knowledge of matter, but of all matter to be known; for, other than by its properties, we do not, and we cannot, know any thing of matter. But the changes, whether the chemical ones of combination, or the mechanical ones of place, are open to our observation, and an endless variety of them is perfectly consistent with perfect sameness in the properties of matter abstractedly considered. The same particle of carbon, for instance, may be at first a diamond, may pass in succession through every animal and every vegetable, and every mineral, that can contain carbon in its composition, may travel millions of times round the globe in the course of its varied combinations, yet maintain its perfect identity of essence and qualities all the time, and return to a diamond at last. That principle is true, not only in the case of animal action, but in that of all action among matter, whatever we may suppose to be its cause; and therefore it is of the utmost importance that respecting it our perception should be clear and our understanding sound. Having noticed it, and it is one of those subjects which should frequently be repeated as a preface, we shall very shortly advert to the general principle of mechanical action in animals. Their actions are all motions, or the results of motions of some sort or other, or they are active resistances to external motions, which, in principle, amount to very nearly the same. If in one instance an eagle cleaves the still air at the rate of fifty miles an hour, and in another it maintains its perch on the pinnacle of the rock, while the tempest sweeps around it with the same velocity; or if in one case a fish darts through the stilly pool with any degree of rapidity, and in another keeps its place in a current which is racing onward just as fast; the mode of action may be different, but the intensity, or, as we may call it, the quantity of action, is the same in both: but, in judging of these actions, we must bear in mind that there is one element of which we are very ignorant—the *energy* of the animal. That is not in proportion to the mass; for if man had the energy of the ant, he could *walk* over a city in a straight line, without heeding the buildings in his way; and if an elephant had, bulk for bulk, the same energy as a flea, it could clear London at a single bound.

The action of all animals may be said to be the result of muscular energy, though the effect of the muscular exertion is, sometimes, increased by structural means. Thus, when the tendon of a muscle passes over the processes of a joint, the tendon is as much pulled by bending the joint the other way, as it would be by the action of the muscle. By that species of action all birds maintain their footing, all perching birds their perch, and birds which kill their prey by clutching or trussing it against the ground give effect to their talons. All animals, indeed, can give different degrees of stability to their feet, by different bendings of the limbs; and these flexures are not so much shiftings of the centre of gravity, as of the part of the base on which the chief pressure rests, though, if the object be mere stability, the centre of gravity is speedily shifted by other flexures, so as to bring the pressure equally upon all parts of the base, and of course nearest to that part which is in the state of greatest tension and best capable of resisting. Bending the knee, or, which is the same in effect, bending the ankle joint, pulls the great tendon of the heel, as forcibly as it could be done by the contraction of the muscles of the calf. If it be done suddenly by a blow behind, when the body is in a very erect position, and the weight chiefly on the heels, the sudden pressure on the balls of the feet in advance of the centre of gravity is very apt to throw the body flat on the back; but in leaping, when the body is bent forward on the hip joints, the very same position of the leg throws it upward and forward when the leap is taken.

Animals which repose on the feet do it, not by muscular exertion, for that is inconsistent with repose—they do it by this adjustment of tension upon the tendons; and if it is against a current, by adjusting the body to that current. When a man stands with his face to the wind he must bend so far forward as to advance the centre of gravity, till the tendency he would have to fall if the wind were not blowing be equal to the force of the wind; and if he stand with his back to the wind, he must lean as far backward. A man has, however, less command of himself with the wind in his back than in his face, just as he has more command of himself in climbing a hill than in descending one; and the cause is, that in facing the wind and in ascending, the tendon alone brings the ball of the foot into action, and there are the muscles of the calf to assist; whereas, in the other cases, the muscles are always in action, and the muscular energy wears out.

Quadrupeds for the most part repose prostrate; but it will be found that all those which repose on the bended legs repose on them so that the tendons are stretched, and will assist as a spring in rising. That is remarkable in the couchant attitude of some of the dog tribe, more especially in greyhounds, and also in cats preparatory to taking their spring—a position in which we may conclude that both muscles and tendons are in that state in which they can act most simultaneously and with the greatest energy.

The positions of birds when perched are well worthy of attention, as they show the perfect state of "preparation for action," in which all living creatures in a state of nature are, when they are at rest, so that in case of surprise they are never taken unawares, or at a disadvantage. Birds on their perch always face the wind; and though many of them "give themselves to," or "turn down" the wind, especially in attempting their escape from rapacious birds, which have not that habit, they all rise with their heads to the wind, and when they "turn down," it is by an oblique posture of the body, and an oblique lateral motion. If a bird were to perch with its tail to the wind, there would be two tendencies to drive it from its perch: the wind would, by turning the feathers, and even getting under the wings, have great power over it; and the action of that power would unbend the legs, and thereby loosen the feet from the perch. But perching with the head to the wind, the bird is enabled to make the wind itself a means of stability. The usual position of repose in a calm in perching birds, is not any effort to keep the perch. It is done simply by the adhesion which results from gravitation, and that too without moving a single muscle of the feet. When reposing, the head is either turned under the wing, or it is bent back, by contrary flexures of the neck, till it rests on or near the shoulders. The whole body is, in fact, concentrated upon that part of the spine which has little or no motion by joints.

The repose of all vertebrated animals is concentrated in the spinal column, which alone is very strong presumptive evidence that the brain and its spinal continuations are the centres or sources of all animal action; but the position of repose in that column varies with the structure and habits. When the spine is flexible, the position of repose is nearly half way between the extremes of the range of motion, or rather that range is divided in the exact ratio of the powers of the *flexor* and *extensor* muscles; and the articulation feels loose, so that the part may be moved to some distance either way, with little effort, and no pain or even disturbance. In the bird, however, which holds its perch by tendinous elasticity, the flexure of the neck is beyond that position which would be repose in a quadruped, so that the tendons of the extensors are tightened; and any cause, which agitates the perching feet, at the same instant brings the neck into action, and extends, elevates, or depresses the head, to the exact extent which the balance requires. Thus, there is in the very structure of the bird a means of resisting any casualty that might drive it from its perch, and that without any more of what we call will or even instinct in the creature itself, than there is *will* or *instinct* in the breathing or the circulating of the blood in man while he is asleep. The sleep, even when most profound and unbroken, is thus not a sleep of the whole animal, for the functions of certain parts of it are going on, and others are ready to obey, not the will of the animal, but external circumstances, as for instance the freshening or abating of the wind. The bird is thus never altogether asleep, neither can it be considered as wholly awake, until all parts of the system are in the full bent of their action.

The nicety with which branch birds bend the positions of their bodies to the fitful wind, or rather the way in which, without contrivance or purpose in either, the bird and the wind act in concert, are well worth noticing. The perch moves in obedience to the wind, or other cause by which it is agitated, and the bird moves along with it; but the bird has also a compensating motion in itself, wholly without design, by means of which, up to a certain degree of agitation in the perch, it maintains its balance with closed wings. When the agitation becomes too great for that, the wings are put out, just as a rope-walker uses his balancing-pole; and when the wind increases to a tempest, and the bird can maintain the perch no longer, it lets itself down by an oblique motion, with so much of the wind under it, as prevents it from being beaten to the earth, or injured by its fall. But to detail all the varieties of muscular action and tendinous relief or repose, with the different structures of feet, wings, and necks, which come into play in this one species of action, although it is one of the most simple branches of the subject, would fill volumes.

The subject, however, not only admits of, but points clearly at, one very general and important conclusion,—namely, that in all these adaptations, perfect and beautiful as they are, the bird profits not a jot, and proceeds not in the least, by what we call experience. And even we, fond as we are of taking credit to ourselves for plan and wisdom, find enough in the action of our animal frame to convince us that that action depends upon principles more stable, and is directed by wisdom more profound, than any to which we can rationally lay claim.

Now if in ourselves, and in the execution of those works of art which are the applications of scientific principles, we find that knowledge and manual dexterity are wholly different in their causes and means of acquirement, and that the chain by which the dexterity is arrived at can be followed downward unbroken, to the involuntary respiration and circulation during sleep, or to the balancing of the sleeping bird upon its perch, we must see clearly that the actions of animals, however complicated or curious, and our own action, in so far as that is animal, are the results of material principles, or rather they are the results of certain arrangements or organisations of matter; that the laws or principles by which those actions are produced are not properties of matter considered abstractedly, or (so to speak) as "the stuff of which animals are made," but principles resulting from the organisation, and from that only; that they do not arise from any property which matter itself possesses in its ordinary combinations and arrangements, but that (though it may in some cases be minute beyond our powers of observation,) there is always a distinct ACT OF ORGANISATION before a new organised being can exist; that though, in our estimation, some of them appear simple and others complicated, some involuntary and others voluntary, yet they are all equally simple and equally certain, never occurring but under the circumstances which accord with their occurrence, and never absent when those circumstances take place; that they are in perfect accordance with all the laws of matter, and have their origin, their growth, their decay, and their extinction, of creation itself, and neither require nor admit of being separated, though, as they depend upon combinations, it follows that, in as far as we can alter the combinations, we can change the result.

This view of the matter—and though it is not the usual it is the only correct one—the only one which will carry us, without nonsense in philosophy and infidelity in religion (twin progeny of the same narrow-minded ignorance) fairly through the analysis, from the eye of the eagle, the proboscis of the elephant, the human hand, or whatever else may be considered as the perfection of organisation, to the primary atom, in which gravitation itself is too minute for our observation,—mightily enhances the value of animal action. It lets us see that the whole of animated nature is in our power, and that we may, according to the extent of our knowledge, either enlist it directly in our service, or copy it as a model, in so far as that which has life can be imitated in that which has not.

Some account of the more obvious kinds of action in progressive motion will be found in the articles CREEPING, WALKING, FLYING, and SWIMMING; and some notice of the more peculiar ones, especially those of the invertebrated animals, in which they appear to us most singular, from having the least similarity to our own actions, will be found in the accounts of the animals by which they are displayed. The other branch of the general question, namely, the means that must be adopted in turning the action of animals to useful purposes, will be found slightly noticed in the article AFFECTIONS OF ANIMALS.

ACULEUS. A prickle attached to the bark, and coming off along with it. It is unconnected with the wood, and thus is distinguished from *Spina*, a thorn. Examples of it may be seen in the rose, the raspberry, bramble, &c.

ACYNOS (Richard). A genus comprising eleven species of European herbaceous plants allied to the common thyme. Some of them are biennials, others annuals. Linnæan class and order, *Didynamia Gymnospermia.* Natural order, *Labiatæ.*

ACYONIA (Leach). A genus formed from the genus *Scalaria*, to distinguish those species whose spiral turns are disconnected, and not touching in any part; but other naturalists have not adopted this genus, considering it at most but a variety, or perhaps merely a sport of nature.

ADAMANTINE SPA. *See* CORUNDUM.

ADANSONIA. A genus of plants which derives its name from the famous French botanist, Michel Adanson. It belongs to the natural family of *Bombaceæ* (Kunth and Richard), or the cotton-tree tribe; and to the class *Monadelphia*, order *Polyandria*, of the Linnæan system. The generic characters are: Calyx naked, deciduous, deeply divided into five segments; petals, five; style very long; many stigmas; capsule or seed-vessel woody, divided into ten cells, containing a farinaceous pulp and numerous seeds.

Isert, a Dane, in his voyage to Guinea, states that he observed several species of the genus; but the only one which has been hitherto known to botanists is the *Adansonia digitata* of Linnæus, the Ethiopian sour gourd. This immense tree, the colossus of the vegetable kingdom, is found in Senegal, Guinea, and the countries on the west coast of Africa, from the Niger to the kingdom of Benin. It was first introduced into Britain in 1724, and may be reared in a mixture of peat and loam, in bark or a moist stove.

The tree is called by the inhabitants of Senegal *Goui*, and its fruit *Boui;* while the French give the name of *Calebassia* to the former, and that of *pain de singe* to the latter. The designation of *monkey's bread* applied to the tree is derived from the French appellation of the fruit.

Its height is moderate, varying from fifty to sixty feet, but the size of its trunk is almost incredible. According to Adanson, trunks are met with having a diameter of twenty-five or thirty feet, and a circumference of ninety; and Mr. Golberry observed one which was thirty-four feet in diameter and 104 in circumference, while at the same time it only attained an elevation of twenty-four feet. The lower branches shoot out frequently to the length of fifty or sixty feet, at first in a horizontal direction. They are covered with a dense foliage, which, from its weight, causes the branches to bend towards the ground; and thus there is presented an immense hemispherical mass of verdure, 120, 140 or even 150 feet in diameter, and perhaps sixty feet in height. At a distance a full-grown tree almost presents the appearance of a forest. Cape de Verd is said to owe its name in part to the foliage of this tree, which adorns the whole of Senegambia and Guinea with its green elliptic arches. The flowers are very large, white, and pendent. At sunrise the negroes religiously watch the opening of the flowers which have been closed during the night. The roots are numerous, and attain a very great length. A main root has been measured 110 feet long. It flowers in July, and its fruit is ripe in October and November. The age to which the tree is said to live is astonishing. Adanson looks upon it as the oldest living monument of the globe. In 1761 he noticed two of these trees growing on an island off the west coast of Africa, which were distinctly ascertained to be several centuries old; and he seems to think that some trees on that coast have existed upwards of 5000 years. His conjectures are probably erroneous, but they are founded on the rate of growth of the trees. The following are his calculations, as given by Dr. Hooker: a tree of—

	Diameter.	Height.
1 year old is	1 or 1½ inch	5 feet.
20	1 foot	15
30	2	22
100	4	29
1000	14	58
2400	18	64
3150	30	73

From this it will be seen that the increase in height is not in proportion to the increase in diameter.

The wood of the tree is pale and soft, and is perforated by bees for the purpose of depositing honey, which is often found in great abundance. The trunk of the tree decays by disease, and is hollowed by the negroes into chambers, which are large enough to serve for temples or habitations. These cavities are, however, generally used as receptacles for the dead bodies of those denominated *guiriots*, that is, poets, musicians, &c.; for whom the negroes entertain high respect, as beings possessed of superior intelligence. They are respected, consequently, during life; and after death superstitious motives prevent the negroes from interring them in the usual way. Their bodies are suspended in the cavities hollowed out of this tree, and there they become completely dried, and are in a short time rendered perfect mummies, without the aid of any perfumes or embalming materials.

The tree is mucilaginous in all its parts, and is used for a variety of economical and medicinal purposes. The bark and leaves when dried and powdered form a substance called lalo, which is used by the natives of Senegal as a seasoning for their food, and which is employed medicinally, both in the form of powder and decoction, to diminish excessive perspiration, and to check dysentery and the epidemic fever, which rage in September and October after the rainy season has ceased. By the use of the decoction Adanson and a friend kept off the attack of fever at a time when it was remarkably prevalent, and were thus enabled to prosecute without interruption their scientific researches in Africa.

The fruit, which is ten inches long, has an agreeable acid flavour. It is used for food, and when mixed with water and sugar is a grateful drink in fever. The fruit is carried by the Mandingos to the eastern and southern parts of Africa, and sold to the Arabs, who convey it to Morocco and Egypt. The pulp when dried and powdered is an article of commerce, and is sold in the market of Cairo, under the name of Lemnian earth. The ashes of the outer rind of the fruit are mixed with rancid palm-oil, in order to form soaps.

A very full account of this wonder of the vegetable kingdom is given by Adanson in the Memoirs of the Royal Academy of Sciences of Paris, in the year 1761.

ADAPIS (Cuvier). A name used by Gesner as a synonym of the Daman, but applied by Cuvier to designate one of the fossil pachydermatous quadrupeds, discovered by him in that great bone repository, the gypsous formation of Montmartre.

In few instances could we point out a more illustrative example of the application of his favourite hypothesis, which he calls "*la loi des corrélations des formes*," or that of Harmony of Forms; the proper application of which enabled that illustrious naturalist and other anatomists to restore, and as it were repeople, the earth with animals which have long since disappeared from its surface.

Three portions of the head only have as yet been discovered among the multitudinous bones obtained from the plaster quarries; yet these alone, from their contour and dentition, are sufficient, when applied to the analogical test of the law before spoken of, to determine characters sufficient to distinguish them from any known animal either recent or fossil.

This animal may at once be distinguished by the following characters: Its general form must have assimilated to the hedge-hog, but larger; each jaw was furnished with four incisors, trenchant, and rather oblique, with conical canine teeth above and below, thicker and more projecting than the other teeth; the tooth a straight one, the lower oblique and couched forwards. The molar teeth appear to have been fourteen in each jaw; six were discovered in one side of the upper jaw, the first trenchant, the second encircled by a crest, the third apparently so; the other three like the posterior molars of the Anoplotherium. In the lower jaw, the two first molars are pointed and trenchant; the third similar, but longer and wider; the next three in form the same as the opposing teeth in the upper jaw; the last is oblong, and seems to have tubercles in the form of unequal transverse hillocks.

This animal, though probably not larger than a rabbit, appears to have closely approximated to the Anoplotherium.

The gypsum quarries, from which these relics were exhumed, belong to the tertiary formation, above the *calcaire grossier* and London clay.

ADDER'S TONGUE (Linnæus). A very small species of fern found in pastures on chalky clays. The leaf is an elongated cup, with one lip lengthened out to a point. The capsules are fixed on a central spike resembling a tongue, hence the name; capsule, roundish, one-celled, opening transversely, seeds angularly round.

ADELIA (Linnæus). A genus of three species of stove evergreen shrubs, natives of Jamaica. Linnæan class and order, *Diœcia Monadelphia;* Natural order, *Euphorbiaceæ.* The flowers of these shrubs are very small; calyx, from three to five divisions in the male flowers; stamens, thirty-one. In the female flower the ovary is surmounted by three stipules.

ADENANDRA (Wendland). A genus of evergreen shrubs, natives of the Cape of Good Hope. Linnæan class and order, *Pentandria Monogynia;* Natural order, *Rutaceæ.* There are ten species, some of them very beautiful.

ADENANTHERA (Linnæus). A family of evergreen shrubs, natives of India. Linnæan class and order, *Decandria Monogynia;* Natural order, *Leguminosæ.* Species two. Generic character: Calyx abbreviated, with five teeth; corolla of five regular petals; stamens ten, equal in length, and separate; anthers terminated by little glands; fruit a long pod, containing round seeds. The species which compose this genus have the leaves bipinnate, the flowers very small and in bunches: one species, *A. pavinonina,* is a large and beautiful tree, the seeds of which are round, of a bright red, and are used as food in some parts of India. The fruit is also used for necklaces and other ornaments.

ADENANTHOS (R. Brown). Greenhouse evergreen shrubs, natives of New Holland. Linnæan class and order, *Tetrandria Monogynia;* Natural order, *Proteaceæ.* Generic character: Calyx superior, tubular, four divisions; stamens four; style one; fruit a nut containing one seed. Species three.

ADENOCARPUS (Decandolle). A genus of deciduous ornamental shrubs, natives of Europe. Linnæan class and order, *Monadelphia Decandria;* Natural order, *Leguminosæ.* Generic character: Calyx, bilabiate, the upper bifide, the lower trilobate. Corolla, papilionaceous. Stamens, tenunited, with one distinct. Fruit a compressed pod. The valves covered with little pedicelled glands. This genus comprises six species.

ADENOPHORA (Linnæus). A genus of perennial herbs allied to campanula, chiefly natives of Siberia. Linnæan class and order, *Pentandria Monogynia;* Natural order, *Campanulaceæ.* Species fourteen.

ADEONA (Lamouroux). A genus of the third order of the third class of *Corticiferous Polypidoms,* so called from being composed of two substances; the one exterior, which may be termed the rind or incrustation; and the other called the axis, placed in the centre of the former, and supporting it. The organisation of the stem of the adeonas is articulated and surmounted by a fan-shaped expansion, both surfaces of which are impressed with small scattered cells, pierced with round or oval holes. Lamouroux, who has closely studied the interesting productions of these wonder-working creatures, appears to consider this genus as the natural connecting link between the corallines and the flexible polypidoms, that are entirely of a stony fabric, comparing it to a millepore fixed to the axis of an isis or of a mopsea; and although no rind has been discovered attached to specimens brought to this country in a dried state, there is every reason to imagine it does exist in a fresh and living state. Supposing that these beings do not change by desiccation, we must admit that in Australia these polypidoms afford us a new example of organised creatures which have no place in our classification of natural history, a circumstance not rare in that division of the world.

The difference between the fan-formed expansion and the stem in the animal is so great, that naturalists, at first sight, were tempted to look upon the two parts as distinct beings; it is, however, easy to prove that they belong to the same animal.

Peron, who had seen them in the very site of their growth, frequently convinced himself that they were identically the same polypidom. If the base of the fan-formed expansion of the adeona be attentively observed, it may be seen to extend itself into the stem, and only gradually to change its nature; when that change is completed in the stony articulations, the same stony substance forms the expansion, differing only from the articulations by possessing cells that are not found in the stem. These facts most conclusively establish that the stem of the expansion of the adeonas, notwithstanding their disparity of form, cannot be the productions of different animals.

The stem of this polypidom is irregularly cylindrical, sometimes branching, composed of calcareous articulations, without pores or cells, as hard as coral, and separated from each other by disks or plates of a horny, fibrous, and flexible substance. The expansion, as has been already observed, is stiff and brittle. Its hardness is equal to that of many of the madrepores, and superior to that of most of the millepores; the cells or pores are very numerous, placed in short curved lines, or dispersed on both surfaces; all those found on the same side appear to communicate with each other by very thin perforated divisions; and the polypi of the two surfaces appear to be insulated by means of a diaphragm, which is very thick, and parallel to the plane of the two surfaces, dividing the polypidom into two laminæ of an equal thickness.

The colour of the adeona is an iron-grey, sometimes of a deep hue; they occasionally attain a foot in height, and are abundantly found in Australia. Six species are known.

ADESMACEA. A family of shells, forming the third class of *Acephalophora*, established by De Blainville, in his System of Malacology. It includes the genera *Pholas*, *Teredina*, *Teredo*, *Fistulana*, and *Septaria*. All the species of these genera possess the extraordinary faculty of piercing hard bodies, such as marble, wood, &c. A more detailed account of the habits of each will be found in their respective alphabetical arrangements.

ADHESION literally means the property which substances have of "sticking together" after having once been separated, or of growing up united as one when, under other circumstances, they grow separately. The term is used in the arts and in the sciences of dead matter, and there it denotes the adhering together of different substances or different masses; and differs from *cohesion*, by means of which the parts of one mass are held together.

In Natural History the word adhesion has a signification somewhat different, namely, that the substances do not merely adhere together, but grow together, and become as it were one. In this sense it is applied to natural substances in their living state only; but it applies equally to animal and vegetable substances, and some of their most remarkable properties depend upon it.

There are some remarkable cases of adhesion that take place in animals, chiefly in the mammalia, though occasionally in some of the other classes, while they are in the uterus or other maternal envelope. These chiefly consist of the union of two subjects, neither of which is quite perfect: at times both nearly in equal perfection, as was the case with the Siamese twins, some time ago exhibited in London; and at other times with the one so little developed, that it seems merely a fragment stuck upon the other—as an additional limb, a finger, or a thumb. These formations, to which the name of MONSTERS has been given, form one of the most obscure portions of the branch of physiology, of which we know the least, inasmuch as we have no analogous knowledge upon which we can ground even a plausible conjecture, neither is it probable that such knowledge will ever be obtained. There are natural causes for their monstrosity no doubt, as well as there are for all the phenomena of nature; but we know not in what direction these causes may lie; and, consequently, any speculation concerning them would, of necessity, be extremely doubtful. If one lamb in a thousand be dropped with five legs, we need not puzzle ourselves about the cause of that, till we have found out "why" the nine hundred and ninety-nine have only four legs each. The number in the one case satisfies our curiosity, and the rarity of the other awakens it, but we are equally ignorant of the "why" in both.

Vegetable adhesions are turned to more account than animal ones; and we are enabled to pursue the subject a little farther, though when we come to adhesions in their primary formation, we get upon ground which is hardly less slippery. In vegetables we can carry the adhesions, at least in some of the natural families, to different species, and perhaps to the whole genus, or, in some instances, to the whole natural family or order. The cases in which we can most easily effect this, are those in which there is a power of forming lateral buds, or buds in the bark, or rather in the living cambium; but there are other cases in which it is difficult, if not impossible, to form an adhesion, even of the parts of the same individual, however recent the division may be. There is no action for the repair of waste in those parts of a plant which have passed their season of vegetation; and therefore we could no more expect a power of adhesion in them, than in the salts of lime in the bones or in the appendages to the skins of animals. It is at the living surface of the wood in the *exogenous*, or the living centre of the *endogenous* plant, where we alone ever find action; and as there is productive action there only while the cambium of the plant is in a state of granulation, there can be no healing or union by the first intention in a plant. It is true, that the action in perennial stems is not confined to the mere surface at which the new substance accumulates during the growth of the season; for there must be some organisation or apparatus for the elaboration of that substance; and thus the action of the vegetable may be said to linger a little longer in the external layers of the alburnum or sapwood, and the inner layers of the bark, according to the habit of the species. But when these structures are once consolidated, they do not unite even by a process similar to granulation; and hence the "internal shakes," which are found in the boles of trees, in those countries where they are exposed to the effects of violent winds. Hence also the union by grafting must be by means of a mere twig; and if that twig is inserted in the hard wood only, it is sure to wither; unless that mould decomposes and forms a soil in which it can take root. Even with the living surfaces of the scion and the stock in contact, there must be a sort of overlaying or overlapping of those surfaces; for though they are adapted ever so neatly to each other, they will not adhere upon a perfectly horizontal section.

The parts of growing plants are often subject to the same kind of adhesion which takes place in animals, when the parts are deprived of the epidermis, and held in contact. This often occurs naturally in trees which bud in the bark, and gives them very fantastic appearances: and it is not confined to deciduous trees, but is met with in some of the coniferæ, such as the yew, the old hollow trunks of which are often covered by a network of younger parts, which adhere and again separate over it in the most singular manner, entwined like open rustic work, after the old part has mouldered away. Fruits and leaves often adhere in the same manner; and indeed, in many species, there are no two similar parts of the living surface that will not adhere if they are deprived of the epidermis, and brought into contact.

This tendency is turned to account in the arts, in what is sometimes called a Dutch hedge, a description of fence which might be advantageously introduced in all places where land is valuable. It consists of twigs rooted in the ground, made to cross each other in lozenges, the surfaces being rubbed where they come in contact, and tied together till the whole unites into one solid piece, occupying only a few inches in breadth, and yet stronger than any hedgerow of detached plants.

All vegetable growth may be considered as proceeding by a sort of adhesive process, at least all which proceeds by a series of growths with pauses between, as in plants which continue to grow for several successive years, and more especially all which increase by layers on the wood and bark, and elongations of the twigs. In these, the part which is once formed, and has rested for one season of inaction, does not again increase its volume, either in length or in diameter; but the new parts are formed external to it, and produced upon it, by different degrees of adhesion, according to the nature of the plant.

This principle of adhesion, which of course is the only one by means of which plants, which are formed as it were by a succession of cases or deposits, which do not increase after they are once formed, could at all increase in volume, and which is in itself a *result* of the peculiar mode of action in the species, has been perhaps carried a little too far by those who are determined to know more of nature than nature itself reveals. It has been described, and that too by modern botanists, not only as *its own cause*, but as the cause of that of which it is in truth but the *effect*, namely, the peculiar habit of the plant, that which makes it one particular species and not another. It has sometimes happened, rather unfortunately for the truth, that those who have attempted to generalise in those matters of natural science where much remains unknown, have been but lame logicians; and though their confounding of causes and effects, in these matters, can do little or no moral harm, it is a stumbling block in the way of knowledge.

It cannot be too plainly or too frequently put, that the character of a plant or an animal, whether we call it generic, specific, or any thing else, is purely and wholly *matter of observation ;* and if we venture to add one word more than what that observation will bear out, we must be wrong, inasmuch as there is but one truth, and all else is error. If we find that certain parts of the character are changed by one mode of treatment, and not by another, we are warranted to conclude that so much of the character as has been changed depends upon that mode of treatment; and if we find a change taking place in nature, precisely similar to that which we effect by artificial treatment, we may conclude that the natural circumstances have been similar to our artificial ones. By thus experimenting, in as far as we can subject the living subject to experiment, we question nature by the test of art, and regulate future art by the knowledge of nature; and thus bring to living nature a portion at least of that inductive philosophy which has worked so many wonders for us in the study and use of dead matter ; but if we invert the order of nature, and call the final result, of which we can know nothing more than the simple fact of its having taken place, its own antecedent or cause, there is an end of all philosophy—of all sense and meaning.

ADIANTUM. A genus of plants belonging to the *Acotyledonous* or cellular order of vegetables; and to the natural family of *Filices*, the fern tribe. The name is derived from the Greek word ἀδιαντος, dry, because the plants are of such a nature that they cannot easily be made wet.

Generic characters : Clusters of capsules, oblong or roundish, with a membranaceous covering arising from distinct portions of the margin of the frond, which is folded back.

Upwards of sixty or seventy species have been discovered in different parts of the world—in Europe, North and South America, the West Indies, New Holland, &c.

Adiantum Capilli Veneris, or Venus's Hair, is an elegant fern, which, with its five green fronds, contributes not a little to adorn the dripping rocks and caves in various parts of Europe. It is rare in Britain, but very common in moist shady places in the south of Europe. Dr. Hooker has frequently noticed it lining the inside of wells with a "tapestry of the tenderest green." It has been found growing at Baguères in water of the temperature of 105° of Fahrenheit's thermometer. Its fronds or leaves are from six to twelve inches in length, and retain their green colour even when dried: hence they have a fine appearance in a herbarium. The plant possesses demulcent and mucilaginous properties.

Adiantum pedatum, another species, is common in France, and is employed extensively on account of its astringent pectoral qualities.

Both these species of adiantum, but especially the latter, are used for the preparation of a pectoral syrup, which has received the name of capillaire. The syrup is made with honey and orange-flower water, and is administered as a lenitive in coughs and catarrhs.

The other species of the genus are not put to any particular use.

ADIPOCIRE (Fat Wax). A substance, in its external or natural history properties, apparently intermediate between the two from which the name is formed.

The chemical properties of adipocire, or the species of chemical action by which it is produced, do not fall within the scope of natural history; but we may briefly notice the circumstances under which it is formed. If animal matter is left on the surface of the ground, or otherwise freely exposed to the atmosphere, no adipocire results; neither is there any formed when the animal matter is in small quantity, and not deep below the surface, in ground which is moderately warm, and not very moist. But when the quantity of animal matter is great, and the depth considerable, it not only forms in the situations that have been mentioned, but, after the lapse of several years, becomes partially transparent, and of a granulated texture approaching to crystalline. This was the case in the burial ground at the church of the Innocents in Paris, where the substance was first noticed, in the year 1787, when the matter of that common place of inhumation was removed. Bodies in vast numbers had there been thrown into pits, thirty feet deep, and twenty in each of their other dimensions. Those near the surface tainted the air very much, which was the cause of the removal; but when they had been heaped to a considerable thickness, the middle strata were converted into adipocire in about three years; and such as were lower down, and had remained as long as from thirty to forty years, had become granular and semi-transparent. When water is present, the change takes place much more rapidly, and at a less depth below the surface; so that the allegation which Shakspeare puts into the mouth of the grave-digger, that "your water is a sore consumer of your dead body," is literally true, and helps to prove the wonderful extent to which that great man had carried his observations. In the warm and dry regions of the globe, bodies do not change into adipocire; and in the cold and humid ones, the change takes place much more generally than in the temperate. It is so common in Iceland that large masses are laid upon the beams of the churches, and kept there for medicinal purposes, nearly the same as those to which the stearine of whales' fat (improperly called spermaceti) used to be applied in this country. How soon it forms in that part of the world has not been accurately ascertained; but as the climate is very rainy, and the soil in consequence very moist, it is probably formed with considerable rapidity. The battle of Culloden was fought in 1746, and the greatest carnage being on a wet and boggy piece of ground, a number of bodies were buried in a common grave there, at a very small depth below the surface. On opening the green hillock over that common grave, in the early part of the present century, and in quest of very different memorials of the battle, large pieces of adipocire were found, and they were almost the only animal remains that were met with, the bones having decayed more than in the drier soil.

The forming of adipocire in the soft parts of animals, or rather the conversion of them into it, indiscriminately and without regard to their appearance and texture while alive, is a curious fact in the animal structure. It is effected wholly by the chemical properties of the parts themselves, and the process is impeded or prevented by external agents; for water only more completely excludes the air than earth does, and cold is merely a less active degree of heat. In substance it must be the same as the parts of the living animal; and as the mass is uniform, it shows that the soft parts, when left to their own action, have all a tendency to pass into the same substance. That tendency must be in them while the animal is alive, though it is then counteracted by the functions of life. It appears to be, or rather indeed it certainly is, the same action by which fat is accumulated; and the gradation from oil and soft fat, through firm fat, stearine, and that half-fatty, half cartilaginous, substance which forms the humps of camels and other humped animals, and collects in the dew-laps of hill cattle when they fatten in the autumn, is a very near approach to adipocire. In the living animal, the fat, whatever may be its consistency, is merely food, assimilated but not organised, stored up against the period of want, whether that period be one of hybernation, or winter repose, or merely one of the absence of food while traversing the desert, or otherwise passing from one feeding ground to another. In some of these cases, as in that of the spermaceti whales, the store thus accumulated appears to be so completely without the range of organic action, that it granulates something in the same manner as adipocire; and in others, as the humps of the camel, it has a slight, though a very slight, trace of organisation. But, whatever may be its structure, it appears to be available for the repair of all the parts of the organisation, as long as the powers of life retain their energy; for when circumstances render it necessary, all the accumulations, even to the hump of the camel, are taken into the system.

From what has been said of the change of the surplus food into fat, the fat into organic structures, and these again (with the exception of earthy salts and coagulated albumen) into adipocire, it appears that the living body is not formed immediately from, or immediately convertible into, the dust; but that there is an intermediate process, that of *assimilation*, by which the food of animals is turned into animal matter, before it becomes, by another process, which is usually called *secretion*, a part of the living animal. It is highly probable that in the last of these processes, the aliment passes through the state of air or gas; and that when the organic structure returns into mere matter, without first becoming adipocire, it again returns through the state of gas. It is matter of common remark, that church-yards do not accumulate soil in proportion to the inhumations that take place in them; and (the dust of bones excepted) it will be found that the mould which is there, is wholly vegetable or mineral, from other sources. The coagulated albumen, which is not the same as boiled white of egg, (and that is an assimilated substance, though not organised till the egg is hatched,) appears to be neither animal nor vegetable, but a sort of mineral matter,—an armour which the living body puts on against the influence of the atmosphere. The earth of bones belongs to the same class of substances, and the bones, like the epidermis and its appendages, act no part in those functions in which animal life may be said to be exclusively displayed.

What may be termed "the working structures" of vegetables do not, like those of animals, pass into adipocire, but into mould when dry, and into peat when wet, and ultimately into coal,—for though the probability be that amber and jet are resins, yet these are not originally working structures, they are products.

This difference of the *destiny*, as we may call it, of the organised structures of animals and vegetables, is a very important point in physiology, as showing that there is a distinct line between these two kingdoms of nature. When they are dead, external causes can dispose of both in the same manner, namely, earth to earth, water to water, and air to air; but when we exclude those causes, each turns to a different substance—the animal to adipocire, the vegetable to mould or coal; and the final state of each bears a very considerable resemblance to that which it had when first taken into the system, and before it became part of the organic structure.

The views which this subject opens up are too vast for a single article, or even for a work intended and adapted for popular reading; but they are especially worthy the attention of those learned persons who, of late years, have lingered so long upon the twilight boundary between the animal and the vegetable kingdom, as to be in some danger of confounding the one with the other, and thereby jumbling the whole system of nature into a chaos. See the articles ANIMAL PHYSIOLOGY, VEGETABLE PHYSIOLOGY, and the various references from them.

ADIPOSE TISSUE. The cellular membrane in which is deposited the fat (*adeps*) in animals. A knowledge of the structure, and especially of the functions of the animal frame, is highly necessary, not only in order to the proper understanding of the anatomy and physiology of animals, but to that of some of the most curious parts of their economy in the state of nature, and some of their most valuable domestic uses. In various animals it is variously disposed, and endowed with different degrees of power in depositing or secreting fatty matter; but in general it is found under the skin, accompanying the muscles on their general surfaces, and also on those of their fasciculi or bundles of fibres, and also covering much of the internal parts, whether their textures be muscular or not. In many instances it appears to pervade the bones, and to produce marrow in the larger tubes, and fatty or oily matter in the more minute cells; and the same surfaces by which it is secreted, or, at all events, deposited, appear to have the powers of absorbing it again, even from the bones of the animals, when, from any cause, that becomes necessary for the preservation of their existence. "Thy bones are marrowless;" this applies not only to the supposed "ghost," but to that state of emaciation, not inaptly termed "ghost-like," to which the bodies of men and other animals are sometimes reduced, by disease or otherwise. The walls of the cells of this tissue are membranous, and do not, in any instance, appear to have the power of muscular contraction. It does not appear to invest directly any part of the nervous system, neither does it appear to contain any nervous fibres in itself; at least it can be distended, and even divided, without any painful feeling. The distension of which it admits is often very great; and the quantity of fat accumulated bears so great a proportion to the membranous matter in which it is contained, that the whole accumulation has the appearance of being an uninterrupted mass of fat; but such is not the case; for, upon burning a portion of the fat of any animal, the peculiar smell of animal matter is invariably given out, unless that fat has been previously freed from every portion of the cellular tissue, by some process of clarification or fining; not only so, but the entire fat of any species of animal gives out, when burned, the peculiar odour of the burning flesh of that animal, if it has such an odour, as any one may observe by comparing the smell of whale oil and of candles made from the fat of different animals in the unrefined state. When, however, the adipose tissue is wholly removed, no animal odour is given out in burning the pure fat; so that the fat cannot in itself be considered as an organised animal substance, but merely as one in a state of preparation; bearing some analogy to the pulp of fruits, the albumen of seeds, the substance in the thickened hybernacula of buds and roots, and partially also to the parenchyma or pulp in the cells of succulent leaves. As it is different both from the portion of the food of animals which is supposed to be taken directly into the system by absorption, and to that which is assimilated as chyle, it must be considered as the result of some sort of secretion; but as it wants the proper indication of animal matter strictly so called, it must be regarded as the product of a first secretion, to which a second must succeed before the matter secreted by the cells of this tissue can form part of what may be regarded as the working structures in the animal system. It would of course be inaccurate to call any one part of an animal the vegetable part; but the function performed by this tissue appears to be somewhat analagous to the functions performed by the cellular tissues of vegetables, if not in product, at least in manner of action.

The varieties of action and their results are so different in the adipose tissues of different animals, are so many, and some of them are so very important both to the capturer of wild animals and to the cultivator of domestic ones, that they cannot be brought within the compass of a single article. Some of them will be found treated of under the article FAT, and the references from that article; others will be found in the descriptions of the genera or species.

ADJUTANT BIRD. The popular English name of several tropical birds of large size, of very peculiar shape, and, generally speaking, familiar manners. They belong to the order *Grallidæ*, and the genus *Ciconia*, and are in fact storks, resembling in their manners the common storks, which are far from rare in Holland and other parts of the Continent; and these live in the towns, perch on the house-tops, and breed in boxes placed for their accommodation; but the European species retire to more tropical latitudes in the winter, and the whole genus are migratory.

Though classed as wading birds, the storks generally, and the adjutant birds in particular, do not find the greater part of their food immediately *in* the waters; but rather upon those places of the land from which the water has retired, though they prefer marshy situations, migrate from places which become dry and parched, and return with the rainy season.

The use of these birds in tropical countries, where the alternations of drought and humidity are in extremes, is very great; and thus they form a characteristic as well as a peculiar feature of those countries. They are voracious feeders, and so daring in their habits, that though they do not exactly take the prey out of the lion's mouth, they seize it in the immediate vicinity of any animal, even of man himself. They feed upon reptiles, fishes, small quadrupeds, occasionally birds, and, in general, all manner of offal and animal subtances; but they do not attack and kill any large animals of the warm-blooded classes.

When the drought sets in, and reptiles either perish or betake themselves to the earth, in which many of them pass that season in a state of torpor or inactivity, the adjutants quit the country, migrating to other parts of the world, if there are not places adapted for them within the range of the country, or otherwise resorting to the lower banks and embouchures of large rivers, and the mud flats which are usually found in such places. There they appear in flocks, after the habit of many of our British birds, which resort to the shores when the state of the weather drives them from the interior; and, while they remain in these places, they feed chiefly upon the young of crocodiles, alligators, turtles, and other large aquatic reptiles, which deposit their eggs in the banks to be hatched by the heat of the sun. In tropical countries the season of drought is the winter or sterile season on land; but it is the time at which the shores of the sea are more than usually productive, as those parts from which the water partially retires act as hot-beds; and, in the time of the dew towards evening, there is an absolute rush of living creatures from their birth-places in the mud to their future abode in the water. At the same time the mature ones come on shore to deposit their eggs. Thus, while the land is barren, these large birds feed chiefly on the margins of the waters; and when the rain sets in, or rather a little before it, they resort to the interior. They are found in the tropical parts of Asia, Africa, and America, though with some specific differences.

The whole race of the storks are, from the structure of their feet, marching birds, rather than runners. Their long journeys are all performed on the wing; and when they advance a considerable way on foot, they do it with the body erect and the wings elevated; though they strut rather majestically, with the wings close. Their feet have the front toes rather long, and united by membranes at their bases; and though the hind toe is articulated on the tarsus, the lower extremity of which forms an elastic knob, that toe is of sufficient length for the first joint to rest on the ground. In flying they do not extend the neck, but fold it back on the shoulders, though they project the feet behind. They are social in their breeding places, and the sexes have little difference in appearance; but the young of the first year have the plumage much more mottled than that of the mature birds. The eggs are two, three, or four, of a dull white colour, and very much elongated. The pairs are much attached to each other, and to their young; and the same birds are said to return annually to the same places, in all their migrations, the several colonies joining as they leave the country, and parting for their usual haunts on their arrival.

Indian Adjutant.

THE INDIAN ADJUTANT (*Ciconia argala*). This bird is ash-coloured, except the belly, and part of the scapulares and the wing coverts, which are white. The head and neck are naked, except a few straggling hairs; and the feathers of the breast are long and pendulous; the bill is very large, and gullet capable of vast extension, so that the bird could easily swallow entire an animal as large as a common wild rabbit. The craw is also very extensile, and hangs like a pouch in front of the breast. The bird altogether is of large size,—measuring nearly six feet in height when it stands, and seven when it stretches the neck; and the wings from tip to tip measure little less than fifteen feet. From the dimensions of their gullets, they have been properly called "wide throats," and also "bone takers," as they swallow animals and parts of animals, bones and all. They do not, however, "grind" the bones with their bills, as has sometimes been stated; and neither the tomia, or cutting edges of the bill, nor the muscles by which they are moved, are adapted for such a purpose, the bones being returned by the gape, after all the digestible part has been removed by the action of the gastric juice.

They are uncouth, and almost, as one would say, "ugly" birds. Their colour is dingy; and the bare head and neck, with the ruff of produced feathers, make them look ragged, as if the plumage of those parts were torn off. Their noise, too, is hoarse and grating, and resembles the roaring of a beast of prey. The length and strength of their legs, however, enable them to march with long strides, and in a stately manner; and when on the wing they appear very large, though they have the swinging flight which is characteristic of all the tribe of herons, cranes, and storks.

In India, they haunt the jungles of the Lower Ganges in the dry season; and as the rains set in they migrate up the valley of the river, being almost as common in Calcutta and the other towns as sparrows are in any part of England. They stand upon the tops of the buildings, walk the streets, and are especially abundant in those parts of the towns which are inhabited by the Hindoos, who pay little attention to cleanliness. Even in the European parts of these towns, there is much food for the adjutants. Animal substances will not keep, especially in the rainy weather, as they do in our northern latitudes; and as the servants are chiefly Hindoos, and their religious prejudices prevent them from eating animal food, the broken meat is thrown into the streets, where it is soon picked up by the adjutants during the day, as well as by the jackalls and dogs during the night. But though the birds are great consumers of offal and carrion, and, in a country where animal substances so soon putrify and taint the air, they are of great service in so doing, yet they do not wholly confine themselves to that description of food. They eat reptiles, many species of which are peculiarly annoying and offensive in those hot countries; they also eat birds, which they sometimes capture in their flight, and they make prize of the smaller quadrupeds, sometimes of domestic cats, the bodies of which, as also those of land tortoises, have been found entire in their craws. The veneration in which these reptile-destroying birds have always been held by rude nations is one of the most conclusive proofs of their value; and though the genius of the Hindoo's religion does not lead him directly to deify the adjutant, as the inhabitants of ancient Egypt did the ibis, yet he regards it as something sacred, and under the especial protection of Heaven. According to the doctrine of metempsychosis, which forms part of the Hindoo faith, these birds are temporary residences for the souls of holy Bramins; and therefore they are not only spared with religious veneration, but considered as invulnerable, in consequence of the sanctity of that *caste*, of whose souls they are, for the time, the special receptacle. The Mussulmans and Christians of the same regions spare it on account of its less saintly and elevated but more useful character of scavenger; and thus, what with religious, what with animal respect, the bird ranges the wide plains and valleys of India at its pleasure, contributing much to the picturesque effect, though little to the beauty of the places which it haunts. When the birds are in a state of quietude on the housetops, they seem as if they were parts of the architecture; and, in the season, an Indian city would look as unlike itself without adjutants, as an English one without chimneys.

But though when there is "nothing going," the adjutants remain at rest on their watch-towers, they keep a vigilant look out, so that offal cannot be cast into the streets, or one of the animals upon which they prey cannot make its appearance, without the bird instantly being on the spot. We have no knowledge of their sense of smell; and indeed the action of that sense in all the tropical birds which feed upon carrion and other tainted substances is a matter of obscurity; but they are exceedingly quick-sighted; and whether when inland or on the shores, few objects of the size or aspect of their prey can stir without their notice. As they partake something of the taste of vultures in the readiness with which they find, and the rapacity with which they devour, carrion, they also agree with those birds in their cowardly nature, and the indisposition they have to attack even a small animal; if it shows an inclination to fight, they scream, or rather roar, elevate their wings, and open their great bills as if they would swallow all before them; but a child may drive them off with a switch; and they avoid the menace of the smallest dog, or even that of a brood hen, though they hesitate not to swallow the chickens if they can do it in the absence of the dam. The quietude of cats, unless when hunting, and their crouching and lurking habit, render them much more manageable prey for these birds, which can pounce upon and swallow them in an instant.

There is another species, of a dull blackish-green colour clouded with greyish ash, and having greenish metallic reflections on the secondary quills, and reddish brown spots on the middle coverts. It is found in Sumatra and Java, and has been named *Ciconia Javanica* by Dr. Horsfield; but its manners, in as far as they may be different from the rest of the genus, are not much known.

The African Adjutant (*Ciconia marabou*).—This species is found on the shores and along the banks of the larger rivers of tropical Africa, shifting its locality with the season, as is the case with the others. This one has been sometimes confounded with the former, from which it does not appear greatly to differ either in aspect or in habits. It is said to be without the white in the wings, and to have the feathers on the breast less produced. It is equally cowardly and voracious, and from the latter propensity it needs no taming, as it will-readily come into towns, or even into houses, if it can get food. Like the others, it swallows animals of considerable size, bones and all; but it does not break the bones, indeed the texture of the bill is not suited for such a purpose. The following account of one in a state of domestication, in the possession of a native chief near Sierra Leone, is in substance from Mr. Smeathman, to whom we are indebted for many other particulars in the Natural History of Africa. The specimen in question stood about five feet in height. It used to be fed in the great hall of the chief's habitation, where he and his guests dined; and so punctual was it to the dinner hour, that it used to plant itself behind his chair before the company arrived. When the dinner was served, it marched about; and if a share, and a pretty large share, was not given it, it made no scruple in helping itself, not to trifles, but substantial fare, for a roast fowl was only a single mouthful. It required, indeed, a good deal of restraint; and the servants had to carry switches for the purpose of beating it away from the meat, and though beaten at one point, it would immediately renew the attempt at another. It is, indeed, a very general habit with those birds which can be tamed through the medium of their rapacious appetites—the chief way, indeed, in which birds can be tamed—to return instantly to that food which they have been beaten for attempting to purloin. They cannot be shamed as a dog can be, neither can they be permanently frightened. The one in question being fed without any other labour than that of swallowing, which is a short and easy process with such width of throat, was accustomed to fly about during the day, or to perch in a grove of cotton trees at the distance of nearly two miles. But, even from that distance, it could see when dinner was serving; and though it did not begin its flight till the said dishes were carried through the court, it was in the hall before all the dinner was in order. Smeathman farther describes these birds as standing full seven feet in height, and as appearing like canoes on the smooth water, when moving along the banks in lines with extended wings. At other times, when feeding on the shores, they had the appearance of human beings engaged in picking up shell-fish, which is no uncommon employment of the women and children in tropical countries.

American Adjutant (*Ciconia maguari*).—This is a much smaller species than the Asiatic or the African, being only about half the length, and rather less than half as much in the extent of the wings. The neck and head are feathered, except a small portion round the eyes. The general plumage in the mature state is white, with the quills and upper tail coverts dusky green inclining to black. It bears considerable resemblance to the common white stork of the old continent, only the bill is ash-coloured instead of red, as in that. It is found chiefly in the central parts of South America, migrating by the valley of La Plata from the central heights between the sources of that river and the branches of the Amazon, which are inundated during the rains, and the marshy shores in the southern parts of the Pampas. It has sometimes been confounded with the *Jaribus*, which inhabit the marshy grounds nearer the shores of the Caribbean Sea. See articles Ciconia and Stork.

ADNA (Leach, Lamarck). This genus of shells was constituted by Dr. Leach, and has been adopted by Lamarck, and some other naturalists; it nearly approximates to the balani. The shell is cup-shaped, sessile, composed of one part, with a lozenge-shaped aperture, closed by four valves or detached pieces; it is slightly ribbed externally; the operculum transversely streaked; and it is of a fine rose colour. The English adna is found on the coast of Devonshire, attached particularly to the *Coryophillia Anglica*.

ADONIS (Linnæus). A showy genus of plants comprising ten species of annual and perennial hardy herbs, cultivated for their flowers. Linnæan class and order, *Polyandria Polygynia;* Natural order, *Ranunculaceæ.* From the natural order, however, it is distinguishable by wanting the nectariferous claw at the base of each petal; and from the other genera by the many dry sharp pointed grains of its fruit. The *A. autumnalis* is found, sometimes in great plenty, in corn-fields, and called by country people the pheasant's eye.

ADOXA. A name applied to a genus of plants belonging to the natural family *Saxifrageæ* or *Saxifrage Tribe;* and to the class *Octandria*, order *Tetragynia;* of the Linnæan system. The name is derived from two Greek words, α, without, and δοξα, glory, in reference to the humble and unassuming growth of the plant. Generic characters: calyx, divided into five segments; corolla, inserted above the germen, and divided into four or five segments; fruit, a four or five celled berry. The only known species is the *Adoxa Moschatellina*, or *Tuberous Moschatell*, a native of Great Britain, found in woods and shady places, and sometimes even growing on the tops of the Highland mountains. It is a very delicate plant. The flowers in the evening are said to emit a musky smell.

ADULARIA. This mineral, which is better known by lapidaries as *moonstone*, was first described by Professor Pini, of Milan. He named it Adularia Felspar, in the belief that the mountain on which he had collected it was named *Adula;* but the truth is, the mountain of Adula where he procured it is not situated near St. Gothard, but in the Grisons.

The variety of adularia which exhibits a bluish pearly light is much valued by jewellers. It is cut in a low oval form, and in such a manner as to present the pearly spot in the centre of the gem; it is set in rings or brooches, with rubies and emeralds, with which it forms an agreeable contrast. Sometimes ring-stones of it are set round with diamonds, and its pearly light forms a striking and agreeable contrast with the lustre and colours of that gem. The finest specimens are brought from Ceylon; but even there, perfect stones are rare.

Another variety of adularia, found in Siberia, is known to jewellers under the name of *sunstone.* It is of a yellowish-grey colour, and numberless golden spots appear distributed throughout its whole substance. The decomposition of light which produces this singular optical illusion arises either from minute fissures, or the irregular cleavage of the mineral.

ÆCIDIUM (Persoon). A genus of plants belonging to the natural family of *Fungi*, or the mush-

ÆCIDIUM CANCELLATUM; *a*, a leaf upon which it is seen growing of the natural size; *b*, peridia, magnified.

room tribe, and to the class *Cryptogamia* of Linnæus. This fungus consists of small membranous sacs or protuberances, which are found parasitic on the leaves, bark, fruit, &c., of several plants; such as the fir, violet, gooseberry, barberry, dandelion, hawthorn, nettle, primrose, &c. The membrane forming the sac has received the name of Peridium. It pierces the bark or epidermis of the leaves, and encloses very minute dust-like seeds or sporles, which are ultimately discharged by an opening in its side or summit. In consequence of the seeds being contained in a membrane, the genus has been referred to a division of the *fungi* which has been denominated Angiocarpi. There are upwards of thirty known species of the genus, and they receive their names from the plants on which they are found. Link has divided this genus into three sub-genera, the *Æcidium*, properly so called, the *Ræstelia* and *Peridernium.* The *Æ. cancellatum* here represented, belongs to the second of those divisions. It is often found on the leaves of pear trees. To the third division belongs the *Æcidium pini*, remarkable for being the largest species, and for growing, not upon the leaves, but upon the bark of the pine tree. They vary in colour; the species which grow on the gooseberry and barberry leaves are red, that found on the Scotch fir is yellow, and that on the meadow-rue bright orange. The Æcidia cause considerable deformities in the plants on which they grow, and some of them are decidedly injurious. The gooseberry æcidium is said frequently to destroy the young fruit of that plant; and the species found on the barberry has been stated, though perhaps erroneously, to be hurtful to corn growing near it.

ÆGERIEDÆ. A family of insects belonging to the order *Lepidoptera*, or those which have the wings covered with scales, or more strictly speaking with minute feathers, and to the division of that order which are *crepuscular*, that is who seek their food, or otherwise appear, chiefly in the twilight. This family are less crepuscular in their habits than most of the division; for though they do not come abroad at midday they are seldom found on the wing after night begins to close in. They bear fully as much resemblance to bees, hornets, or wasps as to the moths, or even to the *Sphingidæ* with which they were confounded by Linnæus; but though in appearance they resemble those insects, they have none of their habits, and indeed none of the characters of the order to which these belong. In the caterpillar state they prey upon the smaller and more succulent twigs of plants, more especially of the currant and other fruit-bearing bushes, and hence they are some annoyance to gardeners. They are popularly called hornets, or sphynges, and another epithet is usually added, expressive of the better-known insect which they most nearly resemble, as the "bee," the "wasp," and that which is troublesome to growers of small fruit is called the "currant hornet sphynx," from the plant which it chiefly infests. The last species (*Æ. tipuliformis*) is the most common in Britain.

They are active swift-flying insects, and rest with the wings stretched out horizontally, and the brush which terminates their abdomen spread out. One genus (*Ægeria*) have the antennæ as long as the body; the other genus (*Trochilium*) have theirs short and stout. Of the first genus we have two species which are indigenous to this country. Several other species are found on the continent, and also in India, South America, and New Holland.

The genus Trochilium consists of several species, of which three are British, which are found to inhabit the poplar and lime trees about the end of June. The caterpillar of the hornet moth (*T. apiformis*) is whitish, with an obscure line down the back; head large and brown, and it feeds on the wood and shoots of the above trees. This beautiful and interesting insect is found occasionally very early in the morning on lime trees, near Wanstead in Kent.

The second species (*T. Craboniformis*), the lunar hornet moth, inhabits the poplar and sallow. The Caterpillar is of a whitish colour, with a brown spot on several of the segments near the legs; it feeds under the bark of the sallow. Stephens saw them in profusion flying heavily along on the south-west border of Dareuth Wood in Kent, in the beginning of July 1817.

ÆGIPHILA (Jussieu). A family consisting of seven species of hot-house ever-green shrubs, indigenous to the West India islands. Linnæan class and order, *Tetrandria Monogynia.* Natural order, *Verbenaceæ.* Generic character: calyx of four teeth; corolla, the tube longer than the calyx, the limb in four open divisions, carrying four equal projecting stamens. Style deeply divided. Fruit, a pod, or capsule of four places, and seeds.

ÆSCHYNOMENE. Hot-house annuals, and trees mostly natives of warm climates. Linnæan class and order, *Diadelphia Decandria.* Natural order, *Leguminosa.* There are eleven species known, some of them have exceedingly splendid flowers.

ÆSCULUS (The Horse Chestnut). A term derived from the Latin word *esca*, food; and applied to a genus of plants belonging to the natural family *Hippocastaneæ*, and to the class *Heptandria*, order *Monogynia*, of the Linnæan system.

Generic characters: calyx, bell-shaped; petals, four or five, with an ovate limb; stamens, having their filaments curved inwards; capsules, rough and prickly; leaflets, nearly sessile. The five species known are hardy trees, remarkable in general for the beauty of their foliage and flowers. Of these the æsculus hippocastanum, or common horse-chestnut, is familiar to every one. The native country of this tree is yet imperfectly known. It is generally said to be indigenous in the northern parts of India, but it has not been found by the most recent travellers in those parts. It is said to have been brought to Constantinople in 1550, and to have been afterwards introduced by Clusius into Austria, whence it has been spread over Europe, and has been long cultivated, and thrives well in Britain. It is clothed with dense foliage, and sends out branches to a great width. Its large cones of white flowers, spotted with red, render it very ornamental in avenues and pleasure-grounds. But it is never cultivated for the purpose of furnishing timber. The young branches are said to grow with amazing rapidity, acquiring an inch in length in the course of twenty-four hours. The fruit, dried and powdered, has been used as a medicinal snuff for the cure of headach and sore eyes. A decoction or infusion of the fruit has also been drawn up the nostrils for a similar purpose. The seeds are large and farinaceous, and have been used as food for animals. The bark is bitter and astringent, and has been used, chiefly on the Continent, as a substitute for Peruvian bark. It has been used successfully in intermittent and continued fever, as well as mortification. The bark may be given in the form of powder, in doses of thirty or sixty grains; or in the form of extract, in doses of five or eight grains. According to the French chemist Pelletier, it does not contain an active alkaline principle, like the Peruvian bark. Starch has been obtained in considerable quantity from the horse-chestnut. The tree also contains so much potass that it may be used in the place of soap.

The horse-chestnut thrives best in rich light earth, but it will grow even in sandy or gravelly soil. A variety is cultivated with striped leaves.

Horse Chestnut (*ÆsculusHippocastanum*). *a*, Flower, showing the seven stamens and single pistil; *b*, the fruit.

Æsculus Ohioensis. The American horse-chestnut, or Ohio buck-eye, is found abundantly on the banks of the Ohio, between Pittsburgh and Marietta. It is a tree of moderate growth, generally attaining the height of ten or twelve feet; sometimes, however, it is thirty or thirty-five feet high, with a diameter of twelve or fifteen inches. The leaves are large, being nine or ten inches long and six or eight broad. The flowers are very numerous, of a white colour, and grow in clusters. The fruit is only half the size of the common chesnut. The *æsculus glabra*, or smooth-leaved horse-chestnut, and the *æsculus pallida*, or pale-flowered horse-chestnut, are also natives of North America, and are found in Virginia, Pennsylvania, and Kentucky. The only other species, the *æsculus rubicunda*, or carnea, ruddy horse-chestnut, is distinguished from the rest by its beautiful scarlet flowers, and is said by some to be a native of North America, but this has not been accurately ascertained.

An allied genus, which has received the name of *Pavia*, and the species of which are very common in America, where they are known under the name of buck-eye, has often been confounded with the horse-chestnut. The smoothness of the capsules, or seed-vessels of the pavia, is, however, an excellent distinguishing character.

ÆSTIVATION, or *Præfloration*, is a term illustrative of the mode in which the various parts of a flower are arranged when in bud or previous to expansion. Thus we have the *imbricated æstivation*, when the divisions of the corolla, called petals, cover each other partially, as in the rose, pear, and cherry, before expansion; and the *puckered æstivation*, when the petals are folded in different directions, as in the poppy. The æstivation is generally similar in plants belonging to the same natural family.

ÆTEA (Lamouroux). A polypidom of the first order, and first class, which contains all such as are celluliferous, and whose polypi are found in shelly or non-irritable cells. This genus appears to unite the first order with the second, having a rampant stem from which the cells issue; but it nevertheless differs essentially in the form of its undulated stem, which is branched and knotted at stated distances, and also in the form of its cells; it is therefore more properly an intermediate species. The cells are solitary, opaque, tubular, in the form of clubs, and arched, opening at the side. At present, only one species of this genus is known; and it is very common on marine plants in the European seas. They embellish these vegetables by the pearly whiteness of their cells, which forms a beautiful contrast with the brilliant red hue of the plocamis, on which the aëtea anguina is frequently found; they appear like many clefted leaves of red coral, delicately clothed on all parts with fine hairs of a silvery white lustre. They are found both in the European and Australian seas.

ÆTHIONEMA (R. Brown). A genus consisting of four species of European annual herbs. Linnæan class and order, *Tetradynamia*. Natural order, *Cruciferæ*. Generic character: calyx, petals unequal; filaments longer than the stamens, often united; silicule hollowed, formed of two keel-like valves, two-celled, containing one or two seeds.

ÆTHUSA. A genus of plants belonging to the umbelliferous family, and containing a few species; one of which, the *Æthusa Cynapium*, common fool's parsley, lesser hemlock, or dog-poison, is a native of Great Britain.

The name Æthusa is derived from the Greek word *aitho*, to burn, on account of the acrid properties of the plant. The *Æthusa Cynapium* is common in fields and in gardens. It has a nauseous smell, and possesses deleterious properties. From being gathered in place of garden parsley, or along with it, it has given rise to serious consequences. It can, however, be easily distinguished, when in flower, from parsley and all umbelliferous plants, by its involucrum, which is formed by three long drooping leaves, all on one side. When not in flower, the dark glistening appearance of the under surface of the leaves, and the nauseous smell they exhale, are sufficient to distinguish it from parsley. The plant is said to contain a peculiar alkali, called cynopia.

In animals this plant causes convulsions, stupor, and death, in a short time. In man, the symptoms produced in the fatal cases have been sickness, vomiting, headach, giddiness, a tendency to sleep, a sensation of heat in the stomach and throat, with difficulty of breathing and numbness of the limbs.

AFFECTIONS OF ANIMALS. Natural history affords few subjects more interesting than the one we are now about to examine. No one can attend much to animals without seeing in them instances of affections, which, as far as they go, would do honour to the human race. The dog, the elephant, the horse, all animals that have been domesticated, afford innumerable instances of affection equally strong and enduring, and far more apparently free from selfishness than that which is shown by the most devoted of mankind; and there is not the least doubt that, if the method of doing it were known, and there were sufficient inducements to the practice of it, all animals could be tamed, and made to render to man the same complete and ready obedience as is rendered by the spaniel. Instances might very easily be brought from the whole of the animated creation. The common seal has sometimes been made a very attached and sportive companion, and taught to keep watch like a dog in the absence of its masters; reptiles and fishes have come to the whistle of their trainers, not merely to be fed, but to be fondled, and every schoolboy has heard of the captive and his companion spider. Similar affections have been observed between animal and animal, not only in those of the same species, but where, in general, and in accordance with the common habit, the one species regularly destroys, or makes prey of, the other. The cat and the mouse, the hawk and the sparrow, and other animals that have what is usually called the same natural antipathy, have lived together in the same cage, with the most perfect harmony. The attachments which animals in the wild state show for each other are every way as striking, more so, perhaps, because they take place without the application of human instruction. The affection of all animals, the females especially, for their young, when it is the habit of the species that the young shall be for some time dependent on the mother for food or for protection; the affection for each other of the sexes, in such as remain together for life, and which are just as striking all the year round as during the breeding-time; the affections of gregarious animals for their own herd, and those of the analogous gregarious tribes for each other, are all very remarkable; and they may all perhaps be regarded as more pure and free from selfish considerations than the associations that are formed by the human race. The male eagle does not show his affection for the female, through summer sun and winter storm, because of the portion which she brought him at the time of their union; neither are her affections in any way bought or captivated by the certainty of a living or the pomp of an establishment.

The principles of those animal affections for each other, for different species, for certain places rather than others, though both in our judgment appear equally fitted for them, for mankind generally, or for apparently selected individuals of the human race, are all obscure and unknown to us farther than as we can infer them from the facts; and it is to be feared that we, in most instances, draw those inferences, as if we had been observing men and not the other animals.

There are some curious distinctions between the males of monogamous and polygamous animals, to which we can find fancied resemblances in the conduct of mankind. Animals, which associate in pairs only, seldom, if ever, fight battles of gallantry. Like good husbands and housewives they take care of the interests of their own family, and often keep intruders from that part of the country which they select as their abode; but they do not intermeddle with the domestic concerns of each other, or fight for mere gallantry: indeed they seldom fight at all. The lion and the eagle are professional butchers, but they are, in no sense of the word, soldiers of honour; they exert their great powers solely to kill, and kill solely to eat the slain. If, on the other hand, the males are polygamous, they are almost invariably pugnacious, some of them at all seasons, and all of them in the breeding season. Bulls, rams, cocks, grouse, and indeed all polygamous animals with which we are acquainted, are valorous in the season of excitement, even though, at other times, they seem the veriest cravens in the world. There is a trace, and a pretty obvious trace, of the same conduct in man, though upon that particular branch of the question it is not so expressly said that either the one or the other acts from the judgment of reason. Yet, in that affection of animals, they show as much conduct as in any other; and the stratagems to which they resort in their combats of gallantry with each other, show quite as much plan and purpose upon their part as any other of their habits.

That not the affections of animals merely, but the whole of their conduct and economy, are wonderful beyond our admiration, and perfectly beyond our imitating, must be admitted; but they are not more so than the economy of plants, or the properties of inorganic matter; and, were it not that we are unable to trace in the substances belonging to the vegetable or the mineral kingdom, any of those resemblances in form and in mode of action to the material part of ourselves which we can trace in animals, there is little doubt that we would also attribute reason to them, so prone are we to make ourselves the standard in all our judgments.

But, if we carefully examine the matter, we are, in all cases, able to discover, that the principles upon which an animal acts, even in those displays of its habits, whether in wild nature or under human training, to which we give the name of affections, are nothing more than the common principles of organic matter, namely, those of yielding wholly to present circumstances, without any relation to the past, or any assistance from it. Their lives pass away without leaving any trace or any lesson that can be useful to them as a guide upon future occasions, or transmitted from one generation to another. As it is most truly and emphatically said, "their memories perish;" for if the individual could profit by experience as man profits, it is not possible to doubt that the wisdom, which is transmissible from day to day, could not also be transmittable from generation to generation. Yet there is no instance of any one race of animals which is a jot wiser, or a jot more foolish, than in the times of its remotest ancestry. Under the same circumstances of climate, soil, seasons, food, weather, and all else by which an animal in a state of nature can be affected, the animal is similar in all ages, just as the plant or the mineral, under circumstances exactly the same, is exactly similar.

That it can be turned and tutored, even to the performance of those feats which we look upon as prodigies, is no proof of reason in the animal, but rather the reverse, because it shows the perfect readiness with which it obeys the circumstances in which it is placed. The training is not conducted upon the principles of reason, and yet the animals to which we are most ready to concede that "inferior degree of reason," are the very same species which we can train most easily and completely. That we can train some species more readily than others proves nothing in favour either of the reason or the superior tractability of the animals; it merely proves that we are better acquainted with their physical wants, to which their physical organisation is obedient. But, as the training is for our purposes, and not for any purpose formed by the trained animal, we must see, that, if the animal had reason and purpose, it would resist our training, and cease to obey those circumstances to which we have, from the knowledge of its habits, taught it obedience. If there were any experience of the past, and any interpretation of the future, in the animal, it would certainly rebel. If the horse, which had been driven and flogged in harness yesterday, pinched with hunger and pelted with rain, then shut up for the night in a close and pestilential cellar, with little to eat, and that little not the most wholesome, had any memory of that treatment—and if he had, he would remember that it began with the harnessing—he would resist to the death rather than be yoked again to-day. Horses do sometimes rebel; but it is momentary, like all their actions, and begins and ends with the peculiar circumstance or combination of circumstances which forms its cause.

Whether we consider the affections of animals as the result of chemical and mechanical principles applicable both to living matter and to dead, or as the result of reason and judgment on the part of the animals, we encounter difficulties of no ordinary kind. The physical theory puts an end to animal life altogether as a portion of creation which man can rationally know and usefully turn to account; and the hypothesis of reason not only shelters the animal from our knowledge and dominion, but reduces us to its level; to the peril, nay to the certain destruction, of moral obligation and eternal hope; for these are so linked together that the one of them cannot exist without the other.

But when we consider, as nature itself would point out to us, if we would keep silence till we have used our eyes, that the animal organisation merely stamps a new character upon matter—a character which varies with the species of organisation; and which, while it wants the operation of that part of the laws of the material creation which determines the powers of dead matter, becomes far more sensible to other parts of the same laws; then we have only to find out what these laws are, and how they operate, in order to bring the energies of animal life as completely within our knowledge and dominion as we do inanimate matter.

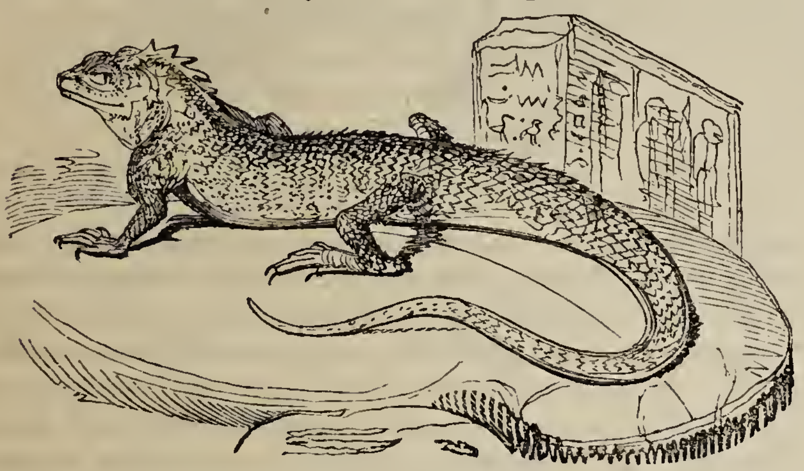
Viewing the subject in this light greatly extends the field both of study and of usefulness, makes them both wide as the world, and varied as all that it contains. At the same time it shows us that what has been already accomplished is a mere nothing compared with what yet remains to be done. Take the list of any of the classes of animals which have been seen and named, and their shapes, sizes, and colours in part described; and mark how very few have been turned to useful purposes, even as so much dead matter. Then turn to the few that have been domesticated, and their affections in part ascertained and turned to account, and mark what services they have rendered to man. The ox, the horse, the sheep, the dog, the rein-deer, the camel, the elephant: these and perhaps not as many more are the whole of the mammalia that have been so studied as to be turned to use *when living*; and yet they have borne a most important part, not only in the improvement of the soil, but in producing and maintaining the civilisation of man himself. But all animals have their peculiar affection, and those affections have only to be studied in order to their being added to the animals on the list of our useful servants.

But by thinking and judging of them as if they were human beings, reasoning from the past, forming plans for the future, and acting by other laws than those of organised matter, we mar the heritage which God has given us, neglect or destroy the servants which he has assigned us. Thus, we often have to toil when we might be superintending and admiring;

and because we elevate the animals to the rank of rational and reflective beings, we are often under the necessity of degrading ourselves to that of mere machines. Animals have no previously formed plans to be overturned, and no prejudices to be got the better of. The causes of their affections are all contemporaneous with the affection itself; and they are all physical and open to our knowledge; so that, if we can by any means bring them about, we can command the affection of the animal and turn it to use, as certainly as we can model clay, or kindle a fire, and melt a metal.

AFRICAN LILY (Agapanthus). A half-bulbous, stemmed, green-house, herbaceous perennial. Linnæan class and order, *Hexandria Monogynia.* Natural order, *Hemerocallideæ.* Generic character: calyx, petaloide and tubular at the base, funnel-shaped, in six divisions, somewhat irregular. Stamens six, declining. Style one. This is one of the most beautiful of the lily tribe. With a little protection during winter it succeeds well in the open air, if placed under a south wall; there are three species.

AGAMA, a very numerous genus of reptiles,



Helmeted Agama.

belonging to the order *Sauria* and the family *Iguana,*—to which the reader is referred for the more general characters. They have no common English name, and the local names given to the different species are neither very appropriate nor are they useful. They all come under the vulgar name of lizards, and so far as they were known in his time they belong to the genus *Lacerta* of Linnæus. Since then, enough has been added to their history to show that his arrangement was wrong, but not enough to put it to rights.

The whole history of reptiles is, indeed, in a very imperfect and even chaotic state; and as the discoveries are only additions of species or varieties, of whose habits and economy very little, if indeed any thing, is known, they tend to make more confusion. There are, in most large collections, many species that are not even named, while, of most of those that have names, the characters are founded on the mere shape of the parts, without any reference to their uses in the economy of the animals. This is unavoidable, inasmuch as we know by far too little of the relation between the structure and the habits of any one species to enable us to proceed by analogy.

In the other classes of vertebrated animals, the case is different. When we meet with a new species of the mammalia or the birds, we not only know where to place it in the system, but from its organic structure we can tell many of its habits, and generally also its haunt,—can know, in short, to what part of nature it belongs, and what function it performs in its general operations,—can state with tolerable exactness over what part of nature it is set, to keep down the redundance by its feeding, and what is set over it, to keep down its redundance. Of the habits of fishes we know much less; but we know enough to enable us to guess at the habit from the form. But the reptiles are quite a puzzle. The four orders of them are so different, not merely in their external powers, but in the fundamental principles of their systems, that they might be made four distinct classes. A frog and a snake are, for instance, in many respects more unlike each other than one of the mammalia and a bird.

Thus, the popular natural history of reptiles is, of necessity, confined to the individual instances of those species which are popularly known; for though a generalisation, grounded upon museum specimens, may be of much use to those who are occupied about them, and may form the foundation according to which knowledge, when it is obtained, may be arranged; yet it cannot be made instructive, or even amusing to ordinary readers. For these reasons, our notices of reptiles, excepting the well-known species, will be more brief than those of the other vertebrated animals. We have stated the reasons in order that the general ignorance of zoologists, in which we of course partake, may not be charged against us individually; we have stated them thus early, because the articles Reptile and Sauria, come late in the alphabetical arrangement; and having done so, we shall briefly enumerate the known characters of the agamas.

Generally speaking, they are rather uncouth, and even somewhat repulsive in their appearance. Their heads are thick and round, or rather ear-shaped, being much enlarged anteriorly; and the throat, and sometimes part of the body, is capable of being inflated to a considerable degree. The body is short, generally thick in proportion to the entire length of the animal; and the tail is, in general, long and round, though in some species it is compressed or flattened laterally. They are wholly covered with small scales, of a lozenge or else an hexagonal shape. These appear reticulated, but the posterior edges are free, and when the skin is inflated they stand up like small spines. The legs are rather slender for the size of the animals; and the toes are five on each foot, all free and armed with claws a little hooked. The toe next to that which answers to the thumb, (though it does not act as such) is generally the longest; and in some of the species it, and the one next it, are much longer than the rest. These, like the rest of the iguana family, are easily distinguished from the lizards, by the structure of the tongue, and the arrangement of the scales on their bodies. The tongue of the lizards is long, slender, extensible, and divided into two filaments at the tip; while that of the agamas is short, thick, fleshy, not extensible, and merely a little cleft at the extremity. The scales on the lizards are arranged in parallel rows or bands at right angles to the axis of the animal, while, on the agamas, they are reticulated or impriential. The scales on the tail again distinguish them from the nearly allied species, Stellio, in which the scales are verticellate, or arranged in rows round the tail, each scale with a spine more or less projecting, and each ring forming a sort of star, or *stellar* arrangement of points; while, in the agamas, the scales on the tail are imbricated or reticulated, as well as those on the body. The scales of the agamas are carinated, and often produced into spines of considerable length, especially on the hinder part of the head. The differences of the scales, which form the chief means of distinction between the agamas and the stellios, are of small value, inasmuch as we do not know the use of the difference in the economy of the animals; but the difference between the family and that of the lizards, in the structure of the tongue, is of importance, as indicative of a different mode of feeding; as the absence of teeth in the palate of the agamas, and their presence in the iguanas, is also a good distinctive character.

The purpose which the inflation of the body may serve in the economy of the animals, whether it enables them to capture insects by beating them down with a current of air, as some fishes are said to do by a discharge of water from the mouth, is not known; and, indeed, the greater part of the history of the race is as obscure as the name, which hangs somewhat in doubt between Αγαμαι, "to be wondered at," and Αγαμος, "unmarried;" but which, in all probability, has no connexion either with the one or the other.

But, whatever function those reptiles perform must be an important one in the general economy of nature, as they are numerous in species, abundant as individuals, and very generally distributed over the warmer parts of the world—in America, in Africa, in Asia, and in New Holland. Many of them are found on the ground only, where they frequent dry and stony places; but there are others which climb with great readiness, and seek their food among the branches of trees. The former have the toes comparatively short: the latter have them much produced. Their food is supposed to consist of insects and other small animals, and also vegetable substances in some of the species.

A list of the sub-genera and species into which the genus has been divided (very differently by different authors) would, for the reasons above stated, be inconsistent with the plan of this work. All of them have the power of inflating the body to some extent, and the inflation is often accompanied by changes of colour, similar to those that have long been known in the cameleon. The greater part of the skin appears to consist of gelatine, which has the power of decomposing light, a power which increases with the thinness of the pellicles, and the convexity of their surface; and thus, as any portion alters its form, all the prismatic colours may in succession be given out by it. This property is of course the most perfect in those that have the finest scales, of which there is a remarkable instance in the variable Agama of Egypt (*Trapelus Ægypticus* of Cuvier). It is a small species, destitute of scales when young; and having them small, scattered, and spineless in the adult state.

One of the most remarkable, as well as most beautiful, species is the blue "helmeted iguana" of the south-east of Asia, known as the cameleon in that part of the world. The body and tail, which is very long, are covered with small reticulated scales; and there are two rows of spurious scales behind the openings of the ears, which form an erectable crest. The colour is a beautiful blue, with transverse white bands on the sides; and the changes are to green and purple; but they are very limited, and reflections rather than any thing else. The eggs of this species are spindle shaped, or much produced and pointed at both ends.

This must suffice as a specimen of this very plentiful genus of living creatures of the tropical climates, a genus of which the history, if once satisfactorily made out, would perhaps throw considerable light upon other points in natural history. None of them are sea animals, and they do not inhabit those parts of the different continents which nearly approach each other, neither could they easily pass from the one to the other upon the sea; and yet in the eastern and western continent and also in New Holland, they resemble each other much more than the mammalia, or even the birds.

AGAMI (Psophia, *Linnæus.*) A very interesting genus of birds belonging to the *gruidæ*, or natural

Golden-breasted Agami.

family of cranes, at least sometimes so classed, and certainly partaking of many of the characters of that family, but combining with them also some of the characters of the *gallinidæ*, and also of the running birds. It is a peculiar genus, and cannot easly be brought into any part of a regular system of Ornithology. It bears some resemblance to the cranes, the pheasants, and the bustards; and yet it belongs to neither. They have one habit of the crane family, that of sleeping upon one leg, with the other drawn up so as not to be visible, and the head bent back between the shoulders. They have also enlargements at the bronchial end of the træchea, by which the peculiar sound afterwards to be noticed appears to be produced.

The generic characters are: the bill short, conical, curved, bent at the tip, and the upper mandible larger than the under; the nasal grooves dilated; the nostrils near the middle of the bill, wide, oblique, curved in front, and closed behind by a naked membrane. The legs long and slender; the tibiæ naked for some distance above the articulations of the tarsi; the toes of moderate length; the outer one in front free, the middle and inner united at their bases; the hind toe articulated on the same plane with the others; the claws not much produced, but sharper and more crooked than those of the gallinidæ. The wings are short and concave, and the bird not adapted for long flights. There is but one known species, *A. crepitans*, the trumpeter, or golden-breasted agami, a native of the forests of tropical America. They are very handsome and very interesting birds; abundant in those peculiar localities which they inhabit, easily tamed and very much attached to man when domesticated, they are very prolific, and their flesh is excellent.

The general plumage is black; the back gray, the breast glossy green with bronze and gold reflections, and a portion of skin round the eyes naked, and of a bright vermillion red, especially during the breeding season. The feathers on the head are downy, those on the lower part of the neck imbricated like scales; on the shoulders pendulous, silky and rust-coloured; the scapular feathers, properly so called, being very long, and hanging over the closed wing. The tail is very short, and consists of twelve feathers. The length of the bird is from twenty-two inches to two feet; but as the great length of the neck compensates for the shortness of the tail, the body is not longer than that of the common fowl, though its form is rather that of the pheasant. The legs are of a greenish lead colour, similar to many of those of the wading or water birds; and when the rains come there is no doubt that the birds are compelled to wade, as they are feeders on the ground; but at other seasons they do not frequent watery places, but rather the openings in the dry woods. They are social, and always proceed in considerable flocks. These flocks are so much attached to each other that they will not separate at the report of a musket, so that when the hunters come upon a flock they are enabled to kill numbers in a short time. They seldom "flush," or take the wing; but when pursued seek to make their escape by running, which they do with great velocity. They are, however, bold birds, and stand resolutely upon the defensive, and are also bold in their attacks, especially during the nesting time.

The broods are three, or at least two, in the course of the year; the eggs varying from two to sixteen, of a light greenish cast, and rather larger than those of the common hen, and much rounder; there is no formal nest, the female merely scrapes a little hollow in the dry ground. The young are capable of running very soon after they come out of the shell; but it is a long time ere they acquire their plumage, as is the case with the bustards. The common cry of the male is not unlike that of the turkey-cock when he wails; but they have another and a peculiar one, on account of which they have obtained the popular epithet of trumpeter, and the specific appellation of *crepitans*. This sound resembles that made by blasts of air in a trumpet, so brief, that, instead of bringing the metal to its tone, they resemble a succession of explosions.

The agami appears to court society rather than shun it, and in some parts of South America domesticated ones answer some of the purposes of dogs. They lead the poultry, and even guide the sheep to or from the pasture; and in the house they are said to be as fond of caresses and as jealous of rivals as the canine race. On foot they are as fleet as an ordinary hound, and though they do not fly far or much, they can, on account of the concavity of their wings, ascend easily into the air, out of the reach of terrestrial foes. They are highly ornamental in their native woods, and also in all places where they have been domesticated; and though they are natives of tropical climates, it is not at all improbable that they might be introduced into England. The flesh of the old birds is nearly equal in flavour to that of the gallinæ, but it is rather dry and tough. The young are, however, very juicy, and the rate at which they multiply would render them valuable in an economical point of view.

AGARIC, or Rock Milk, is an earthy body of a white colour. Specimens are found in various parts of Great Britain; but in much larger quantities in the fissures of limestone mountains in Switzerland, Austria, Salzburg, &c. In Switzerland, where it is particularly abundant, it is used for whitening the walls of houses. The agaric mineral is formed by water passing over and through limestone rocks, and afterwards depositing on their surface the calcareous earth it had dissolved in its course.

Its name is derived from the circumstance of its sometimes assuming the appearance of a vegetable fungus.

AGARICIA (Lamarck). A fixed polypidom, distinguished by subfoliaceous expansions, the upper surface only having stelliferous grooves; the stars are lamellous, sessile, and in rows generally imperfect and difficult to distinguish. The animals are unknown, with the exception of a single species observed by Lesueur in the Antilles; it presents a lengthened opening plaited inwardly, and without apparent tentacules, fringed with a yellow circle, surrounded by eight points of the same colour; the under part is of a fine purple, becoming reddish towards the side.

Seven species are described by Lamarck. They form one of those elegant natural structures well known by the name of madrepore.

AGARICUS (The Mushroom Family). A genus of plants belonging to the *Cryptogamia* of Linnæus, and to the natural order of *Fungi*. This is by far the most numerous genus of plants known; Fries having actually examined and described between eight and nine hundred distinct species, without trusting in any one instance to the authority of other botanists.

AGARICUS MUSCARIUS; *a*, the hollow stipes or stem; *b*, the pileus or cap; *c*, the lamella or gills; *d*, the volva or wrapper; *e*, the velum or veil.

They are in general plants remarkable for their quick growth and rapid decay, some of the species going through all their stages in the short space of four-and-twenty hours; others, however, are formed of tougher materials, and are upwards of a month before they attain their perfect growth; while the greater number last ten or twelve days. In their decay they emit a disagreeable fœtid odour, resembling that arising from putrid animal matter, which substance they are found from analysis strongly to resemble, in this state they afford nourishment to the larvæ of numerous species of insects.

The agarics are found to grow in almost any soil, that of dry and stony places excepted; they are found more particularly in moist and shady woods, where the decayed vegetable matter serves to nourish them; in meadows, on dunghills, on the trunks of trees, especially upon decayed wood; and some species are found to grow luxuriantly in dark mines and caves, where the light of day never penetrates.

The plants of this genus embrace qualities of very opposite characters. Some of them afford wholesome nourishment, such as the *A. campestris*, which form an article of luxury for the table: some of the other species form an important article of food to the Russian peasant; others, however, and indeed by far the greater number, are either poisonous or nauseous in the extreme. Among the natives of Kamschatka, the *A. muscarius* is used as an intoxicating liquor, which produces strong convulsions in all the limbs of the person drinking it, followed by that kind of raving which attends a burning fever. The species that are found useful to man as food will be more particularly treated of under MUSHROOM.

Among the species described by Fries we find very few which are not indigenous to Europe; those which are not so being either of Siberia and the northern parts of Asia, or of North America: in all the colder regions they are found in great abundance, becoming more rare as we approach the equator.

Linnæus and other botanists, particularly Persoon and Fries, have arranged this genus in numerous sub-genera; Fries has made thirty-six of these, in which he considers the leaves of the first importance; the presence of the membrane which covers the leaflets, and the colour of the seed on the contrary, he considers of only secondary importance.

AGATE. An ornamental stone, classed by mineralogists amongst the earthy minerals. The northern part of our island furnishes very beautiful examples of the agate—hence their name of Scotch pebbles.

Moss Agate.

The agate is said to have derived its name from the Achates, a river in Sicily. Its chemical character is principally marked by the large quantity of silica which it contains. The same stone sometimes contains parts of different degrees of translucency, and of various shades of colour; and the endless combinations of these produce the beautiful and singular figures for which, together with the high polish they are capable of receiving, agates are prized as ornamental stones. Although occasionally found in other rocks, they are most usually met with in that variety of the trap rocks called Amygdaloid or Mandelstein, forming detached rounded nodules, not cemented to the base or mass of the rock, but easily separable from it, and having generally a thin layer of green earth interposed, and a rough irregular exterior. In other cases the agate runs in veins for a considerable distance.

There are many varieties of the agate; but one of the most beautiful is the moss agate, in which jasper of various colours, as brown, yellow, and red, appears, as it were, floating in a basis of chalcedony. It exactly resembles moss, and when its arborisations are distinct, it has a very beautiful appearance. The engraving above is copied from a specimen in the collection of the British Museum.

This stone is sometimes cut into snuff-boxes and ring-stones: the larger masses are hollowed into mortars, and sometimes cut into elegant vases. It was much prized by the ancients, who have left us several fine works of art formed of this stone. In the royal cabinet at Dresden, there are some beautiful vases of agate. At Oberstein on the Rhine, the amygdaloid rocks are regularly quarried for the agates they contain, and these are cut and polished, and exported to other countries. The manufacture of the agates of this country, is carried on to a very considerable extent. See JASPER.

AGATHOSMA (Willdenow). A genus of above twenty species, natives of the Cape of Good Hope. They are all evergreen shrubs, suitable for the greenhouse. Linnæan class and order, *Pentandria Monogynia.* Natural order, *Rutaceæ.* The inhabitants of Southern Africa use the leaves of *A. pulchella* dried and powdered, under the name of Buckee, to mix with the grease with which they smear their bodies; to give, in their opinion, an agreeable perfume, though to strangers it is a most offensive scent.

AGAVE (Linnæus). Commonly called the American aloe. A genus of remarkable succulent

Agave Americana.

plants, containing eleven species. Linnæan class and order, *Hexandria Monogynia.* Natural order, *Bromeliaceæ.* Generic character: calyx, coloured, petaloid, tubular and funnel-shaped, in six equal divisions, united at the base to the ovary, which is inferior. Stamens six, inserted in the calyx. Fruit, a longish three-sided capsule, of three places filled with two ranks of seeds. The most remarkable, and perhaps the most generally useful species of this family is A. Americana. The plant propagates itself by seeds, and by a few suckers or offsets. The principal division of the plant extends itself slowly; requiring a period of from seven to ten years before producing a terminal flowers. When these do come forth, they present a most interesting spectacle; the stem rises thirty feet high, bearing hundreds of greenish-white flowers on an elegant branched spike. When the seeds are ripe, the whole division of the plant producing them dies.

This plant has been in our gardens ever since 1640, and occasionally flowers with us; but the low temperature of even our green-houses renders their growth so slow, that forty, fifty, or even (as has been erroneously supposed) 100 years are required to develope the leaves and flower stem. It is quite certain, however, that provided the plant were allowed the requisite heat, it would arrive at its natural amplitude, and flower at its natural period of ten or twelve years. It is also more than probable that any *full grown* specimen of the plant may be flowered in any year the owner may wish, by merely placing it in a hot-bed of bark-leaves or dung.

Its usual flowering season is August, and it continues in flower for two or three months, after which it perishes.

The different parts of this plant are put to a variety of uses. In many countries in the south of Europe the leaves are used for making fences, which on account of the spines along the margins of the leaves are of a very impenetrable nature. The fibres of the leaves, after being deprived of their pulp and juice, are made into thread and cordage of different kinds, not, however, of a very strong or durable nature. The leaves when cut into pieces, are also said to be given as food to cattle. The juice of the plant, in the form of extract and made into balls, has been used in place of soap. The sharp spines are used for pins and nails.

Another species, the *Agave Mexicana*, or wild agave of Mexico, called *Magnay* by the natives, yields in great abundance a juice whence wine called *pulque* is made. From this wine a colourless spirit, like whiskey, is obtained by distillation. This spirit receives the name of *vino mercal.*

AGENEIOSIS. A genus of abdominal malacopterygeous fishes, belonging to the natural family of *Siluridæ*, or those with the skin naked, or without scales; but they have not the fleshy appendages which are attached to the under jaw of some of the family. Instead of which, one species has a short horny spine, notched or jagged in the margins; and the other species (there are but two known) has a small horny buckler in place of the spine. The siluridæ are all fresh water fishes; and the two species of which this genus consists are found in the rivers and lakes of the tropical part of South America. They feed partially upon the seeds of vegetables; and their flesh is not much esteemed as food.

AGERATUM (Linnæus). A family of exotic annuals containing six species, cultivated in botanical collections. Linnæan class and order *Syngenesia Æqualis.* Natural order, *Compositæ.* Generic character: Head of flowers flosculose; involucrum hemispheric, composed of several little leaves; flowers hermaphrodite, tubular, having four or five teeth; anthers united, exceeded in length by the style; seeds quadrangular, crowned with little awl-shaped scales.

AGLAOPHENIA (Lamouroux). The species of this class have hitherto been confounded by authors with the *Sertulariæ*, notwithstanding the many and constant characters which constitute them a very different group. They are plant-like and horny, furnished through the entire length, and on the same side, with auxiliary or insulated cells: their small polypean lodges are sometimes placed between two appendages, like a flower in its calyx; the upper appendage is at other times wanting, and the lower may then be compared to the bractea of an axillary and sessile flower. Some have their cells isolated and placed at regular distances from each other; others form groups at each articulation, but the distinguishing generic character of having the cells on the same side of the branches is invariably observable throughout the species.

The aglaophenias are of a horny substance, membranous, and flexible. Their colour fawn, varying greatly in intensity, does not present those vivid tints that adorn some of the *Sertularias* or *Corallines*, but they excel those polypidoms in the elegance of their form and in the position of their branches, which are gracefully arched over each other, resembling the waving plumes of the ostrich. Their height varies from four to twelve inches, and sometimes more. They are found at various depths in the seas of all latitudes, frequently parasites on the Thalassiophytes and submarine productions; sometimes adhering to rocks by fibres more or less numerous. Twenty-two species are known.

AGLAURA (Savigny). A genus of *Annelides*, adopted by Lamarck in the third division of his Articulata. It is a molluscous animal possessing nine jaws, five on the one side and four on the other, the lower with strong tooth-like processes; it has three short antennæ or fibres; the head is concealed under the first segment of the animal's body, the forehead bilobate; the eyes indistinct, and the animal destitute of tentacular cirrhi. This name is also applied to a little species of zoophyte, which is found at Nice.

AGOUTI. A genus of mammalia, belonging to the order *Rodentia*, or gnawers, and the natural family of *Caviadæ*, which the more modern naturalists have very properly divided into four genera, instead of the single genus of their predecessors. The characters of the order, and those of the group or family, will be found under their respective titles; so that in this article it will be necessary to mention only the genus and the species.

Common Agouti.

In their general appearance and habits, but more in their habits than in their appearance, they bear a considerable resemblance to hares; and they have accordingly been called hares and rabbits by English visitants or residents in the places where they are found. Still, they are so essentially different, that neither of the names is at all applicable. They do not burrow in the earth like rabbits, neither do they squat upon forms, in exposed places, where they can watch, as is the habit of hares. Their lodging-places are intermediate: under fallen trees, in the holes of decayed ones, or under stones and rocks.

Though, like the hares, and many other animals of the order, they can gnaw bark when other provisions fail them, and though their *incisor* teeth are well adapted for cutting, and their *molar* teeth for bruising and grinding vegetable substances which have a considerable degree both of hardness and of toughness, yet both their food and their manner of feeding are different from those of our hares and rabbits, which are the only European animals resembling them in general character and in size.

They are all inhabitants of the American continent, or its tropical islands; and they may be said to inhabit only those places which have a tropical character; for, though some of the species are found as far southward as the Straits of Magellan, yet the country there is much more tropical in its climate, its seasons, its vegetables, and some other of its animals, than the corresponding latitudes of Europe or of North America; and the agoutis are just as well adapted to the more fertile of the comparatively dry places of Central and Southern America, as hares are to the fields of Europe, or squirrels to the Canadian forests.

When first taken possession of by Europeans, the West India Islands, and all the more fertile parts of South America, were literally overrun with these animals; they are still very numerous in all places which are not settled and cultivated; and in some which are cultivated, their numbers are so great as to give no little annoyance to the planters. They are thus very characteristic of the country, much more so than some other animals which are individually more striking; and therefore they are well worthy the attention of every one who wishes to have a knowledge of that extensive and highly interesting portion of the globe.

Their generic characters, or those which distinguish them from those other genera which they most nearly resemble, are: two cutting teeth and eight grinders in each jaw, the latter far apart from the former, all nearly of the same height, and much furrowed on their grinding surfaces by irregular alternations of bone and enamel; the feet with four toes on the fore and only three on the hind, all armed with rather long, flat, and blunt claws; the legs rather short, and the fore ones shorter than the hind; the head roundish, but tapering to the muzzle; the ears of moderate height, erect, broad, and nearly naked; the eyes smaller and less prominent than in the hares; the tail short and naked, or a mere tubercle; the outline of the back arched, and that of the belly nearly straight. The slow motion, rather an awkward walk; the quick one, jerking or leaping. The hair on most of the species is coarse and bristly.

The whole structure and aspect indicate an animal which can make its way either through tall vegetation or along the dry and naked ground, which are the conditions of the places which these animals inhabit in the two seasons of the tropical year, the rainy and the dry. During the first of these there is plenty of green food on the tropical plains, and in the openings of the woods; but during the second, green vegetation disappears from the surface, unless in places which are rather humid for the agoutis. At that time, however, there are an abundance of bulbous and other succulent roots, either exposed on the surface, or situated at no great depth below it; and though the animals do not form burrows for their habitations, their spade-like claws, no doubt, assist them in getting at these. They are, however, timid animals; and, though numerous, their habits are not very well known. It is not ascertained how often they breed in the course of the year, or how many young they have in a litter; but they must breed rapidly, as they have many enemies, and still are numerous. The cats and other beasts of prey take many of them; and they are eagerly sought after, both by the Indians and the European inhabitants, their flesh ranking nearly as high in that country as that of hares and rabbits with us. They do not afford sport as "chace" game; but rather endeavour to hide themselves from their pursuers; and when they are traced to their hiding-places, they utter a feeble and wailing cry, and suffer themselves to be taken without making any resistance.

They are, strictly speaking, "surface animals," which neither dig to any depth, nor climb; and, though they can hold their food between their fore feet, using the two something after the fashion of one hand, their principal strength is in their hind legs, though it does not appear that they use these, or indeed any part o. their bodies, for attacking other animals, or even for the purpose of self-defence. They sit upon their hams, with the fore legs free, as well when they are eating as when at rest; and when the vegetation is tall, they clasp the stems between their fore-legs, and so reach those parts which serve them for food; but it is in the gnawing of roots, especially those of the sugar-cane, that they are most annoying to the planters. Though they resort to the plantations in great numbers, they are not gregarious; but inhabit indiscriminately wherever the situation and food are adapted to their habits. There are, at least, four species.

The Agouti (*A. acuti*) is the size of a hare, that is, almost twenty inches long and a foot high. The ears are round and naked, the eyes rather large, the contour of the head arched; the upper jaw projecting, with the lip cleft, and the nose considerably dilated. The tail is very short and naked. The hair all over its body is coarse and bristly, and about an inch in length, while on the rump, or hinder part of the back, it measures four inches. The elongated hair is bright orange yellow, and inclined backwards; the rest of the upper part is mottled with paler yellow, brown, and greenish black. The under part is pale yellow; and the feet and whiskers black. The range of this species is considerable, being from the isthmus of Darien to La Plata, and it is also found in several of the Indian islands.

The Black Agouti is smaller in size, and has the hair on the upper part nearly black, and the produced hair on the rump entirely so. In form and habits it differs little from the common species, and may be only a variety. It also inhabits nearly the same places, only it is more rare, and probably not so widely spread. It appears to inhabit more dry and elevated places than the other. That may have some influence upon its colour; for our cattle from the northern and elevated moors are smaller in size than those of the low and rich places; and black, while these are generally dun, brown, or similar colours, marked with white.

The Acouchy (*A. acuchi*) is still smaller, lower on the legs, rather more slender in the body, more straight in the outline of the forehead, and more slender and inclining to being pointed in the muzzle. The whole body has something more of a weasel-shape; and there is a sort of tail, though a very slender and nearly naked one. The hair is finer in its texture that that of either of the species formerly mentioned; and in colour it is a sort of intermediate tint between the two. The produced hair on the rump, which is proportionably shorter than in the former species, is black;

and the rest of the upper part, though distinctly annulated with colours nearly similar to those of the common species, is much darker.

The Patagonian Agouti, or *Mara* (*A. Patagonica*), which inhabits regions farther to the south, and therefore less tropical in their character than those which are inhabited by the other species, has corresponding differences of appearance. It is larger in size, shorter and stouter in the body, has the legs longer and clearer in their make, the neck and head more slender, and altogether it has more the air and expression of an animal which ranges over open pastures than of one that threads the brakes, which is indicated by the weasel-like shape of some of the species. When full grown, the mara measures two feet and a half in length, and more than one and a half to the most elevated part of the arched back. The outline of the back does not sink so low at the shoulders as in any of the former species, and the union of the neck with the body is more marked. The ears, too, are longer, more pointed and erect, and the contour of the forehead is nearly a straight line. The texture and colours of the covering are also different. It is soft, and the prevailing colours are fawn on the upper part, and white on the under. Anteriorly the fawn colour is mottled with white, and inclining to black on the mesial or ridge line, which increases in depth to entire black on the croup, forming a definite outline on the hams for half their external breadth, on a level with the rudimental tail, below which the hinder parts of the hams are white, as is also the chin, and the middle of the throat and belly. These markings, and also the form of the hinder part, and the shortness of the body, give to that part of the animal some resemblance to a deer; but the resemblance is slight, and confined to the parts behind the shoulders, and above the dorsal joints. The feet are distinctly those of the rest of the genus, only the toes are more slender, and the tarsi of the hind ones more produced, and have the peculiar flexure of those animals which squat on them and the hams, so as to be able to have the fore legs free while the body is in an erect posture.

The habits of the mara resemble those of the hares more than the other agoutis. They live on the open plains, feed chiefly upon green vegetable matter, of which there is a successsion of crops, such as clover at one time and thistles at another, during the greater part of the year, in America, from the Pampas southward. They do not burrow, but squat on forms, generally in the cover of herbage; and though they are not gregarious, the pairs generally continue together all the year, the female hiding her newly-dropped young for some time in the deserted burrow of some of the digging animals, with which the same districts abound. They are timid animals, and seek safety in flight, so that they afford chase; the mode of capturing them being by following on horseback, and throwing the *bolas* (two iron balls united by a cord), which the people of that country use with great dexterity. In a natural system, or one in which animals were classed according to their general structure, habits, and haunts, it is probable that the mara should be a genus separate from the true agoutis.

AGRIMONY (Linnæus). A genus of herbs found on the northern parts of both continents. Linnæan class and order, *Dodecandria Digynia*. Natural order, *Rosaceæ*. The *A. eupatoria* is a British plant, common on hedge-banks; formerly of some repute as a medical herb, and still used in herb teas.

Agrimonia Eupatoria; *a*, flower, showing the twelve stamens *b*, the five pistils.

The root in spring is sweet-scented, and the flowers fresh gathered smell like apricots. When the plant is coming into flower it dyes wool a dull yellow, and if gathered in September a still deeper shade. Formerly it was used for dressing leather.

AGRIONIDÆ (Dragon Flies). A family of insects belonging to the order *Neuroptera*, the *Libellula* of Linnæus, and which Dr. Leach has named, and separated into two genera, from the *Agrion* of Fabricius.

All this family have a long, slender, and cylindrical body, many of them variegated with beautiful colouring; in some of the exotic species, the length of the body is five inches and a half, and not thicker than a good-sized quill. They are all very powerful on the wing, and possess the faculty of flying backwards and forwards without turning. In some of the genera belonging to this family, the insect rests with the wings expanded, so that it can take itself to instant flight without further preparation; in the genus Agrion, however, this is not the case, the animal always resting with the wings erect.

The A. puella appears to be subject to some variety, but it is possible others have been confounded with it; the body, in general, is of a most beautiful blue in the male, and bluish grey in the female. They inhabit the rushes by the sides of ditches, and are one of the commonest of the British species, of which Stephens, in his catalogue, enumerates ten. We should recommend to the entomologist, as the insects of this genus are very delicate in their bodies, and will not admit the usual process of filling with cotton, after the removal of the contents of the abdomen, as in the larger libellula, that a needle furnished with a coloured working cotton be passed through the body, which would possibly save the colours, and certainly strengthen the specimen.

Genus Lestes, (Leach,) wings membranous, with an oblong-quadrate parallelopiped stigma: abdomen of the male armed with a forceps-like appendage. The

Les. autumnales (Leach) inhabit marshes, where they may be found in August and September.

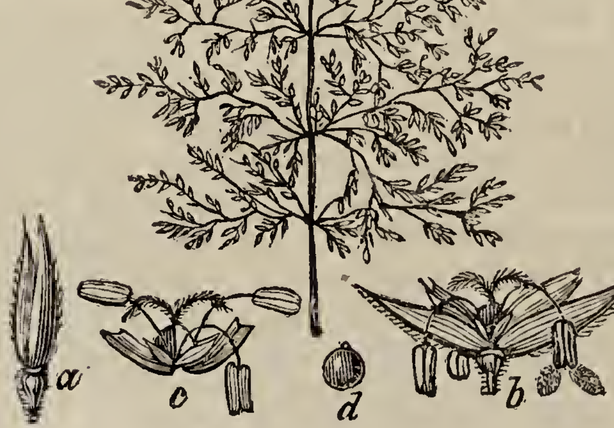
In the genus Calepteryx, the wings are membranous, without a real stigma, in place of which we sometimes find transparent spots; the abdomen of the male is furnished with a forceps-like appendage.

The Dragon-fly.

The species vary much in the colour of the wings, which are sometimes bluish, brownish, black, pellucid with a broad black fascia, pellucid with white tips, or with brown tips and a white dot.

Inhabits in the larva-state streams and rivers, and in June and July may be found on the banks; it is abundant on the Lea, in the Hackney marshes. This is one of the species that require no preparation in the preservation of their colours; it is undoubtedly one of the most brilliant British *Agrionidæ*.

AGROSTIS. A name derived from the Greek word αγρος, *a field*, and applied to a genus of grasses, containing a considerable number of species, five of which are natives of Great Britain. Generic characters. panicle or cluster of flowers loose; calyx consisting of two unequal scales or glumes longer than the corolla; corolla of two unequal valves, the outer one frequently being furnished with an awn.



Agrostis Capillaris. *a*, the bivalvular one-flowered glume; *b*, the same opened, showing the flower; *c*, the flower taken out, to show the two valves of the calyx, and the two scales; *d*, the seed.

The *Agrostis vulgaris*, common bent-grass with its dwarf variety, and the *Agrostis canina*, or brown bent-grass, are abundantly met with in fields and pasture lands, and on account of their earliness are esteemed in agriculture. The *Agrostis setacea*, or bristled-leaved bent-grass, is chiefly found in the south of England; and the *Agrostis spica venti*, or silky bent-grass, grows principally in the neighbourhood of London. Another British species, the *Agrostis alba* or stolonifera marsh bent-grass, is very abundant in Ireland; and under the name of *Fiorin-grass* has been greatly praised by Irish agriculturists for the purposes of fodder. It thrives well in wet marshy soils, and is said to yield an abundant and luxuriant crop.

The Agrostis family are met with in greatest abundance in temperate regions. One species, the *Agrostis algidæ*, is interesting on account of being one of the few plants found in Spitzbergen. In the torrid zone the species of Agrostideæ have been estimated to amount to fifty-eight, or one-fourteenth of the whole grasses of that zone, while in the temperate zone they amount to 220 or one-fifth of the whole. In South America the Agrostideæ occur most abundantly in the elevated mountainous districts.

AI (The three-toed sloth, *Acheus tridactylus.*) A genus of mammalia, belonging to the order of *edentata*, or toothless animals, and the natural family of *tardigrada* or "Sloths," one of the most singular in their forms and habits, and, according to our notions, one of the most uncouth, in the whole range of the animal kingdom; but still as admirably adapted to their haunts and modes of life as those species whose forms we admire the most.

The general characters of the group will be mentioned under its title; but it may not be improper to remark here, that the words "tardigrada" and "sloth," the one expressive of sluggish motion, and the other of indolent disposition, are both misapplied in the case of these animals. In their own proper place, they are neither laggard nor lazy; and their formation, though, according to our common notions, it is singular and ungainly, is not only better adapted to their peculiar haunts than the structure of any other animals with which we are acquainted, but better than any that we could have imagined, if the problem had been proposed to us to find the structure of an animal without wings, which should find its food, and spend the whole of its life, among the tops of lofty trees in close forests, and so maintain its footing there, as that no ordinary tempest—not the hurricane in the utmost of its fury—could shake it to the earth.

The haunts of these animals are the deep, extensive, and luxuriant forests of South America; forests in which the trees are of giant growth, always green, so close that rarely a beam even of the vertical sun reaches the earth; and they extend over districts so wide, and are so festooned and interlaced with various species of *epidendra*, or twining plants, that winds, which would level our single trees with the ground, or rend our most serried woods to tatters, barely agitate their tops, or disfigure a few on the sides of the openings. In all parts of nature there are counteractions; and in order that there may be seeds and successions of races in those luxuriant forests, it is necessary that there should be some consumers of the superabundant foliage, which, otherwise, would completely exclude the sun and air, and the forest would perish of the excess of its own exuberance, leaving the naked and carpetless earth to be converted, by the fervour of the tropical sun, into an arid waste, upon which no living thing could exist. If the forests were, in this manner, to be destroyed, or indeed in any way but one in which their place should be occupied by a close surface vegetation (and in those climates there is none such known, save culture by man), the rain would be gone also, and the land would be put beyond the power of human skill and labour to bring it back to usefulness, either for man himself or for any other living creature. On the deserts with which we are acquainted, in the tropical parts of the world, there are sometimes pestilent dews, from the difference of temperature between the night and the day, the cold of the former being increased by the partial melting of the salt with which the surface of such places is generally strewn; and the heat of the latter augmented both by reflection and radiation from the burning surface; but there fall no kindly showers; and, "once a desert, always a desert," till some of those mightier movements of nature, of which the records are written in the strata of the deepest mines, and the loftiest mountains, shake the ruin to pieces,and mould and temper its elements anew.

Wherever the earth is green, there are browsing animals. But in those tropical forests, the green is not upon the surface, but on the tops of the trees; and the browsing animals must be fitted for making these their pasture. A pasture suspended in the air must have those which feed upon it suspended in the same element; and the question may here be put, "should they be suspended *above* their food or below it?" Green leaves cannot form a *footing* for any animal of sufficient size to feed upon them wholesale as a browser; and it is not easy to see how an animal could browse on the wing; so that, according to all that we know of the laws of animal action and of those of matter, it does not seem consistent, or even possible, that the leaves of a tropical forest could be browsed by an animal above them. But an animal suspended from the twigs or branches upon which the leaves grow, and "holding on" by the action of its weight on the points of suspension, could have command of itself and feed; and this is exactly the habit of the sloths, and their organisation agrees with that habit. Their position is reversed as compared with that of animals which walk the earth; and it is in keeping that their organs of motion should be reversed also.

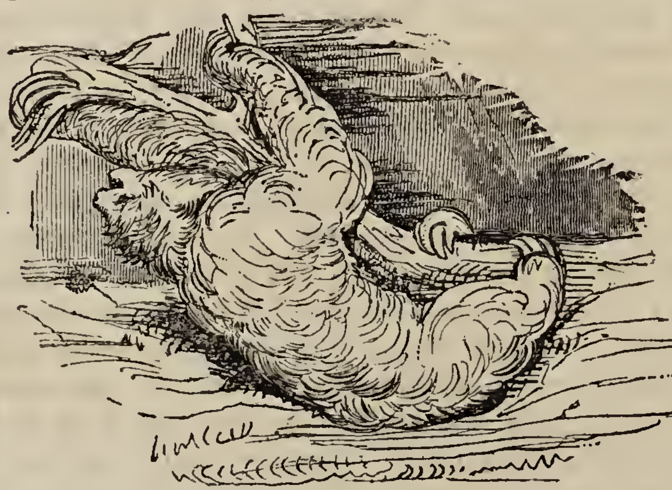
Much as has been said and written about the clumsy and helpless structure of the sloth (for even Baron Cuvier, while forming a system of animals according to their structure, says, they are formed as if Nature had "wished to amuse herself in the production of something imperfect and grotesque"), there are cases in which we take him as our model. When a sailor "warps" along a rope, he is obliged to do it as the sloth does; and the chief difference is, that he does it more clumsily. The arms in man close toward the centre of the body with their most powerful hold; and though the hands can grasp at different angles, the firmest grasp, and that which can be maintained the longest, is when the grasp is in a plane parallel to the mesial plane of the body, as nearly coincident with it as possible, and the fingers turned inwards. The quadrumana grasp in the same manner; but their grasp, as well as our own, is by muscular effort, and as such it is labour, whereas the holding on of the sloth is repose, in the same sense as is the suspension of bats by their hooks. Their suspension is wholly by the claws, so that no part in which there is any circulation is pressed by their weight; and thus, whether in their progressive motion or in their repose, they really appear to suffer less than any other animals. In their repose, they hang by all the four feet, which are as nearly straight as possible, till the last phalanges of the toes are arrived at, and these are "stopped" by processes of the bones, just like a stop hinge, so that they cannot make other than a hook, with its point directed to the mesial plane of the body. When they exert themselves, the claws can be brought close to the upper part of the wrist, and thus they can hold firmly by the most tender twig; and the hind feet, which hold on while the fore ones are bringing the leaves within reach of the mouth, have a projecting heel bone, for greater security. Each foot can act separately, and thus they can feed on the trees as near the extremities of the branches, as four twigs, or as many times four of the smaller ones as they can grasp between the foot and the long claws, will bear their weight. In ascending the stems of trees, their claws act much in the same manner as "climbing irons;" but even then they are always most secure, and move fastest, when the stem leans over them, and they can bring their weight to the aid of their grasp.

Mr. Waterton, in whose "Wanderings" in the forests of Surinam, there is the most correct, and certainly the most lively account of these singular animals, mentions that they avail themselves of those winds which agitate the trees, and bring their branches into contact, in order to make their migrations from part to part of the forest, which they do with considerable velocity; and that they should choose for their most active motions those times when the quadrumana and the climbing birds are forced to descend for shelter, is another proof of how admirably their structure is adapted to their haunts.

That they should be awkward on the ground is not to be wondered at; for as they are seldom there except in cases of accident, to have given them the power of walking well would not only have been giving a superfluous power, but one which could have been obtained only by the injury of that which is most essential to the animals; for it is a principle of the animal structure that the perfection of two systems for the same kind of action, whether that action be locomotion or not, are incompatible with each other in any one species. On the ground, the sloth is out of its element; but it is not so helpless there as a herring upon dry land, or a peacock in the sea. The turning inward of the wrist and ankle joints, so as to make the claws shut on the mesial plane, necessarily brings the side of the foot to the ground, and not the sole, which prevents any of the joints of the foot from coming into play there; and the most ready and powerful action of the knee and elbow joints being in the same direction, renders them of little use; so that the whole of the motion there is at the articulations of the humeral and femoral bones, and not very perfect or powerful even there. We have only to imagine how a man would walk if he had the power of progressive motion only at the hip joints, and that the knees and ankles had a continual tendency to have the parts articulated at them inwards, and then we can form some idea of the sloth's motion along the ground.

The generic characters of the Ai are :. no cutting teeth in either jaw; four molars and one canine in each side of the upper jaw, and three molars and one canine in each side of the lower. The whole teeth nearly of the same form—cylindrical, of soft bone cased with enamel, but with no plates of enamel in their substance. They are not, therefore, adapted either for biting or for grinding, but merely for pulling off the leaves, which are taken into the stomach with little preparation in the mouth. The stomach consists of the same number of divisions as that of the ruminating animals, but the sloths do not ruminate. There are only three toes on each of the feet, the bones of these, answering to the little finger and the thumb, being merely rudimental, and united to the bones of the palm, which also become soldered together long before the natural death of the animal. The fore legs are very long, nearly double the length of the hind ones, and the neck is usually described as consisting of nine vertebræ, while in all the other mammalia, as far as is known, it consists only of seven. This last character is, however, incorrect: there being only seven cervical vertebræ, or those without articulated processes; but the first and second dorsal vertebræ follow (naturally enough when the habit is considered) the structure of birds, and the ribs attached to them are not joined to the sternum. This formation allows of more motion to the head, which is raised upwards, and rests on, or is received, between the fore legs, when the animal hangs from the branches asleep. The young is brought forth on the trees, and hangs suspended to the mother, whose teats are pectoral and two in number, till it is able to suspend itself from the branches, and find its own food. There is, indeed, a curious jumble of resemblance to some parts of the human structure in these very curious animals. Two species are described, similar in habits, though differing in appearance; and there are probably more species, or at least varieties. The places which they inhabit are very difficult to explore; and therefore their numbers and habits are but imperfectly known.

The common Ai, of which the following figure is a representation, appears to be the most abundant



The Ai; or, common Sloth.

species, or, at all events, the one which is best and has been longest known. It is about the size of a large cat, with the head short and round, the face yellowish, with brown rings round the eyes, which give them the appearance of being placed under an eye-brow. The face is covered with very short hair; but that upon the rest of the head, the body, and the feet, down to the very claws, is long, shaggy, and of a very peculiar texture. It is turned back from the face, and divided from a centre near the top of the head, something similar to the crown of the human head, and all over the rest of the body it is matted. The form is very peculiar, being slender at the roots and flattened at the points, as if every pile was a blade of grass, inserted by its narrow point. It wants the gloss of ordinary hair upon the living subject, and feels sapless and dead, as if it consisted of withered vegetable fibres. The colour is grey, but variously marked, and mottled with black, brown, and white, not unlike a portion of a tree covered with lichens; and in its colours, and also the length of the hair, it is liable to considerable variations; but whether of age, sex, season, or difference of exposure, has not been ascertained.

The collared Ai has the head not quite so rounded, the muzzle a little more produced, the face black, a black collar round the neck; the hair on the head yellow, on the rest of the upper part orange, and on the breast and upper part of the belly rust colour. The hair on the head is more produced than on any other part; and over the whole animal is not so flattened, shaggy, and withered, as in the common species.

Both are inoffensive animals, following their curious mode of life in the forests without offering the slightest violence to any living creature. When the air is dry, hot, and still, they are mostly at rest during the day, and their suspension from the under sides of the boughs protects them alike from the action of the sun and from enemies. Whether in that state of the weather they move more during the night has not been ascertained; but it is probable that they do, as the leaves of the trees are then refreshed by the dew. As has been already mentioned, the increasing of the storms puts them in motion, and they then utter their plaintive cry, of which the name "ai" is a pretty close imitation. They are very tenacious of life, more so than most of the mammalia. Their clutch is also formidable, if they are attacked on the ground, where they throw themselves on their backs, and defend themselves with the extremities of the paws with the greatest resolution; and if they seize hold, they do not quit it till the enemy is dead.

The habits of these animals are not only interesting as being characteristic of some of the thickest and most entangled forests now remaining on the globe; but as, in so far, indicating what must have been the state in former times of those portions of it where the skeletons of animals of the same family, but as large as that of the elephant, are found in the ground. See Megatherium and Megalonyx.

AILANTUS (Linnæus). Two very beautiful Chinese trees, one hardy enough to bear the climate of England, usually raised from imported seeds; the other requires the protection of a hot-house. Linnæan class and order, *Polygamia Diœcia.* Natural order, *Terebinthaceæ.* Generic character: male flowers—calyx, one-leafed, five-parted, very small; corolla five petals, acute, convolute at the base; stamina, filaments ten, compressed, the length of the corolla. Female flowers—calyx as in the male; corolla as in the male; styles lateral; capsules compressed; seeds solitary, lens-shaped. Bisexual flowers as on the above.

AILURUS. (Literally "parti-coloured tail," though the same was one of the Greek names for the common domestic cat, and no doubt applied to those varieties which have the tail marked with a series of rings of different colours.) A genus of mammalia, belonging to the order *carnivora,* or preyers upon flesh, properly so called, and of the family of *planti-*

grada, or walkers on the flat of the feet. The last character must, however, especially in the hind feet, be received with some explanation, as there are none of the carnivora which walk on the entire length of the tarsi of these when they walk upon all fours.

Only a single species of this genus is known, *Ailurus fulgens*—the *panda*, *cheetquha*, and various other names of the mountaineers of northern India. The last name is compounded of "cheeta," the Indian name of the smaller leopards, or larger cats, and "quha," the cry of the animal as nearly as it can be expressed by letters.

The panda is but a recent addition to European zoology. The animals to which it bears most resemblance are the *raccoons* of the American continent, but the following figure will give a better idea of its shape than could be derived from a verbal description.

Ailurus fulgens.

The whole length of the animal is about forty-two inches, of which the head occupies seven and a half, the neck four and a half, the body fifteen, and the tail the same. The face and parts of the ears are white, with a few fulvous hairs, and a fulvous patch on each cheek. The neck and back of the ears are deep yellow, which passes into golden yellow on the ridge of the back, and from that to yellowish brown, with sprinkled hairs of golden yellow on the rest of the body. The tail is ringed with yellow and fulvous brown, which pass gradually into each other, and its tip is black. The fur on the body and tail is very thick and close, and rather long. The legs are short and stout, and entirely covered with blackish woolly fur, including the soles of the feet; and as the bright fur of the body hangs so far over them, they have the appearance of being inserted in the body like the feet of a stool. The toes are five on each foot; the claws rather long and partially retractile; but they are straight, and so not adapted for clutching. The teeth are singular. The cutting teeth are conical; the canine nearly straight; there is one false grinder in each side of the upper jaw, and two in each side of the under. The first false grinder is a flat cone shouldered at the base; the shoulder of the second rises into tubercles, about half the height of the central cone; that of the third rises nearly to the whole height; and in the remaining ones all the tubercles are nearly the same, and in the aged specimens they are flattened or truncated at the points. This last circumstance was at first proposed to be made a character of the animal, and led to the supposition that it fed partly on vegetables; but it has been found to be merely the result of wearing.

The panda is a mountaineer, inhabiting the banks of streams and torrents on the secondary ridge of the Himalaya mountains, between Nepal and the snowy summits. It lives much in trees, and catches birds with dexterity. Its furry feet enable it to steal onward with silent tread, and to traverse the snow without inconvenience. Very little is known of its manners, but its aspect is not ferocious; and as it is an animal of singular beauty, and a native of a cold region, there is some probability that, by a little care, it might be added to the list of our domestic mammalia.

AIR. (From a Greek word which signifies "to breathe.") The gaseous fluid of which the atmosphere is composed, which everywhere surrounds the earth to a much greater height than any living creature, animal, or vegetable can be supposed ever to ascend, and which penetrates the earth and the water, at least to the greatest depth at which any creature of what kind soever can live and grow. Air is so important an agent in the economy of nature, that no portion of Natural History can be understood without a knowledge of its nature and properties. In so far as these are mechanical or chemical, and have relation to mechanical or chemical arts, they belong to the first division of the Cyclopædia. But the Natural History properties of the air are highly important, and correspond more nearly with its physical properties as matter, than those of almost any other natural substance.

In order that our understanding of this agent may be clear, and expressed in short space, it becomes necessary to subdivide our notice of it, and consider it as *air*, and also as *atmosphere*. Under the first of these titles, we shall have to consider it as local and temporary, without reference to extension in space, or succession in duration; and under the second (for which see ATMOSPHERE,) we shall have to consider it with reference to varieties of climate and successions of seasons, and all the effects which result from these.

The air, taken in its simple and more restricted sense, needs no definition; and indeed, considered merely in itself, it does not admit of any. It is not apparent to or cognisable by any of the human senses; and therefore it can be described only by negatives, which do not amount to definition. Like animal life, or the human mind, of which in almost all languages it is the type and the name, it is known only by the functions which it performs, or the phenomena which result from the actions that take place between it and other things. These, however, are often as grand, and even terrific, as they are important in their results.

Air is a compound fluid, consisting substantially of oxygen and nitrogen gases, in nearly the same proportions under all circumstances, and it also receives into its mass many other gases, and also liquids and other substances not gaseous, in that state of minute division which is called *vapour*, and by a process, understood to be always the same in kind though differing in degree, which is called *evaporation*. That process is a very important one in the economy of nature, as all land plants and animals may be said to depend upon it for their subsistence; but it belongs to the general consideration of the atmosphere, and not to air as temporary and local.

But though air consists of two principal ingredients, and also admits of other substances being diffused through its mass, it is merely a *mixture*, and not a *compound* in the chemical sense of the word. This state of it is highly important to be known, not only in order to prevent us from drawing false conclusions from those phenomena which take place by the action of the air or of some of its ingredients; but also as affording one of the most beautiful of those instances of design and adaptation of which creation is so full.

It is a law of all action, whether natural or artifical, that no change can take place without the exertion of what we call *power;* and the power by which the change is effected must always be greater than that which maintained the substance or substances in the state out of which they were changed, or, in other words, greater than that by which they were brought into that state. As for example, it always takes a greater exertion of power to separate two substances chemically combined than it did to combine them and hold them in combination; and so also it takes a greater degree of power to combine them anew than that by which they were separated and held asunder.

This is the general law of all natural action, indeed of all action whatsoever; and it is necessary that every one wishing to have scientific knowledge of nature, or indeed of any thing else, should have the clearest possible notions respecting it. A state of perfect equality in power would be a state of total inaction—of universal death and quiescence; and a creation of which that were the law could produce nothing and would be good for nothing. That the stronger only can vanquish, and the weaker only can be vanquished, is, when the facts are known, the law equally of the whole and of all the parts down to the most minute; and it is a law to which there are not even the most temporary exceptions. Ignorance of this law is the cause of all the failures which take place in human attempts; and *impossibility* is only another name for its attempted violation. This alone would justify the length at which the principle of the law has been stated, and strongly recommend it to the most attentive consideration. But if it were our province to treat of the practical application of mechanical and chemical science, we could fill volumes with instances in which human ingenuity has been most lamentably wasted, solely from ignorance of or inattention to this universal and most important law.

It must be borne in mind, however, that time is an element as well as intensity; and though we are not warranted in saying that the effective power is always the product of the time and the energy, yet our inability of doing so depends on the nature of the energies and on the contingencies on time, rather than upon any improbability in the doctrine itself. Before returning to our proper subject, the air, it may not be amiss to mention an instance or two, in order to fix this, the most important truth, perhaps, in the whole three kingdoms of nature, upon the minds of those readers who are not accustomed to such considerations. Then, in the first place, the timber of an oak tree, treated with proper skill, suffices, in the course of not very many hours, to convert, by the help of the workman and his tools, a lump of iron-stone into a steel hatchet. The tree may have taken a hundred years in growing, and the iron-stone a longer time in consolidating; but the rapid decomposition of the tree—the undoing of that which it did during its growth, affords a power concentrated in intensity from being shortened in time, before which the stubbornness of the iron-stone must give way. It may be that the oak is first burnt into charcoal in a smouldering fire, and the iron-stone roasted in a slow oven to clear it of sulphur; but the object of these operations is to get rid of volatile substances which would scatter the heat and also the substances acted upon. Again, a very small quantity of gunpowder, duly applied and ignited, will rend in pieces many tons of the toughest rock; and we cease to wonder at the result when we reflect upon the length of time during which the charcoal was growing, the saltpetre forming, the sulphur subliming by volcanic heat, and the labour of making the powder, all of which were undone in that momentary explosion.

Now, when we turn from these instances of strong natural action, and consider the air, formed of ingredients which can be mixed or separated instantaneously and without effort, save that which is necessary to overcome the inertia of the particles; and that these particles are so small and light that the number of them in a grain probably exceeds that of the grains in the mass of the earth, and that they are all but self-mobile, we see what a wonderful element the Creator has prepared for his creatures. From the giant of the forest to the mucor on the humid stone—from the whale in the ocean and the elephant in the jungle to the viewless animalcule, which prints doubt upon the finest microscope, there is a wonderful range of organs, in magnitude and in energy, but the air is equally obedient to them all; and the little things, of which a thousand may be lifted on a pin's point, or hung in a drop upon the most slender cobweb, find themselves as competent to receive life from that, as those which shake the earth with their tread, or cause the ocean to boil with their plunge.

And the same minuteness of division enables the air to find its way to every place where its presence can be required. There bores not a worm, there descends not a root, so deeply into the ground as that the air cannot reach it, so that to all that grow and live above the surface, on the surface, or under the surface, the air is the breath of life; all are equally refreshed by it, and the most feeble is no more fatigued by it than the most powerful.

To us, the water, whether of the lakes and streams or of the ocean, seems a compact and continuous liquid; and neither the eye nor the microscope can find in it any pores or interstices; and yet we have no reason to doubt that air freely finds its way into the water, to the greatest depth from which the plummet ever brought up a bit of living weed, or a shell containing a living animal, or indeed "deeper far than plummet ever sounded;" nay, it is not impossible that the air pervades the whole mass of the globe, liquid or solid, to its very centre.

The manner in which animals and plants, of different classes and habits, make use of the air, varies so much, that the explanations can be best given in the accounts of the creatures themselves; but it may be stated as a general truth, to which there is no known exception, that all of them, in respiration, or in that process which answers the same purpose, use the air itself, and do not, by that process at least, elaborate it, or any of its ingredients, out of other substances. It may be used rapidly or slowly, the quantity may be great or it may be small, and these will always be found connected with the general activity of the other systems in the animal; but still it is air that is wanted, and it is wanted to some extent, at least, for every living creature, plant, or animal. If the creature lives on land, then the air is taken into the lungs of the animal; and the plant may be considered as possessing lungs all over its living surfaces; and though it is not made out that there is a respiratory system within plants, any more than that there is a circulating one, still there is air in the interior of most plants, perhaps of all; and they may absorb or otherwise act upon that air at the coats of their vessels just in the same manner as the coats of the arteries in buds, are understood to act upon the air in the air-cells of these.

In the respiration of animals, whether of the land or the water, it is understood always to be the oxygen of the air which is the efficient ingredient, not for the purpose of adding any thing to the substance of the animal, but for removing the superfluous carbon, or superfluous carbon and humidity. Now the separation of oxygen from water, or, in other words, the decomposition of that liquid, supposing it to take place at a rate not more rapid than that at which the majority of fishes breathe, is rather a formidable operation; and if all the animals that are in the sea were to obtain air in that way, they would boil themselves in a very short time. These animals it is true receive the current of water through their gills when free, or in and out of their gill-openings when not free. But the water is in all cases, at least of animals in which the organisation is much developed, merely the vehicle which conveys the air to the organs in respiration, just as nitrogen appears to be the vehicle which conveys oxygen to the lungs of those animals which breathe free air; and that the water in time becomes unfit for the respiration of gilled animals, in the same manner as the residuum of breathed air becomes unfit for respiration by lungs, is a farther proof that the oxygen is obtained from air contained in the water and not from the water itself. If the water were decomposed, the liberated hydrogen would escape and the water would remain breathable by fishes as long as a drop remained. But it is found by direct experiment, not only that water which has been deprived of air will not support the life of fishes, but that if they are kept in a still vessel containing only a small portion of water they languish and die, if the water is not from time to time changed.

These facts show that the agitation of the waters, and the rolling and tumbling of their surfaces, which are produced by wind and other causes, are not without their uses to the aquatic tribes, any more than the changes of air which are produced by causes nearly similar, or at least something analogous, are to the inhabitants of the land. Fishes which are kept in small and sheltered ponds, even where they have abundance of food, (as is proved by the greatness of their increase and the rapidity of their growth,) are, when they are allowed to increase beyond a certain number, subject to general and fatal diseases, the causes of which have never been very satisfactorily explained; but which are, no doubt, in part owing to the over abundance of fishes exhausting the air in the water faster than it can be replaced by absorption at the surface of a sheltered and tranquil pond. It has been found that a pond through which there is a considerable run of water will support in health a larger stock of fish, even though the water comes into it in such a way as to preclude the possibility of its bringing any supply of food. Indeed, in those cases of mortality among pond fishes, it does not appear that want of food is any part of the cause; for they take place under circumstances where there is every reason to conclude that the supply of food is peculiarly abundant. The fishes in the overstocked pond, bear some resemblance to the prisoners in the black hole at Calcutta; and additional feeding, by increasing the action of the system and quickening respiration, would only increase the calamity.

Of streams and rivulets, flowing through earth of nearly the same composition and containing equal quantities of water, that which consists of a succession of pools and rapids is always much more abundantly supplied with the more delicate fishes than that which flows sluggishly; and the trout of the former, in point of the quality of their flesh, bear nearly the same relation to the trout of the latter, that beeves and sheep fed on an open hill side, bear to those which are fed in low, damp, and shaded pastures. The cattle are the larger in size, but they are deficient both in flavour and in nutriment. The pool under the driving rapid or the dashing cascade, is always a good trouting pool; and that not merely when it is a difficulty or a *ne plus ultra* in ascending; but apparently from the abundance of pure air with which the water is charged.

The effects of prolonged calms at sea upon the finny inhabitants of that element, have not been observed with sufficient attention; but so far as observation has gone, the fishes, especially the quick respiring fishes which inhabit near the surface, such as the herring and the mackerel, become languid and do not feed so readily when the water has been long still. The shoals of cod also "come up" in long calms, and whiten the water and even the sky with their "blink," much more than when the surface is agitated.

In proportion as the respiration of fishes is slow, they seem able the better to endure a diminished supply of air in their watery element; and their capability of bearing the diminution is always in proportion to their tenacity of life when out of the water, and also to their power of resisting impure substances with which the water may be impregnated. As soon as the water is foul, even though the foulness is only a scum of oily matter upon the surface, the salmon and the trout depart; the flounder and the gudgeon remain a little longer; and the eel continues to wriggle for its existence even after the muddy stream has become filthily impure. How much of the cause may depend on the limited absorption of the air which is in the water, so that the fishes are suffocated for want of breath, or how much must be attributed to the direct application of deleterious matters to the gills, or other parts of the fishes, where they are absorbed and act as poisons, has not been accurately determined, though it is a point of some importance in the economy of the waters.

The doctrine of the air, as an element or agent of life, both animal and vegetable, is however so very extensive, some parts of it are so very obscure, and the uses of it to different species differ so much from each other, that it cannot, though one of the most important in the whole range of human knowledge, be advantageously treated at length in a popular article. In addition to what has been here said, the reader will find some further explanation of the leading principles in the article PHYSIOLOGY; as well as in the general article on plants, and the primary divisions of animals.

AIR-BAG (called also the *air-bladder*, the *sound*, the *swim*, and various other names), an organ with which fishes are very generally provided, and respecting the use or mode of action of which there are many theories and conjectures, but none that are absolutely certain, either as to what is its use, or whether that use, whatever that may be, be uniform in all the species which have it. The common theory is, that it assists the fishes which have it in adapting their specific gravities to different depths of water, and the consequent pressures to which they are subjected at those depths; and the arguments in favour of this theory are, that those fishes which have it not are generally less discursive, both as to depth of water and to range in distance, than those which have it; that when it is punctured the fishes remain at the bottom, while so long as it is entire they can come to the surface. These arguments are not, however, conclusive, or even very plausible. We know of no animal which raises itself by balloons, whether in the air or in the water; and those fishes and reptiles which have the power of inflating their integuments, certainly never use that power to aid them either in swimming or in flying.

The fact is, that this mechanical theory refutes itself, and never would have been adopted if the parties adopting it had not been ignorant of those very principles of mechanics of which they concluded they were making a proper application. If the air-bag were of such dimensions as that the bouyancy produced by it could have any effect on the ascent of the fish to the surface, it would destroy the fish's command of itself in the water to a much greater extent. Besides, the air-bag has not been proved to be muscular, or possessed of a contractile structure; and the reddish bodies which are sometimes attached to it are organs of secretion. The air contained in the bag is chiefly nitrogen, with a mere trace of oxygen in fishes, such as the mullet, which live near the surface, but with a little more oxygen in the fish which inhabit at a greater depth. In no known case, however, has the quantity of oxygen been found to be equal to one tenth of the whole. This composition precludes the possibility of supposing that the contents of this vessel can be atmospheric air. As little are they the remains of the air after having been breathed by the animal; for the chondropterygii with fixed gills, which are the only fishes that receive the air into cavities in the body, have no air-bladders. And yet, if it were the residuum of air taken in from the water, they are the ones in which we might expect to find it, as the fishes with two gills pass the water in a current through these. When there is any connexion of the air-bag with any of the systems of the animal, it is always with the alimentary system, the gullet, the stomach, or both; but there is often no perceptible communication even with these, and when there is not, the air-bag is always furnished with glandular appendages *presumed* to be for the purposes of secretion, though, as in some cases it has both the connexions with the gullet or stomach and also the appendages, there is doubt even upon that point of the subject. Indeed, in those cases where the ducts of communication are the most conspicuous, as with the gullet in the sturgeon, and the stomach in the herring, these ducts are air-tight, so that the bag can neither be inflated nor emptied by pressure through them. That the air contained in the bag is secreted either by the glands or the tunic itself is no doubt true, at least in those cases where there is no communicating duct; and as when there is a communication, that is always with the alimentary canal, the probability is that the air-bag is, in some way or other, connected with the digestive system, but in what way, the present state of our knowledge does not enable us to decide. Enough is known, however, to show that the use is physiological, rather than mechanical—to refute the existing theory, but not to establish a better one. Before that can be done, there must be much careful observation.

The air-bags of fishes vary much in shape, in strength, and in size, as compared with that of the species to which they belong; but till the use of the organ itself is a little better known, no conclusion can be drawn from these differences.

In the arts, the substance of this vesicle is of considerable importance. When freed from fat and other impurities, it is among the most pure animal gelatine with which we are acquainted. Isinglass is the air-bag of the sturgeon, freed from oily matter and dried; and the air-bags of cod are collected and salted in large quantities at the cod-fisheries, and well-known in commerce by the name of "cod-sounds." The air-bags of all fishes may be used for the same purposes, though some of them are much smaller than others and have the gelatine less pure. Inferior ones are, however, often sold for the genuine isinglass of the sturgeon.

AIR-CELLS, and *tubes*, in birds, are cavities in the internal membranes, and also in the livers, feathers, and other parts of these animals, some of which are of use in respiration, and others render the parts in which they are contained more strong and stiff, with the same quantity and consistency of materials. As birds have no motion of the chest in breathing, and no diaphragm, the air-cells act as substitutes; and as, in some cases at least, the coats of the arteries are exposed to the air in them, they answer some of the purposes of lungs; and the bird is enabled to continue long on the wing without getting out of breath. In some species, as for instance, in the gannet, there is a power of inflating the cellular membrane of the breast by means of a communication with the air-cells; but though the quantity of air which the cells and tubes admit into the body of the bird lessens its specific gravity as a whole, it does not appear that they are used in altering that specific gravity.

AIR PLANTS are those vegetables which can live for a considerable period of time, when suspended in the air, without being attached to the ground or any substance whence they can derive nourishment. Many plants possess this property. Thus several species of *ficus*, more especially the *ficus elastica* or Indian-rubber tree, have been known to live for a great number of years suspended in a green-house, and nourished only by the air and the moisture contained in that. Some of the aloe tribe have also been kept growing in a similar manner for a long time.

The name of air plants has, however, been more particularly applied to several members of the orchis and pine-apple tribes, which are met with abundantly in the damp shady woods of the tropical regions of America and Asia. On account of their beauty and the fragrance of their flowers, they are cultivated in these countries for the purpose of adorning chambers and balconies.

The *Tillandsia usneoides*, with its wiry stems and dense leaves, attaches itself to the trees in Louisiana, forming an uninterrupted mass, suspended in the air, which frequently extends over whole forests and completely intercepts the sun's rays.

Tillandsia xiphioides,—Buenos Ayres, is another species which grows on the bare trunks and branches of trees, its airy vegetation being frequently suspended only by a thread. It is cultivated in hot-houses in this country.

Some of the orchideous tribe are also entitled to the appellation of air plants. They constitute the greatest vegetable ornament of the tropics.

Air plants, though frequently brought to this country, have only lately been cultivated with any degree of success.

Aerides arachnoides.

AIR VESSELS. A name given to the spiral vessels of plants, or vessels with a spiral coat which run longitudinally round the centre or pith of the young branches of trees or shrubs. They are well seen in the alder and lilac. These vessels have been proved to convey the sap which serves for the nourishment of the plant, but they would appear occasionally to contain air, sometimes with a greater proportion of oxygen than exists in the atmosphere. This led some physiologists in former times to regard them as true air vessels furnishing the air contained in the leaves. The leaves, however, have been shown not to depend on these vessels for their supply of air.

AITONIA (Linnæus). A small green-house undershrub, native of the Cape of Good Hope. This solitary plant was named in honour of the late W. Aiton, Esq., of the royal gardens, Kew. Linnæan class and order, *Monadelphia Decandria.* Natural order, *Meliaceæ.* Generic character: calyx, monosepalous, four cleft; corolla, of four petals; stamina, eight, protruding; the filaments united in one brotherhood, inserted under the ovarium; style, filiform, tipped with an obtuse stigma. Fruit, a berry, containing several seeds.

AIZOON (Linnæus). A small genus of five species, under-shrubs and herbs kept in green-houses as ornamental plants. Linnæan class and order, *Icosandria Pentagynia.* Natural order, *Ficoideæ.* Generic character: calyx, monosepalous, five-parted, and persistent; corolla, none; stamina, arranged in groups of threes in the angles of the calyx; styles, five, on a pentangular capsule of five places, and opening by as many valves.

ALABASTER. There are two kinds of stone to which this name is commonly applied. The first of these, the carbonate of lime, was much used by the ancients. It is nearly as hard as calcareous spar, and its specific gravity about 2,700.

This species is found encrusting the roofs, walls, and floors of caves, particularly those situated in limestone rocks. It is formed from water holding carbonate of lime in solution; and when the water first escapes into the air, it is capable of holding in solution a large quantity of that earthy body; but when the solution comes to be agitated, or exposed to the atmosphere, or to a change of temperature, the carbonic acid makes its escape, and thus deprives the water of its solvent power. Water thus impregnated with carbonate of lime oozes slowly through the fissures of the rocks: there some time elapses before a drop of sufficient size to fall by its own weight is formed, and in this interval some of the solid particles are separated from the water, owing to the escape of the carbonic acid, and adhere to the roof. In this manner, successive particles are separated, and attached to each other, until a *stalactite* is formed. If the percolation of the water containing calcareous particles be too rapid to allow time for the formation of a stalactite; the earthy matter is deposited from it after it has fallen from the roof upon the floor of the cave, and in this case the deposition is called a *stalagmite.* In some cases, the separation of the calcareous matter takes place both at the roof and on the floor of the cave; and in the course of time, the substance of each deposition increasing, they both meet, and form pillars, often of great magnitude, and which appear to have been originally destined to support the roof of the cave.

Caves of this kind occur in almost every country. Macalister's Cave, in the island of Skye, and those in the limestone hills of Derbyshire, are the most striking appearances of this kind hitherto observed in our island. But the most celebrated stalactitic cave is that of Antiparos, in the Archipelago, which has been particularly described by Tournefort. Similar caves occur in Germany, France, Switzerland, Spain, in the United States of America, and other countries.

In many places springs at a high temperature rise out of the ground, of a greyish white colour, occasioned by a quantity of gypsum, or chalk, which they hold suspended in a state of half-solution. In proportion as these grow cool, and loose their carbonic acid, the earthy particles are deposited, leaving the channels through which they flow covered with a compact alabaster, of a dazzling white colour.

The most remarkable spring of this description in Europe is situated on a mountain, near Radicofani. It supplies the baths of St. Philip in Tuscany, and forms the source of the little river Paglia. Advantage has been occasionally taken of this circumstance to obtain very beautiful impressions of bas-reliefs, by exposing the moulds to a current of such water, till they have become filled with the earthy deposit. The hardness of the alabaster depends upon the degree of obliquity at which the mould is placed to receive the dashing of the water. The more vertical the position, the harder the alabaster. The hardest models not being so white as the softer, the water is frequently caused to make a circuitous course before it reaches the mould, that all the grosser particles may be previously deposited. Even the softer ones, however, are as hard as Carrara marble, and surpass it in whiteness. The time required for these productions varies, according to the thickness, from one month to four. When the mould is sufficiently filled and the ground of the model has acquired a thickness capable of supporting the figures, the whole is removed from the water; the wooden supports are broken by gentle strokes of the hammer, and the incrustation on the outside of the mould is chipped off by repeated strokes. The brilliancy of the models is completed by brushing and rubbing them with the palm of the hand, when they become semitransparent and very beautiful.

The *sulphate of lime* forms another species of alabaster. The most beautiful white varieties of granular gypsum are selected by artists for statues and busts: the variegated kinds are cut into pillars, and various other kinds of ornaments. Those varieties that contain imbedded portions of selenite, when cut across, exhibit a beautiful iridescent appearance, and are named *gypseous opal*. In Derbyshire, and also in Italy, the very fine granular varieties are cut into large vases, columns, watch-cases, and other similar articles. If a lamp be placed in a vase of snow-white translucent gypsum, a soft and pleasing light is diffused from it through the apartment. It is said that the ancients being acquainted with this property, used gypsum in place of glass, in order that the light in their temples might be softened and harmonise with the place. The *phengites* of the ancients would appear to have been foliated gypsum. According to Pliny, it was employed instead of glass in windows, on account of its translucency. Alabaster is employed in agriculture, but its most important use is in the preparation of stucco. See Gypsum.

ALABES. A genus of Malacopterygeous fishes, of the Apodal division, or those without ventral fins, and of the natural family of *Anguillidæ*, or "eel-shaped" fishes. Only one species is known. It is small in size and an inhabitant of the Indian seas. In its general shape it resembles the rest of the family; and its distinguishing characters are the pectoral fins moderately produced, the rudiment of a gill-flap united to the skin on each side, and but only one gill-opening—a small hole under the throat.

ALANGIUM. A small genera of plants containing two species, but of so unique a structure that it forms an order of itself. Linnæan class and order, *Icosandria Monogynia*. Natural order, *Alangieæ*. Generic character: calyx, of six or eight teeth; corolla, six or eight linear petals; stamina, from ten to twenty-three. Fruit, a berry, crowned by the teeth of the calyx, pulpy, having three seeds enclosed in hard cases. They are natives of India, consequently require the temperature of a stove.

ALATERNUS. A species of Buckthorn, and one of the commonest evergreen ornamental plants in our shrubberies. The flowers are inconspicuous; but the dark green glossy foliage, resembling that of myrtle, is always admired, more especially as the foliage harmonises well with architectural forms. There are nine varieties.

ALAUDA—Lark. A most interesting genus of birds, usually classed in the graminivorous division of the passerine (sparrow-like), or small birds; but not living exclusively upon vegetable matter, they are field birds, feeding and nestling on the ground, rather in open places than where there is much cover, and rarely, and that only in some of the species, perching upon trees. They are mostly singing birds, clear, brilliant, and cheerful in their notes; and as they in general sing while hovering in the free air, and begin early in the season, when the odour of the fields is peculiarly grateful to the sense, they are greater favourites and more protected than many other birds which have more beauty in their plumage.

And they merit the esteem and protection which they receive from the country people, not only on account of the gentleness of their manners and the sweetness and enlivening character of their songs, but from the actual services which they render to the cultivator, in the destruction of both animals and vegetables which are injurious to him. These are, during the nesting time, earth worms, earth larvæ, earth insects; and also the winged ones, when they alight on the roots of plants for the purpose of depositing their eggs. At this time, the larks live dispersedly; and as they are very numerous they are found in all parts of the world where the surface is covered with succulent vegetation, but not on the heath-clad wilds or in the forests. The zone of green fields is their peculiar pasture; and although they scatter themselves far and wide during the season when they have their broods to rear, they collect in very numerous flocks in the winter.

Though often described by authors as "migratory" birds, they are not so in the proper meaning of the term. They have not, like the warblers, or the swallow tribe, a distinct and distant movement in latitude toward the pole with the stimulus of the vernal heat; and toward the equator as that stimulus diminishes in the autumn. They disperse, as has been said, in the spring; and, in autumn, they move centrally, or collect in those places which preserve their verdure, and are not subject to be covered with snow, or rendered miry by the stagnation of the winter rains.

During the flocking time they are of great service to the agricultural lands, whether these are under pasture, in stubble, or in winter crop. On the loamy pastures, where earth worms are abundant, and not only injure the ground themselves, but encourage the breed of moles, whose operations are still more deforming and destructive, they arrive about the time that the earth worms begin to pair; and as the worms are then much above ground, the larks capture them in great numbers, and thus prevent the broods; and this destruction of moles' food operates a corresponding diminution in the increase of moles. When the worms retire downward from the cold, the larks resort to vegetable food; and are of vast service in picking up the seeds of plants which are equally injurious to arable and to pasture lands. Even the grains which are left in the corn-fields would both exhaust the ground and contaminate the succeeding crops; they could not be gathered by man, and therefore, if the larks and other birds, which flock during the winter months, did no other service, they would in this be very beneficial to the cultivator.

But on all cultivated lands, whether they are in meadow or under crop, all the annual plants which are not purposely sown by man are injurious to him, as every such plant, which grows, whether in his grass meadow or his corn land, diminishes the return which he wishes to the full amount of its vegetable action. Now most of the injurious weeds are either annuals, and in the state of seeds during the season of repose, or they have annual stems, and die down to bulbous or other roots in the winter; all of them containing succulent, albuminous, or farinaceous matter—matter on which birds love to feed. The larks and other analogous genera pick up the seeds in countless myriads, and there are other races, such as the rooks, which attack the roots; and but for these, the labour of the husbandman would be more than doubled; and the best meadow could not be kept as valuable grass longer than a few years.

The larks have sometimes been confounded with the pipits (see ANTHUS), but though both are ground birds, the form of their feet, and the surfaces which they chiefly frequent, are different; the bill of the pipits is also much more slender, and less adapted for seizing worms or bruising the husks of seeds. The bill of the larks is intermediate in its form between those of the birds which feed more exclusively on insects, and those which feed mostly on seeds; their wings and tails are of that form which suits fully as well for ascent and descent as for straight-forward flight; and the form of their feet is peculiar, and as such may be taken as their best distinctive characters. See CLASSIFICATION, NATURAL, and AVES (Birds), for an explanation of the properties on which characters should be founded; and the use of them in the distinguishing of species, and determining their habits.

The following are the characters of the genus *Alauda*, which vary more or less in the different species:—

Bill, of moderate length, straight, pointed, subconical, the mandibles of equal length and without any notch, the upper mandible with a culmen or ridge advancing more or less on the forehead; the nostrils basal, of an oval shape, and defended by small feathers and hairs which are reflected forwards.

Feet, with the tarsi rather long, three toes before and one behind, all free and articulated on the same plane, so as to act equally in walking; the claws strong and very little crooked, long, especially that on the hind toe, which is called the spur, and from which the word *larkspur* becomes the name of an appendage of similar shape.

Wings, of moderate length, rounded, the third quill being the longest, and the first shoot sometimes rudimental; the tail strong and expansible.

These are the three generic characters of birds as connected with the three grand functions of feeding, walking, and flying. There are some other peculiarities that are sometimes mentioned, such as the feathers on the head produced so as to form a short crest, which is erectible. But the production or non-production of feathers, unless they are flying feathers, that is, unless they belong to the wings or the tail, cannot be made *generic* characters, though they may be *named* as such; and colour is a doubtful one even in the same species, for there have been black and also white individuals of the common lark.

The foot, of which the following is a representation,—

Foot of the Skylark.

is the leading generic character of the larks, and it is a very good indication of their haunt when not on the wing. Its principal functions are walking, and assisting the bird in mounting when it takes the wing; and it is a foot adapted for walking upon peculiar surfaces, namely, those that are uneven or elastic, but not wet—as, among the clods of a ploughed field, or on the grassy sod; but it is not, in general, adapted for perching or clutching in any way; and hence, though some of the larks do sometimes alight on trees, they do not perch there so as to hold their balance and feed, they rather stand, and use the tree as a resting-place, or post of observation. The freedom of all the toes, and their articulation on the same plane, enable them to act equally on all sides; and the long claws are stiffer, and the points of them can be moved more rapidly by the same muscular exertion, than if the phalanges of the toes had been longer and the claws shorter. The claws are levers turning on centres, the one which is pulled not being more than one-twentieth part of the other; and thus whatever velocity the muscles give to the *proximal* end which they pull, the distal end must move twenty times as fast, and thus act against the grass or other surface from which the bird rises with about 400 or (20^2) times the force. The feet of the larks thus can act something after the manner of bows, by which means the bird is, as it were, shot up into the air. They are further assisted by the elasticity of the grass or other surface of the sod, or its resistance to being bent, which in all elastic bodies, indeed in all bodies whatever, increases with the velocity of the body which tends to bend them.

The foot of the lark is thus a subject of very interesting study in the structure and mechanical action of animals; and we can trace an analogy with some of the mammalia, as in the horse, and several of the ruminating animals, and also in the great kangaroo of New Holland, all of which have natural pastures resembling those of the lark, and all leap from a long hoof, single or divided. For some account of the species, see the article LARK.

ALBATROSS (*Diomedia*). A genus of web-footed birds, belonging to Cuvier's subdivision of *longipennes*, or "long-winged birds;"—those which are much on the wing, fly discursively over the ocean, and find their food chiefly upon its surface. In some of their characters the birds of this genus resemble the GULLS, and in others the petrels; but they have enough of peculiarity to constitute them a distinct and well-marked genus, as well as a singular and interesting one.

They are by much the largest in size of all the birds which are *pelagic*, or range over the wide seas, and they are probably also the most discursive. Their proper localities are the polar portions of the great ocean, especially the Antarctic, or southern ones, where the sea bears so much greater porportion to the land than in the same latitude of the northern hemisphere; but the northern part of the Pacific also contains great numbers of them, as that ocean widens much sooner and more extensively in the line of their tropical migrations than the Atlantic. Even in the winter, the time when they are pelagic or discursive, they do not reach the centre of the torrid zone except as wanderers; though in that respect, too, they are more abundant on the Pacific than on the Atlantic. As is the case with all pelagic birds, they congregate in the breeding time; and as they congregate toward both the south and the north, some of them (even of the same species) breed at opposite times of the year; in November and December in the south, and in May and June in the north. Their generic characters are:—

Bill long, very stout, sharp in the tomia, or cutting edges, compressed, straight for the greater part of its length, but much hooked near the tip of the upper mandible, with a truncated point to the lower, exactly fitting the hook. The upper mandible is much furrowed, and channeled to the top by the nasal groove, in which the openings of the nostrils are placed nearly in the middle of the straight part, they are tubular, laterally closed, and open in front; but the nasal tubes are separated by the culmen, or ridge of the bill, and not united as they are in the petrels. The bill is thus a very powerful fishing instrument, as well for prehension as for cutting and tearing. The peculiar way in which the truncated part of the lower mandible slides upon the truncated portion of the other, produces an action much more powerful than that of any two edges of a bill, how hard and sharp soever, that merely shut against each other.

Feet, having the characters of walking and swimming feet combined; the tarsi are short but stout, and the tibia are naked a little way above the tarsal joints, which are formed like those of walking birds rather than swimming ones. The toes three, turned to the front, webbed for their whole length, with short but rather crooked claws; the hind toe wanting, or merely rudimental. The feet are thus better adapted for walking on land, or for tipping the water while the bird is on the wing, than those of the swimming birds properly so called.

Wings, very long and narrow, wedge-shaped in their terminations, the first quill being very short, and the second shorter than the third; but, though rather narrow, the wings are hollow, and take a very powerful hold on the air. The tail is well fortified by coverts, but short and wedge-shaped.

The form of the body partakes more of that of the air birds than of the swimming ones; but, notwithstanding the great length of the wings, the body is not shaped like that of the birds of most rapid flight. The habits correspond; for the birds are not so remarkable for the rapidity of their progress as for the length of time that they can remain on the wing.

They are very voracious as well as indiscriminate in their feeding; and fish even of the weight of four or five pounds, the floating spawn of those fishes which commit that substance to the mercy of the wide sea, and the various mollusca and other animals which are found at the surface of the ocean, are all received by the capacious gullet of those birds. When they fish, the skuas (*lestri*) can, by driving at them as they do at the gulls, make them deliver up the contents of their stomachs; but, in general, when the birds are taken, their stomachs are filled with gelatinous matter, rather than with even the remains of animals, though not with pure oil like the stomachs of the petrels.

There are several species; though, as was the case with even the most common of the gulls till very lately, the same bird, in the different stages of its plumage, may have been described as different species. As might be expected from the sources of our information respecting these birds, much exaggeration exists, both as to their size, strength, and cry: thus Cuvier very gravely tells us that their voice resembles the braying of the ass; on the contrary, we are assured by individuals who have heard the cry of full grown birds, when within a hundred yards of them, it consists of a sort of piping clang, rather deeper than that of the goose.

The largest species, and the one with which we are best acquainted, is

Common Albatross.

The Common Albatross (*Diomedia exulans*), which is also called the "wandering albatross," the "man-of-war-bird," the "Cape sheep," and a variety of other names. The distance from land at which these birds are met with, their great size, the contrast which their white colour forms with the sea and the sky, and the length of time that they will follow a ship, apparently always on the wing, and without ever reposing, or even alighting, cause them to be particularly noticed by sailors.

They are the largest of water birds, both in the weight of the body and the extent of the wings. They vary much, however, in weight, in lineal dimensions, and also in colour. Some of them, when lean, do not weigh more than twelve pounds; others, when fat, weigh as much as twenty-eight pounds. The length is less than that of the wild swan, which averages about four feet and a half, but the difference is in the neck of the swan; and while the wings of the swan rarely, if ever, exceed seven feet in extent, those of the albatross vary from ten to thirteen. The naked parts of the feet are dull reddish brown, the bill pale yellow, and the general plumage white, with reddish grey on the head, a few bluish feathers in the wings, and some hues of black or dusky brown across the back; but the plumage varies much; the reddish tinge on the head is most probably an indication of the breeding plumage; and the mottling on the body an indication of the immature bird. Information upon these points, as well as upon many others in the history of these very singular birds, is, however, very much wanted.

The general flight of the albatross, as it skims over the surface of the ocean in quest of its food, is not only singular, but singularly beautiful, and tends to render somewhat ludicrous those appeals which have been made to the bird, as one of the most wonderful instances of muscular exertion. Now the albatross appears to make less exertion in flying than almost any bird with which we are acquainted, not excepting the common kite, when it hovers, and even when it "gives itself to the wind;" and the only ground of wonder is, how a bird of so much weight can keep itself up with so little apparent labour. When the albatross rises, it tips the water a few times with its feet, striking with the wings at the same time; but when it has "gained its height," which in its ordinary fishing is not great, it will glide about for miles without almost any apparent motion, save the elevation of the external wing, and the depression of the internal one, when it turns. From the attitude of the body and the form of the wings, the air passes under the bird in the form of a wedge, and by that means exerts an upward pressure from its elasticity, which increases with the velocity of the bird; and the ascent of vapour *may* assist, as all birds which skim the surface of the water appear to do so with more easy wing than those that skim the land at the same elevation. At sea, too, the birds have more completely the use of the air, as even the common surface of the earth offers more friction, as is seen by the diminution of a wind from the sea, or even from a lake of moderate dimensions, as one recedes from the shore. Thus, if the pelagic bird has to range further than the bird which beats the surface of the land, its journeys are performed in a more easy manner.

When feeding, in calm weather, the flight of these birds is low, and they repose on the surface far from land; from which circumstance it is that they have got the name of Cape sheep. On their excursions to the feeding grounds, their flight is much higher, and so it is also when the weather is stormy; on both of which occasions they make more use of their wings, and become so exhausted, especially in rough weather, that they alight on the rigging of ships. In both of these cases the birds are deprived of the wedge-shaped current of air under them; and hence, in part at least, their greater fatigue.

When pelagic, the albatross captures numbers of the surface fishes, as well when they come naturally to the surface to feed as when they are forced out of the water by their enemies; as the flying fishes are, by the coryphene especially, the passage of which through the water is so rapid, that they cannot escape from it by swimming; and the moment that they are on the wing (or rather the fin) the albatross makes prize of them. When on the shores, which is chiefly in the high latitudes, their grand fishing stations are at the mouths of rivers, where there are always numbers of fish of moderate size; and there they attend and seize the salmon which leap in order to escape from the porpoise and those other enemies which follow them up the estuaries.

But though the albatross be thus voracious and successful against the finny tribes, it is rather a timid bird in the air. The sea eagles kill it, the skuas rob it, and the larger gulls attack it. When it meets with abundance of food, it gorges till it is almost stupified, and dozes on the water; and when alarmed in that state, it discharges the contents of its stomach, after the manner of the petrels, apparently for the purpose of lightening itself, both in a physical and physiological sense. When wounded, or on the ground, or even in the water, they make a powerful defence with their formidable bill.

As is the case with most of the tribe, the female lays but one egg. It is placed in a rude hollow of the earth, not high above or distant from the water, and not in a hole like the eggs of the petrels; the egg is white, very large, and of singular shape, being much elongated, and both ends nearly of equal thickness. The time depends somewhat on the latitude; being in September (which answers to March with us) on the coasts of South America; but farther into the antarctic summer, in places nearer the north pole. The eggs are eatable, though, as is the case with those of most sea birds, they are not very good; the white is said to consist more of gelatine than of albumen, and on that account not to coagulate or harden, when boiled. The nests are in lonely or desert places; and in those places of the northern hemisphere where they do breed, they appear to do it rather early in the season, as by Midsummer they resort to the northern bays and estuaries. On the east of America there are hardly any, but between the north-west of that continent and the opposite coast of Asia they are very numerous, but at first in very lean condition. Food is plentiful then, however, as June is about the time when the inhabitants of the northern seas are in full activity, so that they soon get fat; and a bird which weighed only twelve pounds in the middle of June, will weigh twice as much in the course of one month. They are easily caught with a large hook, and almost any bait, for they pounce upon and swallow with avidity any thing they see floating, if their gulp, which is a very large one, will take it in. Their flesh is hard, tough, and unpalatable, and not eaten by even the rudest tribes; but sailors, when they have been long in the polar seas without much provisions, contrive to eat them, after skinning, steeping them for a time in sea water, and cooking with pungent sauces. The wing bones are the chief attractions to the people of the northern shores and islands. They are very long, hard, and tubular, and so adapted for many purposes in the rude economy of people whose chief dependence is on the sea, and to whom bone is, in a great measure, a substitute both for wood and the metals.

There are several other species mentioned by authors, one of the best known of which is *D. fuliginosa*, or the "quaker bird" of the sailors. It is brown, with the bill, head, and tail white; but too little is known of the history of the birds for enabling us to speak with precision as to what may or may not be distinct species. The quaker birds have been described as inhabiting more polarly than the one we have described; as seldom appearing without the antarctic polar circle; and as breeding socially, or in numbers together, about or near the middle of summer. But in all parts of the world, and in respect of all the species, whatever may be their number, we do not know the whole year's history of a single albatross; neither do we know the changes in the colour of the plumage, or the beak and feet (which in many birds changes along with the plumage,) of one individual, from the time of its leaving the egg to its full maturity.

Nor can we implicitly depend on the additions that have been made to the natural history of the high seas by the continental naturalists; for, though the voyagers of that part of the world have, till of late years, probably been more attentive to natural history than British voyagers, yet they have been deficient in experience, inasmuch as they have much more rarely visited remote parts; and as they have thus seen the animals, whether birds or others, in a more transient manner, they have stood in more danger of multiplying the changes of a single species into different ones. It has been too much the custom with mere compilers among ourselves to adopt the notions of those foreigners, with some few conjectural or rather random variations, in order to give an air of originality; and hence upon many subjects which, like the albatross, involve curious points in the natural history of the globe, many errors have crept in, much to the disadvantage of the student.

ALBIN. A variety of the mineral called APOPHYLITE, which see.

ALBINOS, literally *white*, a name which was first used by the Portuguese, in their voyages to the coast of Africa, as expressive of certain individuals whom they found among the negroes there, having the same features as the other negroes, but with white skins, white hair, and red eyes, and for these reasons forming such a contrast with their swarthy countrymen, as was well calculated strongly to draw the attention of strangers, especially in an age during which interprise and superstition were both equally energetic. Dampier and his attendants also found Albinos among the red men near the isthmus of Darien, bearing nearly the same relation to the rest of the tribes there as those of Africa bore to the rest of the negroes. Subsequent observation has found them in most parts of the world, though much more abundantly in some than in others. In all places, they have the average features of the rest of their countrymen; but in all countries they have nearly the same colour, or rather the same absence of colour, a pale and death-like white, without tint or bloom of any kind.

Albinos occur most frequently in the tropical regions of the world; as on the coast of Guinea, in Ceylon, Sumatra, and Java, and the intertropical parts of America. As the latitude increases they are comparatively few; and there are no notices of any among the people of the extreme north. It does not appear, however, that the heat of the climate is the chief, or at all events the only cause of their occurrence; for, among the European ones, two, who exhibited themselves in England many years ago, and gained as much money by so doing as enabled them to establish themselves comfortably in their own country, were natives of the cold mountain valley of Chamouni, on the shoulder of Mont Blanc, not far from the perennial icebergs. In such localities they are, as has been said, rare; while in the tropical parts both of Africa and America, they are, in some places, so numerous that they have sometimes been described as a separate race. That, however, is incorrect; and it does not appear that there is any hereditary tendency in albinoism, although it appears to be much more numerous among the old residents than among migrants. Farther, it does not appear that albinoism is produced by or in any respect much connected with disease of any kind, or unhealthiness of climate; for the races among which it is most common are they who can best stand the climate. Indeed, when we would ask for a natural cause for the appearance of those very singular beings, we find ourselves utterly in the dark; and almost the only rational conclusions to which we can come is, that the darker the *aborigines* of any country, and the more equinoctial the climate, albinos are the more numerous. Buffon's notion that it is the "primitive colour" of the human race, to which they are making constant efforts to get back again, is as absurd as the other attempts at philosophy in that eloquent misleader in natural history; and would not be worthy of notice, if his very fascinating, but very faulty, book were not still to be met with in the hands of the ignorant.

The other theories, which claim to be rather more philosophical, are also without any thing like demonstration. The colour of the albino is the colour of death, before decay has begun to spot its chalky whiteness with the prints of corruption; or it is that colour which the body assumes when the owner stands aghast in the extreme of terror, or is, according to the common saying, "dead with fear." There are many well-authenticated instances of extreme terror, or extreme agitation, or grief—all of which have in some measure similar effects, turning the hair white, and not white merely, but silky, like that of an albino, in the course of a single night; and that, too, without any injury to their general health, or without any more than hereditary tendency to turn grey-haired on the part of the individuals so affected. In consequence of this, it has sometimes been supposed that albinoism is the result of fear, agitation, or some other powerful action of the passions in the mother; and though these matters lie beyond the reach of demonstration, there is no doubt, that at certain stages of the period of gestation, the passions and affections of the mother have a powerful influence upon the child. Still, as we are ignorant, and must, from the nature of the case, remain ignorant of the mode of action in all such matters, we can use them only in a conjectural way. The device of Jacob with Laban's cattle, in procuring a "speckled and ring-streaked progeny," by means of the "peeled rods," has been sometimes adduced, but it does not properly come within the scope of the argument.

The European albinos, which have been the most open to philosophic observation, have had nothing peculiar in the cast of their features, the form, strength, or healthiness of their bodies, or the power of their minds. The only peculiarities are, the skin of the most delicate whiteness, the hair white, of silky texture and shining silvery gloss, and the irides of the eyes of a beautiful pink colour. Still there is some difference between him and the albinos of races naturally darker: the skin is not so deadly white, but has more of the transparency of lily-white living beauty than of the opaque and chalky colour of death.

The eyes of albinos of all nations are delicate, and cannot bear the light so well as the eyes of people of the ordinary colour; and though a very fair complexioned European is proverbially weak-eyed, so much so that "blind fair" is a popular expression, yet one of these can bear the equatorial sun better than an albino negro.

The most correct information respecting the structural cause of this singular variety of mankind which we have, (though it does not explain, or attempt to explain the inducing cause,) is from the opinion of Blumenbach, borne out by the dissections of Buzzi of Milan. The redness of the eyes is owing to the absence of the black mucous substance (*pigmentum nigrum*) which, in the eyes of those who are not albinos, is spread over the choroid coat of the eye and the iris; and, in other eyes, the light is always the more difficult to be borne the less abundant this pigment is. Whether the darkness of the pigment is occasioned by its decomposing the more active portion of the light which falls upon it, and thus defending the parts that are below, is rather a delicate point to be ascertained; but at all events it is probable, inasmuch as the darkest eyes are best able to endure the light, which ought to be the very opposite effect of the dark colour if there were no specific action in the pigment. These facts would lead to the conclusion that the colouring matter is charcoal, in that state in which it becomes one of the best conductors of heat; but what the peculiarity of structure may be which enables some eyes to produce this charcoal more easily and in greater abundance than others, we have not any satisfactory means of ascertaining.

Buzzi was the first who demonstrated that the colour of the skin is owing to the imperfection or the absence of one of the three parts of which the skins of ordinary human beings are made up. These parts are, first and externally, the epidermis, cuticle, or scarf-skin, made up wholly of coagulated albumen, without vascular tissue, nerves, feeling, or sensation of any kind, and in most instances fading, after a time, into scales, or other exuviæ; secondly, the mucous web, or tissue (*rete mucosum*), which consists of a coat of fibrous network, loaded with a mucous pigment, something analogous to that on the iris and choroid coat of the eye, and on which the colour and complexion are understood to depend; and, thirdly, the true skin (*cutis vera*), which consists of muscular fibres, nerves, and blood-vessels, is remarkably sensitive, incapable of bearing the action of the air without great pain, and is probably the only part of the triple integument which can be regarded as possessing life and feeling in the ordinary sense of the terms. It has been said that the epidermis has a tendency to fade off in scales, which is more or less prevented by the exudations through its pores from the parts beneath; and there is some reason to suppose that these exudations proceed, in part at least, from the mucous tissue, which is the seat of colour. The ground of that supposition is, that the darker the tint of the skin the softer in general it is, and the stronger the peculiar odour which it gives out; and that in the albino negro the skin is hard and dry, resembling, in some respects, the skin of a leprous person; and it, in a great measure, wants the odour given out by the skin of the dark negro.

The hair appears to derive its substance from the true skin, and its colour from the mucous tissue; and the colouring matter which it receives from the latter seems to increase its volume, and also to give it an unctuous feel. The hair of the Albino wants, of course, the colouring matter; and instead of being humid to the feel, it is silvery or pearly. The same may be said of grey hair, which always wants the moisture of that which retains its colour.

Though, in general, there appears to be a well-established connexion between the degree in which the mucous pigment is deposited on the iris and choroid coat of the eye, and that which it attains in the mucous tissue between the epidermis and the skin all over the body, yet there is not an exact proportion between the one and the other. There are races of people who have the skin dark, the hair deep black, and the eyes very light grey; and there are many individuals who have the skin and hair both very fair, and the eyes black; and the dark eye appears to be able to stand the light when accompanied by the fair skin and hair, as well as where these are of its own complexion.

In the production and continuance of hair upon the human subject, there appears also often to be a difference between the true skin, which produces and maintains the substance, and the mucous tissue which provides the colour; and this to such an extent, as that the yielding of the one is often accompanied by a more certain maintenance of the other. Many of those in whom the hair becomes grey at an early period of life, retain it without diminution in quantity or in growth to the very close of life; and, on the other hand, many of those who begin to lose their hair early in life, retain what remains unaltered in colour to the very last. Indeed, so well marked is the distinction between those cases, that it is a common saying, that the grey man seldom becomes bald, or the bald man grey. There have also been instances of individuals in which the true skin was incapable of producing hair at any period of life; but in them the mucous tissue appears to have been imperfect, as they have been usually of fair complexions and weak eyes, with a reddish tinge on the iris; and those also upon whom hairs are comparatively few and rudimental, have been generally fair, and the few rudimental lines have been white.

That albinoism is owing to the want of the mucous tissue is further proved by the results of those wounds in the skin by which that tissue is topically destroyed. A surface wound upon the finger, especially if it be kept in a state of irritation for some time, will produce a white mark on the nail, which will travel gradually along that organ, until it is cut off at the point; and if the injury has been of a very serious nature, and the irritation long continued, a derangement of the nail may be produced, which will never be removed. Galling the back of a horse also produces white hair after the wound heals, even though the colour has been originally deep black; and jockeys sometimes avail themselves of this, and by destroying the mucous tissue with a hot iron produce a white spot on the forehead of the horse, if such a mark be considered as ornamental.

All these facts tend to prove that the white colour in the albino, whether of the skin or the hair, is owing to the want of the mucous tissue; but they do not throw any light upon the cause of the deficiency, or want of that organ. One can, however, easily enough understand why albinos should be more common among people of darker complexion, because among such a people the mucous tissue is of more importance as the action upon it is greater. That, in any particular district, it takes place more readily among the aborigines than among emigrants, is a further proof of the same position; and on the same fact, it is not very difficult to ground a theory of the differences of colour that are found among the human race, supposing them all to be issuing from a single pair. See MAN.

Human beings are not the only animals among whom albinos appear. They are found among very many of the mammalia, and not a few of the birds; and where they occur, they have nearly the same corresponding colours of the skin and the eyes, and the same pain in the latter when exposed to bright light, which characterise the human albinos. Albinoism among them does not, however, depend upon the absence of the colouring influence of the sun, as it appears to do in those species which turn white during the winter; but there is no such marked diminution of the number of albinos, from the regions of the equator to the higher latitudes, among the other animals, whether mammalia or birds, as there are among the human race. Among the cold-blooded animals no albinos have been found; or at least any traces which have been observed in them have been easily referable to disease, whereas in the albinoism of the warmer-blooded animal there is no disease: but merely a deficiency of the original structure. See COLOUR of Animals.

ALBUCA (Linnæus). A family of bulbous flowering plants, natives of the Cape of Good Hope. There are nineteen species described, which are usually kept as green-house ornamental plants. Linnæan class and order, *Hexandria Monogynia*. Natural order *Aspho-*

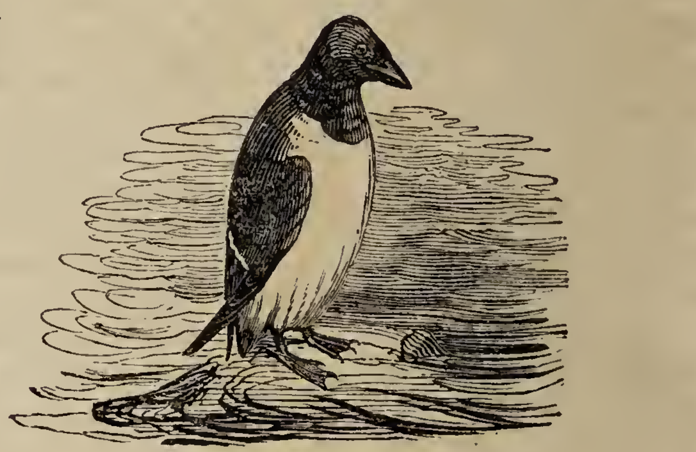
deleæ. Generic character: calyx, six sepals distinct, the three lower ones are strait and connivent, swollen and thicker at the points; the three outer are spreading; stamina, six, rarely all fertile, sometimes only three opposite the inferior petals bearing anthers. Style triangular, terminating in three points; capsule of three places containing seeds.

ALBURNUM is the name applied to the imperfect wood of a tree, that is, to the outermost layers of wood situated immediately below the bark. It is wood in a young state, having not yet acquired the hardness and compact texture which characterise perfect wood. It is also called sap-wood by carpenters, because less durable than the first-formed layers which are called, as well from their situation and hardness, heart-wood. All kinds of timber gain solidity and weight gradually. An oak tree, for instance, of twenty years' growth, if cut transversely, will present in the body of the wood twenty concentric circles indicating the age of them. Of these, twelve or thirteen will be dark coloured heart, and seven or eight will be white coloured sap-wood. Various opinions have been advanced in regard to the mode in which the alburnum is formed. Some suppose that it is derived from the bark, while others say that both it and the bark owe their origin to a peculiar fluid called *cambium,* formed by the descending sap of the plant. This fluid thickens and becomes organised, giving rise each year to a layer of bark and a layer of alburnum.

ALCA—The Auk. A genus of birds, belonging to Cuvier's first division of web-footed birds, or those which are divers. The genus has been subdivided by modern ornithologists, so as to exclude the puffin and some other species; and, as it now stands, the following are the leading generic characters: bill straight, compressed towards the tip, tip of the upper mandible hooked, that of the lower forming a salient angle. Nostrils lateral, near the middle in length of the bill, lineal, nearly closed by a membrane, and covered with feathers, as are also the basal halves of both mandibles. Feet short, placed far back, so that the birds walk upright and awkwardly. The feet, with only three toes in front, completely webbed; and acting obliquely in the water, like those of the other divers. Wings short, and, in some of the species, merely rudimental, and unfit for flight; but others fly with ease, though flying is not their general habit. It is, however, singular, and to be regretted, that Cuvier's mistake, that "their wings are decidedly too short for supporting them, and they cannot fly at all," should have been allowed to stand in the last edition of the *Regne Animal,* when the first species which he mentions, the common razor-bill (*Alca torda*) can not only fly, but fly well, is a migratory bird, and builds very high on the ledges of lofty rocks. It finds its food in the sea, and during the incubation, the male purveys for the female, while she sits at a height of several hundred feet perpendicularly above the water. To *climb* such a height, by the help of the beak and feet, such feet as an auk has, would be difficult, if not impossible. This mistake is the more singular that the species which can fly visits the shores of France, and that which cannot fly does not.

The species which can fly are not, however, air-birds; they never feed on the wing, neither is it their general habit to feed swimming on the surface of the water. They dive and feed under the water, for which their forms and their feathers are equally well adapted. During the greater part of the year they live dispersedly, scattering themselves along the shores, and to the islands which are uninhabited, and at some distance from the main land. About May, they collect to their breeding places; the wingless ones choosing the fissures and holes near the water, and the winged ones the ledges higher up; and when the broods are ready to shift for themselves they again disperse, though some are met with on different parts of the coast of Britain or its isles all the year round. In winter they are found, but not very abundantly, on the flat shores of the continent, from near Calais to the entrance of the Baltic; but they do not resort thither in the breeding season. From what has been mentioned of the male fetching food for the female while sitting, it must be obvious that the birds cannot make long journeys at that time.

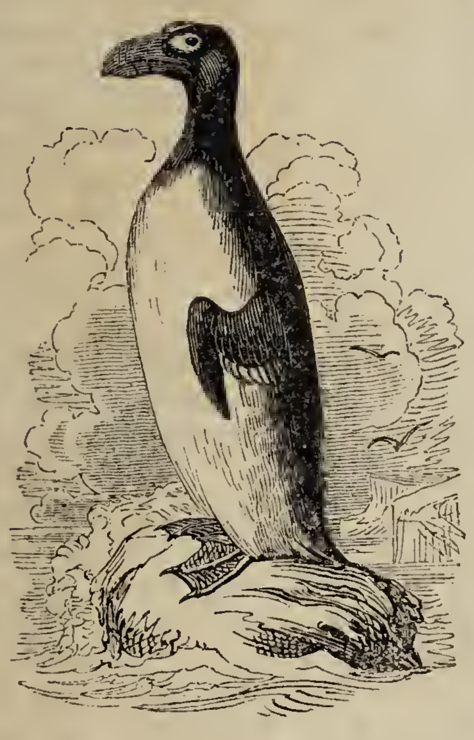
These birds, as well as all the analogous genera, have only one brood in the season, and that consists of but one individual. The egg is, however, very large, and the female is a close sitter. It should seem that the elaboration of a plumage, which shall fit the young birds speedily for diving, requires both a large egg and a careful incubation. Auks are interesting birds, but they are unknown in the interior of the country, and by no means familiar on the coasts, except at the great nesting places of the sea-birds, and these are usually the places to which there is not much resort. There are two species which may be briefly noticed. They are both birds of the northern seas, and do not, in any longitude, range far to the south.



Common Auk.

The Common Auk, or Razor-bill (*A. torda*), is about fourteen or fifteen inches in length; and, though the closed wings do not extend further than the rump, they are about two feet three inches when expanded. The tail is long and wedge-shaped, or rounded at the extremity, and the powers both of that and the wings indicate a bird which ascends and descends readily on the wing. In summer, the head, neck, and most of the upper parts are black; but there is a narrow white band in front of the eyes; the throat and upper part of the breast are brownish; and all the rest of the under parts, together with the tips of the secondary quills, are white. In winter the brown fades to white, and the blue on the upper part becomes dull and brownish. The males and females resemble each other in both plumages; and they have the bill black, with a white band in the middle. The young birds have the breast mottled with white; the white band across the eyes indistinct; the bill shorter than in the mature birds; and the white band upon it is wanting. It is a character of all the analogous genera to have the bill shorter in proportion in the young birds. The egg is very large for the size of the birds, being at least three inches in length. Its ground colour is white, spotted with black. Both the eggs and birds are rather rank and fishy; but the northern islanders, who run no inconsiderable hazards in obtaining the eggs, continue to employ them as food after due seasoning. The nicety with which the eggs of these and other sea birds are balanced on the ledges of the rocks, has led authors to assume that the birds have some means of cementing them; but the assumption needs no refutation.

The Great Auk (*A. impennis*). This is a much larger kind than the former; much more rare in its appearance, and obscure in its habits. It is sometimes seen on the shores of the more remote Western Isles of Scotland in the months of May and June; but not often then, and rarely indeed at any other season. It is a large bird, being about the size of a goose; but it is naturally a water bird, and not adapted for progressive motion, either through the air or along the earth. Its wings are only about four inches in length each, and they have no feathers at all adapted for flying, so that their principal use is in guiding its course under water. Upon land the feet are not much more serviceable than the wings are in the air. The bird cannot move, or even balance itself upon them, without bringing the whole of the tarsi to the ground, and thus it shuffles along in a very awkward manner, flapping its wings, and wriggling. It can, by the help of its bill which is very large, contrive to drag itself a few yards above the level of the water; but the operation is one of great apparent labour, and no little time. In the water, however, it is "at home," and dashes along with the ease and velocity of a fish.



Great Auk.

The bill is four inches and a half in the gape, and more than one inch and a half in depth, much couched in the culmen, or ridge of the upper mandible, strongly and firmly made, and black; it is thus an instrument capable of catching a fish of considerable size. The upper parts are mostly black on the cranium; the under, brown forwards, and white behind; and the presumption is, that it is subject to similar changes from age and season as the common auk.

The egg (there is but one) is not deposited on the ledges, as in the former species, but in a hole of the rock, or an excavated hole on the dry shore. The egg is very large, not less than six inches in length, similar in its colours to that of the common auk. The above figure will give some idea of the general shape of the bird.

ALCEDO—Kingfisher. A genus of birds of which the characters are: bill long, straight, quadrangular, pointed at the tip, sharp in the tomia,

Head of the Kingfisher.

diminishing gradually to the pointed tip, and having the height and breadth nearly equal throughout. The nostrils basal, near the sides of the upper mandible, and pierced obliquely. The tongue very short. The whole organisation of the mouth adapted for fishing rather than the capture of insects. Feet short and weak, and not well adapted either for climbing or for walking on the ground. The three front toes are united at their bases, and the exterior one is as long as the middle; the tarsi are slender and short, and the tibia lines a little above their articulations. The foot can be used in scraping and excavating the earth, but it is very awkward for progressive motion. Wings long and powerful in their motions; but the tail is short, the birds regulating their course by their long bill. The plumage is very smooth and glossy, not easily ruffled or wetted by water. The nests are in holes in the banks of those streams in which the birds seek their food. They are solitary birds in their habits, so much so that the pair are not seen together except during breeding time. They are not abundant in any part of the world, and in most places they are rare. Their variety, their quick motion, their bright colours, their peculiar form, and the times at which they are the most assiduous in their fishing, have rendered them noted birds from very early times. Those treacherous days of more than ordinary stillness and clearness of the air, which are generally, if not always, followed by bad weather have been called "halcyon days," because during them the kingfishers are peculiarly active. The birds, of course, know nothing of the coming storm; but that state of the waters when there is neither ripple nor evaporation at the surface, renders the small fishes on which the birds feed more discernible. There is only one European species. See Kingfisher.

ALCYONIDÆ. An order of birds partaking in part of the characters of the *Anisodactyli*, or unequal yoke-toed birds, and the *Chelidonia*, or swallow tribe. They agree in part with the *Syndactyli*, or second division of Cuvier's great order of Passeres; but the characters of that division are so varied, and in some instances so irregular, and the feet (especially in the *Alcyonidæ* properly so called) form so very unimportant a part of the whole character, that it is exceedingly difficult to obtain any arrangement which is either natural or satisfactory. See Syndactyli.

The *Alcyonidæ*, properly so called, or "kingfisher" birds, have the bill long or of middle size, nearly quadrangular in its section, and either straight or very slightly arched. Their tarsi are short, and their feet very unfitted either for climbing or for walking; and they have four toes, the three before united at their bases, and the hind one more or less enlarged at the base. Their wings are powerful for their size; but the tail in some of them is very short. They all prey upon the wing, some chiefly upon insects, others chiefly upon small fishes. They inhabit the banks on streams and rivers, generally in solitary places, and nestle in holes. The colours of their plumage are rich; and there is little difference in the males and the females, or in the old and young birds. Their motions are exceedingly abrupt and rapid, jerking now here now there, and making their haunts gay with the rich and strongly contrasted tints of their plumage. The style of their flight is very like that of the martins, especially those martins that catch their prey on the surface of the waters. It is on this account that the French call the kingfishers, which may be considered as the type of the order, "Fishing Martins;" but there are some which catch the larger water insects, and seldom fish, unless when their insect supply fails. See Alcedo Merops.

ALCYONITE. A name given to the fossil remains of the Alcyonium, a zoophyte belonging to Lamarck's third class, the *Carnosa*, and which is allied to the sponges. The fruit-like and spongiform fossils belonging to this class are involved in much obscurity, in consequence of the want of a satisfactory arrangement of even their recent species, their nature and structure being very little understood; for which reason a more detailed and particular account of them may be acceptable to our readers, especially as they are so exceedingly abundant, that in some situations scarcely a flint can be broken in which traces of their structure may not be detected: and also, as a condensed summary of what is known concerning these singular bodies is still a desideratum in works of a similar description to the present one.

The distinctive characters of the recent sponges and alcyonia, as proposed by Ellis, Lamarck, Lamouroux, and others, are, generally speaking, of very great nicety, such as the presence or absence of polypi, supposed to be in the former of such delicacy as to shrivel up immediately upon being taken out of the water, and thus to elude observation; whereas in the latter, they may be rendered visible under similar circumstances, or upon others equally difficult of observation, even in the living species. The most marked distinction, however, is, that the alcyonium possesses a spongy or gelatinous body inclosed in a tough cellular integument containing polypi, while the sponge presents a similar body without the fleshy covering, nor have any polypi as yet been discovered as its inhabitants.

Characters like these, as might be expected, are for the most part absolutely impossible to be ascertained in substances in the fossil state, where the solid parts of animals alone are preserved, and consequently numerous obstacles still present themselves to a complete and satisfactory arrangement of these bodies. From the fruit-like forms which they so frequently present, they were in the infancy of the science of fossiology, called by the names of those fruits to which they were supposed to have a resemblance; but their being subsequently found to have a decidedly animal structure, rendered such a nomenclature totally inadmissible; and in order to obviate in some measure the various difficulties which present themselves in the classification of these intricate fossils, various other arrangements have been suggested. In that very valuable work, "The Geology of England and Wales," by Dr. Conybeare and Mr. Phillips, it is proposed to separate the alcyonites into two divisions, the first to include those whose fibrous reticulations run confusedly together, their meshes presenting no regular determinate figure—and in the second to place those in which they are regularly disposed, giving to the whole mass a plicated character. Of the first of these divisions they form five genera. The first includes those of a branched form; those which are palmated with the larger pores arranged in quincuncial order form the second genus; the third embraces the irregularly turbinated and funnel-shaped masses, whose forms are exceedingly various, probably arising from the different contractions of the mass; in the fourth we have those which are fig-shaped, pedunculated at the bottom, and presenting a funnel-shaped cavity, penetrating in the direction of the axis, with large pores radiating from the same; and the fifth is characterised as forming large irregular sessile masses, the upper surface tuberculated and traversed by large irregular ramifying pores. In the regularly plicated division, the most remarkable is the fossil described by Mantell in the eleventh volume of the Linnæan Transactions, to which we shall shortly again refer.

Another arrangement of fossil spongiform bodies is proposed by Parkinson in his Introduction to Fossiology. He divides them into four genera, which he designates as spongia, syphonia, mantellia, and alcyonia, and proposes the following as the characteristic distinctions by which each genus may be determined. "If," says he, "a cellular texture, such as would be formed by the irregular decussation of membranous substance, can alone be traced without any appearance of tubuli, the place of the fossil would be under the genus sponge; but if in addition to the spongeous texture, straight or regularly divaricating simple tubuli should appear, its place would be under syphonia. If, whether spongeous texture appear or not, simple tubes are discovered connected laterally either by anastomosing or intercurrent tubuli, the fossil may be considered as belonging to mantellia; but should the more compact parts of the fossil or its porous substance display the evident labours of polypi, no doubt should be entertained of placing it under the genus alcyonium." The last three of these divisions are those usually included under the name of alcyonites; and to the first of these, the syphonia, are to be referred the various fossils shaped like funnels, cups, and fruits, described by M. Guettard, as found at Verest near Tours and Saumur, and also at Mont Richard in Touraine; and also those mentioned by the Rev. J. Townshend, as found in the green sand of the Vale of Pewsey, as well as many figured in the second volume of the Organic Remains. To these must be added those singular fossils discovered by Mr. Webster in the Isle of Wight, to which, from their long stalks and tulip-formed superior terminations, he gave the name of tulip alcyonia. Specimens of fossils of this genus have also been described by Miss Bennet, as found in the sand in the neighbourhood of Warminster, having a great variety of forms, as round, cylindrical, straight, ramified, oblong, cup, or funnel shaped, elongated like a cucumber, tulip-formed, being exactly like those described by Mr. Webster, and also assuming the figures of various sponges. Some are also lobated, having from two to five or six lobes closely united together upon one stem; and one specimen is described, in which two stems arise from the same base, the one terminating with three, the other with five lobes. A more particular account of these very curious and interesting fossils may be found in the Geological Transactions, and also in the description of them by Miss Bennet. Under the second genus we find the fossil before alluded to as described by M. Mantell, and the name Mantellia is given it as a compliment to that gentleman.

Of the third genus many highly interesting specimens are also to be met with, generally imbedded in flint or chalk; and, indeed, they may be said to be almost entirely confined to the chalk formation, but slight traces of them being to be met with elsewhere.

Since the publication of the works now referred to but little has been done as to the general arrangement of these fossils. The fig-shaped ones described by M. Guettard have been formed into a new genus under the name of choanites; and the genus ventriculites has been established for the reception of the fossil discovered by Mr. Mantell, and described under this name by him in his late very valuable and highly comprehensive work, "The Geology of the South-East of England;" and as the whole description is full of interest, and gives proof of the very great research for which this gentleman is so justly celebrated, we shall, for the information of our readers, give a condensed abstract of it. He describes the ventriculite as a zoophyte of a funnel-shape, having the base provided with radical fibres, or processes of attachment, the external surface reticulated, the inner covered with minute perforated papillæ. The original substance was spongeous or gelatinous, and the zoophyte was probably capable of expansion and contraction. The common species, the radiatus, has the external integument formed of subcylindrical anastomosing fibres radiating from the centre to the circumference; the papillæ on the inner surface are formed by the open extremities of short transverse tubuli. This fossil assumes a great variety of forms, and consequently it is necessary to examine a considerable number of specimens in order to form proper conclusions respecting it. Those which are enveloped in flint are usually cup-shaped or turbinated, while those imbedded in chalk exhibit a broad circular disk; the external surface presents a number of cylindrical fibres extending in a radiating manner from the centre or base to the outer margin, and by their frequent divisions and anastomising constitute a reticulated integument capable of considerable contraction and expansion. In its contracted cylindrical form it is from one to six inches in length; when expanded its diameter occasionally exceeds nine inches; the thickness of its substance is seldom more than 0·2 of an inch.

A specimen, figured in the work from which this abstract has been taken, exhibits a narrow zone of flint surrounding the wider part of the fossil (which is funnel-shaped) at a small distance from the outer edge; when, from any cause, the included zoophyte is destroyed, the ring remaining uninjured, presents the appearance of a broad flat ring, and thus affords a satisfactory solution of the origin of those broad annular flints resembling a quoit, which are occasionally found on the ploughed land of the downs of Sussex. It also leads to the singular conclusion that the silex, at the period of its mineralisation, was in the state of a thick viscid fluid, otherwise it is difficult to understand why it should not extend to the margin, instead of being consolidated in a ring at a short distance from it.

The inferences drawn from a careful examination of these fossils lead also to a very satisfactory explanation of the structure of the ventriculite when living.

Its general form appears to have been that of a hollow inverted cone, having numerous branching fibres proceeding from the base attaching it to other bodies. Externally it was composed of a reticulated integument capable of expanding or contracting according to the impressions received, and internally it possessed a surface covered with the apertures of numerous tubuli, probably the openings of vessels by which nutrition was effected. Its expanded state was possibly favourable for the discovery of the substances destined for its nutriment, which, by the subsequent contraction would be imprisoned in the funnel-like cavity, the nutritious particles being probably absorbed by the openings so numerously distributed on its surface. Whether they were capable of changing their situation by detaching their radical processes cannot now be ascertained; but it is probably that, like the actiniæ and alcyonia, they were permanently fixed to the rock on which they grew.

The alcyonite fossils are found in various situations. Those of the tubular fruit-like forms are found chiefly in the green sand. The ventriculites and other bodies referable to this class are principally met with either imbedded in chalk or in the flint which is so abundant in their formation. The diluvial gravel is also full of them. Those remarkable masses of flint found in great abundance in Ireland, and also in other places, called paramandra, have every appearance of having been formed round some species of tubercular alcyonia, which must have been of enormous magnitude. We may also state, that those singular hollow nodules, known in the days of superstition and ignorance by the name of eagle stones, and to which many magical as well as medicinal properties, such as the preventing abortion and the discovery of thieves, were attributed, have also been referred to this class. They consist of a flinty covering, probably formed over a sponge or alcyonium, which decaying, has left a cavity in the interior, the chalky, earthy, or silicious remains of which occasion the rattling heard upon shaking them. They were called eagle stones from the ridiculous opinion that they were carried by the eagle into her nest, in order to prevent the eggs from becoming addled. They are now called geodes.

After all that has been said, our readers must be aware of the great difficulty experienced by men of science in accurately classing or describing animals of so changeable a nature. As zoophytes in general are constantly in motion in quest of food, and yield without difficulty in every direction to the slightest pressure, the animals, when imbedded, might have been softly covered or rudely crushed, and thus we may account for the immense variety of forms under which they have been discovered.

ALCYONIUM, forms the fourth class of polypidoms not subdivided into orders. It includes all such as are called carnoid or flesh-like polypidoms, being composed of a fleshy mass, wholly animated, entirely covered with polypi, and possessing no central axis; they are of various shapes, having the appearance of a thick, porous, or cellular mass, spread out or ramified, sometimes lobed, and at others in the form of a crust; the interior substance spongy, or like cork, surrounded by a radiated, tubulous tegument, and enclosed in a hard leathery rind.

The cells of this polypidom are round, of various diameters, from the eighth to the fifth of an inch, separated from each other by thin partitions, rendered opaque by a great quantity of solid globules, that appear to form the least animated part of the zoophyte. Each cell encloses a polypus, composed externally of a transparent sac or membrane, strengthened by eight filiform longitudinal fibrous bands, placed at equal distances, and difficult to be perceived, owing to the presence of numerous transverse and parallel fibres. The longitudinal fibres seem attached to the borders of the cells and to the roots of the tentacula. The sac (which is capable of extending and contracting, the upper part falling back when the little animal retires within its transparent covering) encloses the body of the polypus, having in the centre a hemispheric mass, divided into eight equal parts by vertical partitions, whose summits present a round or lozenge-shaped opening, at the will of the animal, which probably forms the mouth; the borders are furnished with irritable appendages, the form of which it is difficult to distinguish. The tentacula fold over each other, and surround the globular mass, which then forms a spherical or pyramidal body.

The general envelope of the polypus rises a small way above the surface of the polypidom, and all the parts it encloses are easily observed with a good lens. The complicated organisation of the alcyonian polypi renders any description of them extremely difficult; many points of resemblance seem, however, to unite them to the animals of the harder polypidoms. This class varies much in the size of its species, some of them extend in patches of greater or less thickness on the surface of the bodies to which they adhere, whilst others raise their branches to the height of several feet. Some live on marine plants; others delight more in muddy waters, raising their animated tubercles above its surface; but the greater number attach themselves to rocks and the larger shells, which they sometimes cover with their polypean mass. They are found in all seas and at all depths; but from the difficulty attending researches into the nature and habits of these creatures, only about fifty species have been distinguished, forming probably but a very inconsiderable portion of the number existing.

This genus is frequently found in a fossil state, and the species are far more numerous than those discovered in a recent state.

ALDER-TREE. A genus of forest trees, indigenous to Britain. Belonging to the Linnæan class and order, *Monœcia Tetrandria.* Natural order, *Amentaceæ.* Generic character: male flower receptacle of the ament wedge-shaped, truncated, composed of three flowers; calyx, scaly; corolla, four-parted; stamina, four-female flowers; calyx, scaly, or two flowered; corolla, none; seed, compressed, oval, naked. The alder affects moist bog earthy soil on the banks of rivers or water-courses. Its natural habit of growth is to run up with a plurality of stems; and when trained with one, though it forms rather a handsome tree, it is not long-lifed. They are much more valuable as underwood than grown for timber, being, like the willow, more vigorous for being cut down; that is, the roots are more active in yielding supplies to young shoots than to old stems. Alder poles are much used by turners and other small ware artisans; also by charcoal burners for the manufacture of gunpowder; and when butts of good size, and sound throughout, can be obtained, this timber is highly valued for piling and planking to lie constantly under water. The bark in some countries is used for tanning, and some quality used in dyeing is extracted from the young twigs. Of the fourteen species, the heart-leaved, the long-leaved, the red, and the saw-leaved, are fit for the arborctum; and among the varieties of the common one, the fringed-leaved, cut-leaved, and oak-leaved,

The Alder Tree.

are ornamental. The common species are raised from the seed sowed on a moist soil in autumn. The curious varieties are propagated by layering—sometimes by grafting on the common.

ALDROVANDA (Decandolle). An Italian aquatic perennial, sometimes seen in British botanical collections. Linnæan class and order, *Pentandria Pentagynia.* Natural order, *Drosceraceæ.* Generic character: calyx, five cleft; corolla, of five petals; stamina five; ovarium is surmounted by five styles and stigmas. Fruit, a capsule of one place, containing ten seeds, which are discharged from five valves.

ALECTORIDÆ,—so called from that Greek name of the cock which describes him as the caller of people from their beds—a character in which he has been equally a favourite with peasants and poets in all ages,—a family of birds belonging to the order *gallinidæ*, or poultry. They are all natives of America, and dwellers in the forests of that country, large birds, and in their appearance and habits bearing a considerable resemblance to turkeys. They all have the wings short, broad, and hollow, the tail rounded, composed of strong feathers, which can be spread out as rays in a wheel. Many of them have naked skins or callosities at the base of the bill, especially in the males; and some have flexures in the windpipe at its bronchial extremity. They all perch, and most of them nestle in trees. They also feed much upon seeds, fruits, and buds. They are social, and easily domesticated; and, when in good condition, their flesh is esteemed. The following are the genera: *Crax*, the hocco, or eurassow; *Ourax*, the pauxi; *Penelope*, the guan, or yacou; *Ortalida*, the parraqua; and *Ophistocomus*, the hoazin. But the species and even the genera are confused, as they have been mixed with the European Gallinæ. They all belong to South America.

ALEPOCEPHALES. A genus of soft-finned fishes with abdominal fins, belonging to the *esocedeæ* or pike family, from the majority of which they, however, differ in many of their characters and habits. They have small scales on their body, but none on the head, which is the character on which the name is founded. They are large fishes, with small mouths, and very large eyes. Only one species is known, *Al. rostratus* (the beaked smooth head) of Risso. It is an inhabitant of the Mediterranean, a deep sea fish, and its habits are very little known.

Notwithstanding the labours of Risso and others, the natural history of the Mediterranean still wants much investigation; and there are few seas which offer a more abundant harvest to the inquirer. The circumstance of this fish, which resembles in its general structure those fishes which inhabit rivers, ponds, and the shallows, or at least not the greatest depths of the sea in other places, being not merely a pelagic fish, but a deep sea one, in the Mediterranean, is a peculiarity worthy of notice. When we further consider the numerous and varied climates, the waters of which mingle in the Mediterranean, without any outlet save the strait of Gibraltar, which is too narrow for allowing a free and rapid mingling with the great mass of oceanic water; and when we consider, also, that the Mediterranean is, in great part at least, as it were "a cauldron on the fire," from the volcanic action which is constantly going on under its bed, and which sometimes penetrates upward to the surface—when we consider these, we may expect that the living productions of the Mediterranean shall correspond with those of the sea itself. The waters from tropical Africa, from those parts of Russia which are for nearly half the year covered with ice and snow, from the temperate valley of the Danube, and from the glaciers of the Alps, all blend in the Mediterranean, and are there subjected to the action of volcanic fire; and, though there is both an outward and an inward current in the strait of Gibraltar, these are not enough to connect the water of the Mediterranean with the general circulation of the oceans. There is no other sea on the surface of the globe that has such peculiarities; and for this reason, the natural history of the Mediterranean is highly interesting.

ALEPISAURUS. A genus of Acanthopterygeous, or spinous-finned fishes, belonging to Cuvier's natural family of *Tænioides*, or "riband fishes," first communicated to the Zoological Society of London by the Rev. R. T. Lowe in 1832. There is but one known species, a native of the Atlantic in the neighbourhood of Madeira, and rare. This species is *Alepisaurus ferox*, of which the following are the leading characters. The head compressed; the gape wide, and distant from the eyes; the teeth, a single row in each jaw, conspicuous, long, and recurved backwards. The body long and slender, and both body and head without scales. Two dorsal fins, the first long and extending a considerable way along the back; the second small, triangular, and soft and fatty as the salmon. The ventral fins of medium size and abdominal; the anal fin of mean length; the caudal large and forked; the gill-flap with six or seven rays. This is rather a curious genus, as combining some of the characters of the spinous and soft-finned fishes. Its habits are little known, but from its structure it must be both voracious and formidable.

ALETRIS. A genus containing two species of perennial herbs cultivated for their flowers. Linnæan class and order, *Hexandria Monogynia.* Natural order, *Hemerocallideæ.* Generic character: calyx, corolla-like, tubular, rough; limb in six regular divisions; Stamina erect; filaments short, inserted into the base of the segments; anthers somewhat arrow-shaped; style and stigma three-sided; capsule seed-bearing, crowned with the style, three-celled, three-valved. Placenta central, seeds numerous, minute, and arched.

ALEXANDERS. See SMYRNIUM. A warm-flavoured aromatic herb, used in salads. The seed is sowed in drills in February or March; and as the plants rise, are earthed up and blanched like celery, and used in the same way. The plant is now, however, seldom cultivated.

ALGÆ. The sea-weed tribe, a family of plants belonging to the acotyledonous or cellular order of vegetables, and to the cryptogamic class of the Linnæan system.

Schizonema Dillwynii. Laminaria saccharina. Fucus vesiculosis.

This family consists of aquatic, leafless, and flowerless plants, which vary much in form and texture. They exist frequently in the form of jointed filaments of greater or less size, or of flat membranes, which are sometimes furnished with distinct stems. Their fructification consists of seeds or sporules, occasionally contained in tubercles or processes arising from the frond. They are attached to various substances, such as stones, rocks, shells, &c.; but they seem to derive nourishment chiefly from the element in which they grow, by a process which takes place over their whole surface. Some species have processes like roots by which they are attached, while others are always met with in a floating state, and seem to grow without being fixed to a spot. The general colour of sea-weeds is olive-brown or olive-green, but they are often of a beautiful red or green colour, and look well when dried and fixed on white paper. They easily become dry and shrivelled by exposure to the air, but they can afterwards be revived by being put into water. Botanists take advantage of this property in making their collections; for even although the plants should have been withered in consequence of having been gathered for a long time, they can be made to resume their fresh appearance before being subjected to pressure for the purpose of being properly dried.

In almost all moist places we find some of the species belonging to this extensive family, which includes not only the sea-weeds or *fuci*, properly so called, but also many plants which exist in fresh water. Some of these plants are found even in hot springs; thus the *Ulva thermalis* grows in the hot springs of Gastein, which have a temperature of 117° of Fahrenheit's thermometer. Under this family are included some plants of the most minute and microscopic nature, and others of the most enormous size; from the green slimy matter covering the surface of wet stones to the gigantic fuci which grow from the greatest depths of the ocean. Some of the plants are nearly allied to the lowest orders of the animal kingdom, and the gradation is so gradual that no distinct line of demarcation can be traced. The difficulty of distinguishing some of the algæ from the zoophytic members of the animal kingdom may be shown by the fact that several species which used to be referred to the former, have lately been transferred to the latter; and many naturalists have even gone the length of supposing that many of the species are plants during one part of their existence, and animals during another.

Though the plants belonging to this family are often passed over as of little importance, we find many of them distinguished for their beauty as well as their utility, contributing to the wants of man both in an economical and medical point of view. They have engaged the attention of many eminent botanists, and several valuable works have been published on the subject. We would particularly refer our readers to the beautiful delineations and excellent descriptions from the pen of Mr. Turner in his splendid work on the Fuci, also to Dr. Greville's Treatise on the British Algæ, and to the excellent arrangement given by Dr. Hooker in the fifth volume of the English Flora.

Algæ exist in all parts of the ocean, but they vary in different regions. Those found in the Mediterranean, for instance, are different from those met with in the Red Sea, while the latter do not resemble those of the West Indian Sea. Each great division has its peculiar marine vegetation, answering wise purposes in the economy of nature, and contributing doubtless in many ways to the comfort of the animals which inhabit the pathless depths of the ocean.

Some of the sea-weeds attain a great length. Thus the *Chorda filum* found in the North Seas, and growing so abundantly in some of the Orkney bays as to impede the passage of boats, attains a length of thirty or forty feet. But this is greatly exceeded by a species of Macrocystes, which is stated to have been met with in the South American seas, 1000 or 1500 feet long. This sea-weed, is of enormous length, and has much thinness of stem. It is supported in the ocean by the aid of small vesicles full of air, which nature has wisely placed at the base of each leaf.

Sea-weeds grow with amazing rapidity. A proof of this may be given in the case of the Carr Rock, a sunken rock near the mouth of the Frith of Forth, which was dressed with the pick and chisel, and completely freed from sea-weeds for the purpose of erecting a stone beacon. Operations were suspended in the month of November, and were resumed again in the month of May; and although the winter had been very severe, still the rock was found again completely covered with sea-weeds, some of them six feet long.

An object which has particularly attracted the attention of navigators, is the Gulf-weed, which consists of two or three species of sea-weeds (*sargassa*), found floating in great abundance on each side of the Equator, in the Atlantic, Pacific, and Indian oceans.. The name of Gulf-weed was given from the supposition, which has been proved to be erroneous, that these sea-plants grew in the Gulf of Mexico, and were carried across the Atlantic by the gulf stream. From the great accumulation of floating sea-weeds between the eighteenth and thirty-second parallels of north latitude and the twenty-fifth and fortieth meridians of west longitude, the Portuguese have denominated this part of the ocean the sea of sea-weeds. Naturalists are as yet ignorant of the manner in which these floating sea-weeds are detached from the bottom of the ocean, and of the reason why they are confined to particular regions. In the economy of nature they seem to be useful in affording food and shelter to fishes and molluscous animals, and they probably tend to maintain the purity of the ocean.

Fucus vesiculosus.

From several species of sea-weeds, more especially the *Fucus vesiculosus*, *nodosus*, and *serratus*, as well as the *Chorda filum*, and several species of *Laminaria*, a valuable article of commerce is obtained, denominated *kelp*. This substance, which consists chiefly of an impure carbonate of soda, is procured by burning sea-weeds, and is employed in the manufacture of glass and soap. The practice of collecting the ashes of the sea-weeds was introduced into Scotland in the year 1722. It had been carried on some time previous to that in France and England. The Orkneys was the first part of Scotland where kelp was manufactured, and though the innovation was resisted at first by many of the inhabitants of these islands, it soon became a profitable article of export, and has contributed not a little to enrich the proprietors. It has also long been manufactured in great quantities in the western islands of Scotland, and a large part of the population of these islands have been chiefly supported by this means. Lately, Spanish barilla, which is an alkaline substance, proceeds from the ashes of the Salsola Kali and other maritime plants, has been found superior to kelp in the formation of glass and soap, and from the removal of the duty on salt or muriate of soda, the impure alkali can be procured at such a cheap rate by chemical means, that the demand for kelp is much diminished. In consequence of this, many poor people have been deprived of their usual employment, and have been compelled to have recourse to other means of subsistence. The value too of many of the estates in the Hebrides has fallen much on this account.

Many of the sea-weeds are used as articles of diet. The *Rhodumenia palmata* furnishes the dulse of the Scotch, the dillesk of the Irish, and the saccharina sea-weed of Iceland. Pepper-dulse and tangle, sold as articles of food in some parts of Scotland, are also kinds of sea-weeds. From the various species of Porphyra and Ulva a substance is procured, which, when pickled or stewed, is brought to table under the name of *Laver.* The edible nests constructed in Asia by a species of swallow, the *Hirundo esculenta,* are composed of several species of *Gelidiciun,* a sea-weed common in the maritime parts of that country. The *Alaria esculenta,* called in Scotland badderlocks, or honey-ware, is also eaten. The *Fucus vesiculosus,* sea-ware or sea-wrack of the English, kelp ware or black tangle of the Scotch, serves for winter food to cattle in several districts of Scotland. The cattle are said to devour it greedily, and to repair regularly to the shores at certain seasons of the year for the purpose of procuring this and other species of sea-weed. The *Chondrus crispus,* a sea-weed known under the name of carageen or Irish-moss, has been employed in Ireland and other parts of this country as an article of diet. It forms a kind of blanc-mange, which is very palatable and nutritive. A year or two ago it was used for a short time in an institution in Edinburgh as a light article of diet for invalids.

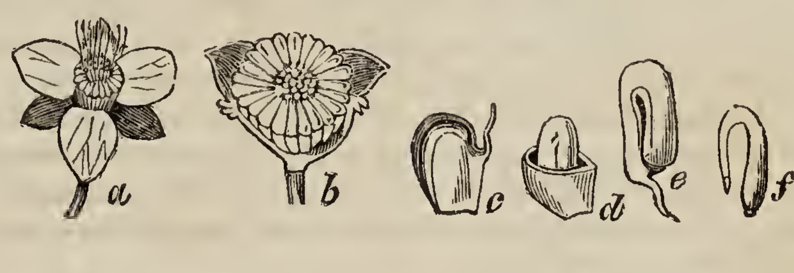
In a medicinal point of view, sea-weeds are by no means destitute of importance. *Gigartina helminthocaton,* or Corsican moss, a sea-weed found in the Mediterranean, was formerly much used as a vermifuge. The *Fucus vesiculosus* was introduced formerly into the British Pharmacopœias, and was used with success to discuss scrofulous swellings. By burning it in close vessels a kind of charcoal was procured, called vegetable æthiops, which was also exhibited medicinally. Not many years ago it was discovered that this and the other species of sea-weeds contained a peculiar substance, which has received the name of iodine. It was found that nearly all the medicinal properties of the sea-weeds were owing to the presence of this substance, which is now extensively prepared from sea-water, and used in place of the sea-weeds themselves, in cases of goitre and scrofulous tumours. It is a curious fact, that several species of Laminaria have been long eaten by the inhabitants of South America as a cure for these diseases; and burnt sponge, which is now known to contain iodine, was formerly in use for similar purposes.

Sea-weeds are also employed for a great many other purposes. The *Gracillaria tenax* is used as a glue and varnish by the Chinese; and the *Laminaria buccinalis,* on account of its hollow stem, is used at the Cape of Good Hope for making trumpets.

The appearance of *red snow,* so often mentioned by Arctic voyagers, is ascribed to a species of sea-weed called *Protococcus nivalis.*

Sea-weeds are extensively used as manure, and for this purpose are gathered in various maritime districts. The Highland Society have also lately made experiments in regard to the value of kelp as a manure, and their success has been such as to induce extensive landholders to purchase considerable quantities for agricultural purposes alone. Next to the algæ which yield the *kelp* above alluded to, the saltwoods (salsola) on our shores are manufactured for the same purposes. This is a genus of plants which, after due preparation and calcination, produce the alkaline salts called barilla, soda, potash, and kelp. These plants, like maritime algæ, require sea air as well as water to bring them to perfection. Most of them are herbaceous and annual, but some have shrubby stems. *Salsola kali* is found on the sandy shores of most parts of the world, and is generally burned for soda for the glass manufacture. *Salsola soda* is cultivated in Languedoc and also in Spain for making barilla; but is reckoned inferior to *Salsola sativa* which grows on the Spanish shores of the Mediterranean, and affords the best soda consumed in Europe. It is called by us Spanish or Alicant soda. In September the crop is cut and laid in small heaps to dry. These heaps are then collected and burned, forty or fifty of them in a hole in the ground. Soda is in common use in the manufacture of glass and soap; with sulphur, it forms Epsom salts; with marine acid, common salt; with the salt of Homberg, borax; and with cream of tartar, Rochelle salt.

ALISMACEÆ. The hundred and eightieth order of the Jussieuan system, containing three genera; viz. *sagittaria, actinocarpus,* and *alisma,* of which there are twenty-six species. The flowers are white, the divisions of the calyx and petals are distinct, and have many seed-vessels. They form a beautiful tribe of hardy aquatic perennial herbs, natives of Europe and America.



ALISMA PLANTAGO. *a,* flower of the natural size; *b,* fruit; *c,* a single capsule; *d,* the same in section to show the seed; *e,* seed (magnified;) *f,* the embryo (do.)

Of the genus *Sagittaria* there are six known species; one of which, the common sagittifolia, is the handsomest of our indigenous water plants. Several of the other species are natives of China, Japan, and North America. In China some of the species are cultivated extensively, the root forming an important article of food. The roots, however, are much larger in those countries than they are with us; of the *Actinocarpus,* there are two species, one a native of England, and the other of New South Wales, both pretty floating aquatics

ALLAMANDA (Linnæus). A splendid flowering tropical tree, native of Guiana. Linnæan class and order, *Pentandria Monogynia.* Natural order, *Apocyneæ.* Generic character: calyx, five parted; corolla, funnel-shaped, but in five regular divisions; five subsessile arrow-shaped anthers; ovarium superior, surrounded by a disk; style one, stigmas adhering to the anthers; fruit round, compressed, covered with membranous spines, filled with many seeds. There is only one species described.

ALLANITE (prismatic cerium ore). This mineral was first accurately described by Dr. Thomson, in the Edinburgh Philosophical Transactions. It is massive in its character, and of a brownish-black colour. Its specific gravity is about 3·6, and it occurs crystallised in four, six, or eight-sided prisms. It may be proper to add, that the ores of cerium analysed by Berzelius, under the name of cerin, approach very closely to it in their composition.

ALLIGATORS. A genus of aquatic Saurian reptiles of large size, formidable structure, and voracious habits. There is not much difference between the crocodiles of the eastern world and the alligators of the western, neither is there much difference in the signification of the two names. The crocodile was named by the Greeks after a yellow lizard, the exact species is not known, from the feet of which there exuded a liquor of a musky scent; and the alligator is only a corruption of the Portuguese words for lizard, and was by them applied to the crocodiles of western Africa before the American species had been discovered.

Alligators are, as one would say, ungainly, and even ugly animals; but they are not naturally ferocious; they kill only to eat, and they kill but one at a time. If indeed the prey is so tough that they cannot break it by the pressure of their jaws, they take it under water, and bury it there till it becomes softened by partial putrefaction. In these cases, the same unquenched hunger sends them to look for more; and they continue the process till they can meet with something which can be eaten instanter. No reptiles masticate or grind their food; and few, if any, give it a second bite. Their jaws close like the sides of a spring trap; and if they do not enclose the whole of the prey, the only way that the animal has of detaching the portion which they do seize, in order to swallow it, is by shaking it; and when they are unable to accomplish this, they bury it under water in the manner which has been stated.

Animals, when swallowed whole or nearly so, take of course longer in digesting than when they are torn or chewed; and thus the alligators are, like the larger swallowing serpents, dull and languid for some time after a full meal.

At all times, indeed, they are indolent animals; for though they can walk tolerably fast, and swim faster, the greater part of their time is spent in inaction, and some of it, in the colder climates, in a torpid or dormant state.

In climates where they hybernate, they dig for themselves hybernating dens with the entrance under the water, but the chamber so high as that the water does not reach it. It does not appear that any animal which breathes free air by means of lungs, has been known to hybernate under water. There is some doubt, in the case of the frogs of cold countries; but the analogy is against it, and there is no direct proof to rebut the analogy. Upon the confines, however, the lungs of some of the aquatic reptiles, and the gill cells of some of the cartilaginous fishes, have so near a resemblance to each other, that the line of distinction, though there is no doubt of its existence, is a nice point to determine. It is worthy of remark, too, that the reptiles and the fishes alluded to are both tenacious of life in proportion to the sluggish action of their system; and there is also something curious in the growth of their bones.

During the heat of the day, the alligators either lie stretched and languid on the banks, or in the mud, on the shores of the rivers and lagunes, which are the favourite haunts of the animals; and as the other natives of such localities (the winged ones which sport in the sun excepted) are generally at rest at these times, the consequence is, that, during the day, they capture but few animals, excepting such as wander near them. They sometimes, however, are put into motion and noise in the heat and drought, by that singular wave called the "bore," which is known in some of the fen rivers of England, and which is often very high and violent in its motion in the level-bedded rivers of warmer climates. Heavy and strong as the full-grown alligators are, the force of the bore rolls them powerless before it; and they rattle against each other, and bellow, adding much to the noise and confusion. There is no bore in the bays or lagunes, and none in rivers above the first rapid, even though that is an inconsiderable one; and thus, during the hot and sunny days, the alligators in these are at peace. When evening comes, however, they begin to move, and the roaring of the larger ones is terrific. It is a compound of the sounds of the bull and the bittern, but far louder than either; and it grates and shivers on the ear as if the ground were shaking. Whether it produces any effect upon the prey of the alligators, in making that prey disclose itself by its efforts to escape, is not known; and, indeed, harsh and terrific as it is, it seems not only to be the common noise of the reptiles, but also their love song, which they emit frequently and freely in the pairing season. The history of the pairing is not very complete; but there are some reasons for concluding that they are polygamous. The males engage in fierce though uncouth battles at that season, and not, as has been observed, at any other; and the fair inference is that these are battles of gallantry. They usually take place in the water, though in the shallows rather than the depths; and, at first at least, they are bouts of cudgel-play, rather than battles with the teeth. When it comes to the latter, it is desperate, and the death of one, sometimes of both, is inevitable. It has already been said, that the alligator can give no second bite; and as little is it disposed to leave the first one, till the object which it seizes is fairly under water. The jaws close in the same manner as those of the "biting turtles," and they can with difficulty be wrenched asunder, even by a lever of considerable length.

As is the case with all the larger reptiles which find their food chiefly in the water, the alligators are oviparous, and the females deposit their eggs in holes of the banks, above the water mark, which they excavate with their paws and snout, and cover again after the eggs are deposited. Though the animal is sometimes very large, fifteen, twenty, or even thirty feet in length, and in the latter case little less than two feet in diameter where thickest, the eggs are not larger than those of a goose, and indeed generally not so large. They are eatable, as also is the flesh of the animals; but the flavour of both is rather musky for European palates. As to the number of eggs which the female drops, authors are not agreed; some say as many as a hundred, and others little more than a fourth part of that number. Both are, probably, in so far right; for as the female returns to the water every day, it is probable that she deposits part only in one hole. During that operation they are not voracious; and perhaps they, like the turtle, abstain in great part from eating at that time. Their grand feasts are during the floods, especially the first of them, whether from the southern rains, or the melting of the snows at the sources of more northerly rivers, such as the Mississippi. These rains by their violence beat down many animals, and sweep away many animal remains, wafting them all to those temporary lakes in the forests, in which the water stagnates with its floatage. Recent or putrid mammalia, birds, reptiles, or fish (for some of the latter are killed, and many lose their management), are all the same to the alligators. Mountain cat, monkey, vulture, parrot, snake, lizard, fish (the gymnotus itself), or even the deadly bushmaster, all find jaws ready to seize them; and while the harvest lasts, which may be about eight or ten weeks in the average of places, the reptiles wax fat, and are able to undergo the labours of the year with little food, as has been said.

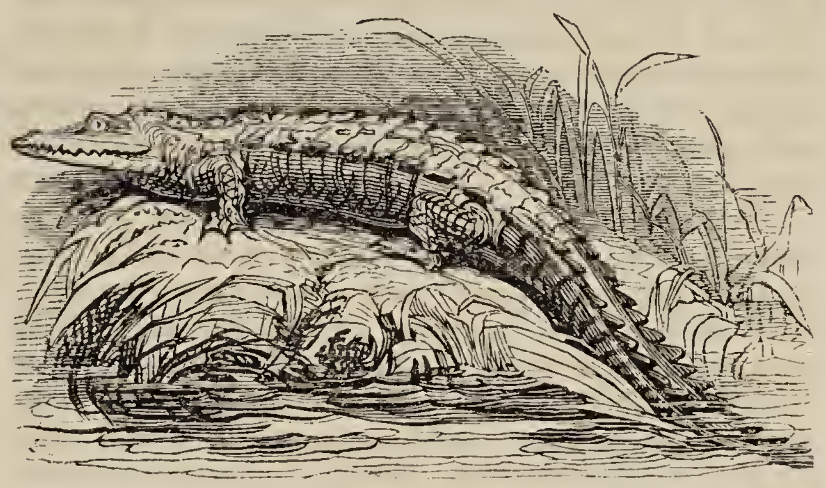
And there is not a doubt that these large and powerful reptiles, whether alligators, as so called, crocodiles, or gavials, perform an important part in nature's economy by so doing. In spite of all that they take, and they are neither few nor indolent at that time (for in them as in other creatures the time of activity and of appetite is the same), there remains enough to putrify and steam up with the returning heat, so as to render the atmosphere abundantly pestilent to all who have the hardihood to encounter it. But if they did not do their work, and if the larger grallidæ and the vultures did not come after as soon as there is provision for them, the banks of the rivers could not be approached within many miles, unless by those who sought to die there.

We mention those scenes and circumstances, not for the sake of those whose taste in natural science goes after "an alligator stuffed;" but who would rather know something of the haunts of the alligator, and of what that very powerful and very peculiar animal does there. And it is for a similar reason, rather than for any urgent systematic necessity there is for it, that we have resolved to divide the family, or perhaps, systematically speaking, the genus, into the three popular sections of alligators, crocodiles, and gavials. By this means we shall be able to render each group an index to a certain portion of the work, equally interesting and peculiar in all its characters.

The most remarkable distinguishing character of each of these groups is the shape of the head. The gavials have it the most produced, the crocodiles the next, and the alligators have it shortest. In them the length of the jaws from the articulation is only one half more than the greatest breadth. The teeth have a ragged appearance, as some of them are long and others short. There are never fewer than nineteen in each side of either jaw, and sometimes two more in each side of the under one. These grow with the growth of the animal; and receiving cavities are formed for them in the upper jaw, especially from those fourth from the front, which are longer than any of the others. The body is low and squat; the hind legs are nearly round in their section, and have no membrane on the sides; the webs of the toes also extend only half the length; and the holes behind the orbits, which are understood to secrete a musky fluid in the crocodiles, are small and obscure, or wanting.

From the structure of the feet, and the want of fringed or pectinated membranes on the hind legs, which are both a lessening of the pelagic structure, alligators keep more to the fresh waters, the rivers and lagunes, than the crocodiles; so that those in the bays of the West India islands, though popularly known as alligators or *caymans*, are rather to be considered as crocodiles, even in the popular sense of that term.

The following figure will afford a better general notion of the shape of the animal than could be given in even a lengthened description.



There are four species or more, all natives of the warmer parts of the American continent; but varying in their appearance, so as in some of the species to resemble the crocodiles, and in others the gavials.

The species which, in the written accounts at least, is the most ferocious and formidable to man is that which inhabits the Mississippi and the other rivers of the southern parts of North America, and the swamps and lagunes which these rivers form when they are swollen by floods. It is the pike-headed aligator (*Alligator lucius*) of Cuvier, so called because its head, in shape at least, bears some resemblance to that of the common pike. This species has been seen as long as fifteen feet; with the head two feet long, and the gape nearly the same. The jaws are more clongated than in some other species, the breadth at the articulation not being in those of the size mentioned much more than one foot. The snout is flattened on the upper surface, and slightly turned up at the extremity, which is bluntly pointed; but the sides of the jaws are, for the greater portion of the length of the gape, nearly parallel. The teeth are large and irregular, with the fourth from the front in each side of the under jaw much larger than the rest, so that they can penetrate through a substance of considerable thickness, and, with their points received into the sockets in the upper jaw, hold on against a very considerable strain. It is by this means that the animal is said to master the larger mammalia, when they come to the shores to quench their thirst. The alligator, having observed its prey, swims slowly toward it, with the snout barely above the water. When within reach it seizes the upper lip and nose; and at the same time incurvating its body with more than ordinary exertion, hits a violent blow on the shoulder with its thick and scaly tail. The bite and the blow together bring the animal to its knees, tumble it headlong and helpless; and as the alligator does not quit its hold while the animal continues to struggle, and also contrives to keep the head under water, the prey soon expires of pain and suffocation. The smaller mammalia are generally foundered by the blow of the tail, and then seized by the head and drawn under water till they are suffocated. But in what state soever prey of this description is eaten, whether recent or after it has been partially decomposed by time, it is always eaten on land. They do not feed under water, any more than they breathe in that situation; but while in the water, they often contrive to feed in the air. They do so both upon birds and fishes. The low-flying ones of the former, they sometimes catch as they skim the surface on the wing; and they get under the swimmers, jerk them clear of the water with the snout, and instantly seize and swallow them. When it preys on fishes, it gets below them and endeavours to jerk them out of the water in a similar manner, in which case it swallows them at once; but if it seize them under water, it rises to the surface, tosses them into the air, and again seizes and swallows them as they fall. The latter manœuvre has been stated by travellers, and the statement has been repeated by compilers, to be performed in order that the alligator may expel from its mouth the water which it has taken in while seizing the fish. This however, an absurdity. The fish in the water is taken crosswise; and consequently the reptile, by merely rising to the surface, could easily retain it and expel the water. But the fish, especially if it be of considerable length, is held in such a way as that it cannot easily be swallowed. It is therefore tossed into the air; and following the general law of animals in that state (for the exception of cats is doubtful), it comes down head foremost; and thus is either killed at once by the bite, or swallowed with ease. Many of the mammalia deal with their small prey after a similar manner. The dog, for instance, seizes a rat across the body; the vital parts are too far within the gape for the canines; the rat bites; the dog gives a whine, tosses it up in the air, seizes it by the head as it falls, and the rat bites no more.

This species of alligator is most numerous in the fresh waters immediately to the northward of the Gulf of Mexico, and it is abundant in proportion as the locality is marshy, full of putrifying things and pestilent. The vast tide of the Mississippi shows, upon the grandest scale any where to be met with, the power of running water over the earth. Trees, forests, islands, are moved about by it, as lightly as dry stubble by the autumnal floods of our rivers; and therefore excepting in the cold season when they remain torpid in their hybernacula under the banks, it is always harvest time with the alligators, and also with the soft turtle (*Testudo ferox*), which is as voracious in proportion to the turtles of other places, as the pike-headed alligator to the other alligators. Many of the accounts of these reptiles as given by authors must be received with deductions; but after every allowance, they are bold and formidable enemies.

The species most frequently met with in the rivers of Guiana, is different in appearance, and not so daring in its manner. It has the head shorter and broader; the teeth smaller, and a bony protuberance over each eye; on which account Cuvier terms it *A. palpebrasus*, the eyebrowed alligator. It rarely if ever attacks any animal on land, though in the season of activity it is abundantly active in the water. It was upon the back of one of this species that Mr. Waterton performed that ride which he describes with such graphic naiveté, in his "Wanderings in South America." The feat seems a desperate one; but, after all, what could even an alligator (or *caiman* as it is there called) do, with the barbs of a hook, the size of an ordinary faggot, lacerating its stomach, by the joint action of a dozen men pulling it to the beach, and its own resistance in endeavouring to keep the water?

There are other species which inhabit the rivers further to the southward, which have the muzzle more produced; and the accounts state that they are milder in their manners in proportion as their habitats are more southerly. Enough has already been said on the general characters; and the specific varieties in form, whether of the animals themselves or of the plates with which their skins are variously armed, are of small value in a popular point of view, as they have been connected with no peculiarities in the habits of the animals. See Crocodile and Gavial.

ALLIONIA (Linnæus). A genus containing two species of ornamental annuals, natives of Cumana. Linnæan class and order, *Tetrandria Tetragynia*. Natural order, *Nyctagineæ*. Generic character: calyx, four irregular coloured divisions; stamina, four; style, one; fruit, an akenium formed by the hardened and persisting base of the calyx.

ALLIUM (Linnæus). Garlic. This is a most numerous family of bulbous-stemmed plants, there being no less than 117 species, and many varieties. Linnæan class and order, *Hexandria monogynia*. Natural order, *Asphodeleæ*. These plants are known from all others by their peculiar scent, taste, and usefulness in cookery. Their flowers grow on globular heads; the capsules have three angles, three valves, and three cells, and the round stems of some of them are hollow and curiously inflated in the middle. Many have showy flowers, so as to gain for them a place in the flower garden. But they are most valued in the kitchen garden, where the following are always cultivated:—*A. cepa*, the onion; *A. porrum*, the leek; *A. ascalonicum*, the shalot; *A. sativum*, garlic; *A. ophioscordon*, rocambole; *A. fistulorum*, the Welsh onion; and *A. schœnoprasum;* all of which will be treated of under their English names.

ALLOCHROITE. A mineral body, usually classed with the garnet; it may, however, be distinguished from the common garnet by its lighter colour, as well as its inferior lustre and transparency. Allochroite is usually of a greenish-grey and brown colour. It is found in Norway, where it is associated with calcareous spa, brown garnet, and magnetic ironstone.

ALLSEED. A genus called Polycarpon by botanists, containing two small annual swamp plants, natives of England and Spain. Linnæan class and order, *Triandria Trigynia*. Natural order, *Paronychiaceæ*.

ALLSPICE. A name given to the fruit of the pimento, or clove tree, well known in commerce; and to the flowers of the *Calycanthus florida*, from their similarity of scent to the pimenta.

ALLUMINITE. A mineral of a snow-white colour, which occurs along with selenite in calcareous loam. It is found both in Saxony and Scotland.

Steffens is of opinion that this mineral, and the selenite with which it is accompanied, are formed by the decomposition of iron pyrites; the sulphuric acid thus formed is supposed to unite with the lime and alumina; with the lime it forms sulphate of lime or selenite, and with the alumina an alum, with a superabundance of alumina.

ALLUVIUM. A term employed by geologists to designate those accumulations of sand, earth, gravel, and other materials brought down by the passage of running streams, or deposited by the action of the waves of the ocean.

Water is one of the most active agents in the changes which are continually taking place on the surface of our globe. Its action in the form of rain, and even in the almost invisible vesicles contained in the atmosphere, though slow, is equally certain in its operation with that of the rushing torrents which were let loose when the foundations of the great deep were broken up. Hard rocks are thus gradually disintegrated, and each change of temperature tends to separate a new layer from many stony bodies which bid defiance to all the ordinary processes employed by human ingenuity.

Alluvial soils, generally speaking, occupy the lowest and most level tracts of country; and when viewed in connexion with rivers, point out in the most striking manner the original level of their waters. Thus we find that when the level of a lake, or river, has sunk in consequence of spontaneous or artificial draining, the alluvial soil which has been deposited will mark a higher line of level than its surface.

The alluvial formations constitute the great mass of the earth's surface. They may be divided into two species; namely, those deposited in the valleys of mountainous districts, and those deposited upon flat lands.

The first species consists of sand, gravel, &c., which constituted the more solid parts of the neighbouring mountains, and which remained when the least solid parts were washed away. They sometimes contain ores (especially gold and tin) and the alluvial soil is washed, in order to separate these ores. On mountain plains there are beds of loam. The second species of alluvial deposits, or that which occupies the flat land, consists of loam, clay, sand, turf, and various fossil remains. Bituminous wood and iron ore also occur. The sand contains various species of metals.

To render our account of this subject more intelligible, in a geological point of view, it may be advisable to notice, somewhat in detail, the Huttonian opinion of the origin of alluvial deposits, in connexion with the formation of our globe.

Dr. Hutton does not go back to chaos to lay the foundation of his habitable world; nor does he borrow much assistance in constructing his fabric from chemical attractions. He rests upon a pre-existing continent, out of the ruins of which our present dry land was formed and arranged principally by mechanical means. The portion of the globe which we now possess, was, according to his hypothesis, the bottom of the sea, and the previous continents having sunk into the depths of the ocean, new land rose to supply their place, which thus became the present terra firma; and, lest we should be alarmed at the recurrence of a similar catastrophe, we are told that it will be followed by a slow but similar renovation. Thus, as one continent descends another rises, like the opposite scales of a balance; and, in the resources of the system, that order of organic nature is supposed to be traced by which the continued existence of the different races is secured, not by the perpetuity of the individual, but by the successive reproduction of the kind. Our present world is thus one in an indefinite series of worlds which have existed in times past, and which are destined in future to appear; and all the less obvious or more striking changes which we witness are but steps in the progress of mighty revolutions, to which the imagination could set no limits, either with regard to duration or magnitude.

Dr. Hutton lays down as a certain position, that the solid parts of our earth are suffering decay from the action of the elements; that the portions detached from the more elevated ground are carried by the operation of water to the lower levels. Thus forming the alluvial masses of our globe. He conceives, that those portions which reach the ocean are acted upon by tides and currents, which arrange what is carried within their influence in layers along the bottom of the sea. Thus every river, every brook, every stream of water that we see, descends towards the ocean, charged with some portions of the surface over which it flows. All the soil and softer parts on which our plants are produced, have been confessedly loosened by water, and may be ultimately transported by it to the lowest levels of the same element. The strata of our dry land have all been thus carried from a pre-existing one, and arranged by the ocean, which then covered it. It may, however, be proper to remark, that effects have been attributed to the action of running streams, much beyond what their mechanical operation would at all seem to warrant. We have seen that Dr. Hutton supposes that the materials of all the strata are the debris of a former world; that they have been detached from it by the operation of the elements; carried, by the agency of water, to the ocean; and there spread in regular order over its bottom by the same power. It is true that most rivers flow towards the ocean, charged with a part of the soil or softer rock which border their channels; but it is not so true that they carry all this burden to their ultimate destination. A great part of it is deposited on their banks, or in the hollows of their courses; and much of what reaches the sea goes to form bars, or, being driven back to the shore, makes an addition to the sea-coast. It is evident that a small portion only can reach the ocean; and if, as Dr. Hutton himself observes, the description which Polybius has given of the Pontus Euxinus, with the two opposite shores of the Bosphorus, the Mæotis, the Propontis, and the port of Byzantium, is as applicable to the present state of things as it was at the writing of that history; if the isthmus of Corinth is apparently the same at present as it was 2,000 or 3,000 years ago; if Scylla and Charybdis remain now, as they were in ancient times, rocks hazardous for coasting vessels; if the port of Syracuse, and the fountain of Arethusa, the water of which the ancients divided from the sea with a wall, do not seem to be altered; and if, on the coast of Egypt, we find the rock on which was formerly built the famous tower of Pharos; and, at the eastern extremity of the port Eunoste, the sea-bath cut in the solid rock on the shore, to all appearance the same at this day as they were in ancient times; if such be the extreme slowness of the disintegration, the reflection is obvious, that, admitting it, a duration will be allowed to the world infinitely beyond our conception, and adequate to any purpose which we can conceive it designed to serve.

We may now, however, proceed from the mightier phenomena which occupy the attention of the geologist, and which have tended to produce such extraordinary changes on the surface of our globe, to the lesser though no less certain effects resulting from the action of rivers in comparatively modern times.

The wearing and transporting powers of a running stream depend upon the volume of water, and the quantity and size of the solid matter suspended, and the velocity with which it moves. A river generally runs with the greatest rapidity in the higher parts of its course, where, indeed, it often consists of a succession of torrents and cataracts for many miles, but it has not yet acquired its full destructive force, because the mass of water is still comparatively small, nor has it yet become loaded with solid matter. In the lower part of its course, long before it joins the sea, it has usually reached a level country, and there its velocity becomes greatly retarded. The Senegal in Africa does not, according to Adanson, fall more than two feet and a half from Podor to the sea, a distance of sixty leagues. But the increase of the volume of water in rivers during the flood seasons is often prodigious. The bed of the Mississippi, at Natchez, about 300 miles above New Orleans, measuring along the course of the river, scarcely exceeds a mile in breadth when the water is low, whereas in the flood season the mass of waters is nearly thirty miles wide. The Orinoco, at St. Thomas's, two hundred miles from its embouchure, is about three miles and a half wide in the dry season ; but when flooded, its waters, according to Dupens, stretch out to the enormous breadth of seventy miles.

Here we find a beautiful provision for fertilising the surface of the earth, which is well worth our examination. Fresh deposits are thus added to the alluvial formation, which are of the greatest value in the processes of vegetation.

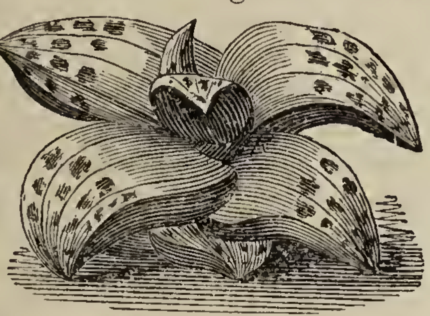
How truly may it be said that where the Nile is there is Egypt, and where the Nile is not there does that in some respects fertile land cease to exist for the benefit of man. The inundation of this river, and the formation of its alluvial deposits, are phenomena which have attracted the greatest attention at every period of scientific inquiry. The ancients, who witnessed no instance of inundation in any other river, exhausted themselves in conjectures as to the cause ; and each found it more easy to overthrow his neighbour's hypothesis, than to establish his own. Even Pococke ascribes it merely to the effect of the Etesian winds blowing from the north at a certain season. The cause is now perfectly ascertained in the periodical rains which fall from June to September, throughout the northern tropical regions. From these the Nile is exclusively fed, as it scarcely receives a single stream in its course, north of the tropic. The rise begins to be felt about the 17th of June, and continues till August, when the river is at its height, and all the level parts of the country are overflowed. On the level plain of the Delta, inundation takes place spontaneously, and at an early period. When the waters have retired, the soil of Egypt is covered with a slime more or less thick. Its colour is at first black, but in drying it changes into a yellowish brown. It then cracks, and exhibits fissures, showing that the slime was deposited in horizontal layers. This slime is about one-half composed of alumine, and contains also a large proportion of carbonate of magnesia. The principles of vegetation are thus copiously contained in it, so that it not only stands itself in no need of manure, but supplies its place to other lands. On the banks of the river it contains a great quantity of sand, which diminishes in proportion as it is carried to a distance from them. Hence clay is produced in all the various states which the arts require.

Water, when in rapid motion, produces alluvial deposits, differing very materially in their character from those we have now been describing. The force of a river, when directed against any obstacle in its course, is very considerable, even by its own weight alone, especially if it be flowing over a highly-inclined surface ; but its destructive power is greatly augmented if it be loaded with sand and gravel. In floods, very considerable blocks are carried by the stream to great distances ; for it must be remembered that these are much more easily moved in water than on land. If the water flows with a velocity of three inches per second, its force, when free from suspended matter, is sufficient to tear up fine clay ; six inches per second, fine sand ; twelve inches per second, fine gravel ; and three feet per second will tear up beds of loose stones of the size of an egg. The flood occasioned by the bursting of the barrier of a lake in the valley of Bagnes, near Martigny, in the Vallois, moved at first with the tremendous velocity of thirty-three feet per second, it was afterwards diminished to eighteen and eleven, and at the end of its course, when the water reached the Lake of Geneva, it was still running at the rate of six feet per second. From the barrier to this point, the fall is 4187 Paris feet, the distance is forty-five miles, and the mass of water passed over this space in five hours and a half. It swept along houses, bridges, and trees ; masses of rock, equal in dimensions to houses, which it tore out of an ancient alluvial soil, were carried a quarter of a mile down the valley. A flood that happened in the north of Scotland, in 1829, afforded numerous examples of the power of running water to transport large blocks of stone. On the river Nairn, a fragment of sandstone rock, fourteen feet long by three wide, and one foot thick, was carried above two hundred yards down the river. The river Don forced a mass of four or five hundred tons of stones, many of them two or three hundred pounds weight, up an inclined plane, rising six feet in a few yards, and left them in a rectangular heap, about three feet deep, on a flat ground. If then such large masses can be moved by the action of water, even by the ordinary and every-day operations of nature, we may easily understand how, in the gradual progress of ages, the whole amount of alluvial soil which we now find may have been brought into its present situation.

Under the article GEOLOGY will be given a general view of the connection which alluvial soils bear to the various stratified masses which form our globe, when it will be shown how admirably they are proportioned to the wants and comforts of man, as well as to the subordinate parts of the animal kingdom.

ALMOND. The well known fruit of the *Amygdalus communis*. There are six species ; two of them are dwarf ornamental shrubs, the rest are small trees, bearing fruit of different qualities, that from the *communis* and its varieties being most esteemed. The shores of both sides of the Mediterranean Sea are the native habitat of these fruit trees, and whence great quantities are annually exported to all the northern parts of the world. In this country almonds rarely ripen their kernels; the trees being planted for the beauty of their flowers only. They are easily propagated by budding on their own or on plum stocks.

ALOE. This is a numerous family of succulent plants, mostly of a half-shrubby description. A few are herbaceous, and all treated as inmates of the greenhouse. Linnæan class and order, *Hexandria Monogynia.* Natural order, *Hemerocallideæ.* Generic character: calyx, monosepalous, tubular, almost cylindric, in six divisions; stamina, six, inserted into the base of the calyx; stigma, three-lobed; capsule, three sided, of three places, containing seeds. The south of Africa is the habitat of the aloe family; and there some of the species grow to the height of fifteen or twenty feet, though by far the greater number are of more humble growth. The leaves are thick, rising out of the embrace of each other; variegated in colour, smooth, or warty, and many are defended by spines as well on the disk as on the edges and points of the leaves. The flowers are not terminal, but rise from among the leaves laterally, and appear on long spikes either erect or drooping. The well-known drug bitter aloes is drawn from some of the species. Soccotrine aloes were esteemed the best; but the spicata fig is in every respect equal. The drug is obtained by draining the juice from the dissevered leaves. *A. soccotrina* is cultivated in the West India islands for the manufacture of the drug.



The aloe family was formerly much more numerous than it is now; many of the species have been removed to form new genera, as *Pachidendron* and *Haworthia;* and several have been removed to old genera. They are altogether a remarkable family of plants; their thick fleshy leaves being in the shape of tongues, cushions. spears, &c.

ALONSOA (Ruiz, Pavon). A small family of exotic undershrubs, containing four species, requiring greenhouse treatment. Linnæan class and order, *Didynamia Angiosperma.* Natural order, *Solaneæ.* Generic character: calyx, monosepalous, persistent, five-cleft; corolla, monopetalous, irregular, lips turned back, divided, upper divisions short, reflected, the two lateral thrice the size of the upper, the lower largest; stamina, didynamous, declining; style, longer than the stamens; stigma, bifid; capsule, oval. This genus is closely allied to *Hemimeris.*

ALOSA—Shad. A genus of abdominal soft-finned fishes, belonging to the *Clupeadæ,* or herring family. The shad genus has been very properly separated from the herring and the pilchard, with which it was classed by Linnæus; as they are different from these in appearance and in habit. The herring and pilchard are migratory fishes; but they migrate in the sea only, and never ascend the rivers above the mean line of separation between the entirely salt water and the entirely fresh, and seldom indeed so far. Shads, on the other hand, ascend the larger rivers into the fresh waters; and they appear to spawn there in preference, whereas the herrings spawn on the shores of the sea. The herrings, too, come later, or perhaps, with reference to the time of spawning, it is more correct to say earlier. They come in winter or even in autumn, and the shads not till April or May The herring fry, or herring "sail," as the countless myriads of the young of these fishes are called, appear, indeed, to form much of the food of the shad as it ascends the estuaries; and the shad is a ravenous fish-eater, which is not understood to be the case with the herring. In its migration it may be said to be intermediate between the herring and the salmon, both in the time and the height to which it ascends the rivers; and, as is the case with the salmon, it lingers for a considerable time in the brackish water, before ascending into the fresh.

The reason why they linger there is an important point both in the natural history and the economic use of this fish. It is a well-known fact in chemistry, that when two liquids of different densities unite together, there is a want of *compenetration,* by which a certain degree of heat is produced, as much as three or four degrees of the common thermometer in the case of sea and river water, supposing that they have both the same temperature previously. At the mouth of a river there is a constant union of this sort; and though the maximum increase of heat moves a little with the tide, it does not move nearly so far as that does, for the wave of tide flows up the fresh water, and ebbs out a considerable way into the salt. By this means the fishes, when, in their migrations, they resort to the estuaries for the sake of the heat, are not moved like tidal things, but rest in a limited space; while the water passes and repasses over them, and procures them plenty of food, both in its ebb and its flow.

While the salmon, the shad, or any other fish having this migratory habit, remains in the salt water, it does not appear to be capable of breeding, or of bringing forward the roe and milt, so as that they shall be fit for depositing. The same appears also to be the case if the fish remain in the fresh water; and, besides, they lose flesh in the fresh water. The descent to the sea is thus necessary to restore them to vigour as individual fishes, and the resort to the brackish water is essential to their fertilisation. When they are first met with in the offing of the estuary they are in fine condition as food, and the roes are small. As they linger in the brackish water the roe increases rapidly, and the quality of the fish falls off, though not so rapidly in proportion. When the roe has attained nearly its full size, the fishes ascend into the fresh water, gradually falling off in quality, so that those caught in the upland streams and in the brackish water do not appear the same species. The difference is most conspicuous in the salmon, but it is very evident also in the shad; and even in the herrings, which do not resort to the brackish water, the first that come are always the best.

The species of shad best known, and indeed the only one, is the common shad (*clupea alosa* of Linnæus), the distinguishing character of which is a cleft in the snout; there is also an irregular black spot behind the gill cover, and the mucous ducts on that organ are finely branched. In the warmer parts of Europe (for the shad inhabits more southerly than the herring or the salmon) it attains the length of three feet; but in our estuaries it rarely exceeds half that length. In Scotland, where it is taken in the salmon nets, though not in any considerable quantity, it is called the "elf-herring," that is, the plague or pest of the herrings; and the name is not an undescriptive one, as the large herrings disappear before the shad comes, and it eats great numbers of the young ones, which are often found entire in its stomach. In some parts of England it is called the "mother of herrings," which, unless we are to suppose that "mother" is a corruption of "mouther," or swallower, is by no means appropriate. It follows the general law, being excellent in flavour when it first appears in the estuaries; but dry, tasteless, and unwholesome, as it descends to the sea.

The *white bait* of the Thames, which is so renowned among the metropolitan epicures, used, till within these few years, to be considered, by writers on British fishes at least, as the young of the shad. The contrary has, however, been very clearly demonstrated by Mr. Yarrell, whose researches have tended much to the advancement of natural science generally, and which have thrown the clearest light upon some of the erewhile darkest points in the economy of our native fishes. The white bait has enough of the distinguishing characters, both of appearance and interest, to entitle it to be made a species, if not a genus. It has more of the herring character than the shad has; and Cuvier very properly ranked it next to the sprat, though it is more delicate and less seaward than that fish. In the whole breeding time it inhabits almost the mean line of the brackish water, seldom, if ever, reaching the perfectly fresh, and being seldom met with at that season when it is understood to be pelagic. See WHITE BAIT.

All the fishes which resort to the shores, estuaries, and rivers, for the purpose of depositing their spawn, are highly valuable in an economical point of view. Taken at the proper place and season they are finer food than any other fishes; they are taken with less hazard; and in one or another of the species they are in season during the greater part of the year. Some general account of their habits, qualities, and mode of being captured, will be found in their order, from the most pelagic, to the most fluviatal, in the article MIGRATORY FISHES.

ALPHÆUS. A genus of crustacea, belonging to the order *Decapoda* of Cuvier. The habits of these animals are very quiet; a habit so well known, that if they remain long in one spot, they become the prey of numerous marine animals of various species, more particularly shoals of fish. The best known and most remarkable species is the *Alphœus avarus*, which has been described by Fabricius. This author first established the genus from four species brought from the Indian Ocean; but many specimens have since been discovered in the European seas, particularly in the neighbourhood of Nice, in the Mediterranean, where Rizzo found four other species, which he has described.

The *Alphœus caramote*, described by Rondelet, was found on a muddy bank in the midst of rocks. It had the four anterior feet terminated by a didactyle claw, the carpus of the second articulated; feelers lateral, situated underneath the middle, having the peduncle covered by a shell annexed to the base; the shell prolonged forward in the form of a beak; the feelers at the middle always being smaller than they are laterally. They are distinguished from all other crustaceæ by their two pair of feelers, and by the manner in which their four anterior feelers terminate.

ALPINIA (Willdenow). A genus of hot-house perennial herbs, mostly natives of the East and West Indies; comprising twenty-four species, and belonging to the first class and order, viz. *Monandria monogynia* of the sexual system, and to the monocotyledonous order *Scitamineœ.* Generic character: calyx, tubular, three-toothed; corolla, double, the outer three-parted and converging, the inner of one lip, and having a tooth at each side of the base; stamens have linear filaments, not extended above the anthers, which are not crowned; style, thread-shaped, rising above the anthers; stigma, concave; seedvessel, a berry. These plants require stove treatment, a rich soil, and a high moist temperature.

ALSODEA (Thouars). A genus of two species of stove undershrubs, natives of Madagascar. They belong to *Pentandria Monogynia,* and to the natural order *Violaceœ.* Generic character: calyx of five sepals, somewhat imbricated: petals of the corolla are equal; urceolus, perigynous, five-lobed, bearing stamens; anthers, inserted at the bottom of the lobes; style clubbed; capsule, of three valves, containing eighteen seeds.

ALSOPHYLA (R. Brown). An ornamental green-house fern, introduced from New Holland.

ALSTONIA (R. Brown). A genus of only two known species of tropical undershrubs, natives of India. They belong to the class and order *Pentandria Monogynia,* and to the dicotyledonous order *Apocyneœ.* The generic character is a calyx of five divisions; corolla salver-shaped, limb five-parted, obliquely lacerated; stamens included in a tube; filaments short, anthers free, emitting pollen along their whole length; squamæ not perigynous; style simple, stigma dilated; folliculi very long, seeds ciliated on both sides.

ALSTRŒMERIA (Willdenow). A family of stove and green-house perennials, indigenous to South America. They belong to the lily class and order, viz. *Hexandria Monogynia,* and to the natural order *Amaryllideœ.* Generic character: calyx, resembling a corolla, somewhat bell-shaped, six-parted, two-lipped, the inner sepal narrow; stamens inserted in the base of the calyx, declining; anthers oblong, erect; style also declining; stigma three-parted; capsule somewhat round, six-ribbed, three-celled, and three-valved; seeds roundish. This is a highly ornamental family of plants, and deserves a place in every collection. The elegant position, and beautiful markings of one of the most common species, *A. pelegrina,* has made it a universal favourite. *A. ligtu* is highly fragrant; and as they have all tuberous roots, those of *A. edulis,* are used like potatoes in the West Indies. Some of them are so hardy as to bear the open air, if planted under and trained to a south wall. There is one peculiarity in the position of the leaves of this genus which distinguishes it from all others, viz. the twisted form of the petioles or footstalks of the leaves, by which the inferior disk is turned to the sky, and doing the office of the superior. There are ten species already described; and it is reported by travellers that there are several others in South America not yet introduced.

ALTERNANTHERA (R. Brown). A genus of green-house and stove herbaceous plants, natives of South America. They belong to the fifth class and first order of the sexual system, and to the natural order of the *Amaranthaceœ.* Their generic character is having a calyx of five sepals; stamens alternately fertile and barren (hence the generic name); style short, stigma headed; the utriculus one-seeded. There are ten species; but none of them bear conspicuous flowers.

ALUM. A mineral salt, much employed in the useful arts. The minerals that afford alum either contain it ready formed, or they contain its constituent parts, which are disposed to unite and form alum, when placed under favourable circumstances. This latter is the most frequent case. It is found in each of the great divisions of our globe, and occurs as an efflorescence, or in delicate curved and parallel fibrous concretions; also crystallised in octahedrons and cubes.

Alum mines are said to have been first found in Italy, in 1460; and in the sixteenth century the process of alum-making was commenced in Germany and Spain, and a little before its conclusion works were established at Whitby, in England, by sir Thomas Chaloner. King James I., by advice of his ministry, assumed the monopoly of it himself, and therefore prohibited the importation of foreign alum; and in 1625 the importation of it was further prohibited by a proclamation of Charles I.

Alum is manufactured near Glasgow, from slaty clay, which is obtained from old coal pits; the slate contains also iron pyrites, and both its constituents combining with oxygen, sulphate of iron is formed, with excess of sulphuric acid, which acting upon and combining with the clay or alumina of the slate, forms a double sulphate or ferro-sulphate of alumina, which crystallises in small filaments of a greenish white colour. When the slate containing this double salt is put into water, it is dissolved; by evaporation, crystals of sulphate of iron are obtained; and to the solution, which is principally sulphate of alumina, potash is added, and crystals of salt are formed; these are purified by re-dissolving them in water and crystallisation. By exposing to air and moisture the slate which remains after the solution of the sulphate of iron and alumina, a further portion of the pyrites is acted upon, and more sulphate of iron and alumina are obtained, which are dissolved, as before, in water.

ALUTERES. A genus of fishes belonging to Cuvier's order of *Plectognathes*, (plaited lipped fishes) and the family *Sclerodermes*, or hard-skinned. They have the body long, slender, and compressed; the muzzle produced, pointed, and ending in a small mouth, with about eight teeth in each jaw. Their first dorsal fin has only one ray, which gives it the worm-like appearance on which the generic name is founded There are several species noticed by authors; but very little is known of the habits of any of them They are pelagic fishes, with large air bladders; and like the file-fish (*balistes*) which they resemble in their more general characters; they are understood to be pernicious—at all events, they are not eaten.

ALVEOLITES. A genus of zoophytes, the major part of the species of which are known only in the fossil state. They are closely allied to the corallines. Four species are enumerated, three of which have as yet been found only in the fossil state. They are to be met with in the environs of Dusseldorf and Dax. They very rarely occur in this country. Specimens referred by Parkinson to two of the species, the incrustans and suborbicularis, are described by him; the one as imbedded in flint, the other in a mass of Portland oolite.

AMARANTHACEÆ. A natural order of dicotyledonous plants, the characteristics of which are: stamens situated below the ovarium, or seed vessels, sometimes abortive; anthers, one or two-celled; calyx, three or four-leaved, persistent, occasionally with bracteæ at the base; fruit in a membranous bladder; seeds, lentiform, pendulous, having a hard brittle shell; leaves, simple, opposite or alternate, without stipulæ; flowers, scabrous, in heads or spikes, usually coloured, generally hermaphrodite, pubescent, simple, the hairs divided by partitions.

AMARANTHUS PANICULATUS. *a*, barren flower, bearing stamens only; *b*, fertile flower, bearing pistils only; *c*, stamen; *d*, fruit bursting its envelope; *e*, vertical section of the seed (magnified); *f*, the embryo ditto.

In the young plants of this order the leaves are of a soft, lax texture; the seeds farinaceous, consisting chiefly of starch and mucus; their virtues are nutritive; and some of them, particularly the root of *Gomphrena officinalis*, are tonic and stimulant. The amaranth, from which the order derives its name, are herbaceous plants, generally annuals, the flowers of which form in bundles at the top of the stalk. The species are very numerous, and are very generally dispersed over both hemispheres, increasing as the distance from the equator increases. Some of the plants belonging to the order are beautiful ornaments in the flower-garden, and much cultivated for the graceful and pendulous masses of their flowers.

AMARYLLIDEÆ. An order of *Monocotyledoneæ*, and the hundred-and-ninetieth order of the natural system. It comprises thirty genera, and four hundred and sixty-four species, of which last there are as many varieties. Some of the most splendid of these will be found in the accompanying plate, of which the following is a description:—

Crinum giganteum.—Few plants surpass this in the majestic beauty of its flowers. It is known to gardeners by the name of the Cape Coast Lily, and was brought, about fifty years since, from the south-western coast of Africa, of which it is a native, and where it is highly prized by the natives; being worn as a charm to preserve them in war, and guard them from pestilence.

Amaryllis formosissima.—This flower, as its trivial name indicates, is the fairest of its tribe. It is propagated by offsets, which may be taken off every year; the best time to shift and part these roots is in August, that they may take good root before winter. They should be planted in pots of a middling size, filled with light kitchen garden earth; and if they are kept in a moderate degree of warmth, they will produce their flowers in plenty from March to the beginning of September.

Amaryllis belladonna.—Is generally considered to be a native of the Brazils. It is now, however, common over the whole of the European continent, particularly in Spain and Italy. Seedsmen receive the bulbs yearly in abundance from Portugal, and these, when planted close to the foot of a southern wall, will blow annually, after they are once settled, which is not till after the lapse of two or three years. We recommend it, for its beauty and fragrance, to all those who love a fair flower in October.

Hæmanthus Coccineus.—There is a deep solemnity about the aspect of this gorgeous flower, which admirably fits it for association with the lighter productions of the green-house. It is a native of the Cape of Good Hope, where it harmonises very finely with the delicate heaths, which in immense multitudes cover its arid plains. Miller first cultivated it in this country in 1731.

They are all herbaceous, bulbous-stemmed plants. The flowers of all are conspicuous; and the ease and safety with which they can be transported from place to place, and from one distant country to another, has led to their more general diffusion from their native habitats than any other order of plants whatever. The constitutional structure of *Amaryllideæ* shows that they are adapted to sandy districts of the earth; and where they would be liable to destruction from drought, were it not from their concentrated body of vitality existing in and protected by the encrassated stem. So that in the burning plains of Africa, the bulbs, whether upon or beneath the surface, remain uninjured, while every green or thin expansion of vegetable tissue is withered up. *Doryanthes* and *crinum* are the Goliaths of the tribe; and though magnificent plants, with their long linear leaves, and ample tresses of flowers, they are far outshone in gaudy beauty by the *Hæmanthus*, the *Amarylli*, and even by the far more common *Narcissi.* Lilies, of whatever size or hue, are attractive. They are often chosen as emblems by the poet. Many are harbingers of returning spring: even the most lowly of the tribe, the humble snow-drop, meets a kindly welcome.

AMARYLLIS. This is a splendid family of bulbous plants, chiefly natives of the more southern parts of Africa and America. They are hexandrious polypetalous flowers, and from their strongly-marked character have given a name to the extensive order described above in the system of Jussieu, viz. *Amaryllideæ.* The generic character is, a spatha generally containing several flowers; germen on a long footstalk, clubbed; perianthium in six parts, somewhat gaping; throat sealy (rarely membranous), crowned, or naked; limb spreading; stamens inserted in the tube, and declining; anthers leaning; capsule three-lobed, three-celled, each many-seeded; the seeds flat, with winged margins.

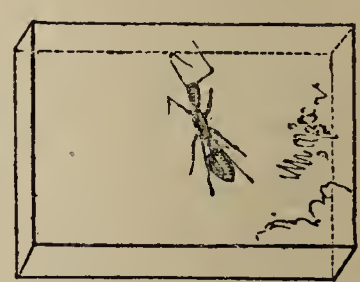
There are above a hundred species and varieties of this fine family, which are supposed to be the "lilies of the field" mentioned in sacred writ. Throughout the winter and spring months they are among the most resplendent ornaments of the greenhouse and conservatory. One circumstance makes them particularly valuable to the florist, viz. the facility with which they hybridise with each other by manual impregnation, by which their various forms and colours are admirably blended: thus giving at once an endless variety, and a source of amusement to the cultivator, and profit to the commercial florist. The amaryllis may be raised from seeds or from offsets. They require (particularly the stove species) a pretty rich loamy soil, and should be kept in large pots to flower them in perfection. The greenhouse species also like rich soil; and after they have done flowering should be kept quite dry, either in the pots, or laid for a month or two on a shelf in a dry airy place. Here they will often present the point of their flowers while yet on the shelf; which is a sure sign that they require repotting. The *blanda, belladonna, reginæ, vittata,* with its numerous varieties, and the *formosissima,* are among the finest flowerers. The flower of the last mentioned is a bright crimson, or deep scarlet, and continues a good while in bloom.

AMATHIA (Lamouroux). Celluliferous polypidoms. It is a branching polypidom; the cells long and cylindrical, united in one or many groups. The amathias, by their numerous cells, their horny and hollow stem, filled in a living state with a gelatinous and irritable substance, exhibit the general character of the order; they differ, however, from their neighbouring genera, by their aspect, their ramifications, and also the form and respective situations of their cells. In some species these are united in isolated groups, resembling Pan's pipes, with reeds varying in length; in others all the groups touch, but can easily be distinguished by the unequal length of their cells; some of them have their polypous cavities united at the sides, forming spiral and projecting lines round the stems, to which they adhere by their base; and there are some in which these lines cease to project forward, and are attached to the stem by the back part of the cells; therefore, notwithstanding the apparent difference between the *A. lendegira* and the *A. spiralis,* it is impossible to place them in separate genera, on account of the intermediate species which imperceptibly link together beings at first sight exceedingly dissimilar.

The amathias are of a horny substance, very slightly chalky; their colour is a fawn brown, more or less deep; they vary in height from one-eighth of an inch to six inches. They are frequently found parasites on the *Thalassiophytes*; sometimes they adhere to rocks or other hard substances by a fibrous base, and they appear more common in the equatorial and temperate seas, than in the cold or icy regions of either pole. Six species are described.

AMBER. A resinous body, called electrum by the Greeks. Some naturalists refer its origin to the vegetable, others to the mineral, and some even to the animal kingdom. It is described by Pliny as a resinous juice, oozing from aged pines and firs, and discharged thence into the sea. He adds, that it was on this account that the ancients gave it the name of succinum.

One of the most singular peculiarities of some amber is the existence of insects of various kinds enclosed beneath its surface. An instance of this occurs in the accompanying figures, copied from a specimen in the British Museum.



Many of the yellow transparent masses containing insects, and sold under the name of amber, are in reality only concretions of the common copal; and in the cabinet from whence the above specimens were taken, the right-hand figure is marked *copal* and the other *amber*, although there are no external marks which would enable an observer to distinguish the one from the other.

Germany affords great quantities of amber, obtained from the beds of lignite, as well as thrown on the shores of its seas and rivers. Saxony, Misnia, and Sweden, and numerous other places in this part of Europe, abound with it; and it is found on the shores of the Baltic in large quantities. Prussia and Pomerania afford it in abundance. The former country was celebrated for its amber, as early as the time of Theodoric the Goth, who, we are told, imported it from thence. On account of its beautiful colour, great transparency, and the fine polish it receives, amber is even now considered as an ornamental stone, and is cut into necklaces, bracelets, snuff-boxes, and other articles of dress. Previous, however, to the discovery of the diamond, and the other precious stones of India, it was the most highly prized of jewels, and was employed in all kinds of ornamental attire. Great quantities of it are annually exported from Dantzig to Constantinople, the Levant, Persia, and France. The most considerable purchasers of amber are the merchants of America and Greece; but it is still uncertain how they dispose of it. Amber forms an important article of exchange in Africa; and when dissolved, it is the principal ingredient in a species of varnish, named amber varnish.

AMBER TREE. Is the *Anthospermum Æthiopicum* of Willdenow; a diœceous plant from the Cape of Good Hope. It bears some resemblance to a heath, and the leaves are highly fragrant when bruised: hence its English name.

AMBASSIS. A genus of spinous finned fishes, of very small size, and inhabiting the fresh waters of tropical countries. The gill-lid is pointed, and there are two spines on the gill-flap and one upon the first ray of the anterior dorsal fin. They bear some slight resemblance to the perches, to which natural family they are referred. Some of them are quite transparent; and they are caught in numbers in some of the warmer countries, and prepared like anchovies.

AMBROSIA (Willdenow). A genus of eight species of sweet-smelling annuals, natives of North America and the south of Europe. They belong to the natural order *Compositæ*, and hold a low rank on the scale of vegetation; their scent being the only property for which they are regarded.

AMBLYGONITE. A pale green mineral, marked superficially with reddish and dark yellow spots. It is found massive, and crystallised, in oblique four-sided prisms; is of a vitreous lustre, fracturing uneven, and the fragments rhomboidal.

AMEIVA. A genus or sub-genus of American Saurian reptiles, belonging to the lizard family, but differing from the true lizards, and also from the monitors. They inhabit the banks of rivers and streams in the forests of tropical America, depositing their eggs in the sand, and occasionally taking to the water, in which they can both swim and dive with much ease. Their tails are round, their heads tryrancidal, they have no scaly plates over the eyes; the scales on the neck and throat are small, and those on the posterior part of the body rather larger. The species are numerous, but not well defined. Indeed, the natural history of reptiles, in all its departments, is very imperfect, there being many unnamed specimens in most collections, and the habits of few, indeed, being accurately known.

AMELANCHIER (Lindley). A name given to a kind of medlar, with which it used to be associated. The genus consists of three species of deciduous shrubs, and one evergreen. Like the medlar, they are icosandrious, and in the natural order *Rosaceæ*. The genus is distinguished from mespilus by its ten-celled ovary. As shrubs they are used in ornamental planting, but only for the sake of variety.

AMELLUS—Asters. A family of three species of North American perennial herbs. They belong to *Compositæ*, but of no striking character. This name is given by Virgil to a beautiful flower growing on the banks of some river, but which has never been truly identified by botanists; the general opinion runs that Virgil's plant is no other than the *Aster amellus*, a common plant in every flower garden.

AMENTACEÆ. Is the hundred-and-forty-second order of the Jussieuan system. The order is well defined, and embraces the greater number of our most useful forest trees. The principal mark of distinction is the unisexual flowers; that is, the males are placed in aments or catkins, quite separated from the females. The catkins of the hazel, or common nut tree, give a very good idea of this mode of florescence. For though the catkins differ in size, colour, and form, according to the kind of tree, yet their agency is the same in all. The development of the males usually precedes that of the females, and on some trees is very conspicuous, as on the willows and poplars, which appear to receive a kind of clothing from the countless numbers of male catkins borne by them. In this order we find the following genera: viz. willow, poplar, alder, birch, hornbeam, hop-hornbeam, hazel, oak, beech, Spanish chestnut, plane, Comptonia, candleberry, myrtle, and casuarina; all of which are described under their English names. See PLATE.

AMERICA, or the Western Continent. One of the grand divisions of the habitable globe; and one which, whether we regard any one of the kingdoms of nature singly, all the three in their connexion, or the whole in their succession, opens a field of great and peculiar interest to the student of nature. From the comparatively recent period at which this vast portion of the world was added to the knowledge of the rest, it is frequently styled "the *New* World;" and in its natural history it is as new as in its geography. Not that it is in any respect a more recent formation, because on it the traces of remote antiquity are as visible as on any other part of the earth; and though, of the parts of it which are now under culture, the greater portion has been won from a state of wild nature, in times so recent as that the whole progress is matter of easily obtained history, yet we can no more assign a date to the first action of those causes which brought America into the state in which it was first known to European discovery, than we can assign a date to the turning of great part of central Africa into a desert, or to the drying up o those waters which, according to the traces which remain, and which are too marked and decided for leaving any doubt, once covered a great portion of central Asia.

The grand point of difference, and the one which gives America its principal charm in the estimation of the naturalist is, that we can have a clear view of the whole continent as it came from the hand of nature, or, which is the same in effect, as it is moulded and fashioned by natural causes only. The cultivation which was carried on by the Mexicans, the Peruvians, and some other people, among the mountains of the west, was, according to the accounts of the parties themselves, (and nations have never shown any disposition to abridge their annals,) of comparatively recent introduction, and limited extent. Human industry had not there, as in many parts of all the divisions of the eastern continent, contended with the flood, the forest, or the desert; but each of them had been allowed to assume its dominion to the full extent of its powers. As little had cultivation clothed the fields with artificial plants, or stocked them with trained animals, the native localities of which, and their habits in a state of nature, had been forgotten and lost, during successive ages of cultivation and change. It is true that the few nations on the American continent among whom traces of civilisation were found were migrant races, for it appears that in no case can there be improvement without migration; but, unlike the migrants of the old continent, they appear to have migrated without carrying along with them the means of their subsistence, and to have trusted to the day for the day's supply, in the same manner as is done by the savage. They drove no flocks or herds, they carried no seed corn. When they settled, indeed, they did make a little provision against the season of want, but that provision was all obtained from the natural produce of the country in which they resided; so that, when the Mexican empire was in the zenith of its power, it could not be said that it had added even one new plant to the soil, or one new animal to the pasture.

Up to the time of its colonisation by Europeans, America may, therefore, be regarded as a country moulded wholly by the operation of natural causes; and throughout the greater part of its vast range in latitude it must, from the extent of sea which lies between it and the other continents, have been moulded by causes operating within itself. The natural history of America is, therefore, in a great measure, a subject complete in itself, between which and the several parts of the eastern continent there are not the same relations as these parts have to each other. No doubt it is subject to the same grand laws of the year, on which climate and seasons depend; and the plants and the animals must be in accordance with these. But there are peculiarities in the form, the position, and the surface of America, which modify its climate, and through that, all its growing and living productions; and we must take at least some knowledge of these particulars along with us in order rationally to understand even the elements of its natural history.

The position of America upon the map is in itself worthy of attention. There is no country which lies so far upon a meridian, or has its central elevation so much in the meridional direction. What with land, what with ice, it may be said to reach the pole at the north, and thence it extends unbroken to the latitude of about 56° south; so that in round numbers it may be said to oppose to the currents of the sea and the atmosphere a barrier of ten thousand miles in length, or, taking the flexure of the mountains which bend much westward in the northern part of the country, of not much less than twelve thousand. That barrier, too, is not only complete against the sea, but against all those lower strata of the atmosphere which can be supposed to have much effect upon plants or animals; for, with few interruptions of any kind, and hardly any save where the isthmus is narrowest, is there any interruption that can be supposed to admit of an interchange of climate; for though there are some passes in the isthmus, these are overlapped by the projecting high land in Venezuela, so that any wind from the east, blowing so far to the northward as to clear Cape Gallinas, would be taken by the table land of Mexico, and turned by the eastern side of the Stony Mountains down the great central valley of North America. To the northward of the Gulf of Mexico, the mountains near the shore of the Atlantic confine the influence of that ocean to the line of the coast, to which the valley of the St. Lawrence barely forms an exception, as the influence of the great lakes at the upper end counteracts that of the sea at the lower, and the entrance of the latter between the high grounds below Quebec is a mere pass, and that pass interrupted by Newfoundland and the other islands. South of the Gulf of Mexico, the wind from the tropical Atlantic sweeps along the valleys of the Orinoco and the Amazon; but these are both, at their terminations, cut off by the lofty cordilleras of the Andes. South of the Amazon the different mountain ridges in the eastern part of Brazil again interrupt the communication between the interior of the country and the sea; and even in the flat country to the southward of La Plata, though the current of sea air sweeps a considerable way over the Pampas, the Chilian Andes form so effectual a barrier to it that it never reaches the western shore.

Thus, the slope from the great summit eastward, which comprises by much the greater part of the whole surface of the continent, is divided into a number of valleys or basins, having their atmospheric motions in the direction of their own lengths; sometimes between the mountains and the sea in nearly a direct line, as in the case of the valley of the Amazon; sometimes oblique, as in the St. Lawrence; and sometimes directly across, as in the central valley of the Mississippi.

On the western side, the mountains are, generally speaking, so near the sea as only to leave a mere margin, or at best but a narrow plain, unless in some places towards the north, where the connexion between the sides of the continent is interrupted by the cross current of the central valley.

In general, the current, both of the ocean and the atmosphere (in so far as the latter of these depends on the former), sets across the Atlantic from the east, sometimes a little south of the equator, and sometimes a little north; but upon the average of the year only a degree or two north of the equator itself. The greater portion of both currents is turned by the northern heights on the left bank of the Amazon, and circulates round the Gulf of Mexico, the aërial part of it ascending the valley of the Mississippi, when the regions to the north have been dried by the action of the summer; and the aquatic part circulating round the Atlantic, in the gulf stream and its continuations. In summer, when the current is at its greatest distance northward, and also at its greatest strength, because of the less interrupted run which it has at that season, the weather up to very high latitudes in the central part is warm, so as to ripen in Canada, fruits which can hardly be brought to maturity in the milder climates of Europe; and were it not for the evaporation produced by the vast surface of lakes in that part of America, and also by the forests with which many parts of the country are shaded, there is no doubt that the surface there would soon assume a more sterile and dreary character than is to be met with even in the bleaker parts of Siberia.

The countries which open to the sea further southward receive an abundance of humidity, though they receive it seasonably only; and in them, though peculiar in its character, vegetation is proportionally luxuriant.

On the west coast there is in general much less action between the mountains and the sea, as the general current both of the air and the waters there sweeps along the line of the coast, alternating with the seasons, and occasioning great disturbances of the atmosphere at its changes—violent storms of thunder and lightning, heavy falls of rain, and winds of hurricane violence.

The general motion of the oceanic waters is thus a current playing round the American shores, northward on the eastern shore to the north of the Equator, and southward along that to the south; and then by Cape Horn around the whole line of the west. The great return current is by the north of the Atlantic, and that current casts the wreck of America—the timber brought down by the spring freshes, and the more constant currents of such rivers as the Mississippi, which continually shift their beds in the soft alluvial soil—upon the islands that lie along the shores of the polar ice, and partially, it may be, upon some of those of Siberia. That wreck consists chiefly of timber, and the quantity of it is so great, that it affords an abundant supply to Iceland and some other places which have no timber of their own. The supply has been afforded from time immemorial; and there are places where immense floats of it are now covered with soil, and others where it has partially been converted into coal by the action of volcanic fire.

America is too remote from Africa for allowing the passage of any animal, even of a bird, from the one to the other, as birds do not migrate much in longitude, especially within the torrid zone, in which these continents make their nearest approximation. With Europe, also, there is no direct communication, even by means of the polar ice; and the communication with Asia is limited to the extreme north-east of that quarter of the world; thus the only part of Asia which has an ice-connexion with America, and in so far resembles it, is by the eastern mountains, and the intervening deserts, in a great measure cut off from the rest of Asia, so that the north-west of America can hardly be said to have an Asiatic character.

The natural productions of America are just what, from the peculiarities of its situation, we should be led to expect. Generally speaking they are very different from those of the other parts of the world; and the situations which they are found most to resemble are those in which there is the clearest connexion.

The mineral productions do not properly come within the scope of these distinctions, because, with the exception of some of the salts found in the soil, we know but little of the effects of difference of climate in the formation of minerals. The mountains of the American continent are, however, peculiarly rich in metals. The gold, the silver, and the copper of the Andes have been all long known and much esteemed; and the mountains of the north are particularly rich in iron. The gold is usually found native or metallic, and in a comparatively pure state; but it is mixed with much soil, from which it is separated by washing, the great specific gravity of the gold causing it to remain at the bottom of the vessels. The places, where that operation is performed, are by the Spaniards and their descendants called *lavaderos*, that is, washing stations; and the search for gold is in general accounted a work of great labour, and very uncertain profit. Silver is found in much greater quantity, and the operation of mining for it, though still one of some hazard and much expense, is one of more certainty to those who can command the requisite capital. In Peru, where it is perhaps more abundant than in any other part of the country, though some of the Mexican mines have been far richer in pure or native silver, it is found high in the mountains, but generally at no great depth below the surface, and sometimes it is disclosed by the mere removal of the vegetable sod. In the richest mines, the silver is generally mixed with brown oxide of iron, and the stratum in which this mineral is contained is often limestone. But notwithstanding the importance of the American mountains, especially those of central and South America, in an economical point of view, the geology is still in a very imperfect state, and so must remain till many additional discoveries have been made.

The mineral kingdom is not, as has been said, under the influence of local or climatal circumstances; and the effect which minerals, at least those at even a moderate depth below the surface, have on the vegetable and animal productions is not very great, or at least not very satisfactorily made out. So that, with these considerations, we must take the living productions as they occur, without seeking to establish any general connexion between them and the minerals which they help to conceal.

The vegetables of America resemble those of the eastern continent much more at the northern extremity of the country than in any other part; but what may be considered as the polar vegetation ranges much farther to the south than it does in the old continent, especially in Europe. The north-west of America and the north-east of Asia, which approach each other in geographical position, also resemble each other in climate and productions much more than the north-east of America and the north-west of Europe. What connexion, if any, there may be between the maximum of cold in the northern parts of America, and the situation of the magnetic pole, has not yet become matter of philosophy, though it does appear that there is some connexion between them. But, independently of that circumstance, there are, in the northern parts of America, sufficient natural causes to induce a very intense degree of cold. There is no current of tidal water by the sea from any warmer region; all the winds that blow come over either cold, and for the greater part of the year, snowy heights, or they come over lakes and swamps which are calculated to produce intense cold by their evaporation. There is thus no means by which heat can come from any other region, and, for a great part of the year, the heat of the sun is much absorbed in the melting of snow and ice; so that, in the extreme north, the average temperature is below that of freezing; and though the difference in latitude is two or three degrees, Melville Island is more dreary and barren of vegetation than Spitzbergen. The plants are very few, and of the most humble growth. Even in our progress southward, especially toward the eastern part of the continent, a latitude answering to the average of that of the British islands must be arrived at before we come to a climate equal on the average to that of Lapland. The trees are not quite the same species; but we find in the country about the southern parts of Hudson's Bay, and on the northern frontiers of Canada, spruces (the black and the white) bearing some resemblance to the same coniferæ on the Lapland mountains; and we find them accompanied by the same under-growth of reindeer moss and other lichens, which, if not precisely the same, are so much alike that they impart similar characters to the countries.

Nor is it in the forest alone that we have this correspondence of vegetation, with considerable difference of latitude, for the swamp and the marsh present nearly the same characters. Cranberries and other hardy plants cover the surface, and give a polar character to the marshy flats south, even to the very margin of the great lakes, or to a latitude answering to that of the finest vine countries in France. When this polar character begins to give place to something more promising, the vegetation gradually changes; and although the trees and plants are often of the same genera with those of the eastern continent, they are generally of different species,—of species, for the most part though not always, more rapid in their growth, more remarkable for the variety of their tints when they fade in the autumn; and, generally speaking, much more spongy and less durable in their timber.

In these respects there seems to be a sort of correspondence between the timber and the soil on which it is produced. There are not in the northern parts of America any of those specimens of a firm green sod composed of soft, kindly, and matted grasses which are so well known, and so much and justly admired in this country. The few grasses which do appear are dry and wiry, or they are hard, and belong only to the marsh or the margin of the pool. The dry land is raw and bare—a pool at one season of the year, and blowing with black powdery dust at another, or if there is any intermediate state, it is that of a land covered with different species of *compositæ*, which, when the land is cleared, often multiply in such numbers that they not only become pests to the farmer, but absolutely choke and keep down all other vegetation; and that too upon land which, but for them, would be among the best in that part of the continent.

When Upper Canada is arrived at, there we find the very extremes of temperature in the course of the year—a polar winter and a tropical summer. In the former, the whole land, or at all events the water in it, is consolidated like iron, and in the latter, the melon, the tobacco plant, the rice plant, in situations which suit it, and probably also many of the other natives of hot climates, can be cultivated with success. But the extremes of heat and cold are severe tests of the soil; and when the primeval forests are cleared off, it is doubtful whether the evil may not be increased by the want of trees, even of those species which, at the time of its first settlement, are accounted the pests of the country.

When the summit level of the great lakes is passed, the vegetation of the country assumes a new character; and though many species of pines still occur on those soils which are favourable for them, and the American cedars muster thickly on the swamps, and the rhododendrons, azelias, kalmias, and other plants, which we consider as the ornaments of our shrubberies, abound upon the peaty slopes and hillocks; yet the more compact soils by the side of the streams are overshadowed with deciduous trees of great dimensions and the most graceful foliage.

As the Gulf of Mexico is approached, the elements of vegetable action become in a wonderful degree energetic. The Mississippi and its tributaries roll toward the Mexican Gulf, probably the largest volume of running water which is to be met with any where upon the face of the earth, not excepting the Amazon itself. Estimating from the remotest source of the Missouri in the Stony Mountains, the length of those giant streams is not less than four thousand miles; and much of the valley through which the main branch flows is humid. Besides, what with rains, what with the melting of snows, and what with the rapid descent of the western waters into the valley, there is a great deal of flooding; and the flooding is not confined to the Mississippi, but belongs in part to many of the other rivers in the southern states of the American union. In summer there is not much direct rain in these parts, as the wind is comparatively steady toward the dry grounds, increasing in temperature and capacity for moisture as it proceeds. Accordingly, while the marshes and swamps are reeking with pestilence, in a heat which is all but intolerable, the cultivation of vegetables, even those of a tropical character, goes on with great rapidity and success; and the crops of tobacco in Virginia and Maryland, of rice in Carolina, and of cotton in Georgia, or of all these and others alternated, are most abundant, and carried on with much success and at great profit, though if the cultivation were wholly managed by Europeans, it would be at no small sacrifice of health and life.

As the country is traversed in longitude the character of its vegetation changes very materially, even in the corresponding latitudes. On the Atlantic side the action is between that ocean and the land, and the Gulf-stream rolls northward along the American shore a volume of water from the tropical regions, which, even in comparatively high latitudes, is several degrees warmer than the still waters and eddies of the same places; that of course carries with it a current of air equally warm in proportion; and thus then is borne to the northward as far as about Nova Scotia, where the current of the stream turns, before it lingers and deposits its load on the great banks of Newfoundland; a climate warmer than that which would otherwise belong to the country. But that climate barely passes within the average line of the Appalachian ridge which runs parallel to the coast; and the centre of the country is within the range of that climate which plays along the valley between the Gulf of Mexico and the north, along the current of a vast flood of water which is continually descending toward the former. On the right bank, too, though the mountains are not bold in their outlines, or apparently gigantic in their altitudes, they rise, by one dull and bleak ridge over another, to a considerable height, and upon them vegetation is but scanty, and trees are comparatively few. The surface there is consequently much under the influence of the season, heated in summer and proportionally cooled in winter, so that even the lower parts abound more in savannahs or prairies, or even in dry and barren plains, than on the opposite bank of the Mississippi. As the latitude diminishes the character improves; but through the greater part of Louisiana, and into the country of Texas, adjoining the northern part of Mexico, much of the surface is of the character which has been described. Near the courses of the rivers, where there is much depth of alluvial soil, and abundance of humidity, the trees grow to large sizes, and many of them are remarkable for their beauty. One of the finest is the deciduous cypress (*Taxodium disticha*), which attains an enormous size, and is equally remarkable for the graceful form and the delicate tint of its foliage. The tulip tree, the black walnut and many others, are also highly ornamental; and all the deciduous ones pass through such variety of tints before they finally drop their leaves, that the autumnal decay of an American forest is almost as gay in its hues as the blossom of the spring is with us.

When the summits of the Stony Mountains are passed in progress towards the shore of the Pacific, the character of the climate again changes, and along with it the vegetation. The Stony Mountains are not one ridge, but a series of ridges, or a succession of clusters of heights, of considerable breadth on the average of their course, and dividing into two branches as they approach the extreme north. One of these branches reaches the shore of the Arctic Ocean to the left of the embouchure of Mackenzie's River, and the other points to the west, terminating continentally in the peninsula of Alaska; but continuing submerged to some distance farther, and having its summits rising above the surface in the islands which lie off that point.

These mountains form a complete barrier between the country on the shore of the Pacific, and that toward the Arctic Ocean and the central valley; and as the set of the current is upon this shore also, generally from the warm latitudes, and Alaska turns any eddy that there might be out to sea, the climate is warmer than in the corresponding latitudes of the centre. The unequal form of the surface, and the vicinity of the sea, cause it also to be more humid; and these circumstances alter the character, and increase the activity of the vegetation. The herbaceous plants are there remarkable alike for the stateliness of their forms, and the beauty of their colours; the shrubs, even the berry-bearing ones, have a gaiety in their blooms, which renders them highly ornamental as shrubbery plants; and some of the forest trees are the very giants of the vegetable kingdom. Some of the pines, or rather perhaps spruces (they are in fact intermediate between the two), would serve singly for the spire of a cathedral; and of the cones of others, the seeds are so large, and contain so much farinaceous matter, that the people roast and eat them as a substitute for bread. It appears that though the plants are, generally speaking, of different form and character, there is some sort of analogy between, at least some parts of the west coast of America, between California and Alaska, and the islands of Japan. The climate of Japan is what may be termed a "collected" climate, brought upon many winds and currents of the Pacific, and tempered by its own varied, and in many places elevated, surface. That climate is substantially temperate; and yet there is a tropical air in the vegetation which it produces. But notwithstanding the tropical beauty of many of the plants, they stand the climate of Europe better than many of the native ones, so that the aucuba, and no doubt also the beautiful camellia, by a little management, might grow luxuriantly in the cottage gardens of all the warmer parts of Britain. The same appears to be the case with the plants of the west coast of North America,—all of them that have been tried, annual or perennial, herbaceous or shrubby, or trees, have grown freely, and multiplied readily; and there is no doubt that, ere many years have elapsed, the majestic pines of those western lands will raise their gigantic pyramids high over the ordinary trees of our forests; and as their timber is said to be good and durable, as well as rapid in growth, there is reason to hope that they will contribute as much to domestic use as to scenic beauty.

In Mexico, though the deciduous cypress still continues on some of the elevated grounds, and the pines wave their green tops over Orizaba and others of the mountain peaks, giving shade and beauty, and supplying timber, the vegetation begins to assume a tropical character. In the sandy and burning plains toward the Gulf, the banana, the plantain, and various other fruit-bearing trees, and the yam, the arrow root, the cassava plant, and many others which accumulate their substance in bulbs or tubers, together with rice and maize in the stronger and more swampy grounds, afford an abundance of food with comparatively little labour of cultivation. Pine apples of various sorts grow wild in the woods; and not the least characteristic or useful plant is the American aloe (See AGAVE) which sends up its spike of many flowers to the height of more than twenty feet, and which in connected rows forms a hedge which no animal can penetrate. It serves the people of the country as a substitute for the vine; as the sugar maple in the northern parts answers as a substitute for the sugar cane. They scoop out the heart of the plant just as it is preparing to send up the flowering stem; and the bottom which is left forms a large cup, in which the substance of the plant accumulates in several gallons of sap from a single individual. That sap is fermented into the common *pulquè*, or drink of the country, which is in very general use all over Mexico; and the pulquè may also be distilled into a spirituous intoxicating liquor, to which the name of *vino mercal* is given.

The country on the coast of the Caribbean Sea to the southward of the Gulf of Mexico, and the westward of Cuba and Jamaica, is remarkable for the closeness of its forests, the violence of its rain-storms at certain times of the year, the quantity of water which stagnates on the low grounds, and the extreme fertility, but, at the same time, the pestilent character of its climate. From that part of America the greatest quantity and largest size of the mahogany of commerce is obtained, though, as it grows in close forests and upon soft and swampy soils, it is inferior to that of Cuba or the other West India islands from which any is still obtained or obtainable. Along with mahogany the same forests yield lignum vitæ, and many woods which, as their colouring matters can be fastened upon stuffs, are of much use in dyeing. On the other side of the central ridge in this part of the country is situated the country of Guatemala, which was once so celebrated both for the quality and the quantity of its indigo.

Passing the isthmus of Panama southward, we come to a country in many respects new in the characters of its vegetation. Here are the same esculent plants as in the hot plains of Mexico; but as the soil is in many places rich, and the surface much diversified, the plants and trees are so numerous, that a mere list of them would occupy a considerable space. The chocolate-tree (*Theobroma*), the nopal (*Cactus opuntia*), upon which the cochineal insects, which yield the finest scarlet dye, are fed; and the various species, the juice of which forms *caoutchouc*, or India rubber, are among the most curious; but the last mentioned substance is the produce of many trees, some of them natives of other parts of the globe.

South America, from the isthmus of Panama to the mouth of the river Amazon, is, taking all the succession of seasons, and all the characters of soil, a compound of almost all sorts of tropical climate that can be imagined. Much of it consists of dense forests, the tops of the trees of which are grazed on by the sloths (see Ai); the branches swarm with birds and American monkeys, all in incessant activity and chatter, the former rivalling in colour the gayest flowers, yet having their flowery rivals in the very same forests, in the magnificent climbing and other parisitical plants which spring up in all places where a root can insinuate itself or a clasper twine, and support a plant which, mouth all over, feeds upon the moisture raised by the heat from those depths of the tropical forest which the light of the sun is unable to penetrate. The lower portions of these forests are often flooded to the depth of fathoms during the rains; and the usual tenants of the wood, the aquatic reptiles, the swimming birds, and the fishes, may be all said to inhabit together in one and the same locality. Places which are bare of trees, and not subject to be flooded by the rains, have generally a very parched character during the dry season; and when the rain comes they change to beds of flowers, or plantations of luxuriant vegetables, as if by magic.

To the south of the Amazon, the vegetable riches of Brazil are even, if possible, more luxuriant than those that have been mentioned. The country stands out more to the sea, and takes the sea-wind, loaded with humidity, upon two of its sides. The soil and surface are, however, both very much varied, and that gives much change of scene to the country. There are not, perhaps, in any part of the world finer bowers and forests than those which are met with in the dells and by the watercourses of Brazil, whether we regard the beauty of the trees, or of the plants which those trees support. The dye-woods of Brazil are of much value, and so are the rose-woods, which are the timber of certain species of *robinia*, the colour and qualities of which are, like those of the mahogany, understood to depend very much on the nature of the soil and situation.

Much of Brazil, and indeed of all the tropical parts of America, where the surface is varied, is, however, covered not by close forests, but by "bush" or stunted shrubs, which are very generally of a hard and prickly character. These, though as tropical in their latitude and more burning in their climate, have none of the perennial verdure and bloom of the tropical forests. They exhibit the tropical clime in a new character, and the year under a new aspect of seasons. During the rains, the bushes put forth leaves, and increase by shoots, in the same manner as our deciduous trees in the summer. But when the drought comes to its full intensity, the leaves disappear, and the bush has the aspect of our hedges and bushes in the winter; not that the plants are burnt up or withered, though the earth to their deepest root may be as dry as the ashes of a hearth. They are fitted to the climate, and they are as conserved and safe as our hardy deciduous shrubs when the ground is frozen around them, and the air far below freezing. Their leaves, when the heat and drought prevent them any longer from performing their living functions, "heal off," and the little buds in their axillæ are as well protected from the drought by their envelopes as our buds are by theirs from the cold. If the rains come twice in the course of the year, at nearly equal intervals, as is the case in some places, these deciduous tropical plants have two seasons of growth in the year.

The plains in these countries are, perhaps, more unlike anything that we are apt to consider a plain, than the woods and thickets are to ours. Their extent is very great, and they are without water, unless when partially flooded during the rains, or when they are crossed by a rough branchless stream, which in the hot season is low between its banks of indurated mud, and diminishes in volume as it crawls along, without perceptibly adding to the life of vegetation even in its immediate neighbourhood. Unless toward the interior, few of those plains in South America are at any time wholly destitute of vegetation; they have generally under shrubs scattered over them which afford some shelter to the herbaceous plants; and there is generally dew during the night, the difference of temperature between which and the day is generally much greater than in temperate climates. Still the vegetation upon them has, in the burning season, much more the character of that of a polar wild after the grass has withered, than of anything to be met with in England. The mammalia on those plains are not grazing animals, but peculiar species of *rodentia*, or gnawing animals, which can subsist upon the sapless vegetation. In some instances, those plains maintain their humidity, and even a perpetual verdure, by means of a double crop, the one part of which affords shelter to the other, till it has covered the ground, and then falls, forming a sort of manure, but sowing its seeds at the same time. One of these crops frequently consists of thistles or other rapidly growing *compositæ*, which begin to sprout as soon as the rain falls, and completely cover the soil, and retain the moisture by the time that it ceases; and under their shade, some more slow-growing herbage comes forward, and again fills the ground, after their leaves have begun to drop, and their stems to become hard.

It is through some such succession as this, changing the species and appearance of the plants with the latitude, that the vegetation of South America passes from the vast forests on the tropical rivers, to the peculiar vegetation of the extreme south. Even there, however, the country has, if not a sort of tropical character, at least a very peculiar one; and one which, though in position upon the globe it is antarctic, is not the same as in any of the other antarctic lands. The araucarias of Brazil, and of Chili, and the southern Andes, are trees unknown any where to the north of the equator; but they are unlike the trees of those southern lands which lie nearest to America, either on the east or on the west. They are not known in Southern Africa, or Van Diemen's Land; and though there are some of the same family in these parts, they have a much lower latitude in New Holland, and are most abundant in some of the smaller isles to the east. Altogether, the vegetation of the American continent is peculiar; and the species become the more peculiarly its own as we advance toward the south. Thus we cannot say that it has derived its plants from any other part of the world, or that any other part of the world has derived plants from it. They are adapted to the climate, and the climate to them; and that is all we are able to say upon the subject.

The animals are still more peculiar; and of those which have not the means of passing by emigration between America and other places, there are few that can be considered as common to it and to the other parts of the world. Our limits will admit of a notice of the vertebrated animals only; and even that must be brief and imperfect. But it is probable that, if they were as well understood, the invertebrated animals would be found to be just as peculiar and as characteristic of the country.

The sea fishes, the cetacea, and the seals, are not, strictly speaking, inhabitants of any country; some of them range over the ocean, and probably circumnavigate the world in all its latitudes and longitudes, and those which are more confined, still range the north seas, from Europe to America on the one hand, and from Asia to America on the other. The pelagic fishes do the same; and so also do many of the bank fishes, and the marine *chelonia*. The cod of the great bank of Newfoundland does not appear to differ specifically from that of the Dogger Bank between Britain and the Continent, at least not more than they differ upon some of our own banks which are not very far apart from each other. The green turtle of the West Indies appears to be exactly the same species as that which is captured on the shores of New Holland; and the hawk's bill or "shell" turtle of the Malay islands in the east appears to differ in nothing from that which is captured in the Bay of Honduras in the west. Many of the migrant birds, which nestle and spend the summer upon the arctic shores of America, are certainly the same species, and in many instances probably the very same individuals, which spend part of the summer with us.

In the fresh water fishes and reptiles more peculiarity may be looked for; and there are certainly many species in the American rivers, to which we have none exactly corresponding in Europe, though to what the difference may be owing it is not so very easy to say. Some of the tortoises of the American rivers are certainly, in so far as is known, peculiar; and probably the same may be said of some of the aquatic sauria. Many of the land sauria are certainly peculiar; and so also are the ophidia—as for instance those two most formidable of poisonous serpents, the rattlesnake of North America, and the bushmaster of South America.

The birds of America, with the exception of the migrant species, are almost all peculiar, and very many of them unknown, or represented by races specifically different, in the other parts of the world. As is the case with the other natural productions, we find the closest resemblance in the north, where we have reason to expect that there may at times be a passage from the one continent to the other. So far as the American species are known, the grouse and partridges of the two continents very much resemble each other, though they are not perhaps exactly the same; and if well made out, the species or varieties in America will probably be found to be the more numerous. The gallinæ are different, there being no American birds at all resembling the common fowl, the peacock, or the pheasant; while, on the other hand, there is no native bird of the old continent answering to the turkey of America. Other than the turkey there is no bird of a strictly gallinaceous character in North America; but in South, where the character of the country is, in certain places and at certain times, better suited to the habits of such birds, we find the *Alectoridæ*. The *Agami*, and some other species, may be considered as in some respects resembling the bustards of the eastern continent, but their structures and habits are not quite the same. The *nandu*, or ostrich of South America, differs from the African ostrich, both in being smaller and in the different structure of the feet. Instead of running upon the loose sand, like its African congener, it runs among the herbage; inhabiting climes which are not quite so warm, and feeding on pastures which are not quite so barren. It has three toes on each foot, all furnished with nails, and it inhabits, from the plains in the interior of Brazil as far south as the extremity of the continent. The most singular races of birds on the American continent are the toucans and humming birds of the southern forests; the last of which are equally remarkable for their diminutive size, the brilliancy of their colours, and their power of wing. It should seem as if they were made to rival the beauty of those flowers among which they are found hovering, and fanning their tiny wings with a rapidity and continuance of motion, which almost takes them out of the class of beings which have their muscular energy clogged by physical weight. They range far and wide over the southern part of the continent, and apparently unaffected by the rigour of the climate. Some of the species are found at the very southern extremity.

The land mammalia have their characters, of course, much more in accordance with those of the land than any other of the classes of vertebrated animals; and it is in their peculiarities that we see most clearly the peculiarities of the American continent. Man, even in the lowest state of civilisation, is adapted, morally as well as physically, to the soil and other circumstances in which he is placed; and on that account, if we include man in our estimate of the adaptation of the mammalia to their country, the argument will be weakened and vitiated to the full extent to which he exercises his mental powers.

In America we find proofs, both that man is so far modified by the physical circumstances in which he is placed, and that he is in other respects proof against those circumstances and can control them. In the extreme north of America we find the Esquimaux nearly the same polar people which are found in the extreme north of the other continent, and who, in all the movements of nations, do not appear ever to have made any progress southward. We look in vain, in even the moderately temperate parts of Europe or Asia, for any colony of the Laplanders or the Samoiedes; and so also we look in vain among even the inhospitable lands of North America for any colony of the Esquimaux. They do come upon the margin of the land in the summer; but in the winter the frozen sea is their wealth, and the ice and snow are their habitation and shelter. Instead of the reindeer, they no doubt yoke dogs to their sledges, because the rein deer cannot subsist upon the surface of the frozen sea, and live upon the flesh and offal of seals and other aquatic animals. But still the races have the same appearance, the same habits, and the same superstitions; and, like all people whose lives are, in our estimation, hardly worth living, their grand excitements, their most intense hopes and fears, are with the dead. This tendency of man to people the northern desolation with creatures of the imagination, the contemplation of which shall so eke out the scanty tale of the occurrences and experience of his life, is at once a curious display of resource in mind, and an unanswerable proof of its existence, independently of all physical circumstances, as well as of its power and capacity of overcoming, and, as it were, trampling upon these circumstances.

But when we turn our attention to the other inhabitants of the American continent, we find man in his colour, and in most of the essentials of his character, proof against the variations of climate; and the hunter who drives the wild animals in the inhospitable neighbourhood of Slave Lake might, without any inconvenience, or, language excepted, almost any means of noticing that he were a stranger, range the continent from the one extremity to the other. Habits, no doubt, affect the individual there, as well as in other parts of the world. Vigorous exercises brace the frame, while indolence dwarfs and softens it. The Mexican or the Peruvian, squatted beside his hut, and finding his food from a few banana trees which cost him very little trouble, is not half so much a man as the Araucani in his forest, or the Indian, who, mounted on his wild horse, sweeps the wide extent of the Pampas, free and fleet as the wind of heaven. It must, however, not be lost sight of, that, if not different races, the Mexicans and Peruvians have long been subjected to very different treatment; and treatment, too, the effect of which has been moral rather than physical. The tyranny of the Mexican emperors and the Peruvian incas seems to have been severe enough, but it was nothing to the yoke laid upon those ill-fated people by Spain. We speak in terms of horror of the cruelties which have been perpetrated upon the natives of Africa, in the cultivated colonies of the western world; but these are nothing in point of hard labour, privation, or even direct and palpable torture, to those which the native Indians have borne in the mining districts.

These circumstances are not mentioned with any view of preserving the memory of deeds which cannot be repaired, and therefore had better be lost in the contemplation and construction of a better system; but they do show that, in considering the relative adaptations between a country and its living inhabitants, man must be treated separately and in a different manner. In the other animals, the organisation is wholly at the control of physical circumstances, though, true to its origin, it maintains its specific character in spite of them, and always resumes the natural form of that character in proportion as the modifying circumstances are relaxed. But in man there is always an active principle, which, however dormant it may be, is capable of reversing the order of physical circumstances, and creating a country for itself in the forest, the marsh, the desert, nay, under peculiar circumstances, and through the excitement of powerful moral stimuli, in the very sea itself. See MAN.

But when we leave man and his moral excitements and mental resources out of the question, the adaptations of the American mammalia to the country which they inhabit becomes a very interesting and useful portion of natural history. Not that we are by any means to conclude that they are the very best adapted to the country, even before the plough and the spade have brought it within the limits of cultivation; for such is the adaptation of the whole earth to the purposes of man, that if he will but bring the requisite degree of skill and labour to the work, and often the labour requires to be very light, he is certain to effect improvement. When the plains of Brazil and Paraguay were first visited by Europeans, there was not one grazing animal in the whole wide extent; and those who first turned loose upon them a few cattle and horses, had probably neither wish nor idea that those animals should become the staple wealth of the country. Yet such has been the fact, and the animals appear to have in a great measure grown their own food. They have kept down the long and wiry stems, brought something like a sod over the surface, and actually in fact prepared the land for cultivation by the plough; the same result, although more recently, and to a less extent, has taken place on some of the plains in the interior of Australia; and places where, only half a century ago, a few kangaroos, leaping from one tuft to another, found a scanty subsistence in the midst of a wilderness of showy but unprofitable plants, now look green and feed large and extensive flocks and herds. These circumstances seem to indicate that, in whatever hemisphere or part of the world man is to become a cultivator, he must, in order to act with proper and permanent effect, become a shepherd and a herdsman; and these two are the resources to which he must look for remuneration when the strength of his cropped land begins to fail.

The most remarkable general circumstances about the native mammalia of the American continent, are the number of species, the few of these which are common to America and the other parts of the world, and their local distribution in latitude within America itself. Of *handed animals* (*quadrumana*), about 82 species out of 187 (or thereabouts) are peculiar to America, not one of them being found in any other part of the world, and none of those of the other parts being found there. Of bats there are about the same number of American species; and though there are 112 of these in the other parts of the world, and only 102 of the handed animals, they are as peculiar to the American continent. If we leave out of our estimate the seals, which being marine animals, may be supposed to range freely round the polar seas, we have only about eighteen species of carnivorous animals (including varieties) which are common to America and the eastern continent; and some of these are aquatic, and even partially marine, while others can range from continent to continent upon the ice. But there are about 106 species of carnivorous animals peculiar to America, not one of which is found on the eastern continent; and it is probable that, from the vast tracts which remain yet to be explored, the number may still be considerably augmented. The marsupial animals of America, of which there are eight known species, are all peculiar to the country; and so are the twenty species of toothless animals, and the six pachydermous. Besides the few carnivorous animals that have been mentioned, the only species of land mammalia common to the two continents, or any part of them, are seven rodentia out of 133; and among these there are the beaver and the water-rat, both to a certain extent aquatic animals; and two ruminating animals, the reindeer and the elk; and in the species which are considered as identical, there are some variations.

All the mammalia which are common to the two continents, even to the extent of being considered as climatal varieties of the same species, belong to the northern parts of America, and almost all of them to the extreme north, within the range of the pine forests. Two out of the seven rodentia are somewhat doubtful. These are the common rat and mouse, which, from the rapidity with which they multiply, and the chance of their being landed by every ship, are not very easily determined as natives of any country. The forests, with their undergrowth of moss and lichen, and their alternating swamps and barrens still covered with coarse vegetation, affording cover to many small animals, and resting places and abundant food to innumerable herds in the summer, are the head quarters of the northern mammalia, more especially of the carnivorous tribes and the rodentia. The greater number of these are fur animals; and the quantity of their skins which is brought from the cold country to the westward of Hudson's Bay is immense. They are races, too, which all the exertions of the hunters (and their lives are no sinecure) do not tend so rapidly to diminish as the exertions of hunters do the animals of some other parts of the world. It is the interest of the hunters themselves that close time in the forests should be a time of peace; because then, and during the whole of the hot season, the skins of the animals are of comparatively little value.

Of the carnivora of the northern parts the bear is the most formidable, just as is the case on the eastern continent; but in the southern latitudes he becomes more feeble. The grisly bear of the Stony Mountains (*Ursus ferox*) is the most powerful animal of this genus; and the spectacled bear (*Ursus ornatus*) of the southern Andes is the least formidable. As the forests yield to the progress of cultivation or the hand of time (and there seems to be a curious sympathy, or rather reciprocal preservation in forests, so that if man cuts down those that are on the better land, those on the inferior land waste away), the bears and all the other tenants of the woods will of course disappear, as they have disappeared from the British islands, and from many other parts of the eastern continent; and the elk and the reindeer will share the same fate. See BEAR. The canine race are numerous, and some of them peculiar; but all of them are confined to North America, and the greater number also to the extreme north. There are among them no species answering to the wild dogs of southern Asia, to the jackal or the hyæna. Of the feline race there are considerable numbers; but, with the exception of the jaguar of North America, none of them are very formidable, either in size or in disposition. There is not naturally in the southern parts of the country any prey requiring the strength and spring of a very large predatory beast; in the herbivorous animals they are either of the slow-moving pachydermata, or the small and timid rodentia. There are no swift-bounding antelopes, no wild asses, no wild oxen, and no giraffes, which, in one or another of their species, form the principal food of the lion in Africa and the tiger in Asia. The larger prey, and the only known American species of antelope, are in the north, and that is the dominion of the more powerful bears. The inhabitants of the tropical forests, the sloths, the monkeys with their thumbless hands, and, in many instances, their prehensile tails, and the chinchillas and other herbivorous animals which inhabit the wide plains, are the most characteristic of the southern parts of the American continent.

It is not a little singular that, though the greatest breadth of the Pacific lies between Australia, on the one side, and that of the Atlantic, Africa, and the Indian Ocean, on the other, there should be a correspondence in the possession of marsupial animals. Of these there are at least eighteen known species in America; and, out of Australia, there are few, not above two or three, species in any other part of the world, and these are met with in the south-east of Asia. It is true that the American marsupialia have very little resemblance in species to the Australian ones; but it is remarkable that these two countries, wide as they are from each other, and different as they are in many of their natural as well as their geographical features, should yet be the places which, as it were, share between them these irregularly constructed animals. See MARSUPIALIA.

We have felt it necessary to give this very imperfect sketch of the leading points in American natural history, because there is not upon that continent any important and commanding animal, indigenous to the climate and characteristic of it, that will carry us over the range. With the rest of the world it is different, in all cases where a general connexion is desirable. The *antelopes* form a key to those medial or southern parts of the eastern continent, which are still (or now) in a great measure in a state of nature; and the *kangaroos* may be made to answer the same purpose in Australia, in so far as that singular continent is known or can be judged of. But there is no such animal which we can connect with the general natural history of America; and therefore some such article as the present seemed necessary, as a vinculum to bind the disjointed parts.

AMERIMNUM (Willdenow). A genus of two species: one an evergreen shrub, the other a tree; both stove plants. They belong to the natural order *Leguminosæ;* and the generic character may be described thus:—calyx two-lipped, the upper one divided, the lower three-toothed; standard reversely heart-shaped, keel of two petals; pods on a footstalk, and membranous, flatted, upper suture straight, the lower one convex. The *A. ebenus* is common in Jamaica, and other West India islands; the timber being of a beautiful colour, and having a close hard grain, capable of taking a fine polish, it is imported into Europe under the name of Jamaica ebony, for the use of instrument and machine makers.

AMETABOLIA (Leach). In entomology, a sub-class of insects embracing the Linnæan genera, *Lepisma, Podura,* and *Pediculus;* by all modern writers and entomologists these views of Dr. Leach have been adopted; the characters of the two orders are as follows, and the genera will be given under the names of the respective families.

The great leading distinction of this sub-class is, that it consists of insects undergoing no metamorphosis.

ORDER I. *Thysanura.* Tail furnished with setæ or filaments; mouth with mandibles, palpi, labrum, or upper lip; and labium or lower lip.

ORDER II. *Anoplura.* Tail without setæ or filaments; mouth in some species furnished with two teeth and an opening beneath; in others with a tubular very short haustellum.

The first order contains two families, *Lepismadæ* and *Poduradæ.*

The second order has also two families, *Pediculidæ* and *Nirmidæ:* these will be treated of under the respective heads.

AMETHYST. A mineral belonging to the quartz family. It is of a reddish or yellowish violet blue colour, and in its pure state of nearly the same degree of hardness and general chemical properties as the oriental topaz and ruby. It is usually divided into two varieties, the common amethyst and the thick fibrous amethyst. The latter is found in agate veins, and is generally accompanied by the preceding sub-species.

The common amethyst, which is by far the most interesting form of this mineral, was well known to the ancients. Its form is usually that of a six-sided pyramid, and at other times that of a six-sided prism, surmounted with the same number of planes.

The common amethyst occurs in veins and cavities in the secondary or floetz greenstone of Fifeshire; it is also found at Montrose, and in the Hill of Kinnoul near Perth. Upon the continent of Europe it occurs in great abundance, and also in North and South America. See Corundum.

AMETHYSTEA (Willdenow). A single species of a pretty little blue flowering annual, a native of Siberia. It belongs to the natural order *Labiatæ;* and is not cultivated in gardens so much as it deserves to be.

AMIA. A genus of soft-finned fishes with abdominal fins, belonging to the natural family of the herrings, and to that division of them which inhabit the fresh waters, and which are most abundant in America. Their bodies are covered with large scales resembling those of carp; but the head has no scales, and is armed with hard bony plates. The air-bag is cellular. They have the teeth strong and conical, and the point of the under jaw is fortified by a buckler of bony substance. The nostrils are tubular, the dorsal-fin is much produced, and the anal one is stout. There is only one species known (*Amia calva*); it is an inhabitant of the rivers of Carolina, and understood to feed upon crabs. The flesh is not esteemed as food.

AMIA. An ichthyolite, figured by Cuvier, and referred by him to this genus of fishes, is described by Blainville as found in a block of gypsum. It is twelve inches long and four high; the head being equal to one-third of the length. Another species is described by Mantell, in his "Geology of the South-east of England," as found in the chalk near Lewes; it is distinguished from the former by the angular shape of the head, the anterior dorsal fin having spinous rays, and by the scales being of a scabrous structure; he has named it *A. Lewesiensis.* Among other curious particulars mentioned respecting this fossil, he states that several specimens not only exhibit the tongue and its papillæ in good preservation, but even the air bladder, which appears of an elongated oval form, situated in the abdomen, immediately under the spine; thus proving that parts of the most delicate structure may occasionally be found in good preservation in a mineralised state.

AMMOCÆTES. A singular genus of cartilaginous fishes, of which the bones are so soft and flexible that they hardly deserve the name of bone.

There is only one species, the *pride*, or "stone-grig" (*A. bronchialis*), a native of some of the rivers of England, and especially those of Oxfordshire, but even there it is not very abundant, it lives in the tough and clayey mud, for which the streams in that part of England are remarkable, and it has many of the habits of a worm. When full grown it is about eight inches in length, and of the thickness of a goose-quill; and its body is annulated or marked with rings, which add to its worm-like appearance. In external appearance it is a miniature of the lamprey; but the maxillary ring or sucker, and, indeed, the mouth altogether, is without teeth, having instead small reflected barbs or bristles, on the palate and the entering of the gullet. When it breathes, the water is received by the gullet, and passes into the gill-cells, and out again by the gill-openings in the sides. This mode of breathing is incompatible with adhering to substances by the mouth as a sucker; and the upper lip only has the sucking form and character, so that the fish is inaccurately named the "lesser river lamprey." Its tail is lancet-shaped, by the dorsal and anal fins meeting in a point without any caudal. Its general habits, mode of feeding, and time of breeding are but little known, and it has not been ascertained to migrate. The probability is that it follows the general law of the mud fishes, and breeds in the very hottest season. Its size and general appearance have caused it to be sometimes confounded with the small lamprey (*Petromyzon plānare*).

AMMODYTES, the launce, or "sand eel," a genus of soft-finned bony fishes without ventral fins, and belonging to the eel-shaped family, but not partaking much of that shape or of the general characters of the eels. There are two species: the common launce (*A. tobianus*), which is seldom found more than five inches in length. It is a beautiful little fish, of a bluish green on the upper part, with a straight line of darker on each side. The under part, the head and the irides are silvery, and there are silvery reflections on the darker parts. The dorsal, anal, and caudal fins are all separate from each other; the dorsal begins behind the pectorals; and the caudal is forked. The head is very slender, the upper jaw in ordinary states is the shorter, but it can be protruded. The other species (*A. lanceolatus*) grows to a larger size, is more slender in proportion to its length, has the dorsal fin commencing as far forward as the pectorals, and the upper part more inclining to silver grey. They have no air bag, or cœca to their intestines. They feed upon worms and the smaller naked mollusca, boring in the sand with great rapidity.

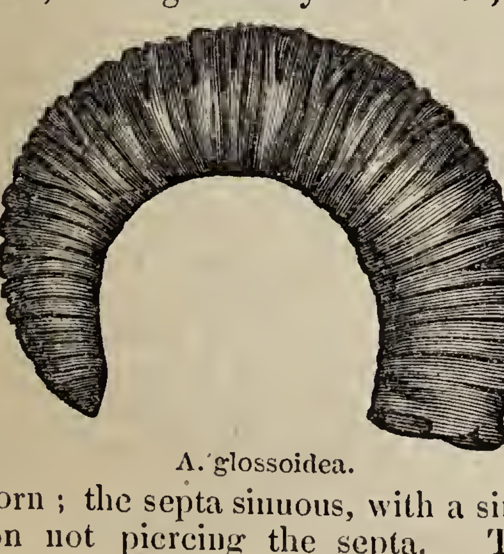
Though but of small size, they are very interesting fishes. They are caught in great numbers, are excellent eating, and much valued by the fishermen as bait. They are understood to form the principal food of some of the more valuable fishes, especially of the salmon when these are in the estuaries of the rivers, and in highest condition. The small sandy bays, at the confluence of the lesser streams with the sea, especially where those streams flow through fertile districts, are their favourite haunts; and the catching of them is often a work of much bustle and amusement. The favourable time for them is the spring tide ebb, and the further that the tide ebbs back the better. It is better also in the morning or evening, than in the heat of the day; and best of all, on those dark and still evenings when evaporation is nearly suspended, and the sands continue wet, and reflect the forms of the people; that state of the weather increases sound as well as sight, and it enables the sand worms to remain near the surface, over a large portion of the beach; the consequence is that the launces are all on the *qui vive*, driving through the sand in all directions, occasionally jerking into the air, but instantly hiding themselves in the sand.

When circumstances are thus favourable, the villagers muster *en masse*, men, women, and children, armed with spades, and shovels, and baskets, and pails, and all manner of utensils, that will turn up the sand, or hold the prey after it is captured. As soon as they come near the margin of the water, the shovelling, and scraping, and scrambling, and shouting begin; and no nutting, or even vintage, can be more joyous than this midsummer harvest of the sea. And it requires all the agility of the youngsters to secure the prize; for though the spade will sometimes disclose a dozen or more, not above one or two are caught, and all hands are searching to regain the fugitives. The very dogs seem to enter into the sport; for they skip about, and whine, and bark, and scrape, as if half the work rested upon their shoulders. It is indeed a most amusing time; and as the fishes, when the beach is favourable, recede and return with (that is near) the water, it may be continued till each family fills a large pail or basket.

Even the gulls seem to know that there is something going on which is a sort of invasion of their territory; for they wheel, and wail, and scream, now menacing the dogs, and anon attempting to assail the baskets, in the hope of regaining part of what has been taken from their preserves. The salmon, too, appear to look on at no great distance; for the porpoises come so near land as to be in some danger of grounding; and when that is the case, salmon are not far off.

AMMONACEA (Blainville). A family of molluscous animals, which includes the genera discorbites, scaphites, ammonites, and simplegas, all of which are fossils, and will be more fully described under their respective names. The animal being totally unknown, the general characteristics of these shells can alone be given; they are, the shell being discoid, separated at short distances by very thin partitions, called septa; the sides generally very thin; the form of the shell is compressed, and spirally rolled round its first turn, so as to exhibit each convolution gradually increasing in size; the last coil larger, consequently, than all the preceding, though not to such an extent as to form a wide aperture. These volutions or coils are variously sculptured, and the chambers or divisions are perforated by several, but most generally only by one tube or siphon, which penetrates through their whole length. One genus of this family, the ammonita, attains an enormous size, while others on the contrary are microscopic.

AMMONCERATITA (Lamarck, Blainville). A genus of molluscous fossils, of the family *Lituacea*; order *Polythalamacea*; class *Cephalophora*. An arched conical shell, forming scarcely half a turn, resembling

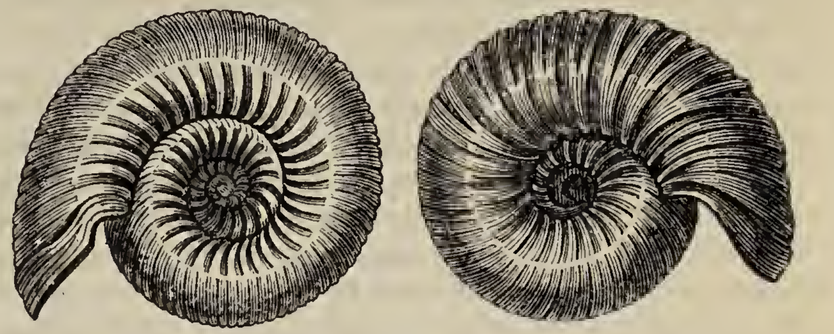


A. glossoidea.

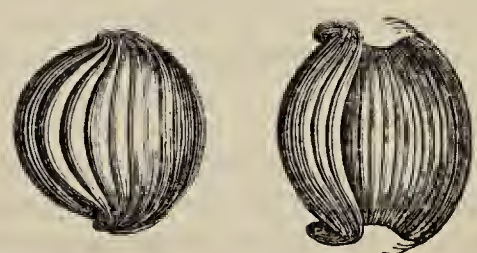
a ram's horn; the septa sinuous, with a single marginal siphon not piercing the septa. The species figured, *A. glossoidea*, sometimes attains the length of nearly two feet. They are found in the East Indies, and in Mount St. Catherine near Rouen.

A fossil shell of this genus is also known; the shell is conical, arched, but scarcely forming half a turn; the septa are sinuous, with a single marginal siphon, not piercing the partition.

AMMONITA (Linnæus, Cuvier, Blainville). A genus of fossil shells, of the class *Cephalophora*. These shells being known only in a fossil state, the



arrangement of their species depends principally upon a uniformity of external configuration; but as most of them are moulds, or internal models, another difficulty is presented, rendering any thing like a correct distribution of their numerous species into families almost impossible: there are, however, other consistent guides, such as the more or less globose form of the spiral convolutions, the keel being double, triple, or quadruple, and either knobbed or plain. But perhaps one of the best and most unerring distinctions is the sinuosity of the septa or partitions, their number and general distribution, with reference to the form of the shells, in juxtaposition with the various species. They are certainly closely allied to the nautilacea, from which, however, among other circumstances, they differ by having the mouth thickened, and in some expanded outwards, while in others it is contracted; so few of the immense number, however, are ever discovered in a complete state, that here again another guide is found deficient, in many essential points, by which a determinate character could be given to the species. The genus may therefore at present be generally described as a discoid shell, more or less compressed, the spiral turns more or less evident and convex, the aperture more or less expanded, the partitions or septa constantly sinuous, with a dorsal siphon. They are variously sculptured, but the greater portion of them resemble the marks of progressive growth or rings observable on the ram's horn, from which circumstance they have probably derived their trivial name of Cornua Ammonis, or Ammon's horn. The Egyptians worshipped Jupiter under the name of Ammon, a deity represented by the ram; and the busts and portraits of Jupiter Ammon are constantly found sculptured with rams' horns, as are those also of Alexander the Great, after he was deified as the son of Ammon.



Ammonites.

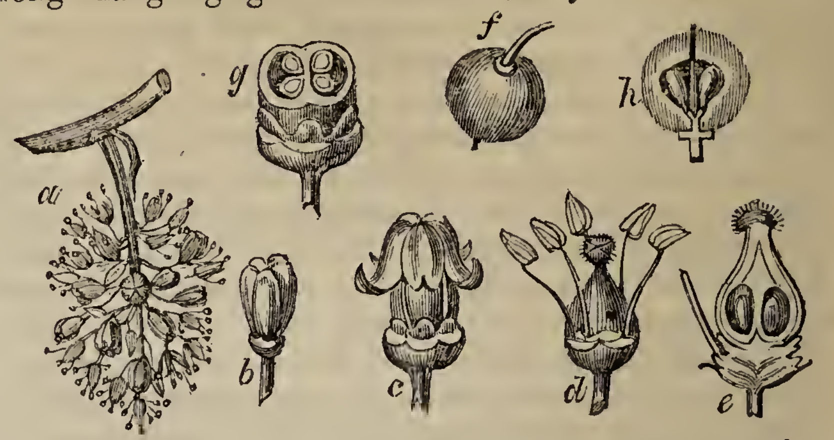
Ammonites are found in all parts of the globe; in France (particularly in Burgundy) they are so numerous as to furnish the principal material for mending the roads, and it is no uncommon occurrence to find them similarly used in some parts of Somersetshire, Gloucestershire, Yorkshire, and other counties, where they are abundant in the lias and inferior oolite formations. Large and fine specimens, in some of these counties, may often be observed built into the fronts of houses, forming an elegant natural ornament, called by the peasants petrified snakes, no doubt from the remains of a superstitious legend recorded in Camden's Britannia, exhibiting one of the many effects of our ancestors' credulity and ignorance, particularly in geology and natural history. He writes, "Upon the same river Avon, which is the boundary here between this county (Somerset) and Gloucestershire, on the western bank of it is Cainsham (now Keynsham), so named from Keina, a devout British virgin, whom many of the last age, through an over-credulous temper, believed to have changed serpents into stones, because they find sometimes in quarries some such little miracles of sporting nature. And I have seen a stone brought from thence winded round like a serpent, the head whereof, though but imperfect, jutted out in the circumference, and the end of the tail was in the centre, but most of them want the head." Walter Scott has happily adapted this legendary tale in one of his elegant poems.

These shells vary from microscopic diminutiveness to the enormous size of two feet and a half in diameter, entitling them to play their part with the ichthyosaurian, pleosaurian, and other gigantic creatures of a former world, whose race has passed away, but whose stupendous vestiges excite in the contemplative minds of us little beings awe and wonder at the vastness of creation, and the immeasurable grandeur of the Creator. See SALGRAM STONE.

AMMYRSINE (Pursh). A genus of plants of one species only; a North American under-shrub, belonging to the class and order *Decandria Monogynia*, and to the natural order *Ericeæ*. Generic character: calyx divided into five lance-shaped parts; petals of the corolla five, oval, obtuse, and spreading; stamens inserted in the receptacle, filaments like hairs, longer than the corolla; anthers egg-shaped, double; style round; stigma truncated; capsule three-celled and three-valved, seeds small and oval. This American plant is nearly allied to the *Ledums*, *Rhodoras*, and other beautiful shrubs from the same quarter of the world. In this country they are cultivated alike, and always in beds or borders of moor (not peat) earth in shady situations.

AMOMUM. A genus of plants consisting of thirteen species, all inhabitants of the warmer latitudes of the globe. They belong to the first class and order of the Linnæan system, and to *Scitamineæ* of the natural system. The generic character consists in the inner limb of the corolla having one lip, another with an entire or two-lobed crest, seeds with an arillus. This genus is allied to the ginger and turmeric families, and partakes of their aromatic and colouring properties. The *A. cardamomum*, and *A. grana Paradisi* are both extensively used in medicine, and others are useful in the arts.

AMPELIDEÆ. The forty-ninth order of the natural system. It comprises four genera, and fifty-three species. The grape vine belongs to this order, and gives a value to the whole. Its congeners are as follow, viz. *cissus*, *Leea*, and *ampilopsis*, the genus which gives name to the order. With the exception of the vine, all the plants belonging to this order are of little interest. The prevailing habit of the order is a long dangling growth of stem, thyrsus of simple



VITIS VINIFERA. *a*, a bunch of the flowers; *b*, flower before expansion; *c*, flower expanding; *d*, stamens, pistil, and germ; *e*, vertical section of the pistil and germ; *f*, fruit; *g*, horizontal section of the ovary; *h*, vertical section of the fruit, showing the position of the seeds.

colourless flowers, or tendrils opposite the leaves, and yielding bunches of berried fruit.

AMPELOPSIS (Michaux). A genus of North American climbing and shrubby plants, consisting of four species. They belong to the fifth class and first order of Linnæus, and to the natural order *Ampelideæ*. Generic character: calyx entire; petals cohering at the end, withering; stigma headed; ovary immersed in the disk, two to four-seeded. The *A. quinquefolia* is a useful plant for hiding naked buildings, or forming shady bowers, or summer screens in dressed grounds. It grows rapidly and needs no nailing up against walls, it being supported by its own tendrils.

AMPHIBIA. The third and last of the three groups into which Cuvier divides his sub-order *Carnivora*, properly so called; that is, mammalia which prey upon vertebrated animals.

The term amphibia is rather objectionable, unless received with some explanations. The old acceptation was, that animals to which the name applied, were supposed to be capable of performing all the functions of life either on land, in the air, or *under* the water; but there is no known animal that can breathe in the free air and also in the water; and, from the nature of the two fluids, as well as from the difference of the organs by which they are breathed, there is every reason to conclude that there can be no such animal. Cellular lungs, into which air is received, and fibrous gills, among the fringes of which the water plays, are so perfectly distinct, and each is so well and so solely adapted to its own purpose, that it cannot be made to perform the function of the other. The introduction of even a very small portion of water into the lungs of an air-breathing animal, would, in all the cases with which we are acquainted, be speedy and almost instantaneous death; and there is not an animal which breathes water which is not thrown into convulsions the moment that its gills are exposed to the air. Some lunged animals can, no doubt, remain a considerable time in the water, without access to the air, and some gilled animals can live for a considerable time out of the water; but neither the one nor the other so lives because it can breathe under the altered circumstances. On the contrary, it survives merely because it can live for a time without breathing; and the attempt to breathe the fluid for which it had not the proper apparatus, would occasion instant sickness and speedy death.

There are thus no amphibia, in the literal sense of the word, no animals which,

> "As some rats, of amphibious nature,
> Are either for the land or water."

There are some, as the common frog, which have gills and breathe water during one stage of their being, and have lungs and breathe air during another; but they have not even the use of the two systems for a single instant. The sealing up of the gills of the tadpole previous to their being removed from the system by absorption, as lumber for which there is no longer any use, takes place before one atom of air is inhaled by the newly perfected lungs; and when the seal of nature's condemnation is thus set upon the organs which have accomplished their purpose, they must go back to the common stock of materials, be decomposed, and again produced by the same process as at the first before they can again perform even one single movement.

What is meant by amphibia in the system of Cuvier is, therefore, nothing more than air-breathing animals, which are so formed that they can find their food, perform most of their other functions, and spend the greater part of their lives under water; and which, in some parts of their bodies at least, retain so much of the structure and appearance of animals which live habitually on land, that they cannot be classed with the CETACEÆ, or whale tribe. There are two genera of them, the seal (*phoca*), and the morse (*trichecus*); to which the otter (*lutra*), and perhaps the beaver (*castor*), might, without much impropriety, be added. Their appearances, habits, and haunts, will be noticed under their respective names. See plate AMPHIBIOUS ANIMALS.

AMPHILOBIUM. A genus of plants of which only one species is known; a West Indian ever-green creeper, considered ornamental. It is a didynamous plant and belongs to the order *Bignoniaceæ*. The calyx is bell-shaped, the limb double, outer rank spreading, undulated, or curled, the inner of two lips; corolla somewhat leathery, the tube being short, throat largely bellying, limb two-lipped, the upper like a helmet, the lower erect, having three teeth; anthers two-celled, stigma bi-lamellate; seed-vessel oval.

AMPHIPODA. The third order of the *Crustacea*, in Cuvier's arrangement of the animal kingdom. The bodies of these animals are generally compressed and curved upon the sides; the eyes are sessile and immovable, mandibles furnished with a palpus, and many of them have vesicular bursæ either between their feet or at their external base, the use of which is unknown.

Pernys.

The first pair of feet, or that which corresponds to the second foot-jaws, are always annexed to a particular segment, the first after the head. The antennæ, which, with the exception of the phrominæ, are four in number, projecting and gradually tapering to a point; the tail is articulated and styliform.

Many species of the amphipodes inhabit springs and rivulets, others are met with in the salt waters; they are always found reclining on one side, and in this position they swim and leap about with much activity. These animals may all be comprised in the genus *Gammarus*, although they are divided by authors into various sub-genera. Among the most interesting species is the *Pernys*, which is found on the coast at Rochelle, where it wages continual war against the nereides, and other marine annulata, which inhabit the same locality. When the tide is coming in, these crustacea present a curious spectacle; myriads of them may then be seen moving in every direction, beating the mud with their arms, and diluting it so as to discover their prey: when they do discover prey larger than themselves they unite to attack and devour it, which they never fail to do. The fishermen even assert that they will mount on the hurdles which contain their muscles, and cut the threads that confine them, in order to precipitate them into the mud, where they devour them at their leisure.

AMPHIPRION. A genus of spinous-finned fishes, belonging to that division of the *Scæinadæ* which have fewer than seven rays on the gill flap. They have three spinous appendages to the gill lid, only one row of teeth in each jaw, are richly coloured, and have peculiar appendages to the head. They are natives of the warm seas, but their habits and manners are very imperfectly known.

AMPHISBÆNA. A genus of serpents of very harmless and retiring character, of which, however, many strange stories are told in books, and which have been turned to account both by the sublime and the ludicrous among the poets. Milton, in depicting the most formidable of reptiles says, in sounding numbers :—

> "Scorpion, and asp, and amphisbæna dire;"

and Arbuthnot (I believe) gives much point to his satire on the two "dunces" who drew different ways in their attacks on the Scriblerus Club, where he says :

> "Thus, amphisbæna, as 'tis said,
> At either end assails,
> None knows which leads or which is led;
> For both heads are but tails."

The story was, that the amphisbæna had a head at each end, or, at all events, could move indifferently in the direction of either. What the amphisbæna of the ancients may have been it is of little use to inquire, perhaps it was the common blind worm (*anguis fragilis*), which, however, is not blind, though its eyes are very minute. At all events their amphisbæna could not have been one of the present species, which are all natives of the warmer parts of America.

They are nearly of equal thickness at both ends, so that when the eyes are closed, and the tongue, which is forky and glutinous, for assisting in the capture of the insect food, not protruded, it is not very easy to determine which is the head.

They are the most gentle and harmless of all the serpent tribe. They do not poison, or crush in their folds, or swallow with distended throats. Their mouths are small, with only a single row of minute teeth in each jaw, and their gape is narrow.

They inhabit ant-hills, and subsist entirely, or chiefly, upon the legitimate inhabitants of them. Hence they have been sometimes called "kings of the emmets," though their only attribute of royalty, if indeed that be one, is devouring their subjects by wholesale.

Gentle as they are in their manners, they are not less perfectly adapted to their way of life than the most formidable serpents of the bush. The uniform thickness of their bodies, the arrangement of their small four-cornered scales, which they can elevate at right angles to the plane of their length; and the wriggling motion, with which they twine along, enable them to move through the soft earth of the ant-hills with either end foremost.

There are several species and varieties, the best known of which is *A. fuliginosa*, which grows to the length of eighteen inches, and is of a brown colour more or less marked with white. The tail is very short, and the eyes are nearly concealed by membranes. The rings of scales are very numerous, not fewer than two hundred on the body. *A. alba* is not white, but of a pale straw colour. There are many species in the warm parts of South America and in the West Indies; but there is little interest in them. It does not appear that any of them have been found in other parts of the world. They are viviparous.

AMPHISILE. A genus of spinous-finned fishes, belonging to the natural family of those which have the mouth pipe-shaped, or small and produced. Their backs are fortified with strong scaly plates, of one of which the spine of the first dorsal fin appears to be a continuation. They, like most of the family in which they are arranged, are fishes of singular shape. They inhabit the tropical seas.

AMPHITRITES, a family belonging to the class *Annulata* of Cuvier, and to the order *Tubicoli;* they are easily recognised from the other annelides by their golden coloured setæ, which are arranged like a crown, or the teeth of a comb in one or two rows, on the anterior part of the head, where they probably serve as a means of defence, or, as the baron Cuvier suspects, they enable the animal to crawl about so as to collect the materials of its little dwelling. This name was originally applied by Muller to a generic group, to which he added the *Terebella* and *Sabella* of Linnæus. Lamarck and Cuvier have since adopted the same with some modifications, and Savigny has formed them into a family, which he divides in five genera: the animals belonging to this family have from one to three pairs of branchiæ, more or less complicated, fixed to the foremost part of the body; the feet are very unlike the other families of this order, the first pair being entirely without branchiæ, and the second, on the contrary, having a great many of them. Numerous tentacula encircle the mouth, and on each side of the fore part of the back are pectiniform branchiæ; the skin which envelopes the body is thin and transparent.

Some of the amphitrites construct light tubes of a conical figure which they carry about with them, formed by the assemblage of grains of sand, fragments of shells, and other remains, which are held together by means of a sort of mucus which exudes from the animal, and which seems to serve as a sort of glue applied in the same way that many birds and other terrestrial animals construct their nests; these animals inhabit the ocean; many of them are found in the Mediterranean, and indeed on most other sea coasts, but like all other annelides and soft-skinned animals, their history is very obscure, and in all probability will long remain so, from the little interest they excite, although no doubt they also have an important part to perform in the scale of creation.

AMPHIUMA. A singular genus of Batrachian reptile, which is described as inhabiting the waters of certain parts of the American continent. This, as well as several other analogous genera, which are all American, resemble the common water eft, more than they do any other British reptile; but some of their characters are so peculiar that they stand alone. In their physiological character they resemble the frog, though they differ less or more from that animal, according to the genus. In the first stage of their lives they are tadpoles, living only in the water, breathing by gills, and having swimming tails, but not even rudiments of feet. As they advance to maturity, lungs are formed, and four or two rudimental feet are produced; and these changes are in some instances accompanied by an absorption of the gill, so that they afterwards breathe air by means of lungs only. In other cases, however, the gills remain as well as the lungs, and they can use either system at pleasure.

The genus under consideration have the body long, and bearing some resemblance to that of an eel, only the tail is more pointed and they have no fins. The feet are very small, and far apart, one pair near the head and the others at the insertion of the tail. They are not adapted for walking, though from being furnished with lungs, the creatures can live out of the water. The feet are merely a sort of swimming power, though they may assist in crawling through the mud. There are two species named, the chief distinction of which is, that the one has three rudimental toes on each foot, and the other only two.

They are found chiefly in the shallow stagnant waters of the southern parts of North America; and as these are at certain seasons apt to be dried up, the double system of respiration comes into use, and they are enabled to scramble in quest of pools, breathing the air as they proceed; but when they again reach the water, they assume their aquatic habits. They are produced from spawn, something after the manner of frogs.

AMPHODUS. A climbing evergreen perennial, a native of Trinidad. The flowers are diadelphous, and of course arranged in the order *Leguminosæ.* The calyx is bell-shaped, in five divisions, each oval-shaped, the upper ones approximating; vexillum turned back, with inflexed teeth at the base; filaments leaning back, keel narrow; pod linear, flattened irregular.

AMPULLARIA (Cuvier, Lamarck). *Helix* (Linnæus). A shell of the second order, *Asiphonobranchiata;* the third family, *Ellipsostomata* of Blainville's System of Malacology.

The animal is globose, spiral, the foot oval, with a transverse groove at its anterior side; the head large; the upper tentacula very long, conical, and sharp pointed; the eyes situated at their external base, and supported on a very delicate peduncle; mouth vertically situated between two horseshoe-shaped lips, forming a species of snout; no upper tooth, a bristled lingual cord, but not prolonged into the abdominal cavity; the respiratory cavity very large, divided into two parts by an incomplete horizontal separation.

The shell is thin, globular, inflated and umbilicated; the spire very short, the last turn larger than all the others united; the aperture oval lengthwise, not so wide as it is long, the edges united, the exterior lip sharp, and without any callosity; the operculum is generally horny (though some species have it calcareous), thin, oval, without a spire, but formed in concentric circles, obliquely overlapping the right side of the aperture, but attached to the left side in a small groove. These shells sometimes attain to a great size, and probably it is one of the species, the *Ampullaria crassatina,* whose inhabitant formed a gastronomic delicacy at the repasts of the luxurious Romans, by whom they were kept in stews called cochlearia, and fed upon bran and wine-lees, till they acquired an enormous size, and possessed the desired degree of juicy perfection. Varro, indeed, informs us that they sometimes were able to contain ten quarts or more; a size so incomparably greater than any thing subsequently seen, that the assertion is evidently founded in an error as to what measure *his* quarts really contained, and it needs no learned commentator to prove the fact, since Pliny the younger, whose temperance formed a theme of praise to his friends and contemporaries, used to provide for each of his guests a supper consisting of *three snails*, two eggs, a barley cake, with sweet wine and snow. This delicacy is said to have been introduced by Fulvius Hirpinius a short time before the wars of Cæsar and Pompey; after which they were regularly imported from the interior of Africa, Asia, &c. in vast quantities, forming a considerable article of commerce. Ampulla, from whence their name is derived, was a small wide-mouthed bottle holding a given measure of liquid, and it is most probable that these snail shells, in their greatest size, were capable of containing some quantity bearing a relative proportion to that quantity, whatever it may have been.

This genus is evidently intermediate with the Paludinæ and Naticæ, and the species now constituting it, are probably all fluviatile. Lamarck enumerates eleven; and all of those whose habitats are known, come from the rivers of Africa, India, and South America: none have been found in Europe or North America. Several species are found in a fossil state.

Ampullaria rugosa.

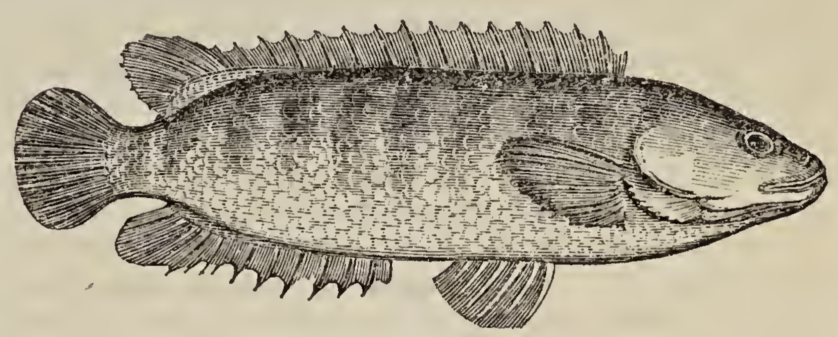
Blainville forms three divisions of the Ampullariæ. The first he calls normal or dextral, of which the figure given of the *Ampullaria rugosa* is the type; the second is sinister, or with the whorls turned to the left hand; and the third sinister shells, of which the very wide umbilicus is spirally carinated.

AMSONIA (C. Amson). A genus of three species of herbaceous perennials from North America. They belong to *Pentandria Monogynia* and to the natural order *Apocyneæ*. They are pretty little plants, and easily propagated by cuttings or by dividing the roots.

AMYGDALOID. A geological term descriptive of one of the varieties of the trap-rock formation. The base of amygdaloid is described by Brongniart as being petrosilex (compact felspar). Dr. Macculloch observes that the base is commonly indurated clay. Clay, claystone, and compact felspar, are described as passing into each other; nodules of various substances imbedded in a base or paste of petrosilex or indurated clay, constitute amygdaloid; it is therefore a *porphyritic* rock, but the imbedded substances are occasionally wanting, when the rock becomes simple, at least in appearance, and is closely allied to cornean; but when the nodules have disappeared through disintegration or decomposition, leaving the cavities they once occupied, the rock resembles a cellular lava. The minerals most commonly imbedded, are agate, quartz, mesotype, analcime, stilbite, chabasic, prehnite, carbonate of lime, green earth, lithomarge, and iron pyrites. Amygdaloid generally occurs in large masses, rarely in veins. The traprocks of Derbyshire are sometimes amygdaloidal.

AMYRIS (Myrrh scented). A genus of tropical trees and shrubs from South America. They belong to *Octandria Monogynia*, and to the natural order, *Terebinthaceæ*. They have a calyx of four persisting teeth; having clawed petals situate below the germen; stamens shorter than the petals; gynobasis thick and formed like a disk; germen one-celled, stigma sitting; drupe a papery nut. The resinous gum of some of the species is an excellent perfume; almost all of them produce some valuable gum or resin. *A. Gileadensis* produces the celebrated "Balm of Gilead." It is a shrub with purplish branches, with crowded ternate leaves, and protuberant buds, loaded with balsamic resin.

ANABAS. A very singular genus of spinous-finned fishes belonging to Cuvier's family of *Pharyngiens Labyrinthiformes*, or those which have the upper part of the pharynx furnished with little branch-like appendages and cells. This formation, which is peculiar to this family—a family consisting of only a few genera, all of them natives of warm climates, and most of them inhabiting fresh water—enables the fishes to subsist for a longer or shorter time out of the water, as they can keep their gills moist by gradually discharging the water contained in the labyrinthal sacs of the pharynx, and thus breathe freely after the body is completely dried. Hence they are often found marching, in such fashion as fishes can march, along the dry land, climbing the sides of tanks and ponds, and even, in the genus under consideration, climbing trees, though the last feat is a little doubtful. There is no question, however, that these fishes are sometimes found alive with their bodies perfectly dry upon dry land; that they leave the water voluntarily, or at least, without being forced out of it by enemies, as is the case with the flying fishes of the warmer seas; and that when the purpose of their land journeys is accomplished, they return to the water, and resume the functions of fishes there.



Anabas.

This curious habit in fishes was known to the ancients; and Theophrastus expressly mentions little fishes resembling mullets, which leaped out of the water, and could climb. There is no doubt that he alludes to the genus *Anabas*, which is very common in India, and was, in all probability, seen during the expedition of Alexander, and probably known to the Egyptians long before that period. It does not appear, however, that the ancients were at all acquainted with the peculiar organisation, by means of which these fishes are able to breathe with gills when on dry land, and exposed to the ardour of an Indian atmosphere; for, at that time, the exact correspondence between structure and habit, which forms so beautiful a part of natural history, was but little understood or attended to; and, as was the case in many other matters, instances of the most perfect design and adaptation, were described as prodigies, or departures from the ordinary course of nature. The monsters with which the fertile imaginations of the ancients peopled all countries which were imperfectly known, had all probably some foundation in nature; and were it possible to trace them to these, it would be both amusing and instructive—amusing to see upon what slight foundations fancy can build its structures, and instructive in preventing us from falling into similar errors upon subjects with which we are but imperfectly acquainted.

Fishes of this family are adapted to those climates where the seasons are divided into rainy and dry, much of the surface flooded, or covered with pools of water during the first, but parched up during the second. During the rains and floods there is, of course, abundance of fishes' food in the waters; and it is a law of nature, that where there is abundance of food, there will be a corresponding abundance of consumers. Those creatures on which the fishes feed, are of much more rapid growth than the fishes. Many of them are in the egg state during the drought, in which state they can, without injury, bear a very great degree of dry heat; and others of them are deep in the earth. The state of these last, during the arid season, is not well known; but it is probable that they remain inactive, just as snails and slugs do with us when the weather is dry. At all events, the water is peopled almost as soon as it falls to the ground, and the fishes soon come to the feast.

This rapid stocking of the waters upon what was only a few days previously a parched desert without any living creature, no doubt led to the vulgar belief of the spontaneous generation of the myriads of small animals, and the raining of fishes from the sky, though there may be instances in which the latter are taken up by water-spouts, in like manner as dust and leaves are taken up by whirlwinds upon land.

The doctrine of spontaneous, or equivocal generation, though subversive of the very foundations of rational philosophy, appears to be one which flits onward before the progress of knowledge, and attaches to one subject as soon as another is freed from its influence. It is easy to see the reason; we confound the relation of coexistence with that of succession, and thus call the one of two accompanying phenomena the cause of the other; and if we find this still done in matters of which our knowledge is imperfect, we must not expect that more ignorant ages could be more philosophic than ours. We see the larger steps of the process, but the little ones are concealed, and so we treat them as if they were nonexistent. It is not long since the belief of the actual production of animalculæ by infusion was pretty general; and now that more careful observation has disproved it, at least in many of the species, the restless spirit of speculation has taken up a sort of theory of the spontaneous vitality of the elementary *monade* of matter. [See Animalcula.] If this disposition *to make things their own causes* (and that is the direct and immediate effect of the doctrine) is kept in its own place, there is no harm. Its place is the unknown; and though it may be somewhat sinuous and screw-like, it is "the screw of the augre," by which that instrument is drawn forward, and enabled to open a passage for the direct and straightforward light.

When the creatures multiply so fast, as they do in the seasonal waters of the tropical countries, there is always a disposition to attribute them to the weather, or the other palpable and striking circumstances under which they occur. We have all heard of "blight winds" and "insect-breezes," as the actual parents of the pests of our vegetation; and we find the birds that keep them down, endowed with much more wonderful powers than the fishes under consideration. When the season requires it, the bird flies guideless to Africa; and as the season again comes round it returns true to its time.

The portions of the earth which require fishes capable of locomotion upon land are peculiar—India, tropical America, and some other places. As much of the flood water there passes off by evaporation, the fishes cannot follow the flood so easily as in more temperate countries; but they make their way from pool to pool; so that not more of them are stranded and perish by drought than in the floods of our own rivers upon the meadows.

Of the genus *Anabas*, there is only one known species, *Anabas testudineus*, the climbing perch (*Perca scandens*) of the older naturalists, which is represented on the preceding page.

The leading characters are,—the appendages to the pharynx much produced and complicated; the body round; the head large and obtuse; the mouth small; the body covered with large strong scales; the gill-lid and margin of the gill-opening strongly toothed, and the gill-flap without any tooth, and consisting of five rays. The dorsal and anal fins consist of many spinous rays. They are found in all those places of India which are adapted to their habits.

Their colours are, dull green on the upper part, fading into paler on the sides, and yellowish below. The dorsal fin consists of seventeen spinous rays; the anal of eight; the pectorals, which are obtuse, of twelve each; and the caudal of six, with one spinous ray in each. The time of breeding and most of the habits are very imperfectly known; as indeed are the habits of most of the animals which are affected by the monsoons, or other changes of wet and dry in tropical climates. The seasonal waters no sooner come than they are fully inhabited with living creatures, from the most minute water insect to the largest wading bird. Many of them are migratory, retiring to the shores and estuaries of the rivers, as is the case with the adjutants [see Adjutant]; and others flitting from country to country, as the cranes; but there are many which have not the means of migration, and indeed have no place to which they can go. A creature fitted for living in the shallow fresh water which stagnates in every hollow during the rains, could not live in the sea, or in the running waters, even if it had the means of getting there. The annual animals, or those which, like the insects, pass through a dormant or chrysalis state before they arrive at their perfect form, are no doubt in that state, or in the egg (in which most of the smaller animals can be preserved for years under even great variations of temperature), proof against the ordinary seasonal changes of any part of the world. Mollusca and reptiles too, and other species which live for several years, and do not undergo changes, have their periods of torpidity induced by drought as well as by cold. As long as there is food for insects, there is also food for lizards in those arid seasons; but when the surface for a great extent, is reduced to mere sand, the flies and other insects perish, and the lizards burrow in the sand and become dormant. Whether any of the fresh water fishes of tropical countries become dormant in the remaining waters during the time of the drought, in the same manner as, with us, eels become dormant in the ooze on the shores during the cold of the winter, is a point which, though interesting, has not been ascertained. It is at least probable, inasmuch as the numbers of fishes belonging to this curious family, to be met with any where during the dry season, bears no proportion to those which appear almost contemporaneously with the rains; and the intervals between one portion of water and another are often too great either for the supply of water in the labyrinths to moisten the gills, or for the locomotive powers of the animals. The progressive motion of the genus under consideration has not been very carefully noticed; but there is no doubt (from what has been observed of analogous genera in Guiana) that the chief organs of motion on level ground are the pectoral fins, by the action of which the animal wriggles along something after the fashion of a seal. The fish seems to have some means of measuring distance by the eye, even out of water where the bank is low; if the state of the water warns them that it is time to depart, they will leap clear out of the water and on the top of the bank; but if the bank is more elevated, they climb, in which progress they bring their fins and also their tails into action.

There is here a very curious point, which appears to show that though the eyes of fishes are differently formed from those of man or the other land animals, they are subject to some optical deceptions. Those fishes which come upon land in their migrations, whether they work chiefly by their fins, as the *anabas* and the analogous genera, or by wriggling, as is the case of eels, never attempt to leap at banks of earth or breasts of dry rock which are too high for them, while those which ascend in the water only are incessant in their attempts, even where those attempts seldom succeed. In the season when instinct leads the salmon to ascend the streams, they may, in many of our own rivers, be found making continual attempts to surmount those cascades above which a single salmon has never been found; from which it should seem that the descending water deceives their vision, much in the same manner that we imagine that the sea billows are rolling ashore, even when the whole mass of the water is ebbing away with the tide.

It is worthy of remark that there seems to be some analogy between the labyrinths of these fishes and the water-cells in the stomach of the camel. It is true that the animals require the water for very different purposes, or at least for very different immediate applications. To the camel it answers the purpose of drink; but to the fish it immediately answers that of respiration; and though "to drink *like a fish*" be a common saying, it is very probable, nay, it is almost certain, that fishes do not drink. Even in land animals, though the fact has been but little attended to by writers on physiology, it should seem that the grand purpose of drinking is to moisten the organs of respiration. At all events, the great waste of aqueous humidity is by the lungs; and when one is parched with thirst, the breathing is always painfully hot and laborious. If this view of the matter is correct, and it agrees well with the observed facts, there is much less difference in essential act between breathing by lungs and breathing by gills, than the usual theories on the subject would lead us to suppose. It has already been mentioned (see Air) that fishes and other aquatic animals do not, and cannot, separate the oxygen which is necessary for the arterialisation of their blood from the water by a direct and immediate decomposition of that liquid. They breathe the air which is in the water, and if the water contains no air they are suffocated as certainly and almost as speedily as if there were no water there. The quantity of air which they require for that purpose is much smaller than that which is necessary for mammalia, as birds, and the surface at which they receive air is much more limited; and as that surface is moistened by the water in which they for the most part reside, they do not require that apparatus which, though it has not been clearly pointed out by anatomists, land animals possess for the moistening of their breathing surface. But, in all cases, it appears that if, by any means, the breathing surface can be kept duly moistened, respiration, and with that all the functions of life, can go on in the animal; and that, as long as the supply in the labyrinth of the one, or the cells of the other lasts, the *anabas* can live on land, and the camel endure the burning heat of the desert.

There is another fact which throws a good deal of light upon this most important but rather novel view of what may be considered as the most important point in the whole range of natural history. Surface fishes, such as the herring and the mackerel, which live in that portion of the waters which may be considered as abounding much in air, die almost the instant they are taken out of the water; but bottom fishes, such as the eel, will live a longer time; and in these last, the breathing surface is always less extended, and what may be called the vital action less energetic.

It does not appear that fishes have any organisation, by means of which they can bring, from any other part of their bodies, a supply of water for the moistening of their gills. It has been said that there is no reason to suppose that they drink; and there is as little reason to suppose that they absorb water at the surface of their bodies, or any part of it, the breathing surface excepted; and this accounts for the speediness of their death in the dry air, and also for the necessity of the supply of water in the labyrinths of the family under consideration.

With land animals, the case is quite otherwise. Different species have, no doubt, different absorptive powers; but of all warm-blooded animals it may be said that they have some means of absorbing moisture from the air when they are deprived of it as drink; and we know how readily all the parts of the body sympathise with and give up their humidity to the lungs when those organs are panting in agony. The rapid breathing in fatigue or in fever, parches the body; and parches it not by perspiration, sensible or insensible, at the surface (for that, when it comes, brings relief), but by a drain of moisture internally from the other parts, to moisten the lungs, which, in proportion as they labour faster, require an increased supply.

The breathing and circulation of the blood are so intimately connected, and so simultaneously affected both by exertion and fever, that we are unable to say in which the painful exertion begins; but the effect of bathing, and especially of the affusion of cold water in reducing the heat, lowering the pulse, and rendering the breathing more easy, shows that a supply of humidity highly favourable to health may be obtained by absorption.

This subject of the adaptation of animals to climate, is one of the greatest practical importance; and would, if properly worked out, throw much light upon the best and simplest means of preserving health, especially under the extremes of exposure and exertion; but, in its application, it does not properly come within the scope of natural history, though it is there that the principles are alone to be found.

The supply of water which these labyrinth fishes take with them is sufficient to maintain them in life for several hours, even when they are making considerable exertions; and if they do, as there is reason to believe they must, in some instances, remain torpid during part of the dry season, it is probable that, when they have hidden themselves in the mud, so that the action of the sun does not beat directly upon them, and they make no exertion, it may last much longer, and they may pass gradually into that state in which all the animal functions are suspended; and then, as is the case with all animals which do become torpid, they may bear extremes of temperature which would destroy them if in their active state. The subject is, however, much too new, too intricate, and too extensive for a single article. See Animalcula.

ANABATES. A genus of birds belonging to the natural order of *Anisodactyles*, or those that have the toes unequally yoked, that is, the outer toe articulated upon the middle one; and also partially reversible, so that the toes can act two against two forwards and backwards, and laterally, at the same time. These are the most efficient of all the forms of climbing feet, at least in climbing the stems and large branches of trees, as the birds can run with equal ease in almost any direction. In Cuvier's system they belong to the *tenuirostres*, or "slender-billed," division of the papavers, or little birds.

Various names have been given, but it is probable that there is only one species (indeed that one is very imperfectly known), *Anabates cristatus*, an inhabitant of the thick forests of Brazil, and probably of other parts of tropical America. The European bird, which it most nearly resembles both in structure and in habits, is the nuthatch, but it differs considerably in both respects. The bill is convex in the upper mandible, something similar in shape to that of the blackbird, but without any notch. The tail is long, stiff, and wedge-shaped, and used as a point of support when the bird holds on upon the bark of the trees. The whole structure is well adapted for making way through the close and tangled foliage of those places which the bird inhabits, or for having command of the trunks and branches of the trees. It is strictly a forest bird, and seldom found on the wing in the air; indeed not very frequently any where: hence its food, mode of nesting, and other habits, are not known.

ANABLEPS. A genus of soft-finned fishes with abdominal fins, belonging to the carp family, and sometimes considered as a species of *loche*, from which, however, it has very distinguishing characters. There is but one species, *Anableps tetrophthalmus*, a native of the rivers of Guiana, and of its habits little is known.

The name *Anableps* is given because the fishes have the eyes elevated, and *tetrophthalmus*, because they appear to have four eyes. It is true that in the real structure there are only two eyes,—one retina, one crystalline lens, and one vitreous humour; but there passes a band of membrane over the middle of the eye, and forms two pupils, being the only instance among vertebrated animals in which there is even the external appearance of four eyes.

The body is cylindrical, the head flattened, the muzzle blunt, the mouth opening transverse the muzzle, with teeth on each jaw, and numerous small globular teeth on the bone of the pharynx. The body is covered with large scales, and the pectoral fins are in part scaly. The dorsal fin is small, and placed in advance of the anal. They have the air-bag very large in proportion to their size. The females are ovo-viviparous, and the young, when brought forth, are of considerable size, able to swim about and find their food.

ANACANTHES (without spines). A genus of chondropteryginous or cartilaginous fishes with fixed gills, and intermediate in their characters between the sharks and the sting rays, or skate. The genus which they resemble most in form is that of the sting-rays (*trigon*). The form of the body, as in that, is triangular; but the tail is rather longer, more slender, and without any dorsal fin, or that sharp and formidable spine from which the sting-rays have obtained their name. These fishes grow to the length of three or four feet, and are found chiefly in the warmer seas, and near the shores, rather than in the wide sea.

ANACARDIUM (Cashew nut). A genus of two species of East and West Indian trees. They are polygamous, and belong to the natural order *Terebinthaceæ*. They have a calyx of five sepals, coloured, deciduous; corolla of five lance-shaped petals with reflexed points; ten stamens inserted in the base of the calyx; anthers fixed by their backs, divided at the base, and bursting longitudinally; style awl-shaped; stigma headed; fruit kidney-shaped, cartilaginous, one-seeded, appended by a pear-shaped, fleshy peduncle called cashew nut. The following account of this curiously formed and useful fruit is extracted chiefly from Long's Jamaica. This is an elegant tree, bearing handsome corymbs of sweet-scented flowers, succeeded by an edible fruit of the apple kind, of a yellow or red colour. The fruit has an agreeable subacid flavour, with some degree of astringency. The juice, expressed and fermented, yields a pleasant wine: and distilled, a spirit is drawn from it far exceeding arrack or rum, making admirable punch, and powerfully diuretic. The dried and broken kernels are occasionally used for mixing with old Madeira wine to enhance the flavour. Some planters in the West Indies roast the ripe fruit, or slice one or two into a bowl of punch to give it a pleasant flavour. The astringency of the juice has recommended it as a very signal remedy in dropsical habits.

The cashew nut protrudes from one end of the apple. It is of the size and shape of a hare's kidney, but is much larger at the end next the fruit than at the other. The outer shell is of an ash-colour and very smooth: under this there is another which covers the kernel; between these there is a thick inflammable oil, which is very caustic; this will raise blisters on the skin, and has often been very troublesome to those who have incautiously put the nut in their mouths to break the shell. This oil has been used with great success in eating off ring-worms, cancerous ulcers, and corns; but it ought to be applied with caution.

Anacardium Occidentale.

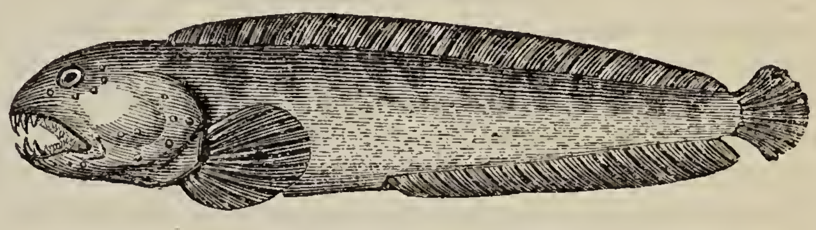
The kernel, when fresh, has a most delicate taste, and abounds with a sweet milky juice. It is an ingredient in puddings, &c. When older it is generally roasted, and in this state is not so proper for costive habits. Ground with cocoa, it makes an excellent chocolate. When kept too long it becomes shrivelled, and loses its flavour and best qualities. The thick oil of the shell tinges linen of a rusty iron-colour, which can hardly be got out; and if any wood be coated with the oil, it prevents it from decaying. From the body of the tree is procured, by incision, a milky juice which will stain linen a deep black, that cannot be washed out again. This tree also annually transudes from five to twelve pounds' weight of a fine semi-transparent gum, similar to gum arabic, and not inferior to it in virtue or quality, except that it has a slight astringency, which perhaps renders it in some respects more valuable."

ANALCIME. This mineral is generally found in granite, gneiss, trap-rocks and lavas. It occurs in the Calton Hill, Edinburgh, at Talisker in Skye, in Dumbartonshire; in the Hartz, Bohemia, and in the Faroe Islands. Analcime is feebly electrical by friction, but not by heat. The specific character of this mineral is taken from its form, which is that of a cube. Its specific gravity is rather less than 2·4.

This mineral might be confounded with borate of magnesia and muriate of soda, both of which take the cube for their primitive form, were they not strongly distinguished by their physical and chemical qualities; its specific gravity being smaller than in either of those substances. When broken it is found to be slightly undulated in the transparent portions, and compact, with a fine grain, in those which are opaque. This mineral only exhibits three marked varieties.

ANANCHYTES. One of the divisions of the Echinodermes, formed by Lamarck, and by him characterised as "irregularly helmet-formed, ovate, or conoidal. The ambulacra radiating from the vertex to the margin, and even to the mouth, which is labiated at one end, near the margin, the vent at the opposite end." Twelve species are described, the whole of which occur only in the fossil state. They have hitherto been principally found in France.

ANARRHICAS (the climber). A genus of spinous-finned fishes belonging to the family of *Gobiodes.* They obtained that name from a supposed power of climbing the rocks by means of their fins and tails; but if they have such a power at all they have it only to a small extent. They live much among the rocks, however, feeding upon crustacea and shelled animals, which they easily break by means of their powerful teeth.



Anarrhicas lupus.

The best known species is the "sea wolf" or "wolf fish" (*A. lupus*), called the "cat fish," on the shores of Scotland, where it is perhaps more common than on those of England, although it is not rare there, and is indeed one of the most common inhabitants of the sea, being found from the extreme north to nearly the most southerly latitude which has been reached, and in nearly equal numbers in the colder and the warmer climates. Its flesh tastes very like that of the larger sea eels; and it forms a staple article of food with people of many different climates and having many different manners. The people of Iceland and other places of the extreme north salt and dry it for winter store; but the negroes of Mauritius relish it in quite another style. They hang it up in the sun till it is so putrid that a European can with difficulty approach it on account of the smell, in which state it is called "ourite," and is esteemed the most delicious food that they can procure. In Britain, in Scotland especially, it is not relished, and there appears to be a considerable degree of prejudice against it, owing to its appearance.

It is indeed by no means a handsome fish; and it has a ferocious appearance, the mouth being armed with powerful weapons. Its body is lengthened, sometimes as much as six or seven feet, but it is compact; and the head rounded, something resembling that of a cat. The gape of the mouth is considerable, and the teeth, which in front are very large, strong, and of a conical shape, are displayed. The dorsal fin, composed exclusively of simple rays, extends from the nape along the whole upper part of the body; and it and the anal fin meet and form a rounded fin on the tail; the pectoral fins are also rounded. They contain sixteen rays each, the anal contains forty-six, the caudal sixteen, and the dorsal seventy-three. The general colour is brownish above and yellowish below, with darker wavy transverse branches; and the skin, though tough and firm, is without scales. The whole of the palate is covered with osseus tubercles, rather large and pointed, and the teeth in the jaws are, as already mentioned, very large and strong.

There is no air-bag, the stomach is fleshy and the intestines short.

On the British coasts it is rarely found exceeding three, or at the most four feet in length; and in the clear water on the rocky shores, where its favourite food is abundant, it is a very delicious culinary fish, especially when thoroughly boiled as soon after it comes out of the water as possible; and indeed it should seem that all the fishes which frequent rocks, and feed chiefly upon mollusca and crustacea, are firmer and finer in flavour than those that eat one another.

Formidable as are the teeth of this fish, and suspicious as is the vulgar name "wolf," which has been given to it, it does not appear that it preys upon or intermeddles with any of the other finny tribes, but goes on quietly in its rocky pastures, cracking its periwinkles, its limpets, and its other shells, and using its powerful teeth only for that purpose. The teeth stand a little forwards, so that it can take up a very small shell from the bottom, or bite the limpets from the rock; and though the fact is not fully established, it is by no means unlikely that it may sometimes rise a considerable way out of the water, and reach those which the ebb tide leaves there. The figure given in the previous page will afford an idea of the general shape of the fish.

ANARRHINUM (Desfontaines). A family containing three species of biennial herbaceous plants, natives of Europe, belonging to the Linnæan class and order, *Didynamia Angiospermia.* Natural order, *Scrophularinæ.*

Generic character: calyx five-parted; corolla two-lipped, throat open, swollen at the base, and somewhat horned; upper lip margined, the lower palated, or a little raised, three-lobed; stamens connivent; anthers three-celled; style thickish; capsule two-celled, four-valved, valves bursting.

The daisy-leaved *anarrhinum* grows abundantly in the south of France. Desfontaines also found two species in Africa, which he has named *A. pedatum* and *A. fruticosum*; and the same species Bory de St. Vincent found in Spain, in the provinces of Valentia and Andalusia: the name was given in contradistinction to the snapdragon (*Antirrhinum*), from being without the peculiar flower of that plant.

ANAS, the duck genus—ANATIDÆ, the duck family. We have taken these two titles together, and purpose noticing them both in this article, commencing with *anatidæ;* because then we shall follow the order of nature, and save both reference and repetition.

Anatidæ. The general characters of the *anatidæ* are—the bill broad and flattened, covered for the greater part with what may be considered as a sentient skin, but often with a hard nail on the tip of the upper mandible: the edges of the bill are fringed with small transverse laminæ, which, however, vary with the habits. The wings are of moderate length; the tail is in general short; the body large and flat; the legs rather far backward and wide apart from each other; the plumage in general close and difficult to be wetted; and on the under part often mixed with fine down. The characters vary much in the genera, and even in the species; but still there is a family likeness among them all.

This is one of the most important families of birds, both in a natural history and an economical point of view. In the former, it constitutes that part of the succession between birds chiefly in the air and birds chiefly in the water, which extends from the gallinaceous and wading birds on the one hand, to the true divers, which seek their food wholly under water, and chiefly in the sea, on the other. As the three motions of flying through the air, running upon the earth, and swimming along the surface of the water or under it, are more perfect in some species of birds than in any other vertebrated animals; and as, though in each species there is universally one which is predominant, and forms the chief locomotive character of the bird; there are many which possess at least two in considerable perfection, and some which possess all the three: the birds are the best class in which to study the locomotive organs and their action in relation to the other parts of the economy.

When we consider them in this way, we often find that families, which are very opposite in their characters at what may be called the one extremity, gradually approach each other, as they reach the other extremity; and that there the compound character is taken up by a new family, which, in the progress of its genera, gradually assumes a character different from the two of which it appeared to be at the first made up, and goes on changing till it again is merged in another which is in great part new. Not only this, but we can trace the order in an inverted direction, and find the characters of one family divide into two, which gradually diverge from each other till the characters of the first one are lost, and we pass to a new family on each part of the division, having no relation or resemblance to that from which we set out. If, in these analogical tracings, we take along with us both the external and the internal characters, we soon find ourselves in possession of far more useful ornithological knowledge than if we had ever so long attended to the mere characters of individuals; and indeed it is owing to this analogical mode of procedure that all the branches of natural history have, of late years, made so much progress. When we take the external form and the internal structure, compare them with each other and with the observed habits, and carry this compound analogy from race to race, we have a certain and easily used key to their whole economy; and not merely to their economy in wild nature, but to the way and the means of their domestication, and their value when that is accomplished.

The family of the *Anatidæ* is properly divided into the three genera of swans (*cygnus*), geese (*anser*), and ducks (*anas*). [The systematic names, from what language soever they are derived, are always best in the *singular* number, as being collections, expressive of the *one* set of characters in which all species agree, and not the *many* that are the foundation of the specific distinctions. The names of families, and higher divisions, are better in the plural number, as expressing a plurality of generic characters. [See Classification.]

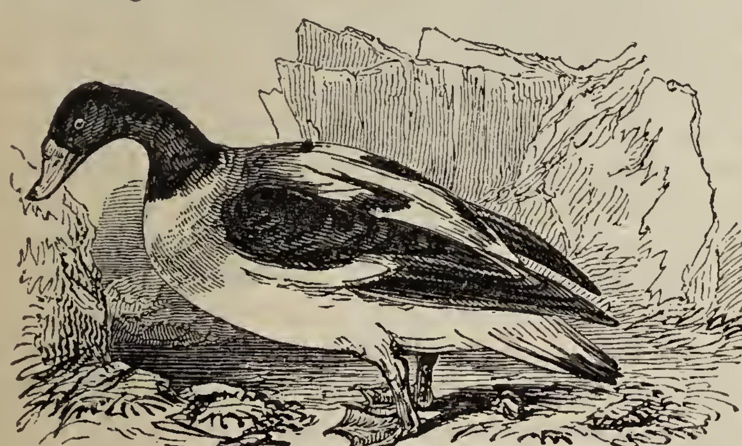
In tracing the gradation from the less to the more aquatic, it is very evident that we should end with the ducks: because many of them find their food almost exclusively in the sea, seldom come on land even for the purpose of breeding, and are very ill adapted for walking.

But when we turn our attention to the other two genera, we find some of the characters of the gallinaceous birds and the cranes so much mixed up in each, that it is not easy to say which has the greater analogy, though, upon the whole, the geese perhaps most resemble the gallinaceous birds, and the swans the cranes. The natural order of the genera is, however, usually understood to be the swans, the geese, the ducks. See CYGNUS and ANSER.

ANAS. The ducks are the smallest birds of the family, and at the same time the most numerous, and the gayest in their plumage. The general characters are so familiar to every body that it is unnecessary to describe them; for, though there are considerable differences of shape, size, and colour, there is nobody who is familiar with ducks of any species, that can easily or even possibly mistake a duck for a swan or goose on the one hand, or for one of the true divers on the other.

All the ducks can perform the three motions: they can fly, they can swim, and all of them dive upon emergency, and some of them well; and they can all walk, but some of them are bad walkers, and none of them walk either very elegantly or very fast. All of them perform their long journeys upon the wing, and most of them their shorter ones by swimming along the water. Referring to the article DUCK for the details and the economical uses, we shall devote the remainder of this article to a short notice of the natural gradation or arrangement, as the basis of which we shall take a very clear and luminous paper by Mr. Yarrell, in the 15th volume of the Linnæan Transactions.

The natural gradation, in the species which visit Britain, (and those which do not are nearly allied to one or another of these,) is from the sheldrake to the golden-eye. The first of these has in the shape and carriage of its body a considerable resemblance to some of the wading birds that frequent the shores—to the oyster catcher in particular; and were it not for the form of the bill, the length of the neck and the webs to the toes, it might be readily mistaken for a shore bird which finds its food in the banks and beaches, and does not swim. Its habits correspond: it does not go out to sea or inland to the lakes, nor does it venture into the mid water of even the narrow streams which flow into the sea. It lives mostly on the banks, just by the margin of the water, and seldom if ever dabbles so deep as to bring the axis of its body to the horizontal position. The following figure will give an idea of the form of the sheldrakes.



The Sheldrake.

The golden-eye is, in many respects, the very reverse. Its legs are so short, placed so far back, and so wide apart from each other, that it walks with great awkwardness and difficulty. But it rides beautifully buoyant upon the water, and swims along with great velocity and apparently very little effort. Its wings and tail are short, and the latter is wedge-shaped or pointed; but they are close and stiff and not easily ruffled. All its plumage is indeed so compact that it can hardly be wetted or turned upon the living bird, even though it moves backwards in the water. Its habit is to be very little upon land, not much on the fresh waters, and seldom, if ever, upon the smaller streams. The following is its figure.

The Golden Eye.

The species which are intermediate between these admit of division into at least two sections, though in some respects, these approach each other on the confines; and there are a few species which might perhaps be classed with either. One of the most obvious distinctions of these two sections is the structure of the feet. At the commencement of the first section it is nearly as much a walking foot as a swimming paddle; and at the termination of the second it is much more a swimming paddle than a walking foot. But though the sheldrake swims little and the golden-eye walks as little, it must not be supposed that the extremes of walking and of swimming feet are to be found with them. These extremes are found with the ostrich and the penguin, the one confined wholly to the land and the other to the sea, and neither of them capable of any motion in the air. The whole genus of ducks are much nearer the penguin and the seal than the ostrich are, as they all have webbed feet and can swim; and they can also call the wing to their aid when required.

The feet of the first section of ducks have the *tarsi*, or foot-bones (improperly called legs) longer and rounder than the others; they have the front toes less produced in proportion to the size of the birds, and the necks not so compact; and they have the hind toe free, or without any web connecting it to the rest, although in those species in which the sections approach each other, the hind toe has a slight margin. The legs are placed so far forward that the axis of the body can, when the neck is bent a little backwards at the middle, be carried in nearly a horizontal position. The neck too is much larger in proportion to the size of the bird; their wings are also larger in proportion than those of the second section, reaching generally to the end of the tail. In their internal structure, they have the sternum or breast bone with a much deeper keel or ridge, but not extending so far backward, or ending behind in an ensiform process or projection at the middle. The ribs extend little further backward than the sternum, so that a considerable part of the abdomen is unsupported by bone. The enlargement at the bronchial, or inner extremity of the trachea, in all of them, consists entirely of a cavity of bone. They have the stomach a true muscular gizzard; and the intestinal canal long and furnished with cæcal appendages of considerable length.

Their habits correspond with these peculiarities of structure both external and internal. They frequent the fresh waters only or chiefly; and do not launch themselves on the broad lakes, but keep near the shores and in the shallows, very seldom feeding with the whole body under water. Their food is miscellaneous, and resembles in its nature that of poultry, though some of it is more aquatic than poultry can naturally reach. They feed upon farinaceous vegetable matters, as well as upon small animals, the peculiar structure of their organs giving them sufficient digestive powers. The use of the bony enlargement of the trachea is not very well known, neither is that of the cartilaginous convolutions in those of the cranes, the swans, and the semipalmated goose. It seems, however, to be in some way connected with the habit of eating the food with the head and interior part of the body immersed in water.

The haunts and habits in feeding render it necessary that they should be much on the wing, not only on their migrations from place to place, but from one part of the shore or shallow to another: hence the length of the wings, and the depth of keel on the sternum, for giving insertion to the powerful pectoral muscles by which these are moved.

The leading species which belong to this first section are the sheldrake, the Muscovy duck, the common wild duck, the gadwall, the shoveller, the pintail duck, the widgeon, the bimaculated duck, the gargany teal, and the common teal, all of which, as well as the other species named in this article, will be described under the article Duck.

The intermediate species, which partake more or less of the characters of both sections, are the eider, the king eider, the velvet scoter, and the scoter. These are all, to a certain extent, sea ducks, rarely coming to the fresh waters; but they have no very clear distinguishing characters. The eiders rather more resemble the first division and the scoters the second. The eiders are stationary in their haunts, but they make considerable use of the wing in their daily excursions: the scoters dive more, and have altogether more of the habits of the second section.

The external characters of the second section are, the neck short and not adapted for dabbling in the same depth of water as that of the others; the wings are shorter, reaching only to the root of the tail, while those of the first section reach nearly or altogether to the tip. The tail also is close and stiff. The tarsi are much shorter and more slender in proportion; they are compressed laterally, placed far back, wide of each other, and have a sort of rolling articulation to the tibiæ. The toes are larger in proportion and the webs more complete; the hind toe is lobed, and the lobe is continued to the inner toe in a margin or web of greater or less breadth.

In the internal structure, the sternum has a much lower keel, but extends farther backwards; and toward the end of the section, where the genus may be said to border with the most duck-like of the true divers, the central portion backwards is produced in an ensiform process. The ribs also extend much farther backwards, so that the portion of the abdomen which has no support of bone is much smaller. The enlargement of the bronchial end of the trachea is a membranous sac, supported upon fibres of bone. The gullet is much more dilatable than in the first section, so as to admit of the swallowing of food in much larger portions; the stomach is still muscular, although perhaps not so completely a gizzard as in the others; the intestines are shorter, and porportionally of larger diameter, and the cæcal appendages are much shorter.

These differences, both of external appearance and of internal structure, point at different habits, which observation proves to be the same as theory would lead us to conclude.

They do not frequent the fresh waters, unless it be the deeper portions of the large lakes, neither do they dabble in the shallows, or pick up their food upon the shores. They feed much less upon vegetable matter, and more upon fish, which they catch by diving; but they also feed upon molluscous and other small aquatic animals.

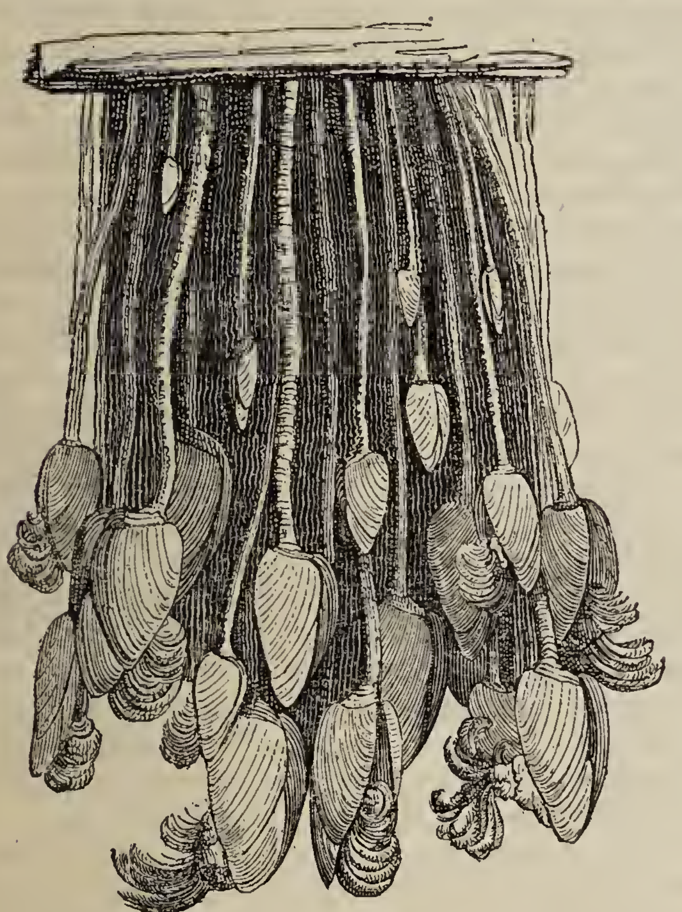
Their modes of life are more adventurous, and they can contend better with the troubled waters. They swim beautifully, dive readily, remain for a considerable time under water, and shoot along with so much ease and rapidity there, that one is surprised at the distance from the place of their descent at which they again come to the surface. Most of them are compact in their forms, and beautiful in the closeness, gloss, and colours of their plumage. One remarkable coincidence between them and the divers is, the possession of crests, more or less produced, and inclining backwards from the top of the head. In this also they have a resemblance to the herons, and many of the cranes; to most birds, indeed, which seize large prey in the water by a forward stroke of the head. The crest appears to answer a purpose similar to that of the feather of an arrow, or the long tail of a springing beast of prey—it keeps the head steady to its line.

The leading species in their order are, the red-crested, the pochard, the ferruginous, the scaup, the tufted, the harlequin, the long-tailed, and the golden-eye; the first having many of the characters of the velvet scoter, and the last a very considerable resemblance to the mergansers, which live almost exclusively by catching fish with their serrated bills.

ANASTOMUS (open-bills). A genus of birds belonging to the order of *Grallidæ* or waders; though in this and many other of the genera, Cuvier's *Echassiers*, or "stilt birds," is, on account of the length of the legs, and the birds not wading, rather more appropriate. The genus in question belongs to the natural family of the *Gruidæ* or cranes, and to the branch stork; and in their habits they do not differ much from the true storks, only that they are more shy and do not come so close or so habitually to the habitations of man. The chief difference between them and the storks, and the one upon which chiefly they have been made a separate genus, is the form of the bill, especially of the *tomia*, or cutting edges of the mandibles. In most of the tribe, whether the outline of these be straight or curved, they generally close for the greater part of their length; but in the *Anastomus*, they touch only at the base and the tip, and have a considerable opening at the middle. The basal part of the upper mandible is, however, wider than that of the under, and when the two are lapped over each other there, the tomia at the middle come very nearly into contact. It should seem, therefore, that this form of bill, though rather ungainly in appearance, is by no means inefficient in use. The tips are seizing forceps, the basal portions act like scissors, and the middle like cutting nippers. Like most of the family they are migratory birds, found in India, and also in Eastern Africa, and probably pass seasonally from the one of these localities to the other. One is described as being white except the quills and tail feathers; another as being grey of various shades, from whitish to blackish, with the same exception; and a third as having the shafts of the feathers terminated by a produced and flexible horny plate. Those which differ in colour only, are in all probability the same species at different ages; for many of the order are subject to great variations of colour with age.

So far as can be judged from the little that is said of them, they appear to be intermediate between the storks and herons, being more aquatic in their feeding than the first, and less so than the second. Of their nidification or the numbers of their broods nothing is said.

ANATIFA, or ANATIFERA. A genus of molluscous animals belonging to the class *Cirripoda*, and to the order *Pedunculata* of De Blainville, but better known as the barnacle-shell. The name of Anatifa was first given to the genus by Bruguière, for the purpose of getting rid of the name Anatifera, from *anas*, a goose, and *fero*, to bear, given to them from a ridiculous tale of early credulity, which supposed the barnacle goose to have been bred within these shells. This tale, although refuted in the thirteenth century by Albert de Grand, and subsequently by other authors, was gravely repeated by Gerard, a writer who lived in 1558, with some additional facts, said to have been witnessed with his own eyes, but which are too absurd to be repeated here.



Group of Anatifa, attached to a ship's bottom.

The body of these animals are contained within a shell, supported by a tendinous tubular peduncle or pipe, with numerous long and unequal tentacular arms, articulated and ciliated, emanating from the summit on one side. The shell is compressed on both sides with five contiguous unequal valves, the lower lateral ones being the largest. Linnæus included this genus among the *Lepades*, and De Blainville has formed of them his genus *Pentalepus*. They inhabit the European seas, where they are generally found attached to rocks, pieces of rotten timber, or to the bottoms of vessels, generally in groups, even attaching themselves to each other.

The peduncle of some of the species is very short, but it is generally long, sometimes as much as a foot; it is very flexible, susceptible of being clongated, and again contracting itself, apparently for the purpose of securing its food, as the animal is not locomotive.

Bruguière mentions that the *Anatifa* take pleasure in exposing themselves to the alternate motions of the sea, and that the species which attach themselves to vessels, prefer doing so a few inches under the water-mark, and above all near the rudder, or where the dashing of the waves is most considerable. Some of the species may be eaten with safety, particularly the common barnacle.

Several fossil shells of the *Anatifa* have been described, but they are without those indications that belong exclusively to the genus. They are very rare, and it is very doubtful whether they belong to the genus or not.

ANATINA (Lamarck). MYA (Linnæus). A genus of shells. In the modern system of conchology it is classed with the *Acephalophora*, and forms the family *Pyloridea* of the order *Lamellibranchiata* of De Blainville.

Anatina subrostrata.

The shell is very thin, semi-transparent, fragile, long, oval, gaping, and much inflated at one end, somewhat resembling a duck's bill, from which it appears to have derived its name. It is equivalve, very inequilateral. The anterior side rounded and much longer than the posterior; summits rather distant, hinge indented, the ligament internally attached to each valve on a spoon-shaped process.

ANATINELLA. A genus of bivalve shells, established by Mr. Sowerby, in his "Genera of recent and fossil shells," of which the following is a description:—"Shell ovate, equivalve, nearly equilateral, the anterior side rounded, and the posterior slightly beaked and subtruncated; the ligament is internal and fixed to a spoon-shaped process in each valve. The muscular impression of the mantle is entire, without any lining. No clavicle or testaceous appendage before the ligamentiferous process."

A few specimens of this interesting genus were brought to England by the celebrated Dr. Solander; but, owing to their imperfect state, their generic character could not be determined till the subsequent arrival of some specimens from Ceylon.

ANCHOVY (*Engraulis*). A genus of abdominal soft-finned fishes, belonging to the natural family *Clupeadæ*, or herrings, but separated from the genus

The Common Anchovy.

"herring," of which it used to form part, in consequence of certain structural differences, and corresponding differences of habit and haunt. Of the structural characters, the most obvious are, the gape extending farther back than the eyes; the maxillary bones straight and elongated; the intermaxillaries small, the muzzle small and pointed, and projecting beyond the mouth; the gill-flap consisting of at least twelve rays; the anal fin very small, and the dorsal situated immediately over the abdominals. In all the herring family the gape is proportionally shorter, the muzzle less produced, and the rays in the gill-flap fewer.

The habits of all the herring family are similar; they are migratory, and migrate in shoals; and, with the exception of the shad, and those species which frequent the great fresh-water lakes and do not migrate to the sea, they all remain in the salt water. The anchovies inhabit more equatorially than the herrings, and may be said to take up the sea where they leave it off; though, owing no doubt to currents, the smaller itinerating fishes are very apt to meet on the confines, or come a little way upon each other's ground. They also appear to follow the same law as the herrings in respect of quality —the most northerly inhabiting species are the best in flavour, and also in flesh. Out of the six or seven species which are named, the common anchovy, so well known as a zest, and as forming a sauce for almost all other fishes indiscriminately, is the only one which has attained any great degree of celebrity. One, or perhaps two other species, frequent nearly the same places as the anchovy of commerce, and bear about the same relation to it as the pilchard and the sprat do to the herring. The remaining species are found in the tropical seas, and none of them has acquired much reputation there; that may, however, depend not a little upon the mode of curing. For, in the case of the herring, there is no doubt that as well-conditioned fish are taken on our shores as the Dutch can procure; and yet a Dutch pickled herring is very superior to any thing of the name that can be prepared in this country. Haddocks, too, are certainly not worse upon many other parts of the coast than they are on the shores of Aberdeen and Kincardine; and yet the delicious half-dried half-broiled haddocks are no where prepared in their very highest state excepting on the range of coast from Aberdeen to Stonehaven. As good herrings are also obtainable at many other places as at Yarmouth; and yet there are no red herrings equal in flavour to those which are prepared there. The operations by which all these are prepared are abundantly simple, and they are said to be the same at all places; but the effect is so different, that there must be a difference in the mode.

Something may, no doubt, depend on the condition in which the fish are caught; and it is agreeable to the analogy of all the migratory fishes, and also to a well-known law of physiology, that the fish should be better when taken not too near the spawning-ground, or rather when not too near the time of spawning. When the fishes begin to shoal (for in the case of the whole family, the fishes are solitary except when they approach the shores for spawning), they are always in finest flesh and flavour; and as the roes and milts advance to maturity, they do so at the expense of the fishes, which then become comparatively thin and flavourless. This is in part proved by the fact that, in the Mediterranean, which may be regarded as the grand nursery-ground (if not the permanent head-quarters) of the common anchovy, the finest ones are obtained off the little island of Gorgona, and superior to those taken nearer the main land. The common anchovy is found in prodigious numbers along all the shores of the Mediterranean, especially the European ones, which, from their form, are of course the eddy shores, and as such abound most in food both for the fish and the fry, and also disturb the spawn-beds the least. The months during which the fishing is chiefly carried on, are May, June, and July; the best fish in May, the most abundant in June, and inferior, mixed with "shotten" ones, or those that have spawned, in July. They are found not only in the Mediterranean, but on the Atlantic shores without the Straits, along the west of Spain and Portugal; less abundantly in the bay of Biscay; rarely in the English Channel; and still more rarely to the northward of the Straits of Dover. When, however, they do make their appearance in the North Sea, it is on the eddy shore, that of the Netherlands rather than England. The fact that those fishes which come in shoals to the shores for the purpose of spawning, choose the eddy shores, just as those which feed in shoals seaward (as the common cod, for instance) choose the eddy banks upon which the revolving currents let fall their deposits, is one of much importance in the economy of the sea; and if those eddies were well ascertained and described, it would greatly extend the theory of the fisheries, one of the most useful, though unfortunately much neglected, branches of economical philosophy.

The vulgar opinion [we do not, on any occasion, use the word "vulgar," in an offensive sense, but merely as expressive of "the herd of authors, who follow their leaders as unreasoningly as sheep do the 'bell-bearer'"]—the vulgar opinion respecting anchovies is still much the same as it long was respecting herrings. They do not, like them, come from the "polar seas," but from the Atlantic, and "enter the Mediterranean in vast shoals," which, however, have never been seen choking up the gut of Gibraltar, or at all in that passage. The truth is, that, like all the family, they disperse when the spawn is deposited, and go to *the nearest deeps;* but being apart from each other there, they are just as seldom seen as the herring, the shad, or the salmon are in the offings of our own shores in the intervals between the breeding times. That they are most abundant on the northern shore of the middle longitude of the Mediterranean, and also in *best condition*, shows that there they have come the shortest distance; and that, though found in the Atlantic, it is in smaller numbers, and the Mediterranean is their grand home. The number caught every year is immense; and the only preparation they receive is said to be drawing, decapitation, and salting down in casks, containing about ten pounds on the average, though they vary considerably.

The real anchovy is about a span long; less, of course, when the head is removed; plump and round in the body; brownish blue, with a silvery lustre on the upper part, and silvery white on the under; the flesh is salmon-colour when salted; but if the fish are not in high season, it is pale as well as thin and tasteless. There is another species in the Mediterranean (*E. meletta*) which bears about the same relation to the common anchovy that the sprat does to the herring.

It is said that the anchovies of commerce are often adulterated with an admixture of the sardine (*Clupea sardina*), a fish very much resembling the pilchard, only smaller in size; but as it has neither the colour nor the flavour of the anchovy, it can be used only in mixture with that.

The trade in anchovies is very considerable, and the quantity annually imported into Britain is not small. The time when it became so general a seasoning for fish is not precisely known; but it was used as a sauce or pickle of some sort or other in the time of the Romans. It is a curious fact, that the anchovy does not improve the flavour of any of the family to which it belongs.

ANCHOVY-PEAR. Is a stem-flowering tropical tree found in Jamaica. It is called *Grias cauliflora* by botanists, and belongs to *Polyandria Monogynia* and the natural order, *Gutiferæ* (*affinis*). Generic character: calyx adhering to the germen, cup-shaped, a little four-parted, persisting; petals four, leathery; stamens many, inserted on the disk; filaments like bristles, connected at the base; anthers kidney-shaped, very small; style, none; stigma thickish, four-sided, crossed, hollowed; drupe large, each side thin, crowned with the calyx, having eight furrows; nut oblong. The unripe fruit of this tree is used as a pickle; and the foliage and flowers are ornamental. It generally grows in low moist places or in shallow water.

ANCILLARIA (Swainson). ANCILLA (Lamarck). A genus of shells belonging to the class *Paracephalophora*, order *Syphonobranchiata*, family *Angyostomata* of de Blainville. These shells are smooth and highly polished, appearing as if rubbed to an even surface by art; they are oblong oval, pointed behind, enlarged, and appear as if truncated in front; aperture oval, rather lengthened, and angular behind; not very deeply channelled in front; the columella anteriorly with an oblique callous band, and the right lip obtuse. They inhabit the East Indies, but the animal is quite unknown. Twenty recent species are described and five fossil.

The genus is distributed into two subdivisions: the first species having the spire rather elevated and bucciniform, as in the *Ancillaria buccinoides*; the second species here figured with scarcely any spire, as the *A. cinnamomæa*. This shell is chestnut brown, with white bands above; columella reddish, and somewhat striped; the length is about one inch. The name of this genus is probably derived from *ancilla*, a damsel. The columella never being plaited, readily distinguishes this shell from the volutes, with which Linnæus had blended it; and the callous oblique thickening at the base of the columella, separates it from the terebellum, but it appears closely to approximate to the genus *Eburna*.

A. cinnamomæa.

ANCYLODON. A genus of spinous-finned fishes, belonging to the family of *Scienoideæ*, the type of which is a fish of the Mediterranean, which has been known and esteemed as food since the days of the Romans. Only one species of the present genus is named. It is a native of the warm seas, but neither its haunts nor habits are known, any farther than can be inferred from its structure; and there are no animals of which museum specimens are, not so useless merely but so mischievous, from being apt to mislead, as fishes: the soft parts cannot be preserved; and thus, as the internal structure is unknown, we can safely infer nothing from the skin, the jaw-bones, and the teeth. The species under consideration has but one dorsal fin; the tail is pointed; the head thick, short and round; and the teeth, especially the canines, very long, strong, and formidable.

Hence it is probable that the chief food is shelled mollusca and crustacea; that the fish is an inhabitant of rocky shores; and that, from the nature of its food, its flesh should be wholesome and palatable.

ANCYLUS, of modern naturalists: *Patella* (Linnæus). A genus belonging to the class *Paracephalophora*; third order, *Scutibranchiata*; first family, *Otidea*, in De Blainville's system of malacology.

The body of the animal is oval, conical, nearly straight, a little bent backward, with a rather large oval foot; the mantle with thin edges, not tentacular, nor extending beyond the head, which is very visible and very large; two large tentacula, cylindrical, and contractile, having a foliaceous appendage at their external side; the mouth is altogether beneath, and pierced in the middle of a buccal mass, prolonged on each side into an appendage; and on the left side the lateral branches in a sack or cavity, situated in the midst of the animal's left side, between the foot and the mantle; it is closed by an operculated appendage. The shell is nearly symmetrical, entirely covering the animal; the summit pointed and inclined backward, the base oval and smooth. Linnæus was guided in this, as in many other instances, by the form of the shell only, and consequently classed it with the patella, which it greatly resembles; modern naturalists have very properly constituted a distinct genus of it. Lamarck observes that he has only provisionally placed it with the Calyptræ; but the animal existing altogether in *fresh water*, and habitually breathing air, renders it very different from the inhabitant of the latter. Drapaunand has placed this genus following that of Lymnea, which the animal's organisation narrowly approximates; and Blainville says that, not knowing enough of the animal's organisation to class it positively, he has placed it near the Haliotidia, by a similarity in the position of the branchiæ.

They are fresh water shells, attaching themselves to flags and other aquatic plants; they are nearly amphibious; and in summer, when the brooks become dry, they remain in the soft mud until the return of rain. The minuteness of the species renders the study of these animals rather intricate.

ANDALUSITE. An earthy mineral of a red colour. It occurs in gneiss, mica slate, and clay slate, and was first found in Andalusia, in Spain; hence its name. It is now found in mica slate in Aberdeenshire, in the Isle of Uist, at Dartmoor, at Killiney, near Dublin, and at Douce Mountain, in the county of Wicklow.

This mineral is usually seen in a hard and brittle state; indeed it will readily scratch common quartz; but we are told by Herr Von Voith that the andalusite of Herzoyan is so soft in its original repository, that he could flatten it between his fingers, and cut it with a knife, but that it became very hard by exposure to the air.

ANDERSONIA. A greenhouse evergreen shrub, introduced from New Holland by Robert Brown, belonging to the Linnæan class and order *Pentandria Monogynia*. Natural order *Epacrideæ*. Generic character: calyx coloured like bractea; corolla, bottom of the limb bearded; stamens below the germen; anthers fixed to the middle; five scales round the germen; capsule contains a central placenta like a column.

ANDIRA (Lambert). A genus of two species of hot-house trees, natives of the West Indies, belonging to the Linnæan class and order *Polydelphia Decandria.* Natural order *Leguminosæ.* Generic character: calyx like a bladder, five toothed, teeth rather unequal; vexillim roundish, margined, spreading; legumen on a footstalk, round, hard, containing one seed.

ANDRENIDÆ (Leach). A numerous family of insects of the order *Hymenoptera,* and the genus *Apis* of Linnæus. The insects belonging to this family have the lip with the apex subcordate, with one auricle; generally nearly straight, but in some of the species slightly curved; in others reflexed, the tongue being shorter than the sheathing tube; the tarsi have the first joint compressed, and are of an elongated square shape. They all live in societies much in the same manner as the bees: but they only consist of two individuals, the male and female; like the bees also they collect the pollen from the various flowers on which they feed. This family is divided by Dr. Leach into three divisions, from the form of the lip. The first has the lip with the apex dilated, nearly heart-shaped; to this division belongs only the genus *Colletes,* Latreille; the superior wings with three submarginal cells; antennæ with the third joint longer than the second; abdomen much elongated, more or less downy; ocelli forming a curved line; tongue obtuse, the apex divided into two lobes. Of this genus we have three species in this country, the *Apis succincta* of Linnæus being the most remarkable; the second species, *C. fodiens,* has been ably illustrated by Mr. Curtis, who observes that we are indebted to Reaumur for a knowledge of the economy of these bees, and it is a little singular that no one appears since his time to have discovered any of their nests, which are stated to have been formed amongst some earth filling up the spaces in a stone wall. These nests are cylindrical, and composed of many cells of different lengths, placed in a horizontal line, each cell being formed like a thimble and fitted to the next; sometimes, however, when a stone obstructs their course, the line becomes irregular. The cells have alternate transverse bands of two or more colours; the shorter ones at their junction are white, the longer ones enveloping the body are reddish brown. These cells are constructed of many layers, lying one over the other; and although their contexture is close, they are very transparent in consequence of their extreme thinness—sufficiently so to discover the colour of the substances contained in them, which causes the variegated line above described.

The second division has the lip with the intermediate process oblong and acutely pointed; when at rest a little deflexed. This division contains three genera, the superior wings having two submarginal cells; genus *Dasypoda,* Latreille; maxillæ inflexed at their middle, or below; their terminal process triangular, lanceolate, and longer than the palpi; hinder feet with the first joint of their tarsi as long or longer than the tibiæ.

Only one species is described of this genus, the *D. Swammerdamella,* a very elegant insect, which has been long known, as it was in the collection of the celebrated Swammerdam, one of the fathers of entomology, and has been tolerably figured by him. Panzer has an admirable figure of it, under the name of *Andrena plumipes;* but his description of it does not agree with our specimens, which renders his synonym rather doubtful.

"No person at first sight would take the male and female of *D. Swammerdamella* for the same species, so widely do they differ in most particulars; nor should I have suspected that there was any connexion between them, had I not discovered their retreats. In the month of August, 1797, I saw a female take her flight from a grassy declivity of a southern aspect, which was much entangled with roots and shrubs. Upon examining this spot more narrowly, I discovered a number of small burrows, each of which had a little heap of sand, which had been excavated from it, lying before it. In some of these burrows I saw this insect sitting with her head at the mouth enjoying the sunshine; at the same time I observed many other insects flying about the spot. Upon my attempting to take them they disappeared, but they soon returned to their amusement. With some difficulty I at length succeeded in taking one, and it proved to be the female just described. I have since frequently visited the same spot, and at the proper season have always found these insects there, both males and females, employed in the manner I have mentioned."

A. negro-anea.

In the genus *Andrena* of Fabricius, the maxillæ are bent at their extremity; they are longer than broad; the hinder feet with the first joint of their tarsi shorter than the tibiæ; labrum or lip little elongated, shorter than its palpi. The species *A. negro-anea,* represented above, inhabits the blossoms of mallows, where it may be found in the spring. It has the body black and densely covered with tawny-coloured hairs; the head has the front covered with tawny hair; on the summit may be seen the ocelli placed in a triangle; the antennæ are black; thorax black and covered with reddish hair; wings transparent and slightly irridescent towards their extremities; the legs black and covered with brown hair; the thighs and shanks of the hinder legs beneath covered with long white hair. This bee is not uncommon in April and May. We have figured it in order to remind the entomologist of the very curious parasite that is occasionally found on it, namely, the stylops. Many species of these insects have been added since their discovery, Mr. Curtis having enumerated six species; the same entomologist has also added a new genus.

The species of the andrena are extremely numerous, and a very large portion of them inhabit Britain. Their proboscis is downy and thick. The hinder legs of the male are furnished with a floccula at their base, the tibiæ with a thick scopa or brush, and their anus is covered by a fringe of hairs. They nidificate under ground in a light soil, some choosing banks over which bushes are scattered, others bare perpendicular sections, but all seem to prefer a southern aspect. They excavate burrows of a cylindrical form, from five inches to near a foot or more in depth, of such diameter only as to admit the insect. In making these holes they remove the earth grain by grain, which they throw up outside their holes in the form of a hillock. Some species penetrate in a horizontal, and others in a perpendicular direction. They construct a cell at the bottom of this hole, which they replenish with pollen made into a paste with honey, and in this they deposit their eggs. The pollen they carry in the scopa or brush of their hinder tibiæ, upon the flocculus at the base of the hinder thighs, and on the hairs of the metathorax. When the female has committed her egg to the paste, she very carefully stops the mouth of her hole to prevent the ingress of ants, or of other insects which might be enemies to the larvæ.

The genus *Cilissa* (Leach) have the maxillæ bent near their middle, the terminal process very much longer than broad; lip elongated, longer than its palpi; superior wings with three submarginal cells, the second small. This genus is not only distinguished from Andrena by the characters of the lip and maxillæ, but also by having a longer tongue with very minute auricles.

In the third division we find the lip with the intermediate division incurved, or nearly straight, not twice the length of the head; superior wings in all, with three complete submarginal cells; it consists of four genera, the first of which, the genus *Sphecodes* (Latreille) has the labrum, trigonate, of the male entire, of the female generally emarginate; antennæ of the males long, almost moniliform; abdomen with the greater portion smooth. The species of sphecodes make their nests in bare sections of banks exposed to the sun, and nearly vertical. According to Reaumur, they excavate to the depth of nine or ten inches, and deposit their eggs in a mass of pollen mixed with honey.

In the genus *Lasioglossum* (Curtis), the antennæ of the male is inserted near the centre of the face, longer than the head and thorax, slightly fusiform, composed of thirteen joints very similar to *Halictus;* labrum transverse ovate, the sides straight, having the angles rounded and slightly emarginate; anterior margin convex and ciliated with long hairs, broadest at the base; mandible not so much dilated at the base as in *Halictus;* maxillæ very slender; abdomen ovate and convex, considerably broader than the thorax. Wings ample; the cells similar to halictus, as well as the legs.

In the *L. tricingulum* (Curtis), the male is black, shining, and pubescent, exceedingly minutely and thickly punctured, and clothed with soft ochreous hairs; abdomen with a whitish fascia, narrowest at the middle; at the base of the second, third, and fourth segments, the fifth segment slightly grey with pubescence, the apex ochreous; wings iridescent, the posterior margin slightly fuscous; stigma ochreous; nervures pale brown; posterior tibiæ ochreous; and tarsi, excepting the first pair, whitish ochre, tipped with ferruginous.

Curtis says, "this singular, and, I believe, nondescript species, appears to form a beautiful connection between the *Andrenidæ* and *Apidæ;* but, unfortunately, the female is unknown. I took three males at Ventnor, in the Isle of Wight, flying about flowers near the sea shore, the 12th September, 1826; they look very long on the wing, in consequence of the head, antennæ, and bodies, being carried horizontally."

The genus *Halictus* (Latreille) have the antennæ inserted near the middle of the face, long, filiform, and with thirteen joints in the males, the basal joint being the longest, and clothed with long feathery hairs; second, cup-shaped; third, semi-ovate; fourth, stouter and oblong; the remainder slightly decreasing in length, and becoming very ovate or convex on the under side; terminal joint rounded at the apex. The males are smaller and slenderer than the females; having the head orbicular, depressed, the eyes long and ovate, ocelli three, thorax globose; the abdomen is elliptical in the males, and ovato-conic in the females, with a groove on the back at the apex; wings superior, with one marginal and three submarginal cells, the central cell the smallest; tibiæ, with long spires or spurs; posterior robust in the female; tarsi, five jointed, basal joint long and stout in the females, the others minute; claws bifid in both sexes.

Mr. Curtis says, the remarkable elliptical impression on the back of the penultimate segment of the abdomen, distinguishes the female halieti from all other bees, and the head of the male is narrower and more elongated than in Andrena, and the second joint of the antennæ is not much larger than the second. Twenty-nine species have been found in England; they are mostly taken in the spring and summer months.

The last genus of this family is the *Hylæus* (Fabricius), in which the lip is lance-shaped, the hinder feet in both sexes being alike; the last joint of the abdomen in the females with a longitudinal groove above. The *Hylæus quadri-cinctus* is found occasionally near London. The males of this genus are remarkable for an elongate cylindrical body. The wings of many of the species are beautifully iridescent. They nidificate in bare banks, where they may be found in June, July, and August.

ANDREOSKIA (Decandolle). A genus of annual and biennial weeds found in the north of Europe, allied to Sisymbrium, and in the natural order *Cruciferæ.*

ANDROCYMBIUM (Linnæus). A family of bulbous-stemmed herbs, natives of the Cape of Good Hope. Linnæan class and order, *Hexandria Trigynia.* Natural order, *Melanthaceæ.* Generic character: calyx, corolla-like, six-petaled; sepals, long-clawed, convolved like a cup, honey-bearing; stamens inserted in the hollows of the sepals; anthers, leaning, opening outwards; styles terminating the cells of the germen, distinct; capsule, three-parted, three-celled, three-valved; cells, many-seeded, and fixed to the dissepiment in a double rank. There are three species of this family, all curious and ornamental.

ANDROMEDA (Linnæus). An extensive genus of beautiful under shrubs, chiefly natives of North America. Linnæan class and order, *Decandria Monogynia.* Natural order, *Ericeæ.* Generic character: calyx, five-cleft, coloured, persisting; corolla, bell or bottle-shaped, limb, four-toothed, reflexed; stamens, inserted into the base of the corolla, included; filaments awl-shaped; anthers, two-horned, opening by pores at the top (rarely with a back bristle or awn); style, cylindrical, persisting; stigma, blunt; capsule, five-celled, five-valved, with many seeds; valves placed contrary, opening in the middle, with a central placenta, in five lobes.

There are nearly fifty species and varieties of the Andromeda, and are usually seen in our gardens in the American borders, intermixed with azaleas, kalmias, &c. They thrive only in peat earth, or leaf mould and sand; and in their natural habitats they all affect moist situations; they are in general pretty little plants, some of them considerable shrubs, and even trees, for the *Andromeda rigida* rises to the height of about twenty feet. The beautiful red flowers of *Andromeda hypnoides* are spread over great tracts of the Lapland Alps, and assist much to adorn the scenery with their moss-like appearance. According to Sweet, they are increased by layers, and also from seeds, which must be very thinly covered with earth, and transplanted when about an inch high into pots, until they are sufficiently strong, when they may be planted out in the open ground.

ANDROSACE (Linnæus). A family of small annual, biennial, and perennial herbaceous plants, natives of the mountainous parts of the continent of Europe. Linnean class and order, *Pentandria Monogynia.* Natural order, *Primulaceæ.* Generic character : calyx, five-sided, five-toothed; corolla, salver-shaped, throat glandular, limb five-lobed ; stamens, within the tube ; capsule, five-valved, five to ten-seeded. The large round hollow leaf of the common androsace has been compared to the buckler of the ancients, and hence its name.

ANEILEMA (R. Brown). A genus of exotics, chiefly evergreen creepers requiring the protection of the greenhouse. Linnæan class and order, *Triandria Monogynia.* Natural order, *Commelineæ.*

ANEMONE (Wind-flower). An extensive and beautiful family of ornamental herbaceous plants, mostly natives of Europe. Linnæan class and order, *Polyandria Polygynia.* Natural order, *Ranunculaceæ.* Generic character : flower having an involucrum, often at a distance from the flower ; calyx resembling a corolla with many petals ; nectarium none ; stamens below the germen ; filaments like threads, sometimes dilated at top ; anthers oblong, two-celled ; style filiform, short ; stigmas headed or flatted ; caryopses naked.

Of this genus there are forty-one species described, of many of which, particularly the *A. coronaria,* there are numerous varieties ; and the structure is also so different that botanists have divided the family into six sections, founded on the different appendages of the seeds and form of the involucrum. The greater number have tuberous roots, among which the coronaria or garland anemone has been raised to the dignity of a bed flower by professional florists, and for some of the newest and best high prices are charged.

The anemone is propagated and new varieties are obtained by sowing the seed. This should be chosen from the best old flowers, impregnated with semi-double flowers, having the desirable properties of rich colour and fine form. The seed being liable to be blown away by wind, should be gathered as it ripens, and be preserved dry till the month of January, when it should be sown. It requires to be prepared for sowing by being mixed with, and rubbed in sand, to free it from its downy covering. The seed-bed should be composed of fresh garden ground or loam, from twelve to eighteen inches deep, well broken and aired, to free it from worms and insects ; and, for the better security against these, a layer of lime, three inches thick, should be laid in the bottom of the bed ; and, to prevent the approach of slugs or worms to the surface, the outskirts of the bed should be frequently sprinkled with lime-water.

A shallow one-light frame is necessary for the defence and nurture of the seedlings. In this, when the soil is settled and levelled, sow the seeds equally, and press them into the earth with a board, or back of a spade. The bed should be kept rather moist. While the seeds are vegetating the glass-light should be kept close ; and as they swell and rise above ground, a slight covering of loam may be sifted on occasionally till the seeds are hidden. Air must be afterwards given at all times when the weather permits ; and should the bed become too dry, it must be lightly watered. If the surface appear crusted when the seedlings are rising, it must be cautiously loosened with the point of a stick. This treatment must be continued till the leaves begin to die off, and when they are quite withered the tubers may be taken up.

As these small roots are irregular in form, and of a dingy colour, they are not readily found, unless two or three inches of the surface be passed through a fine sieve, to separate them from the mould. When freed from earth and dried, they are kept in boxes till the planting season.

These seedlings, planted in a nursing bed, will mostly flower in the second year ; all that are worthless may be discarded, and the best kept to breed from, or take a place among the finer sorts. The finest double varieties are only procurable by a long course of successional sowings from individuals of good colour, and which show a tendency to become double.

Anemones may be planted either in the month of October, or in February. The autumn is the most natural season, provided the bed is defended by proper coverings during severe frost. By spring planting, the risk of injury and trouble of covering is avoided ; but in highly kept flower-gardens, they are planted in both seasons to ensure success. When coverings are necessary, they should be of bass or reed mats, and raised on hoops a foot or two from the surface, and always rolled off when the weather is mild.

The habits of the anemone, as being a production of the moistest season of the year, seem to point out the soil most congenial to it; viz. a mellow, moist, rich loam. It is such as absorbs and retains an equable degree of moisture, without repletion or deficiency ; and, though surface-water be neither naturally necessary or suitable, yet a substratum of rich soil retentive of moisture is indispensable.

In forming the bed, the bottom must be loosened sufficiently deep, say two feet at least ; and, about eight inches from the surface, let a stratum of strong loam and rotten dung, well incorporated, be laid, and on this a surface layer of lighter loam to receive the tubers. The bed being formed and levelled, drills are drawn across about five inches asunder, on which the roots are placed, crowns upwards, four or five inches apart, according to their size, covering them as near as possible about two inches deep.

The subsequent management consists in defending the bed from frost, slugs, and insects. If the month of March be dry, the state of the soil should be examined ; if found too loose, a little fresh loam may be added and pressed tight to the plants ; and if too dry, a good soaking of manured water may be given, and this occasionally repeated, if dry weather prevails. When coming into bloom, shading as well as watering will be required ; as well to ensure perfect flowering as to preserve their beauty. After the flowering, and when the leaves fade, dry weather matures the tubers readily ; but if very wet, the bed should be protected from rain : because this keeps them excited, and tends to weaken them. About a month after the bloom the roots may be taken up, carefully cleaned, dried, and stored up.

There are four species of this plant found in Britain ; the wind-flower, *A. nemoralis,* and the Pasque-flower, *A. pulsatilla,* are among the gayest ornaments of the spring.

ANGEL-FISH, or "Monk-fish." The common English name of a species of *Squatina Angelus*, a genus of chondropterygious or cartilaginous fishes, with fixed gills, and in their characters intermediate between the sharks and the rays or skate. These three genera may, indeed, be considered as forming a series which, in the gradations of the different species, extends from the surface of the sea to the bottom, at least to the bottom of the shallows near the shores; and from the wide range of the ocean to particular spots, from which they seldom migrate. The white shark is the most discursive as well as the most formidable and voracious of the series; and the spineless rays, as, for instance, the common skate (*raia batis*), the least voracious, and the most localised. They are all, however, rather voracious, and they are active and powerful fishes.

The genus to which the angel-fish belongs gets the name of *squatina*, because the body is in all the species flattened or depressed, though not so much so as in the rays, but much more so than in the true sharks, with which this species used, very improperly, to be associated; but the body is not nearly so much depressed as in the rays, and the pectoral fins, though large, do not pass insensibly into the body, and appear to form part of it, as in those. The tail also is not nearly so slender as in the rays; and the whole outline of the fish can be distinctly traced, the large pectoral fins having something the appearance of wings, but still bearing the character of distinct appendages. It is from this wing-like, or tunic-like form of the fins, that the fish gets the names of angel and monk, for otherwise there is nothing either very angelic or very monastic in its appearance or its habits.

The mouth opens at the end of the muzzle, and not below, as in the sharks, and, generally speaking, in the rays. The teeth are formidable; they are broad at the base and narrowed to the points, so that they pierce and cut like broad arrows, and they admit of a lateral or sawing motion upon their articulations; but they are not quite so ragged and formidable as those of the sharks. The eyes are placed in the upper part of the head, whereas those of the sharks are placed laterally. The pectoral fins, as has been hinted, are very large, and they are armed with small spines on their margins. They stand forward at the front edges, something like the wings of a dragon-fly, only they are broader in proportion. Their front edges are closely united to the body, but their posterior ones are separated by a sort of slit. They have two dorsal fins; and the ventral fins are abdominal, or placed behind the last dorsal. There is no anal fin, and the caudal is placed equally upon the upper and under side of the termination of the vertebræ. The skin is rough and granulated, ash-coloured on the back, having a row of osseous plates with sharp points along the ridge, and white on the under part.

It often attains the length of eight feet, and is withal a most formidable fish, and dangerous to be approached when taken alive, as it not only bites desperately, but tears and lacerates with the spines on its pectorals and the points on the ridge of its back. It is not uncommon in the British seas, especially the Atlantic and the parts contiguous to it, but it keeps near the bottom, and thus it is not often seen in proportion to its numbers. The sole and flounder banks are its favourite haunts, and it captures vast numbers of those fish. There is, however, no danger of its exterminating them, for they breed so much faster, that a brood of flounders can support a brood of angel-fish, and yet have abundance for a succession. Like the sharks and rays, the angel-fishes are ovo-viviparous, or perhaps almost viviparous, though these are points difficult to be ascertained; and fishes which are either one or the other are never so prolific as the oviparous fishes.

ANGELICA (Linnæus). A large herbaceous plant cultivated in gardens, a native of Britain. Linnæan class and order, *Pentandria Digynia*. Natural order, *Umbelliferæ*. Generic character: no universal involucrum; fruit somewhat flat, margin winged, three acute costæ on the back, furrowed below. Species, nine; biennials and perennials. In a wild state angelica is unpalatable, and even dangerous as a salad herb; when cultivated it is increased in bulk, and loses its harshness of both fibre and flavour, partaking of that of celery, chervil, and parsley.

Cultivation. Sow the seed in March, and when the seedlings are three inches high, transplant them on a shady border three feet apart, there to remain. As it is a large rambling plant, it may be planted in any open part of a shrubbery. Being a biennial, annual sowings are necessary. The confectioner makes an elegant sweetmeat of the leaf-stalks.

ANGOPHORA (Cavanilles). A genus of two species of greenhouse shrubs introduced from New Holland. Linnæan class and order, *Icosandria Di-Pentagynia*. Natural order, *Myrtaceæ*. Generic character: calyx turbinated, five-ribbed, and five-toothed; corolla five-petaled, inserted in the calyx; stamens numerous, inserted in the throat of the calyx; filaments awl-shaped; anthers somewhat round; style like a thread; capsule three-celled, three-valved, three-seeded; seeds roundish, plane on one side, convex on the other, appended by their back; seed-leaves roundly foliaceous. These plants resemble metrosideros, and are esteemed ornamental.

ANGRÆCUM (Thouars). A small family of hothouse perennials belonging to the orches tribe. Linnæan class and order, *Gynandria Diandria*. Natural order, *Orchideæ*. Generic character: perianthium, somewhat resupinate; three upper petals like a helmet; labellum sitting, jointed with the column, often united; columna without wings, curved, produced above the anthers; pollen united in a glandular mass. All of this curious tribe of plants are interesting, but difficult of culture.

ANGUILLA (Eel). A genus of soft-finned fishes, without ventral fins, belonging to the family *Anguillidæ*, and form the leading or typical genus of that family. Every one is so familiar with the general form and appearance of eels, that they need no description; but many of their habits are so singular, they are so valuable in an economical point of view, and, now their physiology is a little better understood, the fresh-water ones, at least, may be rendered so much more valuable by culture, that they demand more particular explanation than could well be given in a general article upon a genus the species of which are so numerous. [See Eel, for the popular history of the eel, properly so called; and Anguillidæ, for the names of the several genera of eel-shaped fishes, under which their generic character and particular history, where necessary, will be found.]

ANGUILLARIA (R. Brown). A genus of three species of herbaceous perennials, chiefly from New South Wales. Linnæan class and order, *Hexandria Trigynia*. Natural order, *Melanthaceæ*. Generic character: calyx six-petaled, spreading star-like, regular; stamens inserted in the bottom of the petals; anthers burst at the back; styles three; capsule three-celled, three-valved; seeds numerous, roundish.

ANGUILLIDÆ. Eel-shaped fishes, which are arranged into the following divisions, or genera: *Anguilla, Aphisnous, Murænaphis, Sphagobranchus, Monapterus, Unibranch-apterus, Alabes, Aschioquathus, Gymnotus, Gyannarchus, Aphidium,* and *Ammodytes*, which see.

ANGUIS (snake). A genus of *Ophidian reptiles*, or "serpents," but differing in much of their structure and most of their characters from the true serpents; so much as to form a sort of link between them and the most simple of the saurian reptiles, or reptiles with produced tails and feet.

The animals which are included in the genus *Anguis* are among the most harmless, inoffensive, gentle, and retiring on the face of the earth; more so than almost any of those which the most refined and amiable of the human race cherish with the fondest affection, and caress to the display of an excessive and not unfrequently ludicrous degree of affection. To such, the gentle snakes are objects of aversion and horror, and they seem to have a "Cain's mark" set on them; for, even where the parties would be a little squeamish in the case of other creatures really noxious, "whoso findeth 'the poor snakes,' slays them," without mercy, and even with exultation.

This is one of those evils which can be removed only by a more general diffusion of the knowledge of natural history; and leaving the gratuitous murder of the poor snakes, and the mischief done by the prey which it is their province in nature to keep within due bounds, out of the question, the evil is really a serious one; and many a human being has suffered more mental agony at the sight of a little creature which could not have killed a kitten, than if about to be pierced by the fangs of the bushmaster, or crushed in the folds of the boa constrictor. All this, too, has been again and again suffered, simply because the snake has, in so far, the form of a serpent, and because there is a prejudice against the whole race.

Thus it is very important to understand the nature of the snake; and the more so, that it is common in many parts of Britain, and apt to be mistaken for the poisonous viper, which is not so common, and the venom of which is rendered far more virulent than it otherwise would be, by the fears of the parties that happen to get bit: for even the viper never bites man, or any large animal, if it can help it.

There are several species, or rather genera, of harmless snakes, that is, of snakes with neither crush nor poison, varying from the common blind worm of Britain (*Anguis fragilis*) to the *Acontias* of warmer climates; but they are all equally harmless.

The external characters are, the scales on the back and belly alike in size, whereas the true serpents have those on the belly larger and free at their posterior edges. Their large scales, or *scutæ* (shields), are, in fact, the substitutes for feet in the true serpents. [See OPHIDIA]. The upper jaw-bones are articulated immediately to the skull and the intermaxillary bones, so that on opening the mouth, the animals cannot raise the upper jaw; and the lower jaw is so articulated to the ossa quadrata, that they can depress it only a little way; their gape is in consequence very narrow, and does not extend far backward. Their eyes are very small, and furnished with a third eye-lid. Their motion is not the motion of a serpent, but that which we might imagine to be resorted to by an animal with a flexible backbone, if deprived of its feet. They advance by steps which consist of alternate straightenings and archings, the forepart of the body being advanced during the first, and the hind part brought up during the second. Their movement is thus a sort of gallop; but it is a singular one, being made without external legs.

The internal structure corresponds: there are shoulder bones and clavicles under the skin; and the rudiments of a breast bone, and the bones of a pelvis resembling that to which the posterior extremities of footed animals are articulated. These characters are most distinct in the blind worm; they gradually become less and less so in the others, and are almost entirely obliterated in the acontias, which have some resemblance to the more harmless of the true serpents, the first of which is the amphisbæna, which is as gentle a creature as the acontias; but even the amphisbæna has no vestige of shoulder bones, sternum, or pelvis, and no third eye-lid; but, like the true snakes, it can move both ways, which the serpents cannot do.

When the blind worm moves fast, its muscles are in so rigid action, that it may be broken in pieces by a slight tap with a small switch. It is for this reason that it is called *fragilis*, "easily broken." The others are less and less fragile as they depart from it in structure; but none of them can bear a severe blow, especially if hit when in the form of a bow.

In Britain, the blind worm is but small of size, seldom more than a foot in length, and never more than eighteen inches. The upper part is greyish, with two brown stripes down the back, and one on each side, from the eye backwards. The head is small, the neck slender, the body rather thicker, and continuing nearly the same to the tail, the tip of which is blunt. There are four rows of scales on the head; first one, then two, three, and four, in succession. It has small recurved teeth in each jaw. The scales on the neck are very small and imbricated. It lives in holes in woods, among heaps of rubbish; feeds upon very small animals; lies dormant in the winter. It is ovo-viviparous, or hatches its eggs internally.

The above described is the only species of the genus *Anguis* found in Britain. The other harmless species, which is more common, and grows to a larger size, is the "ringed snake," *natrix torquata*. The latter consists of a yellow spot and a black one on each side of the neck. The colour above is brown, with two rows of black spots, and irregular bands of the same across; and the under part dusky, with a black tinge. The head is flattened, the muzzle round; four rows of scales on the head, first two, then two, three, and two again toward the neck. It is oviparous. It frequents marshy places, and feeds on insects, frogs, and mice. It is mild and gentle in its disposition, and easily tamed. The *viper*, the only poisonous one in Britain, is rather smaller, and found in dry heathy places. Its head is broad behind, and has large scales on the edges of the jaws. It is black between the eyes, and has two black spots on the crown. There are three rows of spots on the body, one down the back of four-cornered ones, and one down each side of three-cornered. The ground colours of the body are apt to vary; but they are generally yellowish on the upper part, and dusky blue on the other. In all the varieties of colour, the three rows of spots distinguish it, unless when the upper part is black, and that is a distinction, as the harmless snake is never darker than brown. It also has always bands of dark spots across, while the other has none.

ANIMALCULE is literally the diminutive of the word animal, and as such signifies "a little living creature," a sense which is abundantly vague; but its application is restricted to an exceedingly numerous class of animals, which are, generally speaking, invisible to the naked eye, forming, as it were, a new world, which has been revealed to human knowledge by the microscope, and to which there appears to be no limit, save in the powers of that instrument. As these minute creatures are found only in liquids, in which vegetable or animal matters have been partially dissolved by infusion, they are sometimes called *Infusoria*; but the term is apt to mislead, as an infusion can no more of itself produce an animalcule, than the water can of itself produce a fish, or the air a bird, or than a house can produce a human being. The infusion favours their development, just as the development of larger animals is favoured by certain states of the weather and other circumstances; but the analogy of all nature demands that the germ of the animalcule should be there as well as that of the elephant or the whale, otherwise it would be as vain to look for the small animal as the large one. This fundamental principle we must carry along with us in every case of organised being, even though the details of the organisation be too minute for our perception, and the fact of its existence more an inference from the function than a direct result of observation.

And, upon this microscopic confine of our knowledge it behoves us to be very circumspect, inasmuch as the animal function is often as obscure as the organisation; so that it is only with the best instruments, the most careful and patient observation, and minds totally divested of all theory, or preconceived nature of what we are to find, that we can arrive at the truth. The grand law as to function is that inorganic matter obeys only certain attractions and repulsions, while that which is organised obeys new laws in opposition to these. Under a powerful microscope, however, there is always doubt, unless we can discern both organisation and function; and therefore this is not a department in which ordinary popular observation can well extend the bounds of knowledge.

But it does not thence follow that the subject is not one of popular *use*, for many of the most valuable parts of our knowledge, can be extended in themselves and their connexion with each other only by the few who are content to forego the common pursuits and pleasures of life, and toil and study without associate and without sympathy, supported by the sure hope that that which they are sowing in silence and secret will grow up and enrich the world with its fruits.

In this way, microscopic labours in natural history, and especially in the natural history of animalcules, are of very great importance in a popular and practical sense. They show us that, if we follow it in the direction of the minute, there is just as little limit to nature as when, by the aid of the telescope, we follow it to the vast. When we think of the myriads of stars, myriad behind myriad deepening into space, which a powerful telescope discloses in a very small portion of the heavens; when we consider that all these are certainly further apart from each other, and the nearest more distant from us than the swiftest-winged bird could fly in ten thousand years; that each of them is, by the most rational analogy, a sun surrounded by many worlds, all peopled with growth and life; that what the telescope thus reveals, is limited by the imperfection of that instrument, so as only to constitute the mere beginning; and that, though we could reach the most distant of those stars as easily in the body as we can in thought, we should not perceptibly change our place in the universe:—when we think in this manner, we feel what a wonderful thing creation is, and how unspeakably beneficent it is in the great Creator of all things to give such a system for our contemplation, and according to our knowledge for our use.

But even this view, grand and sublime as it is, is not complete, until we take hold of the microscope, and view the series the other way. Then we discover that the little globule of water that we can lift on a pin's-point is a miniature of this giant universe, instinct with living creatures which no arithmetic can count; and that in them, organisation and life are, according to their species, as perfect as they are in the largest animals which walk the earth or sport in the waters; that the fluids of plants and animals are full of life and its germs; and that the eye cannot so divide space, even by the aid of the instrument, as to enable us to say of the smallest sensible portion, "there is no living creature contained here." But here again we are limited by the imperfection of the instrument, and know not how much may lie between what has been discovered and the final bourn, at which organic life touches on the elementary particle. And when we glance our thoughts along this wonderful series, the first thing that strikes us is, that it is all equally perfect. Their functions are as varied as their forms and magnitudes; but when we compare each with the circumstances in which it is placed, we cannot say that one is relatively stronger or weaker than another: the animalcule in its drop of water is just as much "adapted and at home" as the elephant in the jungle, or the sun careering through measureless distance with all the planets in his train.

And it is further worthy of remark, that the law of life from the whale to the animalcule is one law. This unity and uniformity are established by the study of this branch of the animal kingdom. They, like the larger animals, have their different degrees of organisation; and, in conformity with what was said of these in the introduction to this work, the simpler the organisation the more retentive are they of life. Besides, in all cases where it is discernible, the germ can endure more than the developed animalcule, and there may be an initiatory point in its living in which it is proof against all destroying causes.

Some of the species of more simple organisation can bear to be boiled in close vessels, and others can bear a greater degree of cold than that at which water freezes. In general, however, the freezing of the water kills them; and some of those of the more complicated organisations cannot bear a temperature so high as that of the human body in ordinary health. In the case of freezing and thawing, it is not always easily ascertained whether it is the animals themselves which are resuscitated, or merely the eggs or other germs preserved and brought to maturity.

As those creatures appear in every liquid and infusion which is adapted for them, if freely exposed to the air, the origin of the germs has been a matter of curious inquiry; but if we compare the size of the eggs in the roe of a fish, when they are shed, and consequently matured, with the size of the fish when full grown, and apply the analogy, with every allowance, to the animalcules, we shall find that, until some microscope of much greater power shall be invented, it will be in vain to attempt to find their minute rudiments. In a fish which attains the weight of 25 pounds, the egg does not weigh more than 1-100th part of a grain, or, in round numbers the fish may be 175,000 times the weight of the egg in the roe. The cube root of that, in the proportional dimensions in line is, making allowance for the more regular shape of the germ, about 1-60th of that animal. Now many of the common animalcules require a magnifying power of 500, and some of them of 800 in line, before they are distinctly visible; and, supposing the germ to be in proportion as above stated, it could not be seen without a power in line of 30,000, which, according to the usual estimate, would require a focal length of only 1-300th of an inch, an instrument which could not be constructed upon any principle at present known in the arts. It may be proper to mention that the magnifying power, in surface, is 900,000,000! or one which, if it could be applied, would make the floor of Westminster Hall appear as large as all England.

But minute as those germs must be, and vain as is the hope of finding them in their rudimental state, they are as much within the action of the common laws of nature as those of the largest animals. The action of the air is necessary for their development. The experiment of Spallanzani is conclusive upon this point, though it does not warrant the conclusion which he draws that the germs necessarily descend from the air. They are indeed so very minute that it is impossible to imagine an atmosphere so still as not to move them about, and difficult to imagine a place where they cannot find entrance. Spallanzani's experimental vessels contained infusions which had been boiled for an hour. Some of them were left open, others closed with cotton wool, a third set had wooden stoppers, and the fourth were hermetically sealed. At the end of twenty-five days there were animalcules in them all; very abundant in the open ones, and less and less so in the others, till in the sealed vessels they were very few. A film of oil on the surface of the infusion had nearly the same effect, and apparently from the same cause, that of preventing the action of the air.

It is by no means impossible that the germs of animalcules may ascend with water in the process of evaporation, and descend again with the rain; and it may be also that they are carried by the water into the earth, and flow out again into the most pure and limpid springs; but the developed animals are very rare in water in its pure state, so that, as is the case with the spawn of fishes, the eggs of insects, and the seeds of plants (with all known germs of living creatures indeed), a specific elementary action is necessary for their development.

That action appears to be heat and humidity jointly, and the heat appears to be in part derived from the putrid fermentation; as they are not only brought forward by artificial infusions, but appear in all shallow waters where vegetable matter is in a state of decomposition; and as they are found in vinegar and in sea-water, they can at least endure the acid and salt which are in these. That they can exist in pure vinegar, or vinegar in which there is no vegetable mucilage, is not probable; and they are prevented from being developed by a small admixture of sulphuric acid with common vinegar, which hinders the formation of "mildew" as it is called by dealers. From the observations and experiments of Dr. Power, it appears that these inhabitants of vinegar (*vibrio aceti*) have some peculiarities of character. If the temperature is raised a little above that of the human body in a state of health, they die; but they can bear to be frozen in the vinegar and again thawed out of it. They do not, however, bear this intense cold patiently or willingly, for they escape if they can, even into a substance in which they are not naturally produced.

The structure and functions of animals so very minute cannot, of course, be well understood; but still enough has been gleaned, partly from one partly from another, for enabling at least a rational guess to be formed. They all have a mouth and stomach, of some form or other; and some of them are as ravenously carnivorous, and eat up their brethren with as much avidity and gusto, as the most voracious fishes. Some of them are *polygastric*, or have many stomachs, in the form of little sacs united by tubular connexions; and others are *monogastric*, or one-stomached, and have generally alimentary canals. Of course nothing is known of the nervous or circulating systems of animals so minute; and the existence of these is inferred rather than proved. Some are furnished with eyes; and all have some means of perception by which, to a certain extent at least, they keep themselves out of danger. Muscles, and other organs of a considerable degree of complication, have been distinctly observed in several of the larger ones; and as they are all locomotive, and some have the power of attaching themselves to other bodies by means of little hooks or otherwise, and all of them can partially alter their shape, it is probable that the whole have muscular systems more or less complicated in proportion to their functions. Some of these muscles must be exceedingly minute, not the ten-thousandth part of an inch in length, or the millionth in thickness; and yet they are probably made up of fasciculi containing as many fibres and contracting on the very same principle as those of the largest animals. It does not appear that any of them have internal bones; but they seem all to be invested with an integument sufficiently tough for allowing of insertion of the muscles; and some are covered with shells which, in some of the species, are regular bivalves, and when the valves are shut enclose the whole body.

Some are coloured, but the greater part are nearly colourless, and some are quite transparent, so that they are seen by the refraction and reflection of light at their surfaces; and it affords a wonderful proof of the delicacy and divisibility of light, when we consider that it can be differently acted on by the several parts of the bodies of creatures of which the whole mass is so small.

Their modes of reproduction are not the least curious part of their economy; and in these, as in some other matters, the different species resemble more than one class of the larger invertebrated animals. Some propagate by spontaneous division;

and that division takes place in many ways, so that the new animals might be often taken for different species. Some are gemmiparous upon peduncles; some are oviparous, some ovo-viviparous, and probably some are simply viviparous. It is not known whether the mode is uniform in the same species; but the probability is that it is not always so, but that some increase both by germs and by teguments; and that, as is the case with some of the small invertebrated animals which are visible to the naked eye, their modes of reproduction are different at different seasons.

The natural periods of their duration are not known; neither are their seasonal appearances. It is in the temperate climates chiefly that they have been examined; and in these they are mostly summer animals, but appearing at greater differences of period than the larger seasonal ones. A portion of water in the sun and another in the shade appear to be the West Indies and Melville Island to the animalcules, though probably the germs of them may be equally numerous in both. When the limna on the surfaces, and the confervæ and other small plants at the bottoms of the shallow waters have arrived at maturity and begin to decay is the time when these creatures are most abundant; but which of them perish, and which hybernate after the cold weather sets in, has not been ascertained.

There is one curious fact in these occurrences; and that is, the power which many of the species have of being revived again, not from a state of torpor merely, but from one of perfect dryness, in which they are not to be distinguished from small and light particles of microscopic mould. Analogy would lead us to suppose, or rather we are certain, that the apparent dead state of the animalcules cannot be real and absolute death, because from that there can be no return of the individual but by an effort of creative power, and none of the matter composing the individual but by the assimilating powers of another living creature; but still it should seem that all the functions of life are totally suspended, and can so remain for a considerable length of time. One of those in which the process of being dried and again reviving has been most observed is the common wheel animalcule, *vorticella rotatoria*, which is very curious in its form and motions, and has the advantage of being visible to a good eye without the microscope.

While it has sufficient water, at a temperature not exceeding about 110 degrees of the common thermometer, it is a very active creature; but when the water is nearly exhausted by evaporation it becomes languid, the motion of the wheels is suspended, they are withdrawn and disappear; the animal shrivels, becomes hard, and if touched with the point of a fine needle, it bursts in pieces, as if it were a little tear of unannealed glass. One would imagine that there could be no signs of death more unequivocal than these; and when the animal is blown to powder by being touched with the hard point, there is no question of the fact. But it is not only not dead, but if sharp points are kept away from it (the action of which, though most curious, is inexplicable upon any known principle), it is more difficult to kill than when it has the use of all its members. They bear a considerably higher temperature if perfectly dry; but if moisture is applied with the increase of temperature, the animal is instantly killed. If kept dry, and the heat not excessive, it can be kept for weeks, months, and even years, indeed for any indefinite time; and all that it requires to restore it again to the world of animation is simply moistening it with water.

The return of the animal to activity, as observed by Leeuwenhoeck, whose observations have not been surpassed for accuracy, is curious. Some revive in a few minutes, others not till after several hours; and this difference in the time of resuscitation appears to have nothing to do with the period during which the creatures have lain dormant. The animal first enlarges in size, then it begins to move and elongate at the head and the tail, after this the wheels expand and begin to move, and the animal is soon as brisk as ever. Nor is it only once that this death and resurrection (so to speak) can be made to take place in the same individual. Spallanzani revived the same ones several times over, though with a diminution of their numbers each time; and at the sixteenth attempt none of them revived. It should seem, both from this and from the different times which they take in reviving, that they are not all equally strong; but what are the differences of age or other circumstances upon which the powers of endurance depend, is not known.

The fact is a most singular one in physiology; and as we cannot suppose that they have this property only to be developed by experiment, we must conclude that they are subject to these temporary deaths and resuscitations in a state of nature; but from their small size we can observe them only experimentally. Their breathing apparatus must be different from every species of gills with which we are acquainted in any larger animals which breathe in the water; because all these, so far as is known, perish beyond the possibility of resuscitation as soon as their gills become dry. That they do breathe to some extent is certain, because they can neither be produced nor live in vacuo; and when cut off from a supply of air they perish before the water is evaporated, nor does it appear that, in any case, they revive again after they have once ceased to perform their functions in a humid state.

Whether they are the only animals that can be seasonally preserved by perfect desiccation, and again revived by moisture, is a question which it would be desirable to solve, as connected with the seasonal history of other aquatic animals of those countries where the grand alternations of the year are wet and drought; and one would be almost tempted by analogy to conclude that some of the leeches which infest the earth of Asia (in particular) almost the instant that the rains set in, and before we can reasonably suppose that they have grown from the egg, or other germ, must pass the dry season in a similar state. We know that many of the plants of those countries which die down into their tubers, pass the season of drought with the greater safety, and grow the more vigorously, the more completely that they are dried while the drought lasts. So well is this understood that, in many of our cultivated plants (and the greater part of them are natives of warm climates), we preserve their floral beauty and their culinary usefulness by taking up and drying the roots during the season of vegetable inaction. Other occasions will, however, afford us a more complete investigation of this curious and interesting subject; but as the animalculi are miniatures of animals, and make their appearance in that portion of our year in which the alternate dry heats and showers form a sort of miniature of the tropical year, the study of them leads very naturally to that of analogous animals and seasons upon the grander scale. It is one of the great points of superiority in natural history over all other studies, that there is no part of it but which, when properly followed up, guides us to the rest.

The details of animalcular history are somewhat nice and difficult, because of the fine instruments and minute observation which they require; but even here human ingenuity has been able to accomplish a good deal. At first it would seem that nothing could be known of the *internal* structure of creatures invisible to the naked eye, and in general perfectly transparent and colourless in all their parts; but by means of infusions of the colouring matter of vegetables or animal colours, first made use of by Baron Gleichen, the alimentary structures of many have been made out; and, partly by being seen against the vessels filled with the coloured infusions, and partly by other means, muscular tissues have been traced. Indigo, sap-green, and carmine have been found to be the colours best adapted for this purpose, and that they should tinge the vessels of these minute creatures to their most delicate ramifications shows how fine the division of the colours must be.

The indigo and sap-green are direct vegetable substances; and we need not wonder why the animalcules swallow them with avidity, because putrid vegetable matter is both the nidus in which they are brought to maturity, and their food during life. But that species which breed and feed on vegetable infusions only, and which we have every reason to conclude are generically or, at all events, specifically different from those that are bred in animal matter, should feed on carmine, which is usually regarded as an animal substance, is a different matter, and throws a sort of new light upon the nature of carmine, or rather of cochineal, of which carmine is a preparation. Cochineal is obtained from the *coccus cacti*, and from that insect in substance; but still the most rational view of the matter (and it is much strengthened by this fact of the animalculi swallowing it with avidity) is that the colouring matter of cochineal is, like wax and lac, a vegetable substance, absorbed by the insect, and retained for a particular purpose, but not assimilated or animalised.

The result of those observations has been a sort of double means of arrangement in the animalcular province; those that have one stomach and an intestinal canal, and those which have many insular stomachs: first, according to internal structure; and secondly, from the external structure; those which have appendages to the body, and those which have none. There is still a third means of classification; those which have the body covered with a simple integument, and those which have it covered with a shell, or second coat of some description or other; the first of these are called *nuda* (naked), and the second *loricata* (clad in armour).

The first and second of these means of classification harmonise tolerably well, so as to admit of a division of the greater number into two classes: *polygastrica*, or many-stomached; and *rotatoria*, or those which have appendages that seem to revolve. These last are curious instruments, and differ from those of all the larger animals, except that there is, perhaps, a slight resemblance to them in the spines of the *echinæ*, or sea-hogs. These are often placed in the circumference of a circle; and as each of them has a rotatory motion on its base while at an angle, and thus describes a little circle with its base points, the whole circle appears to revolve round like a wheel, very rapidly, as the apparent revolution of the whole takes place in the same time as the real rotation of a single one. See POLYGASTRICA, ROTATORIA, and VIBRIO, for the details.

ANISANTHUS. A family of Cape bulbs, usually grown in a frame or greenhouse. Linnæan class and order, *Triandria monogynia.* Natural order, *Irideæ.* These beautiful plants were formerly ranked with their near neighbours the antholyzas and gladiolus, but separated by Mr. Sweet. Their culture is similar to that of other Cape bulbs of the same character, viz. keeping them in a frame, either with or without pots, of peat-earth and sand.

ANISE. The *Tragium anisum* of Linnæus, placed by him in the second order of his fifth class, viz. *Pentandria Digynia.* Natural order, *Umbelliferæ.* Generic character: involucrum neutral; fruit, oblongly egg-shaped, downy, raphe smooth. This is a highly aromatic herb, and in former times was much prized as a condiment in food, either used green, with other herbs, or the seeds alone. As a salad or pot-herb it is now but in little requet, its seeds only being used by the confectioner and druggist.

It is cultivated on light finely prepared ground in an open situation; the seed is sown pretty thickly, either in drills a foot apart, or broad-cast on a border about the middle of April. During growth the crop is kept free from weeds, and the seeds are gathered when ripe.

Aniseed tree.

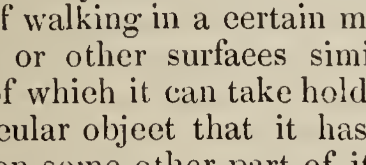
ANISEED TREE, of which the above is a figure, called by Linnæus *Illicium anisatum*, from its scent being like that of aniseed. Class and order, *Polyandria Polygynia.* Natural order, *Magnoliaceæ.* Generic character: calyx three-sexpetaled, deciduous; sepals unequal; corolla nine or more petals, unequal; stamina, inserted on the receptacle; filaments very short; anthers erect, oblong, emarginated; style very short, stigmata lateral, oblong; capsules several, disposed in a circle, ligneous or leathery, opening at the top, one-seeded; seed hard and albuminous.

This is a very beautiful, highly aromatic plant. The flowers are dark purple, and hang from the branches by slender footstalks. The ripe capsules are used in China as a spice, and sold under the name of "five-fingers." It flowers readily in our stoves, and is propagated by cuttings.

ANISODACTYLI ("Unequal-toed" birds). A peculiar order of birds, most of them of small size, and some the most minute of the feathered tribes, being less in dimensions and weight than many of the insects, but still preserving all the characters of birds in their parts, plumage, and modes of life, and often displaying the warmest floral colours, and the richest metallic reflections, which are any where to be met with among the productions of nature.

They are all bark, or at least tree, birds, and most of them feed upon insects, though some are understood to feed upon the honey of flowers. Some are continually running in all directions along the boles and branches of trees, and others are much upon the wing.

The character upon which the order is formed, is that of having the outer toe united to the middle one at the base; the other two free; the hind one strong, and capable of being bent a little inward, while the outer front one can be partially reversed. All the toes have the claws strong, sharp, and considerably hooked, and the peculiar articulation enables the bird to grasp with the foot in all directions, in the line of the body, across that line, or at any angle to it, so that whenever the bark of a tree will allow of the insertion of the points of the claws, the birds can run upwards, downwards, or round the bole; and those which feed chiefly on the trees generally have the tail so stiff, and so capable of muscular action, that they make use of it as a strut, by which means the weight of the body makes the claws keep a firmer hold. The following figure of the foot of the common nuthatch will show the structure of the anisodactylic foot:—



Foot of Nuthatch.

As this order is founded upon the structure of a single organ only—the foot, it cannot be regarded as a natural one for any very general purpose of utility. All that it positively shows is, that the bird which has it is capable of walking in a certain manner upon the bark of trees, or other surfaces similar in position and posture, of which it can take hold with its claws; but the particular object that it has in so walking must depend on some other part of its organisation; as, for instance, on the food which its bill can take and its stomach digest. For that reason it is not necessary to refer from this order to the groups and genera.

ANISOMELES (R. Brown). A genus of undershrubs, natives of India and New Holland. Linnæan class and order, *Didynamia Gymnosperma*. Natural order, *Labiatæ*. Generic character: calyx, a swollen tube, with ten ridges, and five-toothed; corolla, upper lip small, whole; the lower three-lobed, the middle one margined; stamens with short two-celled anthers, unequal in length; caryopses smooth.

ANISOPETALUM (Hooker). A genus of one species, introduced from Nepaul. *Gynandria Monandria* (Linnæus). Natural order, *Orchideæ*. This plant, like all the natural order to which it belongs, is curious in habit and manner of flowering. Its name is commemorative of Dr. Carey (*A. Careyanum*), a friend of Dr. Hooker's.

ANISOTOMIDÆ. A family of insects, belonging to the order *Coleoptera*, consisting of six genera, several of which contain a considerable number of species. In this family the antennæ are generally moniliform, or bead-shaped, somewhat elongate, and rather slender at the base, gradually increasing towards the apex, the terminal joint being of an elongate club-shape varying in the number of its articulations; palpi various, generally filiform, the head small and ovate, the body being mostly convex, but never linear; the tibiæ in some of the genera compressed; the tarsi various, the four anterior ones being five-jointed, and the posterior ones four-jointed. In the

A. Tritoma, (Fabricius), the maxillary palpi have the last joint large, transverse, and compressed; maxillæ with a minute tooth at the apex; antennæ short, of an ovate three-jointed club-shape, having the head somewhat triangular, the thorax being elevated in the middle behind; the legs moderate; the tibiæ compressed; of a broad, elongate, triangular shape. Of this genus only one species has yet been found in this country. It is found in fungi in the spring months, and is described by most writers under the name of bipustulatum. It is also figured in Samouelle's Entomologist's Compendium.

A. Phalacrus (Lati). In this genus the palpi are filiform; maxillary with the terminal joint elongate; labial very short; maxillæ with the apex strongly bidentate, or double-toothed; antennæ rather slender, distant at the base, a little elongate; the capitulum oblong; the terminal joint ovato-conic; head small, triangular; thorax gibbous, with the hinder angles ovate; body hemispheric-ovate, or oval; elytra entire; legs short, compressed; tibiæ short, straight, not spinous; tarsi slender; the penultimate joint cleft.

Stephens, in his British Entomology, describes twenty-eight species of this genus.

The Phalacri are usually rather brilliant insects, and are very frequently adorned with metallic colours. Unlike the other genera of this family, their body is generally very convex, and incapable of being contracted into a ball, as in Agathidium; the club of the antennæ is three-jointed, and the penultimate joint of the tarsi two lobed. The various species are mostly found in flowers.

A. Ephistemus (Stephens). This genus differs from the preceding by having the palpi stronger, the maxillary with the basal joint being rather robust, the terminal one elongate; labial very short; mandibles, rather prominent, with the apex entire; antennæ rather elongate, approximating at the base, the two basal joints robust, the third more slender than, but not so long as, the second; the five following very short, globose; the remainder forming a triarticulate club, with the terminal joint obtuse; head minute; thorax slightly gibbous, a little narrowed anteriorly; elytra entire, slightly attenuated behind, rounded at the apex; body elongate-ovate, and sharp pointed at each end, somewhat convex; legs short; tibiæ slender, not spinose; tarsi very slender, all five jointed, the penultimate joint simple. Only three species have yet been found, and they were detected in the environs of London.

A. Leiodes (Latreille). Palpi scarcely filiform; maxillary with the terminal joint nearly cylindrical and acuminate, the preceding minute labial rather shorter, with the apical joint nearly ovate; mandibles somewhat protruded, acute. Antennæ, with the three basal joints nearly cylindrical, the third rather the longest, the three following short, nearly globose, the remainder forming a five-jointed club, the second joint of which, or the eighth of the antennæ, is very minute, and the terminal, or eleventh, large and subovate; tibiæ compressed, externally spinose; posterior sometimes bent; tarsi, four anterior five-jointed, slightly dilated in the males, two posterior four-jointed.

This genus is rather an extensive one, but the species are far from abundant in Britain, only twenty-six species being described by Stephens. They differ considerably among themselves, but may be at once distinguished from the other genera of this family by the minute eighth joint of the antennæ, or the second of the capitulum. The species are found in Boleti, Agarici, beneath the bark of trees, putrid wood, damp banks, &c.

A. Agathidium (Illiger). In this genus the palpi are filiform; maxillary with the last joint conic; labial small; mandibles with the apex acute; antennæ short, with a subovate club; head rather large, inflexed; thorax with the angles rounded, large, the sides inflexed; body globose, hemispheric, capable of being contracted into a round ball; elytra entire, inflexed laterally; legs short.

The Agathidium resembles Leiodes in several respects, but may be readily known by the structure of the antennæ, the eighth joint not being smaller than the seventh, and the three last forming a subovate club, which, however, varies a little in the different species; and from the facility these insects possess of rolling themselves up into a ball when alarmed. They inhabit putrid wood and fungi, and may be occasionally found in sand and gravel pits, into which they fall by accident.

Twelve species are described by Stephens, most of which have been found near London.

Genus Clambus (Fischer). Trophi minute; antennæ as long as the thorax, slender, pilose, the two last joints large, oblong, forming a club; head large, nearly or quite as broad as the thorax, rounded anteriorly; thorax transverse, the lateral margins more or less attenuated; elytra very convex, and gibbous anteriorly, attenuated, and declining posteriorly, the apex rounded; body contractile into a ball; legs short; tibiæ slender, slightly pilose; tarsi obscurely articulated.

Like Agathidium, the species of this genus have the power of contracting themselves into a ball when alarmed. From the genus just mentioned they may be known by the great width and bulk of the head, and by the club of the antennæ being composed of two joints only, a structure which also obtains in the genus Orthoperus: but in that genus the head is small, the elytra but slightly gibbous, and somewhat truncate posteriorly. As in the kindred genera, the species are found beneath putrid leaves and wood, or in fungi, and in sand and gravel pits, &c. Owing to their extreme minuteness, and the want of specimens, we have not been able to detail their generic characters so completely as could be wished.

Genus Clypeaster (Andersch). Trophi very minute; antennæ rather slender, the three terminal joints forming an elongate ovate compressed club; head minute, concealed beneath the anterior margin of the thorax, which is produced and semicircular; the thorax itself semioval, pubescent; scutellum minute, rounded; elytra ovate, slightly convex, the apex obtusely rounded, pubescent; legs slender, the posterior pair remote from the intermediate; tarsi slender, four-jointed, posterior with the terminal joint very long and curved.

The minute head of the insects of this genus, which is concealed beneath the thoracic shield, distinguishes it from clambus, from which genus it also differs by its depressed body, triarticulate clava of the antennæ, and semi-oval thorax; from Sericoderus, which has also the capitulum tri-articulate, the rounded apex of the elytra removes it; and Orthoperus has the head minute, not concealed beneath the thorax, and a biarticulate capitulum. The only indigenous species is found beneath the bark of trees, &c. at Darenth Wood.

Genus Sericoderus (Stephens). Trophi very minute; antennæ rather elongate, slender, the three last joints forming an elongate capitulum; head small, concealed beneath the anterior margin of the thorax, which is slightly produced; thorax sericeous, broad, sub-triangular, the hinder angles somewhat acute; elytra sericeous, slightly gibbous anteriorly, a little depressed behind, the apex distinctly truncate; legs slender; tarsi obscurely articulated.

This genus is at once known from the rest of the family by its truncate elytra, combined with the tri-articulated capitulum of its antennæ, minute head, and projecting anterior margin of the thorax, exclusively of other characters.

ANNELLIDÆ (from *annellus*, a little ring). A class of invertebrated animals, and the first of the four into which the *articulata*, or jointed animals, are divided in Cuvier's *Animal Kingdom*. See Articulata. In common language they are known as worms, leeches, and other names, according to the species and the habit. The annellidæ must not be confounded with the *annulosa* of some systematists, which includes all the four orders of articulated animals, and is therefore synonymous with that term. Annulose means that the body of the animal, taken in the direction of its length, is divided into a certain number of rings, segments, or joints, of which the principal ones are the head, the breast, and the belly: the distribution could, however, be much better described upon other principles than that of being so divided into *annuli*, which, in very many instances, have little resemblance to rings, being generally different from each other on the upper and under sides of the body. The annellidæ are free from those objections. Their rings surround the body, they are very small, and proportionally numerous. They seem also, in all the known species, to be the only substitute which the animals have for a skeleton; and they are the chief, indeed the sole, organs of locomotion, either by their own edges, or by means of small but stiff bristles, with which many of the species are furnished, singly or in little tufts. The power of expansion or contraction which those rings possess is truly wonderful, as may be seen in the common earth-worm, the leech, and especially the horse-leech. In other countries there are species which have this property in a still greater degree. Those leeches which are so annoying in Ceylon, and some of the other Eastern countries, when the earth is moist, by fastening upon the legs in multitudes, and which are as difficult to be removed as mosquitoes, can draw their bodies out to as fine a staple as the hair of the human head, or even finer, and thus it is scarcely possible to exclude them from any place. When drawn to their utmost possible thinness, they retain their strength, and thus they glide away with wonderful velocity, so that one can scarcely discern the expansion and contraction of the rings. Those that have this power have no bristles, or other substitutes for feet, upon the rings; so that they are enabled to bring the whole of these into action in each progressive effort. Their means of holding on are two suckers, one placed at each extremity; the posterior one being fixed when the body attenuates and lengthens, in advance, and the anterior one when the body thickens and is drawn towards the head. Thus these animals proceed by a sort of steps, each as long as the distance to which the body stretches when attenuated; and performed by the two suckers something in the same manner as if these were two feet; only the rear foot never comes quite so far in advance as the front one. Those with bristles to the rings do not move so rapidly along, but crawl and wriggle, moving parts of the body in succession, and not using the whole of it for single majestic strides.

The Annellidæ are, by Cuvier, designated "red-blooded worms;" because their blood is generally of that colour; and, which is not a little singular, the flesh, if flesh it can be called, of some of the land ones, has, both in its recent and its putrid state, nearly the same smell as that of the mammalia. Their bodies are more or less elongated, and more or less capable of elongation when they walk; they are always divided into numerous small rings, of which the first is usually styled the head, and contains the mouth, and probably the organs of sense, but the latter are obscure in all the species, and in some they cannot be traced. The mouth, in some instances, consists of jaws more or less developed and strong, and sometimes of a simple tube. There are no visible nostrils or ears; and the dark spots, which in some are regarded as eyes, are very questionable, and they are wanting in very many of the species.

The circulating system is double, consisting of both arteries and veins, sometimes without anything that can be considered as a heart, and sometimes with several distinct fleshy ventricles. The organs of respiration differ much both in position and in structure. Sometimes they are situated in the posterior part of the body, sometimes externally on the sides, and sometimes in the interior of the body. Those which inhabit the land, or the earth rather (for they live under the surface rather than on it), have the breathing apparatus always internal; and it must be considered as lungs. Those which inhabit the water (and the majority of them live more in the mud and silt than in pure water), have the breathing apparatus sometimes internal, when the body is naked, and always external when they live in tubes. The tubes which they inhabit differ however from the shells of the mollusca, even when these are tubular in their form. The annellidæ secrete part of the tube in all cases, that is, the cementing matter by which the harder substances are held together; and when the harder matter is salts of lime, they probably secrete these also. But the tube forms no part of the animal, and is not in any way attached to it; it is merely a house or case which it inhabits, in so far defended from danger, and which it has the power of enlarging as necessity requires. In all those species which inhabit the water (and they are far more numerous than the land ones), the breathing apparatus is to be considered as gills; and those gills are often of very elegant structure.

The nervous system consists of a double longitudinal chord, united in two or more ganglions; but it is difficult to trace the minute ramifications of the nervous tissue, and still more, perhaps, to determine the number of senses or the organs in which the specific ones are allocated. It is certain, however, that many of these animals have extreme sensibility in some way or other; but whether that belongs to the whole surface of the body, or to any particular portions of that surface, has not been, and in all probability cannot be ascertained. The use of the common leech, in foretelling changes of the weather, long before these are cognisable by any of the human senses, or even by the generality of hygrometrical instruments, is well known; and the common earth-worm is also exceedingly sensitive; but whether its sensibility arises from the mere concussion of the earth, or the air acting upon its muscular and sentient system generally, or whether it is to be considered as a peculiar modification of the sense of hearing, has not been ascertained. In the reproductive system, the greater number, if not all the class, are true hermaphrodites, but not, in as far as is known at least, self-fertilising in any of the species. In many of them, however, the pairing is reciprocal, the young are brought forth alive, and undergo no metamorphosis.

Though the place which the annellidæ occupy in nature appears to be a humble one, they are by no means without their usefulness. The marine species, which are by far the most numerous, supply a large portion of the food of many of the shore and bank fishes; and they furnish the fisherman with one of his most easily-acquired and useful baits. Of the land species, the use on land is not so clearly seen, because they generally disfigure lawns and other portions of grass which mankind wish to keep neatly trimmed; and as their chief enemy under ground is the mole, he, in his hunting after them, disfigures the surface much more than they do. Still about the time when larks and various other species of ground birds begin to flock, the common earth-worms are much on the surface, and afford the birds an abundant supply of food, while the young of the worms come in time to supply largely the young of many birds. It is probably in the waters, however, that even the land species are of the greatest utility. When the meadows are flooded during the rains the worms are driven from their holes under ground, and carried down in vast numbers by the current of the water; and whenever that water stagnates, and especially where it forms eddies, they are deposited, and the fishes, trout especially, are on the *qui vive*, feast daintily, and become rich prizes for the angler. Nor is it to these alone that the annellidæ are highly useful. Many of the flat-billed birds, whether they dabble in the shallows, or dive where the water is a little deeper, subsist in great part upon the annellidæ; and the flesh of those that do so is far superior to that of the species which live chiefly upon fish. The annellidæ, in many of their characters, have a considerable resemblance to the mollusca; and it is worthy of remark, that birds or fishes, which feed upon the one or the other, are generally superior in flavour to those which feed on vertebrated animals, and especially to those which feed upon radiated animals, many of which are understood to give poisonous qualities to the fishes that feed upon them.

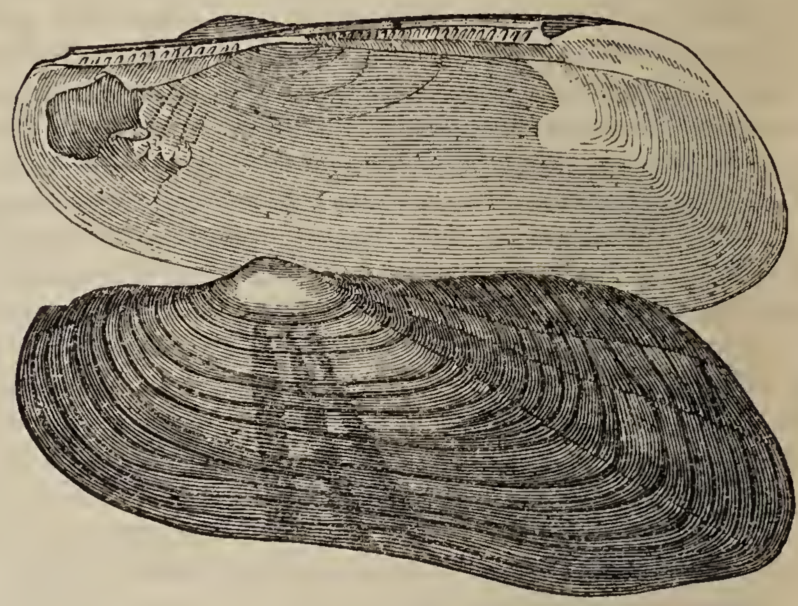
The annellidæ are, from the structure of their breathing apparatus, readily divisible into three orders, *Tubicola*, *Dorsibranchia*, and *Abranchia*.

Tubicola. These, as the name imports, inhabit tubes or pipes. Sometimes the tube is calcareous, of a structure tolerably uniform, though coarse and bearing some resemblance to the shells of mollusca; but in no case is it united to the body of the animal by any muscular or tendinous connexion. Tubes of this kind are generally understood to be formed of a sort of secretion or exudation, furnished by the body of the animal, but by what part of it has not been ascertained. The tubes of these often proceed by curious convolutions and ramifications along the surface of submarine stones; they are not found in fresh water. Other species unite together by a sort of cement, grains of sand, little pieces of mud, and portions of shells; and there are some which construct for themselves membranous tubes, formed entirely of flexible or horny substance, but their bodies are not more united to these, than when the tubes are chiefly composed of foreign substances. The animals of this order have the breathing apparatus in the form of small plumes of feathers, or minute branches of trees, exquisitely ramified, and attached to the head or to the anterior part of the body.

Dorsibranchia. These have the breathing apparatus spread over the surface of the body in the form of brooches, rings, scales, or tubercles. A small number of them live in tubes; but by far the greater part either live naked in the mud or swim freely in the water. All the species of the two orders now mentioned have their sides furnished with small bristles, stiff, and having a metallic lustre, sometimes single, and sometimes in little clusters or tufts; these bristles are to be considered as their organs of locomotion, whether along hard substances, through the ooze and mud, or through the water.

Abranchia. The animals of this order have not, as the name imports, any external organs of respiration that are apparent to common observation. Those which inhabit the earth, and of which the internal breathing apparatus must be considered as lungs, appear to breathe with the whole surface of the body, or at least by means of minute pores generally distributed over the surface. Those which inhabit the water and have the internal breathing apparatus, as gills, appear to breathe by receiving water into the internal cavities. This order admits of a very obvious division into two families: those which have the rings furnished with bristles, and those which have them without. Some of the first inhabit the land, and the most familiar type is the common earth-worm; and the others of that family mostly inhabit fresh water, and one species at least live in tubes. These move on by the action of their bristles; but they can move; for some distance at least, with either end foremost, as may be seen in the case of the common earth-worm, which, if it has the least bit of the tail in its hole, can speedily draw in the whole body. The common leech is an example of the second family, the members of which are chiefly aquatic: they move along solid surfaces by means of their suckers; and through the water by flexures of the body. See Lumbricus, Hirudo.

ANODONTA, *or more correctly* Anodon. (Lamarck); Mytilus, (Linnæus). A genus of molluscous animals belonging to the class *Acephalophora*; order *Lamellibranchiata*, and family *Submytilacea* of De Blainville's Malacology. The body of this shell is rather thick, slightly compressed, more or less oval; the mantle, with thick edges, plain or



Anodon Dipsas.

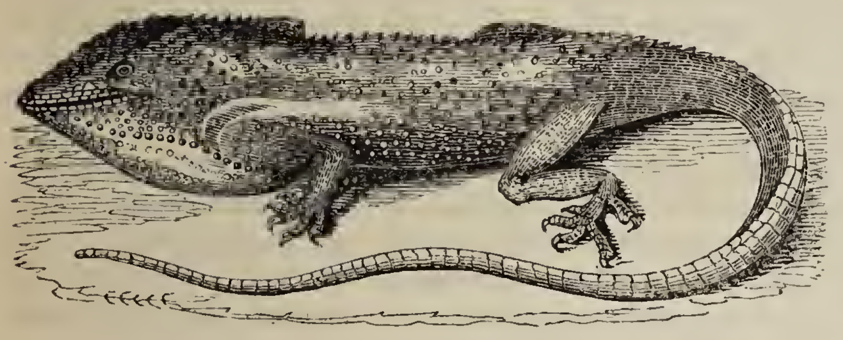
fringed, open the whole length of the circumference, except towards the back, a distinct oval orifice for the vent; a species of little tube, incomplete and fringed with two rows of rather long cirrhi, forming the respiratory cavity; the foot lamelliform and sharp. The shells of this genus have been separated from the Linnæan *Mytili*, with which however they are so nearly allied that it requires a careful examination of the hinge to distinguish them from each other; this genus, however, wants the cardinal and lateral teeth, and merely presents a smooth internal rim round the edge, whence it has very characteristically been named Anodon, from α, not, and ὀδοὺς, a tooth (having no tooth); this rim is terminated at the anterior end by a sinus or notch, in which the anterior extremity of the ligament is sunk or attached. This species of shells is usually eroded or rubbed by the frequent opening and shutting of the valves, which takes place while in the act of feeding or removing from one spot to another. The substance of the shell is pearly (*and some of the species produce pearls*); it is covered with a false epidermis; the valves are generally thin and concave, they occasionally attain a considerable size; the valves are similar in size, transverse, inequilateral, with two distinct internal muscular impressions, the ligament external, insinuated at the anterior extremity into the sinus of the cardinal ridge.

They inhabit ponds and lakes in every part of the globe, particularly in North America, and the animal is supposed to be viviparous; that is, to bring forth its young alive.

De Blainville divides this genus into five species: the first, such as are thin, oval, much elongated, not oared, the hinge very long, straight, and crenulated its whole length, as in the *Anodon exotica*, which forms Lamarck's genus *Iridina*; the second species are oval, with the hinge arched, and without any trace of ears, as in the *A. rubens*; the third species are oval or elongated, a linear hinge, and oar-shaped at the anterior only, as in *A. cygnea;* the fourth species is oval or rounded, auriculated at both ends, as in *A. trapezialis;* and the fifth is much more auriculated, with a lengthened blade, and much more salient at the hinge, as in *A. Dipsas*, of which Leach has formed his genus *Dipsas.*

Lamarck enumerates fifteen species; but it is certain that more must exist in those countries over which scientific research is now rapidly extending.

ANOLIS. A genus of saurian reptiles belonging to the family *Iguana*, having, like the rest of that family, teeth on the palate, and resembling the lizard agamas (*Polychrus* of Cuvier,) of which the marbled lizard of Guiana is the type more than any other genus. They also have some resemblance to the Geckos; but still they possess sufficient characters of their own for constituting them a genus.



Anolis equestris.

Their most distinguishing character, and the one in which they are intermediate between the genera that have been mentioned, is the structure of the feet. These in the lizard agamas are covered with scales on the whole of the under part, and in the geckos that part is without scales, and formed into adhering pads or suckers, by means of which they can run up or down a perpendicular wall, or even along the ceiling of a room or the roof of an oven with the back undermost. The anoles have scales on the under sides of the terminal joints of the toes only; the next joints are extended into soft pads, but these have not the property of adhering, so that the animals can neither walk with the back undermost, nor ascend a perpendicular surface in any other way than by holding on with the claws.

Their haunts correspond, of course, with the structure of their feet: they do not inhabit places so humid as those sometimes inhabited by the lizard agamas, and they do not climb so exclusively as the geckos. They inhabit places which are dry, sometimes on the ground or the rocks, and sometimes on trees, in the holes of which they usually nestle, but they do not climb to any considerable height. They are agile and lively, leaping much, and one of the chief uses of the pads on the toes is to break their fall, or make it easy, though it also prevents their slipping upon the irregular substances over which they pass with much rapidity and ease. The claws, instead of being flattened, as in those genera which walk chiefly upon the earth and occasionally on humid ground, are long, round, considerably hooked, and have some resemblance to those of climbing birds.

The head is rather elongated and straight, and covered with small five-sided or six-sided scales. The body is rather slender and firm, the ribs being united to each other below, and forming a series of rings all round the body. The tail is in all the species as long as the body, and in some longer, tapering to a point, compressed in some and nearly round in others. In those which have it compressed, the processes on the upper part of the vertebræ are produced, and support a row of scales, which form a serrated ridge or keel, continuous from that of the upper part of the body. Those in which the tail is nearly round have the serrated keel along the ridge of the body, but not on the tail.

In both, but most conspicuously in those that have the tail compressed, the hind legs are much longer and stronger than the fore ones; so that, while, in walking, the arm from the elbow downwards is nearly perpendicular, the knee joint is bent till the heel almost touches the thigh. This structure indicates considerable power in leaping by the extension of the knee joint; and the formation of the tongue shows that the animals must take their prey by leaping. The tongue is not protrusile beyond the mouth, nor divided, or furnished with fibres, or an adhesive liquor, or any other means of prehension: it is smooth, and adheres to the floor of the mouth for nearly the whole of its length. The animals cannot therefore capture their food with the tongue, but must leap at it and seize it with the jaws. That structure necessarily gives much more liveliness of motion than if they lay in wait, and used the tongue as a snare in the capture of their food. It is to be presumed also that they live upon larger prey than the tongue-feeding saurians. Their food is not exclusively animal, for some of them climb trees, or shrubs at least, and feed upon berries. They have the power of inflating the throat to a very considerable extent; but the use of that operation in any reptile (or fish) possessing the means of performing it, is not known.

All the species, of which there are about eight, are inhabitants of the warmer parts of the American continent. They are most numerous within the tropics, but some of them are met with in the southern parts of the United States. They are always found in dry places, and generally where there are hard and shrubby plants, but seldom in the thick forests in the bottoms.

It has often been stated by authors that they answer the same purpose in the Western continent, as the chameleons do in the Eastern; but the structure and habits of the two genera are so different, that no useful or even possible analogy can be established between them, any more than between the greyhound and the glutton, which, comparing one class of animals with another, is about the best comparison that can be made. The chameleons have anisodactylic feet: all the toes of the anoles are free. The chameleons have prehensile tails: the anoles have not. The chameleons have the power of distending the skin of the whole body, by the copious inflation of their ample lungs: the anoles merely inflate the throat, without any particular reference to the operation of breathing. The chameleons have very large and prominent eyes, though in great part covered by the eye-lids; and they can look two ways at once, to such an extent of divergent squinting, as almost to command the whole horizon: the eyes of the anoles are of moderate size, placed like those of the majority of animals, and looking both the same way. The chameleons are liers in wait, and capture the whole of their food by means of the tongue, which is protrusile to perhaps a greater proportional extent, and with more rapidity, than that of any other animal: the anoles catch all their prey with the mouth, and arrive at it by speed of foot. Such are the grounds of analogy upon which it has been so often said and repeated that the two genera occupy the places of each other in the two great continents. Perhaps the best expression of their characters, in few words, is to say that the chameleons are singular; the anoles admirable.

They are indeed the beauties of the saurian race: their forms are light and delicate; their colours often rich; their expression mild and gentle, yet (as one would say) full of speculation; and their motions more resemble those of birds than of merely footed creatures. They start, they leap, they climb, bounding now here now there, as if life were to them one continued holiday; and as they are found chiefly in the dry and healthy spots, they seem to point out to man where he should take up his dwelling. They are mild and inoffensive, but they are not timid: they do not skulk away from our sight, as is the case with those reptiles which have the power of mischief in them. They move, "come when they are called," for if the chirp of at least some of the species is imitated, they come out of their holes, and approach man, as if to know what he wants, eyeing him mildly but steadily all the time. This curiosity, or whatever it may be called, often costs them their lives, as the boys call them, and then capture them with snares. They are, however, animals which it is desirable to protect, as well on account of their beauty, their lively motions, and their frank and confiding manners, as of their usefulness in keeping down those broods of insects which are both annoying and destructive. In short they are animals, in whatever point of view we survey them, which man should always think twice before he destroys.

The species are not very well made out, but the most beautiful, though rather the smallest in size, appear to be those which have not the serrated keel on the basal part of the tail. Among them the red-throated anolis (*anolis bullaris*) is the finest in its colours. Its prevailing tint is green with golden reflections in some lights, and a black spot upon each cheek. The dilatable skin on the throat, when not inflated, is of a dark russet colour; but in the course of the inflation it passes through many tints, with more rapidity than even the skin of the chameleon; and when fully distended, it is of a bright cherry red, glossy and shining. This species is found to a considerable distance northward in the United States, and also in the West India islands. With the exception of the keel on the tail, and differences of size and colour, the species are so much alike that the detail of them is unnecessary for popular purposes; and enough has already been mentioned to point out their general characters, and the place they hold in the scale of animated being.

ANOMIA (Linnæus, Lamarck, Cuvier). A genus of shells, belonging to the class *Acephalophora*, order *Lamellibranchiata*, and to the family *Ostraceæ*, of De Blainville's system of Malacology.

The animal inhabiting this shell is very much compressed, the edges of the mantle very thin, not adhering, and furnished on the outside with a row of tentacular filaments; the abductor muscle is thick, divided into three portions, of which the largest passes partially through a notch on the lower valve, adhering to marine bodies by a small *calcareous piece* at its extremity, which in some species is wanting. The shell is adherent, irregular, inequivalve, inequilateral, and much resembling an oyster; the inferior valve flatter than the upper one, divided at the summit into two branches, forming a notch or an aperture of an oval form; one of them, large and thick, forms the part to which the ligament is attached; the superior valve is much larger and more convex, with an oval excavation beneath the summit, for the other attachment of the short and thick ligament; a subcentral muscular impression, divided into three parts.

Like the oyster, the anomiæ possess no locomotive power, they live and die on the spot which gave them birth; the small osseous portion by which they are affixed to marine bodies has been mistaken by some persons for a third valve, but it is, in fact, no more than the thickened extremity of the tendon, or interior muscle of the animal, by means of which it becomes attached to the object on which the egg was hatched. It is so constructed as to close the hole or notch, at the summit of the upper valve, when the muscle of the animal is contracted. In this genus the smaller perforated valve is the lower one, being always placed in contact with and conforming to the shape of the substance upon which it lies; in the oyster, on the contrary, the larger and the most concave valve is the lower one.

Poli describes the animal of this shell as being very similarly organised with that of the oyster, and its habits appear perfectly congenial.

It is not easy to characterise the shells of this genus; Lamarck enumerates nine species, other writers have mentioned a greater number; but from their assuming in most cases the form of the substance to which their thin valve is affixed, that circumstance may be presumed to have led to an erroneous conclusion of their being distinct species.

Anomia ephippium.

The two divisions De Blainville has made are such as have the small osseous appendage to the muscle, and such as have it not; the first is exemplified in any *Anomia ephippium*, the other is the *A. squamata*, which is affixed by the valve itself, a figure of which is here given, to the object on which it was hatched. Lefranc admits ten fossil species.

The difficulty of defining properly the classification of these shells, probably occasioned their having been named anomia, α, not, and νομος, law, (*without law*), implying that they did not fall within any law or system of arrangement established with respect to other species of mollusks.

ANONACEÆ. The fourth order of the Jussieuan system. It contains nine genera, *viz.* Anona, Monodora, Eupomatia, Asamina, Uvaria, Unona, Artabotrys, Xylopia, and Guatteria. Of these there are forty-seven species. The genera are all trees or shrubs, and mostly tropical. The fruit of the Anona

ANONA SQUAMOSA. *a*, the flower; *b*, fruit; *c*, the same in section, showing the position of the seeds; *d*, seed; *e*, the same in section, showing the position of the embryo.

are estimable; and, under the name of Custard Apple, will be more fully described. The Ethiopian pepper of the shops is the fruit of the Uvaria; and in South America the bark of the Xylopia is used for cordage.

ANOPLOTHERIUM. A genus of extinct animals, belonging to the order *Pachydermata*, which is found exclusively in the fossil state. Nothing, perhaps, can show more fully the perfection and precision to which the study of comparative anatomy has been brought, by the indefatigable researches of the great naturalist Cuvier, than his discovery of various extinct genera and species of animals, by the application of those invariable laws upon which organised animal bodies are formed. By the application of these laws, the skilful comparative anatomist is enabled to re-construct, as it were, the whole animal, and to form certain and indisputable conclusions as to their habits and mode of living; thus bringing into view beings which have long ceased to be inhabitants of this earth: many of which are distinguished as much by their remarkable forms, gigantic stature, and massive proportions, as by peculiarities of structure, to which nothing analogous at present exists.

These results being so remarkable, a concise account of the principles upon which such conclusions are founded may not be considered uninteresting. The fundamental law upon which every other depends is, that every organised being must of necessity be considered as a whole, possessing a peculiar system of its own; every part of which is in strict accordance with each other, and all concurring to produce a certain definitive action by a reciprocal reaction. No change can possibly take place in any of these parts without producing corresponding changes in the others; and consequently each part taken separately exhibits and enables us to ascertain all the others. Thus an animal whose stomach is so constituted as to enable it to digest recent flesh only, will have every part of his frame strictly in accordance with this arrangement. A peculiar system of dentition must prevail, as the teeth must be sharp-edged in a greater or less degree, as they have flesh more or less exclusively to divide; and their bases will be solid, according to the quantity and size of the bones they will have to break. The jaws must be powerful, and the condyles of a peculiar form. These, however, would be of but little service to the animal, unless it had claws for seizing and tearing its prey. These, again, absolutely require a peculiar construction of the phalanges, joined to a facility of rotation in the fore arm, and analogous changes in the humerus. The whole system of their organs of motion for pursuing and overtaking their prey must also be strictly conformable to the other parts. On the other hand, it is perfectly evident, that all hoofed animals must be herbivorous, as their feet afford no means whatever of seizing their prey; accordingly we find their masticating and digestive organs correspond with this peculiarity, their teeth having flat unequal crowns suited to the bruising and grinding their food, and every other part agrees strictly with their peculiar system.

Such are the principles which Cuvier applied to the investigation of the bones found in the plaster-quarries near Paris; and he quickly, to his astonishment, perceived that there were many genera and species among them which had no living antitypes. On those immutable laws which nature has prescribed to living beings, he proceeded to reconstruct these ancient animals, and a creation, long since extinct, rose to his view. Nothing, he says, can express his pleasure as he perceived, on the discovery of each peculiar character, the consequences he had predicted gradually and successively unfold themselves. Thus he found the feet correspond with the peculiarities announced by the teeth, and the teeth, in like manner, with those indicated by the feet. All the other bones proved also conformable to the judgment previously formed by him from the consideration of other parts. Among these he found one genus distinguished by two characters unknown in any other animal, viz., by the teeth being in a continuous series without any intervening gap (a structure observable in man alone), and also by having two toes, whose metacarpal and metatarsal bones are separate on their whole length. From the circumstance of the canine teeth being short and similar to the other incisors, he gave it the name of *Anoplotherium*, or a beast without weapons. It has six incisors in each jaw, one canine, and seven molars on each side, both above and below. The first three molars are compressed, the four others in the upper jaw are squared with transverse crests, and a small cone between them in the lower jaw; they form a double crescent, with a neck at the base. The head of this animal was of an oblong form; and there is no appearance indicative of the existence of a proboscis. They are divided into three sub-genera, the anoplotheria, properly so called, the xiphodus, and the dichobuner, whose distinctions are founded upon slight differences in the crescents and other parts of the teeth. Of the first division, the *Anoplotherium commune* was about the size of a wild boar, but much longer in the body, and had a tail of enormous length, equalling, if not surpassing, the body; and there is reason to believe that its thickness was also very considerable. There is also another species, a little smaller, called by the Baron *An. secundarium*. There is but one *Arphodon* known; it appears to have been very slender and delicately formed, much like the gazelle; to this the name of *An. gracile* has been given.

Of the last division, the *Dichobunes anoplotherium leporinum* is about the size of the hare; and besides its sub-generic characters, it is distinguished from the two former divisions by its having two small and slender toes on each foot at the sides of the two great toes. Two other species have been observed, which appear to have been very small animals.

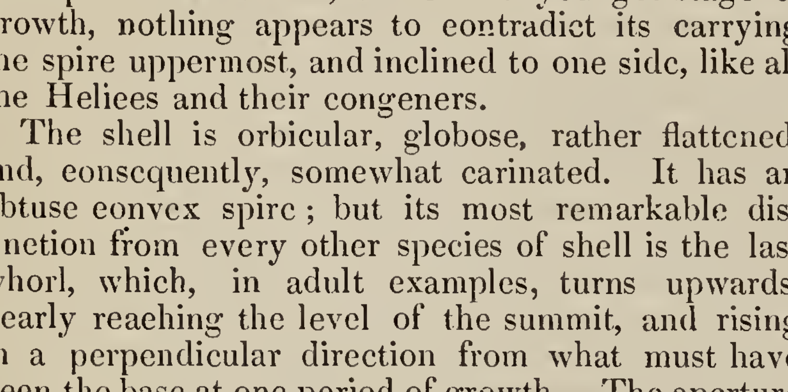
These remains have hitherto been found only in strata, belonging exclusively to the Eocene period of

Lyall. They are exceedingly abundant in the fresh water formations, which are exposed in the gypsum quarries near Paris, and have also been detected sparingly, in similar deposits, in other parts of France; and a tooth referrible to this genus has been discovered in the quarries at Binsted, in the Isle of Wight, which also belongs to the same period; and it is not improbable that future researches will point out various other localities of this highly interesting fossil.

ANOSTOMA (Lamarck, Cuvier). *Helix ringens* (Linnæus). *Tomogerus* (De Montfort). In De Blainville's system of Malacology, this shell is classed with the family *Limacinea*, of the order *Plumobranchiata*, in the class *Paracephalophora*.

The animal inhabiting this extraordinary shell is not as yet known; but it may reasonably be presumed to differ in *many* respects from that of the well-known Helix, with which it was classed by Linnæus; though De Blainville is of opinion that it probably differs but *little*. The structure of the shell clearly indicates that on the completion of the final whorl, with its reflected and dentated lip, the animal would then be compelled to carry its dwelling with the spire downwards; while in a younger stage of growth, nothing appears to contradict its carrying the spire uppermost, and inclined to one side, like all the Helices and their congeners.

The shell is orbicular, globose, rather flattened, and, consequently, somewhat carinated. It has an obtuse convex spire; but its most remarkable distinction from every other species of shell is the last whorl, which, in adult examples, turns upwards, nearly reaching the level of the summit, and rising in a perpendicular direction from what must have been the base at one period of growth. The aperture is rather oblong than round, and horizontally attached to the body-whorl on the upper side, presenting two strongly defined teeth or plaits on the columella, with three, or sometimes more, on the right side. The outer lip is reflected on the side not affixed to the spire; and, in one of the species, there is a very small puncture on either side of the lip, not noticed by Lamarck. It may not unaptly be compared in form to that of an antique Etruscan lamp.



Anostoma globosa.

There are two species described, the *Anostoma globosa* and the *adepressa*. The former is here figured in two points of view. They are terrestrial shells inhabiting the East Indies, and are extremely rare. The name is derived from *ανος*, upward, and *τομα*, a mouth, (the mouth turned upward,) which is so admirably descriptive of its peculiar structure, that it appears singular De Blainville should have adopted De Montfort's name, *Tomogerus*, without he wished, by so doing, to distinguish it, beyond all manner of doubt, from the genus *Anastomus*, established by Illiger in ornithology, and Cuvier's *Anastomus* in Ichthyology, with which it might possibly be confounded by persons ignorant of the derivation of its name, or from a similarity of sound to many ears.

ANOTTA (Linnæus). Called by botanists *Bixa orellana*, a South American genus of three species of lofty trees; class and order *Polyandria Monogynia*. Natural order *Bixineæ*. Generic character: calyx of five sepals; sepals imbricated in opening, knobbed at the base; deciduous petals inversely egg-shaped; stamens below the germen; filaments like threads; anthers ovate; style elongated, the top like a thin tongue; capsule like an egg or heart, rough, two-valved, valves furrowed, seed contained in a farinaceous pulp; albumen fleshy; seed-leaves foliaceous and flexuose.

ANSER—Goose. A well-known genus of flat-billed and web-footed birds, belonging to the family of *Anatidæ*, and usually ranged between the swans and the ducks. Considered as a genus they are, perhaps, the least aquatic of the family, and feed more upon vegetable substances. By the semipalmated goose, of which the feet are very imperfectly webbed, they are connected, in some respects, with the swans and also with the cranes. The chief structural peculiarity is the convolutions at the bronchial end of the trachea. But in the cranes and swans, these, if extensive, are imbedded within the bones; whereas in the semipalmated goose they pass outside the muscles, and along the side of the animal just below the wing, without any defence save the common integuments. The investigations of Mr. Yarrell show that these convolutions are not always of the same form; that they are sometimes on the right side of the bird, and sometimes on the left; and that, whatever side they are on, the clavicle on that side is enlarged, and has upon its inner surface a projecting point to which the trachea is attached. If these variations in the internal structure of the bird are general or common, it is rather unusual, as the structure of the internal parts is generally understood to be uniform in the same species.

At the other end of the genus, the geese approach the ducks, in the Egyptian goose, which, in the form of the trachea, in the male at least, has an enlargement of bone similar to that in the fresh-water ducks, or those of the first division. See Anas. In the latter bird the habit is found to correspond with the structure; for the Egyptian goose is, in some respects, as much a duck as the sheldrake: it has even the bright colours of the ducks, which are not found in any of the geese properly so called.

Besides the two species that have been mentioned, it is not known that any of the geese have an enlargement of the trachea; and they are seldom in the habit of finding their food under water. If the expression can be admitted, they are more of grazing birds than any others with which we are acquainted. Their leading characters are: the bill of moderate length, narrowed to the tip, and the upper mandible rased at the base, so as to make the height there more than the breadth, and having a nail on the tip; the body thick and heavy; and the legs strong, and articulated near the centre of gravity. For the general appearance and characteristics of the species, see Goose.

ANT (*formica*.) A very common, very numerous, and highly interesting genus of insects, with the appearance of which every one is so well acquainted, that a minute description of it is not necessary. They belong to the order *Hymenoptera*, or that of insects with four membranous wings, in which the nervures or shafts are comparatively few and inconspicuous. They belong to that section of the order which have no auger, an instrument for boring holes in the bodies of animals or the substance of vegetables, in order to place their eggs there for the purpose of being hatched; but the females of many of the order have stings with which they inflict poisoned wounds. The ants however have no stings, but, at the place where the sting is usually situated in others of the section, they have glands which secrete a very pungent liquid; and this liquid they are sometimes supposed to insinuate into the wounds which they make by biting with the jaws, thereby causing a great increase of pain to the creatures bitten.

Cuvier forms the ants and some closely allied species into a distinct family, under the very appropriate name of *Heterogynia*, from the very peculiar distinction of the sexes. Of these there may popularly be said to be three: males, females, and undeveloped females; that is, individuals which have, the wings excepted, the external form of the perfect females, but the sexual parts are merely rudimental, and they have no sexual propensities. These last greatly exceed the others in numbers and in activity; and, except in the analogous cases of the bees, and some other insects which inhabit warm countries, they form quite an anomaly in the history of nature.

It should seem that the lives of all those insects, which have this threefold distribution of sexes, are exceedingly laborious, more so perhaps than those of any other living creatures; and, as they are exceedingly numerous and have many enemies, they multiply at a rate much greater than that of most insects. Their young are also reared with more care, and their social habits, their diligence, their ingenuity and their courtesy to each other are quite exemplary. The eggs of most insects are left to nature; they are deposited in or upon substances which shall afford nourishment to the young as soon as they are hatched, and thus they are left to find their way to the last or perfect stage of their existence as they best can; their parents being in general previously dead, the father before the eggs are deposited, and the mother very soon after. All those insects, which are thus reared without attention, grow up to be perfect males and females when in their last stage, though they have no sexual distinction or propensity in the previous ones; and the grand work, in the case of many at least, in this last stage, is to secure a generation of successors and then to die; and the life which is devoted to this single purpose is often only a few hours, and sometimes only a few minutes in duration.

Of these insects, many are often exceedingly laborious, and curious in their labours, when in the grub or larva state; but among the ants and the other species which, like them, have the greater number consisting of undeveloped females, no labour, excepting perhaps that of spinning a cocoon in which to pass the chrysoloid state, is performed till they arrive at the last and perfect stage. But it is curious to notice that the analogy of insect life is so far kept up as that the ones which have a perfect sexual development are exempted from almost all labour in these, excepting such labour as is connected with the perfecting and depositing the eggs, the subsequent rearing of which devolves chiefly upon the undeveloped females.

There are some indeterminate points in the natural history of ants, which throw doubt and perplexity upon the whole of it; and though there is certainly no inconsiderable degree of analogy between ants and bees, of which the history is more complete, yet the analogy is of that loose and imperfect character which is very apt to mislead. In the more social bees it is doubtful whether there is even, for any length of time at least, more than one perfect female, except young ones, which are rearing a succession. In large communities of ants there are many such females, and it does not appear that they evince towards each other the same deadly hostility which is shown by the female bees. In both races, the pairing appears to take place external of the nest or habitation, and probably only in the atmosphere on the wing. When the eggs of both are deposited, they are to appearance all exactly alike, whatever is to be the character of the beings produced from them; and it is here that the analogy becomes imperfect, and the natural history of the ants obscure. It is tolerably well ascertained that in bees, at least in the common hive bees, the undeveloped females, or the neuters, or workers, or nurses as they are sometimes called, have the means of determining what sort of progeny shall issue from the eggs; and that, by placing an egg of the very same description in three different magnitudes of cells, and feeding and attending it in different ways, they can make it a common worker, a male, or a female (or queen, as the perfect females are styled) just as they see occasion. We know nothing of the principle which leads them to do the one or the other; and therefore we say that it is the result of *instinct*, a name which comes in very conveniently to conceal our ignorance in all cases where, in truth, we know nothing about the matter. By means of this instinct, however, it is evident that a community of bees, whether great or small, can so regulate the numbers of its three classes of members, as that they shall always be in that proportion to each other, which is most conducive to the present welfare and the succession and continuation of the race. See Bee.

It is here that our knowledge of the ants is deficient, and hence the whole of the natural history is broken and imperfect; for the natural history of any animal resembles a machine in this, that the whole of its parts, taken together, are no better than the most imperfect of them taken singly. The neuter, or nursing ants, certainly do pay a great deal of attention to the young, up to the period of their escape from their cocoons or pupa cases, after which they are able to shift for themselves as independent members of the community. They expose them to certain genial degrees of temperature, generally in the mornings; they remove them from the strong action both of heat and of light; they remove them from the influence of damp and rain; and they feed them when in the larva state. But it has not been ascertained that the difference of sex, or of development of sex, depends upon any specific treatment which the young receive in any one of these stages; and this is the grand blank, the filling up of which is necessary, not only to complete the natural history of ants, but to make it rational and philosophic so far as it goes. Analogy would lead us to suppose that the neuter or working ants, on which the burden of the community, in a great measure, devolves, should have such a controlling power as well as the working bees; but this is a case in which we can trust but little to analogy.

There is another point upon which information is also much wanted, and that is the time and manner of development of the wings both of the males and females. Those organs are not required for the ordinary purposes of life as they are in the bees, and therefore the undeveloped females, that is by far the great majority of ants, never acquire them. In the males and females they are apparently absolutely necessary for the purposes of pairing, and the continuation of the race; and for that purpose both sexes appear in great numbers furnished with them in the warmer months. But when we endeavour to ascertain when they come, how they come, whether they accompany the sexual development, or come after it, whether the perfect sexed animals are furnished with them when they escape from their pupa cases, or whether they are developed by some future process in the individuals themselves, or some difference of treatment from the rest of the community, we are left entirely in the dark, and here again, of course, the history of those very singular creatures is quite vague and uncertain.

In the ants, as in all insects which contain a number of individuals with the sexual powers undeveloped, all the males that appear are perfect animals; but to all useful and efficient purposes, they are mostly inferior even to the undeveloped females. They seem formed for the single operation of pairing only, and that once performed they die. They have no weapons of self-defence; they have scarcely the means of finding their own food; and they take no share whatever in the labours of the community. Among bees, as soon as their seasonal services are over, they are tumbled headlong from the hive or slaughtered on the threshold; and among the ants, after they have once left the hill for their seasonal purpose, it does not appear that one of them returns, or is indeed suffered to return.

The probability is that, in our climate at least, neither the males nor the perfect females of the ants survive the winter; and that only the labourers, or undeveloped females, pass the inclement season in a dormant or hybernating state, until the weather becomes so genial as to call them forth anew to energy and labour. This point, however, depends upon the indeterminate one already mentioned, and till that is determined, it must remain indeterminate also.

It is true that no winged ants appear in the earlier months of the season, although then the wingless ones are equally numerous and industrious. But no sooner does the strength of the equinoctial heat come, than winged ants are by no means rare in every locality in which ants of any description are met with; and in those places where ant hills are large and numerous they are often found in such numbers as absolutely to cloud the atmosphere. Now, the question here is, whence come those winged ants? Do they hybernate wings and all, or are they transformed out of the working ants, by some process which these have the power of performing? The latter may be the case with the females, but with the males it is exceedingly doubtful; and the only account which, in the present state of our knowledge, is, that we know nothing about the matter. It is true that the pairing of the warm months *may*, as in the autumnal pairing of aphides, impregnate more than one generation of females; it is also true, that the perfect females, after they have deplumed themselves of their wings, and deposited their brood of eggs, may turn to the state of imperfect females; and in that state pass the season of hybernation, and also the more early and inclement portion of the spring and summer. None of these suppositions, however, account for the midsummer appearance of the males; and as they are merely conjectures with regard to the females, this, one of the most important points in the natural history of the race, must remain indeterminate until accurate observation shall throw the necessary light upon it.

But wherever they come from, or in what manner soever they are produced, the males and females do meet in the air, in vast numbers, at the season which has been mentioned; and as this is the only instance we have of the pairing of the parties, we must consider it as the annual preparation for the grand reproduction of ants.

Indeed, it seems expressly, and only for this period, that both males and females are furnished with wings, as they never use them at any other time or for any other purpose than that of meeting each other on those aërial excursions. There are some circumstances too, which would lead to the supposition that the wings and the sexuality are developed by the joint action of the season, and of some peculiar mode of treatment on the part of the labourers. Every one knows that the common ants are very sensitive to the weather, and that the passage of the slowest and most momentary cloud over the sun will produce a change in their operations. At large ant-hills, they may, for some time previous to the appearance of the winged swarms in the air, be seen restraining the escape of both males and females, hauling them back by main force by the wings and legs, and taking them under cover, and keeping them there, as if aware that the proper time, or rather the proper temperature, for their departure had not arrived. After the swarms in the air begin to make their appearance, there is no longer any struggle to prevent either male or female from quitting the ant-hill; and after that period there is no instance of the working ants hurrying a male back to the hill, or giving themselves the least trouble about him. With the females it is different; and numbers of the working ants may be seen running about in all directions in search of these, which are understood never to alight from the wing till they are impregnated, and as seldom to mount into the air afterwards.

The crowds in which winged ants appear in some countries at certain seasons show the vast number of these insects, without taking into account the neuters, which are a large majority of the whole. To those who have been in the habit of examining them, the males are easily distinguished from the females, they are considerably smaller, much more slender, and so feeble on the legs that they can hardly walk. The wings of the females are very thin and filmy, but in other respects they are robust, and they walk well. It does not appear that the male ants are able at all to contend with the wind, which bends their wings, and blows themselves before it like dust. Indeed it is probable that none of the males remain in the air longer than a single day; and it is doubtful whether the females remain as long. The absence of the queen bee from the hive, when she sallies forth for the same purpose, does not exceed half an hour, and yet a foundation has been laid for an entire new swarm of bees, drones, queens, and altogether. As the female ants are not understood to be individually so fertile, there is no reason to suppose that their aërial excursions are of longer duration. Hence, in an ant country, the number in all the successions must be absolutely countless; and, as is the case with bees, the males probably are manyfold more numerous than the females. Clouds of males chiefly, if not exclusively, have often been blown on the surface of waters, to the shores of the sea, and into the streets of cities, in some of which they have been so numerous as that they might have been taken up in handfuls; and in some parts of this country, the roads crossing the pine forests, which on particular soils are favourite places for ants, are literally covered with them. It should seem, however, that all which are found thus have answered their purpose in nature, and so it is of little consequence whether they fall down and die in one place, or be wafted by the wind to die in another.

The females escape these casualties by their superior strength, and their descent to the ground; after which they remove their wings as quickly as possible, and are then not very easily distinguishable by a common observer from the ordinary labourers.

The casting off of their wings is a grand era in the lives of female ants; for at that time each one seems to be inspired with the ambition of founding a nation. This erratic propensity causes the distribution of ants, even those that are the most social, to be so very general in places well adapted for them. It is not many, however, at least not the majority, which are able to carry this scheme of general ambition into effect, for the workers are just as inhabitive as the females are discursive; and, as if they felt their bones ache (or rather their muscles and skins, for they have no bones) with the labour of building their existing cities, towns, and palaces, they exert themselves to the utmost in order to prevent these from becoming desolate through a failure of their progeny, which, though they can tend with the fondest and most solicitous care, they can in no wise originate but by laying hold of and detaining their fertile sisters. From very large ant-hills the number of scouts sent out upon these occasions is proportionally great, and so is the extent of surface over which they range. Indeed the inhabitants of a very large ant-hill have, generally speaking, to work much harder than those of a smaller one, inasmuch as their larger supply of food must be brought from a greater distance; so that even among ants there seems to be a practical inconvenience in overgrown communities, and the labourers must toil more severely both in finding their own food, and in nursing and feeding the young, than when the community is of more reasonable size.

The writer of this article has seen very large deserted nests of the common wood ant, while there were little hillocks all round, inhabited probably by fragments of the erewhile mighty nation; and the scene had at least some resemblance to the Arab building his hut or erecting his tent beside the mighty remains of Thebes or of Tadmor: so pass the ancient glories of ants as well as of men. In other somewhat overgrown hills of the same species he has been able to trace more great roads diverging from the hill in all directions than diverge from London to the different parts of England; and what is most remarkable for travellers, individually so light, the roads, though across pretty sturdy short heather, were beautifully smoothed and beaten. In the immediate vicinity of the hill, that is, for the first yard or two, there appeared to be but little passage from one to the other, as if that portion of the pastures had been but little worth searching; but as the distance increased, the roads became gradually obliterated, as there the industrious inhabitants seemed to begin seeking food for themselves and their young in real earnest.

From the number of labourers which are on the alert all day long about the time of the pairing, from the comparatively little that there is then to perform in the ant-hill, as there are then no males or females to feed, and the consequent probability that the workers, having nothing to do but to find their own food, enjoy their holidays, and rest in the fields whenever they are weary, there is as wonderful a distribution of them over all surfaces that can be considered ants' pastures, as there is of females in the air; and though it has sometimes been said that a female goes to found a colony for herself, nobody has ventured to set it down in print that they have seen the fact in free nature with their own eyes, and indeed it is not very probable, nor is it very clearly established, that a female is capable of rearing and feeding her brood without assistance, or even that she lives to do so. Her grand work seems to be accomplished in the laying of the eggs, and as individuals, proved to be perfect females, have never been found assisting in nursing in the larger societies, it is rather against the analogy that, under other circumstances, they should perform the whole of that labour.

It is certain, however, that many females never return to the society from which they departed, for it is ascertained that wandering parties of the labourers, and probably parties from different hills or nests, finding situations fitted for their purpose, seize these stray females and found new colonies.

When the females have got rid of their wings, and have been conducted to an old hill, or had a new one made fit for the purpose, they immediately begin to deposit their eggs, which is done under ground, and even the average number is not known; indeed, at this point the history begins to be very obscure, as though the eggs can be found at all stages of their growth, from the recent in which they are small round white, and of a pearly lustre, up to that in which the perfect animal is ready to be liberated from its film, they are always under the immediate and most solicitous care of the workers.

These carefully regulate the depth in the earth, degree of heat, moisture, and all other circumstances necessary for hatching the eggs. As the process goes on the eggs enlarge very considerably in size, especially in length, and gradually become transparent; and when they have acquired their greatest length, the larvæ come out as grubs, which are of an arched form, but incapable of performing any very important functions, or even feeding themselves. That is done by the all-attentive neuters, which, as the larvæ are much more delicate than the eggs, are more solicitous in guarding them against extremes of temperature; and they feed them from their own stomachs, but whether with their common food partially digested, or with a peculiar fluid, has not been clearly ascertained. At all events, though these undeveloped females are barren they are not dry nurses. In this there is involved another argument against the fertile female ever rearing a brood without the aid of these nurses. How many of the nurses are necessary for the feeding of one larva, does not appear to have been examined; but from the voracity with which almost all larvæ eat, it is highly probable that more than one are required; and, therefore, to speak about one mother supporting two or three dozen, looks at least very suspicious. When the larvæ are full grown they enclose themselves in membranous cocoons or cases, in which they undergo the rest of their changes until they are fit for coming into activity; and it has been said that the males and females, at least, have not the power of extricating themselves from those cases till they are liberated by the workers. If this is true it shows at what stage of the business the sexual development begins, and seems to indicate that ants have the same means of keeping their perfect sexed animals in confinement till they are wanted, as the bees have of confining their germs.

The attachment of the workers to these cocoons is even greater than that to the eggs or the larvæ. They may be seen bringing them out in the fine fresh air of the morning, taking them in when the heat and light are too strong, sheltering them from the rain, and if a breach is made in their dwelling the cocoons are the first objects of their solicitude; and although they are more than double the size of the ants themselves, the little creatures run as fleetly with them to places of safety as if they had no weight whatever. The working ants are valiant in the breach of their dwelling, determined in their strifes and combats, and most perseveringly industrious in the search of their food; but it really seems that the care of larvæ and cocoons, the latter especially, is their great ruling passion to which they willingly sacrifice all else, and for which they are ready to give up their lives. In the common garden ants it is scarcely possible to find an individual in possession of a cocoon without finding other individuals constantly tendering their assistance; and if the aperture, through which the one in charge attempts to get it into the concealment of the nest, is at all unmanageable, a number of others come unbidden to assist, some hauling and others pushing till the treasure is safely lodged. So fond indeed are they of cocoons, that when the little nests or colonies of this species are near each other, parties of the one are very apt to make free with the cocoons of the others, and battle and strife to ensue upon the point, though it does not appear that different tribes of this species, or indeed of any species, fight much or at all about the prizes they meet with. It seems, indeed, that one of these labourers can no more see a cocoon without trying to nurse it, than a cat can see a mouse without endeavouring to catch it.

It is probably upon the strength of this instinct (for we must call it an instinct as we have no knowledge of its cause), that certain species of ants have been described as invading the dwellings of others, for the purpose of carrying their partially developed young into *slavery*. The species against which this charge has been brought are principally the blood-red ant (*F. sanguinea*), and the reddish-brown ant (*F. rufescens*), both of which are common in central Europe, though not hitherto observed in Britain.

That they do invade the hills or nests of feebler ants, and carry the larvæ, and especially the cocoons, from thence to their own dwellings is highly probable, and it is probable that all ants which can gain the mastery either by individual strength or by numbers, do the same; and it seems the general law of their nursing instinct (if the term can be allowed), that the labouring ants of every species bring home to their own dwelling all the impregnated females and all the developed young that they can; but that they seize them for the purpose of enslaving them is purely a gratuitous assumption; and it may be said, without fear of contradiction, that there never was an ant of any species found attempting to make one of another, or of the same species, perform its labour for it. There is, in fact, the most perfect equality among the labourers in an ant-hill; and labour seems to be so much their enjoyment, that they will not, upon any occasion, stand by and see it done by another. When any task is too great for an individual, that individual seeks for, and speedily obtains, assistance; but however hard it has laboured previous to the coming of the assistance, the arrival of that is rather a signal for fresh exertion upon its part, than for any slackening of its labour. The true explanation of the alleged slavery seems, therefore, to be that the ants take the cocoons merely for the purpose of nursing them with the same tenderness and solicitude as they would nurse those of their own species.

It has sometimes been said that there is a division of labour among ants—that one squad fight, another keep the hill in repair, a third bring in provisions, a fourth nurse the young, and so on. But as all animals work according to their organisation, and, generally speaking, up to it, it would be contrary to the general law of nature to suppose any division of labour without corresponding differences of organisation. And upon examining ants, it is found that the labourers, if unoccupied, are equally ready and willing to put their hand (such hand as it is) to any work which is requisite for the welfare of the community; and the confidence with which they all go in quest of assistance, and the readiness with which they receive it, are among the most beautiful traits in their characters. The task which defeats an ant is, as compared with those performed by the strongest of the larger animals, a most formidable one; for an ant will carry in proportion as if a bull-dog were carrying a buffalo. Therefore, among all the innumerable substances which are brought home to the nest in the season of the larvæ, there is not one, even the very largest, but which a single ant will attack, and labour with all its might to move along. If the prize cannot be made to stir, the ant after some time darts off at a tangent, and encircles the prize round and round, widening the circle a little each time, and proceeding with so uncommon velocity that one would suppose an ant's mode of rest to be increased exertion. If in the course of these gyrations it meet with any of its associates, they are sent in the direction of the prize; and in this way, one who attends to the common garden ants, may often see a large caterpillar, an earthworm, or some other goodly prize, borne lightly to the nest by the united strength of twenty, thirty, or forty, at which a single individual had been tugging in vain for half an hour previous.

Among the species which inhabit in larger societies, the field-ants and the wood-ants especially, the labours of a much larger party are often required. They can contrive to move along the largest beetles, and even a young mouse; though it is not known that they attack these animals in the living state. But whatever may be their labour or the number engaged in it, all the individuals appear equally on the alert and equally skilful in the performance of it. Whether it be in the mere seeking of their own food, in the preparing of their habitation, or in any other duty, they are all equally prompt and able without ruler and without counsellor. Thus they pass a most energetic season, till their supply of food in the fields fails, and the temperature sinks too low for their remaining in a state of activity. Previous to this they seek their dwellings, and in the inmost recesses of these cluster together, and so pass the inclement months in a torpid or hybernating state. Their nests are constructed of various substances according to the habits of the species, and according, as it should seem, as materials are to be found. Some dig into the trunks of trees, seldom, however, till these have begun to decay. Sometimes they excavate the earth in bare places, sometimes they make portions of the mud edifice artificially, and sometimes (as in the case of the wood-ants) the hill is exclusively made of little bits of sticks, so placed as that while perfectly water-tight and laid without any apparent order, they can be entered at almost any point. Some naturalists mention having found the nests of ants excavated in solid clay: these must be a wonderful species, inasmuch as both the physical and physiological arguments against ants hybernating in clay, or even living comfortably in it, are exceedingly strong.

The different modes in which ants construct their dwellings, and the different situations and materials which they select, has led some, not a little whimsically, to apply to them the names of certain human trades, such as masons, carpenters, and others: at best those comparisons are childish and trifling, and at worst they have not a little of the "odium" which is said to attach to comparisons generally. The operations of these insects have no resemblance whatever to those of the human artificers after which they are misnamed; and, therefore, besides being beneath the dignity of natural history, these misapplications of names invariably produce one or other of two results, they either give young and ignorant persons an erroneous meaning, or they destroy to them every vestige of meaning.

Any one who considers the very general distribution of ants, their countless numbers, their great strength as compared with their size, their unwearied assiduity in labour, the promptitude with which they assist each other, the care which the rearing of them compared with that of most other insects requires, and the curious fact that by far the largest majority of the race are formed for labour only, must see that the place which they occupy in nature cannot but be one of very great and general importance; and though they are sometimes a little (and it is but a little) annoying in gardens, disfigure dry meadows and pastures with their hills, and sometimes speed the termination of rotting trees, there is no question that the services which they render counterbalance, many thousand times over, any little ravages they commit. The exertions of some of the smaller ones in clearing the leaves of trees from that honey-dew with which aphides cover them, to the great injury of their growth, is much noticed. But honey-dew is far from being the principal food of the ants; they do not go into grounds unfavourable for their nidification for the sake of this substance. Over some of the tough clays where ants cannot subsist in the earth, the leaves of the hedges may be often found so dripping with honey-dew, as that a large phial might be filled with it in no great length of time; and yet in the places where it was so abundant, the writer of this article has never seen a single ant, though there was no want of wasps, and also of wild bees, feeding away with apparent gusto. So also it does not appear that the presence or the absence of aphides on the fruit-trees, has much influence on the number of ants.

The food of the species which inhabit different localities no doubt varies; and there is little question that, besides honey-dew, most of them are fond of sugar, gum, and all the sweeter exudations of trees; but still their staple food appears to be animal matter, either those larvæ which are injurious to plants, or small carrion, the incredible quantity of which that occurs, especially after the Midsummer rains, would otherwise very seriously taint the air, even in climates which are not excessively warm. A district which swarms with ants is always a dry district, and as such its atmosphere is sweet and favourable to human health; a clayey district, where they are few, has invariably a rank and unwholesome atmosphere; and though the presence of the ants is not to be considered as the only cause of healthiness in the one place, and their absence of unhealthiness in the other; yet they are accompaniments, inseparable from the result, and therefore, to some extent, influential in bringing it about.

But ants are valuable, not merely on account of the creatures and substances which they eat, but on account of the creatures which eat them. Some of the finest, both of song and of gallinaceous birds, are understood to be fed almost exclusively in their very young state upon the cocoons of ants; many other birds feed largely on them; and in foreign countries there are peculiar genera of animals formed exclusively for feeding upon ants.

ANT-CATCHER (*myiothera*). A genus of birds which feed almost exclusively on those insects from the capturing of which they are named. They are found in both continents, chiefly in the warmer latitudes, and in the wastes and forests where ants are so very numerous; but though these forests are the chief haunts of the greater number, they are never found high upon the trees, but rather hopping about among the lowest branches. On the ground they are more at home, their tarsi being long and stout, and their feet altogether admirably adapted for walking. They, in consequence, run with great swiftness, and appear never to tire while the ants are abroad. They are, in fact, upon the ground, very similar to what swallows and swifts are in the sky, and capture their wingless prey as adroitly as these capture winged insects.

Their pastures, especially in the tropical countries, are so highly productive, that they are generally found in packs, or small flocks, and often several species may be found on the same ant-hill feeding away in the greatest harmony. They are, of course, day-feeders, and as the ants are out at certain times of the day, and in certain states of the weather only, their feeding is limited to these times. But the ants are so numerous, that an ample supply may be picked up in a very short time, so that the lives of the ant-catchers are much less laborious than those of many other birds.

These ant-catching birds are rivals of the ant-eating mammalia and reptiles, especially of the ant-eaters properly so called, some account of which will be found in the next article. But the two do not come upon each other's ground. The mammalia attack the ants in their hills, and bring them out by breaching these; and the reptiles generally watch by those paths along which the ants pass in great numbers. Both of these too, in general, capture by means of a protrusile tongue, which is limed with a very adhesive viscus, so that many ants are taken at a time. The birds, on the other hand, capture them singly with the bill, and capture them whenever they are inclined. Each ant-feeding class has thus its particular season, and the one does not interfere with the other; even if they did, the ants in the warm countries are so numerous, and they breed so fast, that there would still be ample provision for them all.

The ants, the *white ants* [see TERMITES], and various analogous tribes, act a very important part in wild nature in the tropical climates. They are scavengers to a very great extent in clearing the wreck and rubbish both of animal and of vegetable matter, consuming even the boles of large trees, which are constantly decaying in those places, and which, if they were to remain, would not only taint the atmosphere with pernicious gases, but would float away when the rains came, and thus exhaust and impoverish the soil. This preventing of the matter, which has once been organised, and which, on that account, is fit for the support of new organisations, from floating away, is a very important matter; and, but for it, the whole of those tropical countries which have extremes of dry and humid seasons, would be in rapid progress toward the desert state. But the matter is taken up by those countless myriads of insects; and in them it lives anew for a season. Then the birds and other vertebrated animals feed upon them, and it passes into new forms of life, each one supporting some other, and the whole preserving and maintaining the fertility of the country. This is what may be termed nature's mode of culture: the fungi among plants, and the insects among animals, take hold of that which is on the brink of ruin; and from them it passes from race to race, till at the end of the circuit it arrives at the most stately trees of the forest, and the largest animals which feed and repose in their shade; so that, by a circle of minor destructions, the grand destruction of the whole is prevented.

The forests of tropical America are at least among the places where this natural system is in the fullest operation, without having been interfered with by man; and from the peculiarity of its structure, and the large portion of it which is in a state of nature, the system, perhaps, extends more polarly in North America than in any other region on the globe. The valley of the Mississippi, especially that on the right bank of the river, from Louisiana northwards, skirting along the Rocky Mountains, has its atmospheric action from north to south, and south to north, between the tropical climates and the polar ice; and though the average temperature is much lower, there are many features in it which have at least a relation to tropical ones. Among the rest, there are numerous ants and ant-catchers, some of which are better known than those of more southerly latitudes. The species best known, indeed the only one which has hitherto been found in these northern parts, is

The *Rocky Mountain ant-catcher* (*mygiatheria obsoeta*), of which the following description will serve as a specimen of the American birds of the genus.

"The Rocky Mountain Ant-catcher," says Lucien Bonaparte, in his addition to "Wilson's American Ornithology," is six inches long. The bill, measured from the corner of the mouth, is more than one inch in length, being slightly curved almost from the base; it is very slender, being nearly two-eighths of an inch in diameter at the base, and only the sixteenth of an inch in the middle, whence it continues to diminish to the tip; and is of a dark horn colour, paler beneath. The feet are dusky; and the length of the tarsus is seven-eighths of an inch. The irides are dark brown; the whole plumage above is of a dusky-brownish, slightly undulated with pale, tinted with dull ferruginous on the top of the head and superior portions of the back. The sides of the head are dull whitish, with a broad brown line passing through the eye to the commencement of the neck. The chin, throat, and breast are whitish, each feather being marked by a longitudinal line of light brown. The belly is white; and the flanks are slightly tinged with ferruginous. The primaries are entirely destitute of undulations or spots; the tail-coverts are pale, each with four or five fuscous bands; the inferior tail-coverts are white, each being bifasciate with blackish brown. The tail is nearly two inches long, rounded, broadly tipped with ferruginous yellow, and having a narrow black band before the tip; the remaining part of the tail is of the same colour with the wings and is obsoletely banded, these bands being more distinct on the two middle feathers, which are destitute of the black and yellowish termination: the exterior feather is dusky at tip, marked by four yellowish-white spots on the exterior, and by two larger ones on the inner web.

"The specimen of the rocky mountain ant-catcher we are describing, is a male, shot in the month of July, and possibly not adult. As it is the only one brought by Major Long's party we cannot determine the extent or nature of the variations the species may undergo from age, sex, or season.

"The note of this bird is peculiar, resembling the harsh voice of the terns. It inhabits the sterile country bordering on the river Arkansaw, in the neighbourhood of the Rocky Mountains, where it is frequently observed hopping on the ground, or flitting among the branches, or weather-beaten, half-inclining trunks of a species of juniper: when it flies among the crooked limbs of this tree, it spreads its tail considerably, but was never seen to climb. They were generally observed in small associations of five or six individuals, perhaps composing single families."

The following general observations, by the same author, are also worthy of quotation.

"The ant-catchers may justly be enumerated amongst the benefactors of mankind, as they dwell in regions where the ants are so numerous, large, and voracious, that, without their agency, co-operating with that of the *Myrmecophaga jubata*, and a few other ant-eating quadrupeds, the produce of the soil would inevitably be destroyed in those fertile parts of the globe. The ant-hills of South America are often more than twenty feet in diameter, and many feet in height. These wonderful edifices are thronged with two hundred-fold more inhabitants, and are proportionally far more numerous, than the small ones with which we are familiar. Breeding in vast numbers, and multiplying with great celerity and profusion, the increase of these insects would soon enable them to swarm over the greatest extent of country, were not their propagation and diffusion limited by the active exertions of that part of the animal creation, which continually subsist by their destruction.

Ant-Catcher.

"The ant-catchers run rapidly on the ground, alighting but seldom on trees, and then on the lowest branches; they generally associate in small flocks, feed exclusively on insects, and most commonly frequent the large ant-hills before mentioned. Several different species of these birds are often observed to live in perfect harmony on the same mound, which, as it supplies an abundance of food for all, removes one of the causes of discord which is most universally operative throughout animated nature. On the same principle, we might explain the comparative mildness of herbivorous animals, as well as the ferocity and solitary habits of carnivorous, and particularly of rapacious animals, which repulse all others from their society, and forbid even their own kind to approach the limits of their sanguinary domain.

"The ant-catchers never soar high in the air, nor do they extend their flight to any great distance, without alighting to rest, in consequence of the shortness of their wings and tail, which, in fact, seem to be seldom employed for any other purpose than to assist them in running along the ground, or in leaping from branch to branch of bushes and low trees—an exercise in which they display remarkable activity. Some species, like the woodpeckers, climb on the trunks of trees in pursuit of insects; and it would appear, from their restless habits and almost constant motion, that their limited excursions are entirely attributable to the want of more ample provision for flight. The ant-catchers are never found in settled districts, where their favourite insects are generally less abundant; but they live in the dense remote parts of forests, far from the abodes of man and civilisation. They also dislike open and wet countries.

"The note of the ant-catchers is as various as the species are different; but it is always very remarkable and peculiar. Their flesh is oily and disagreeable to the taste; and, when the bird is opened, a very offensive odour is diffused, from the remains of half-digested ants and other insects contained in the stomach.

"The plumage of the ant-catchers very probably undergoes considerable changes in colour. The size of the sexes is different, the female being much larger than the male. Such variations may have induced naturalists to consider many as species that really do not exist, as such, in nature.

"The nest of these birds is hemispherical, varying in magnitude, according to the size of the species, composed of dried grass, rudely interwoven; it is fixed to small trees, or attached by each side to a branch, at the distance of two or three feet from the ground. The eggs are nearly round, and three or four in number.

"The discovery of any species of this genus in the old world, is quite recent, and it had previously been believed that the genus was peculiar to South America; and though the existence of ant-destroying birds was suspected in other tropical regions, they were supposed to be generically distinct from those of the corresponding parts of America, as was known to be the fact in the case of the ant-eating quadrupeds. This opinion was founded on the admitted axiom, that nature always varies her groups in remote tropical regions having no communication with each other. The reverse, however, is the fact, in the case of the ant-catching birds, as we find perfect analogies between the species residing in those distant parts of the globe, even throughout the different sections into which the genus may be divided."

The Asiatic species are in general more gay in their plumage than the American ones, but their habits are nearly the same. They are not birds of the cultivated and thickly-inhabited districts, but of the wilds, and they are but seldom seen in proportion to their numbers. None of them are birds of much show or display, or in any way of popular interest; their peculiar place in the system of nature being the only point of importance in their history. It is not understood that any of them are migratory, though, during the season when the heavy falls of rain confine the ants to their hills and other burrows, they must in so far change their food, and pick up such other insects as they find among the lower branches of the trees. They are not met with in places which are flooded during the rains, because such places are not suited for the habitations of ants; neither are they so abundant in the deep and tangled forests as in those where the trees are straggling and interspersed with dry open patches.

ANT-EATER (*Myrmecophaga*). A very singular genus of mammalia, belonging to Cuvier's order of *Edentata*, or "toothless;" and with the strictest propriety so arranged, as not one of the genus has a vestige of a tooth in either jaw. They are all natives of the warmer parts of South America, and perform nearly the same part in the economy of nature there as is performed by the pangolins, or scaley ant-eaters of the eastern world. They have been, by some naturalists, confounded with the "ground pig" of the colonists of southern Africa, *Orycteropus* (earth-foot) *Capensis;* but that animal is different both in structure and in habits. It has grinding teeth, though of peculiar structure, whereas the true ant-eaters have none.

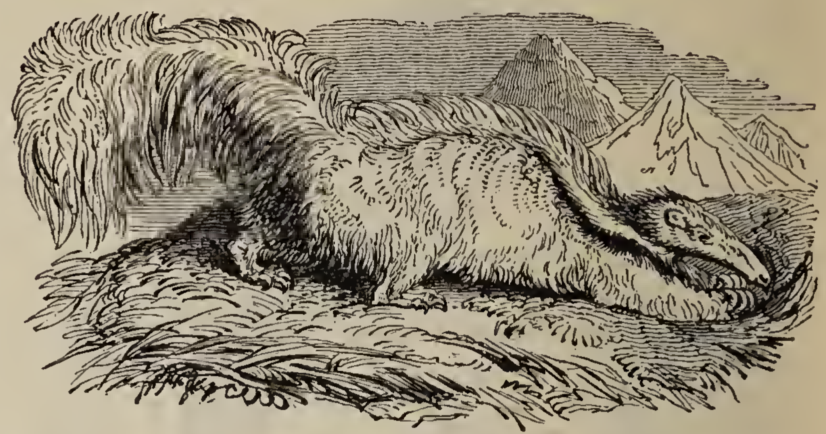
The connexion between the teeth and hair of animals has often been noticed. The hairless dogs, which are met with in some parts of the world, generally have the teeth deficient; and though it has not been established in the human subject, that the falling off of the hair is always accompanied by dental decay; yet it has often been noticed that a dry and unhealthy state of the hair very generally accompanies disease of the teeth. In the different orders of animals, the correspondence is more remarkable; and the hairy covering of the edentata, whatever may be their other characters, always has some resemblance to the substance of scales, or rather perhaps to *baleen*, or, as it is improperly called, whalebone. This holds, whether the animals have grinders, or are wholly toothless, and also whatever may be the country or the situation of their residence. The sloths which inhabit trees, and never come to the ground if they can avoid it; the ant-eaters which never climb; the echnida of New Holland which burrow in the ground, and the ornithorynchus of the same country, which inhabits pools of water; all have the hair flat or tubular, or in some way less apparently connected with the living part of the animal, and more withered and dead to appearance than the hair of the toothed mammalia.

But the ant-eaters have many peculiarities of structure which are well worthy of attention; nay, in some respects, they have a slight resemblance to the human subject. The females have the mammæ on the breast, and two in number; and though the animals walk upon all fours, it is the hind feet only that can be properly regarded as walking feet. These are strictly plantigrade, that is, the whole length of the tarsus or foot bone comes to the ground, and so affords a very broad and firm base. The first joint above the ground is a forward bending one, or true knee; and the toes, whatever may be their number, have all their phalanges united; and the claws on these are small and weak. They are thus slow-walking feet; but not adapted for climbing, leaping, or any other function.

The fore-feet are very different, and their structure shows that walking is only one of their secondary uses. The number of toes varies in the different species; but they are always fewer on the fore-feet than on the hind. The form of the fore-feet resembles that of small rakes or pronged hoes; and as such they are awkward in walking. The phalanges of the toes are united in these as well as in the hind feet; but they are armed with much larger and more formidable claws. These claws are, in repose, folded inward upon the palm, by the action of elastic ligaments; and even when they come into use, they do not open beyond a right angle to the line of the palm. Thus they form an instrument which is very peculiar, but which is admirably adapted to the habits of the animal; and which, in turning over the mould with ease and speed, is superior to our garden rakes and pronged hoes.

When, however, it comes to be used for walking, it is not so convenient. From the position of the claws (which, though intended for a very different purpose, bear some resemblance to that in the sloths), the animals cannot walk on the palms of the fore-feet; and besides, its so walking would speedily blunt and wear the claws, the only instruments on which the animal has to depend for unearthing its food. It therefore walks on the outsides of these feet; and as they do not apply well in that position, its walk is slow. Even when driven to a trot, it moves with difficulty, and slower than the ordinary walk of most animals. Walking, except at its ordinary stealthy pace, is not, however, an operation essential to its mode of life, for which it is as admirably adapted as the fleetest animal that scours the plain or bounds from cliff to cliff.

The bodies of all the species are long, the heads long, and the tails very long. The proportions and uses of the parts will be most clearly and briefly stated in a notice of the largest species which has the peculiar characters of the genus in greatest perfection. That species is the great ant-eater (*Myrmecophaga jubata*).



Great Ant-Eater.

This species is a large animal. The head from the point of the snout to the ears is about thirteen inches, thence to the insertion of the tail nearly three feet and a half, and the tail nearly two feet and a half in the solid, and a foot more to the points of the hair. The whole length is thus about eight feet. The height is about three feet three at the shoulder, but half a foot less at the croup. The hair, excepting on the head, where it is short and close, is shaggy, and dry like that of the sloths. The mouth is small and the tongue slender, but remarkable for its length. It is in the form of a worm. When in repose it folds back within the mouth; but it is protrusile to the length of at least eighteen inches beyond the snout; and the celerity with which it can be protruded and retracted forms a remarkable contrast with the sluggish locomotion of the animal. This celerity of motion in the tongue is, however, just as necessary for a large animal which feeds on such small food as ants, as swifter progressive motion would be unnecessary. The tongue is covered by a viscid secretion, by which the ants are captured; and as it is laid over them, they are rubbed off against the palate when the tongue is doubled back into the mouth.

In order to understand how the parts of this rather singular organisation work, we must suppose that the animal has arrived at the side of an ant-hill, or other burrow of social insects; and that he is hungry and inclined to feed. There is every reason to believe that his sense of smell is acute, as is generally the case with long-snouted animals, and that in immediately feeding he is fully as much guided by that as by the sight of his small eyes. Well, he arrives at the ant-hill, his broad hind feet forming a firm base, and his long tail balancing him on those feet as on a pivot. The fore-foot is then extended to its utmost stretch, but in its general position, and with the claws curving a little backwards. In this species, the claws on the fore feet are four in number; the first and fourth smaller, but the second two inches, and the third two inches and a half in length, strong in proportion, and grooved on their posterior surfaces. The stroke of the foot plunges these into the ant-hill up to the roots; and the animal pulls the foot home, tearing a rugged furrow in the insect earth. The ants, as is their habit, instantly come to the breach in numbers; and while they are in agitation there, the tongue is protruded over them and withdrawn at the rate of about twice in a second, many dozens being captured at each time; and when the first breach is cleared, others are made in the same manner. But though the animal subsists in this manner, it is said never to get fat, notwithstanding its indolence at those times when it is not feeding. It is capable, however, of enduring great privation in the way of food, which might be inferred from its sluggish habits. The position of repose is that of partially rolling itself into a ball, with the snout doubled on the breast, the legs brought together, the long and bushy tail covering the outer part, and the whole animal having something the appearance of a bunch of withered grass; and probably much of its defence from enemies depends on this position, in which it spends the greater portion of its time.

The muscles of the fore-legs of these animals are powerful, and the claws are formidable; and on these accounts, the efficacy of the latter, as weapons of defence and even of attack, appear to have been much exaggerated. It has been said (though those who have said so do not pretend to have seen it in the fact) that the great ant-eater, or "ant-bear," as it is sometimes called, can seize with its claws and hug to death the most formidable and active beasts of prey that inhabit the same countries. But the probability is, that the animal has been endowed with the powers of the sloths, and also of the bear, after which it has improperly been named. The claws of the sloths are clutching claws, and their feet do act against each other while they move along the branches in quest of their food. Hence it is perfectly natural to suppose that a sloth would clutch an enemy upon the ground; and as its clutch habitually supports its own weight without effort, it is natural to suppose that it would be formidable to other animals. Bears, too, have hugging feet, which they use in climbing trees, and it is also quite natural that they should use them against their prey, or against an enemy. But the great ant-eater does not climb, or clutch with its paws, or hug any thing in any one of its natural habits; and it would be at variance with all the analogies of nature to make it a new animal, either when it attacks or when it defends. The position of the fore-paws in repose, is with the claws folded down upon the pad of the palm; and if the animal get hold of any thing there, it might retain that hold; though it is against the general rule to suppose that the position of repose should also be the position of excitement.

The ant-eater is not the only animal which has got credit for performing feats which are equally contrary to its habits and inconsistent with its organisation. The works of travellers and compilers in natural history are full of them; and they are sometimes suffered to vitiate the pages of those who ought to know better. These matters spoil natural history as a useful study, and therefore no better service can be rendered to the reader than the exposure of them, and no means so certain for preventing the inexperienced from falling into such mistakes, as a careful study of the structure and habits of animals. From these, and these alone, we can learn what the animal is best capable of doing; and when we have ascertained that, we may rest assured that it will be the first thing the animal will attempt.

Great ant-eaters are pretty generally distributed over all the warmer parts of South America; but they are not numerous in any one locality. The low and swampy grounds, by the sides of streams and pools, or in the forests, are his favourite haunts, though he never either climbs in the wood or swims in the water. He is wholly a ground animal, but a surface one and not a burrower.

They are slow-breeding animals. The female has only one at a birth; she carries it on her back, and tends and nurses it for more than a year. They are remarkably quiet and harmless animals, living and feeding among the ant-hills, and not, so far as is known, offering or doing harm to any other creature. So retired are they, indeed, that they are considered as rare, even in their native forests. The Indians and negroes eat the flesh of this species, which is not unpalatable; but, as is the case with several others of the ground animals, it has a rank musky flavour, which is rather offensive to Europeans. The species now noticed is the only one of the genus which is literally an "ant-eater" and a dweller exclusively upon the ground; and the remaining species, though they agree with it in having no teeth, have many of their characters so different that each of them might perhaps be made a separate genus.

The *tamandua* (*M. tamandua*), is a much smaller animal than the ant-eater properly so called. It is five inches from the snout to the ear, one foot nine to the origin of the tail, and the tail is about one foot four; making the total length three feet and a half; but the tail and snout are shorter in proportion, and the body is stouter. The legs are also stouter in proportion, and the animal walks much better upon them, the fore legs being more plantigrade, and the claws not quite so much in the way. The feet are adapted for climbing, in which operation the animal is assisted by its prehensile tail, which grasps round the branches readily and with a firm hold. It stands more equally on its feet than the ant-eater, and is altogether a more lively-looking animal. Its fur is also short and silky, and its tail round and tapering, covered with very short hair. There are five or six varieties enumerated, but as the differences between them are chiefly in colour, it is probable that they are merely climatal. The prevailing tint is dull straw-colour, variously marked with black, or with a silvery hue. These markings may be the effects of age, as the young are all over of a dull straw-colour. The female has two pectoral mammæ, like the ant-eater; like that she has but one young at a birth, and carries it on her back, but for a much shorter time.

This species inhabits the thick and pestilent forests of South America, spending the greater part of its time in the trees; and, indeed, the ground under its haunts is so often under water, that it could not find footing there. It feeds upon tree insects and wild honey, reaching the latter in the very tops of the trees by means of its feet and tail. It also sleeps in the trees, but not suspended, after the habit of the sloth. When it prepares for repose it finds a hole or secure crevice, where, rolling itself up partially as a ball, it remains in safety.

The *little ant-eater* (*M. didactyla*—two-toed), is as improperly called an ant-eater as the species last mentioned. This species is about the size of the common squirrel, has the snout less produced than the last species, and the feet not so well adapted for walking. The fore ones have however powerful claws (two on each foot), bearing some resemblance to those of the sloths; and the tail is very prehensile

The dimensions of this species are small compared with those even of the tamandua. Its length is only about thirteen inches and a half, of which the head occupies less than two inches and the tail above seven. The tail is very thick and strong at its insertion, and tapers gradually to the tip. The colours are either bright yellow with the back brown, or silver gray with the back darker. The hair is soft and silky, but in some parts curled or matted at the points. The tail is slightly annulated with the prevailing colours of the body, except a portion of the under side near the point, which is naked, as is usual in that organ when prehensile. The hind feet are squat and flat, with the phalanges of the toes united and covered with hair. They have four small claws on each. The fore-feet (which the animal can use like hands, resting on the hind feet, and holding on with the tail if necessary) have only two claws on each, an outer and very large one, and an inner and smaller, which lies in the curve of the former.

Like the last-mentioned species, these animals live in the trees, and feed chiefly upon wasps and other insects in the larva state, which they are very dexterous in capturing with their nippers. It is probable that they also use the tongue in feeding, though certainly not so habitually as the anteater properly so called. As is the case with many of the other inhabitants of the dense forests in the humid parts of South America, they repose during the day, at least in the dry season, when the larvæ are unable to bear the heat of the sun. They partially roll themselves in balls, remaining anchored by the prehensile tail, and sometimes suspended by it. The females of this species are described as having four mammæ, two on the breast and two on the belly, and yet they are said to have only one young one at a birth. The details of their economy and habits are not, however, very well known.

They, as well as the tamandnas, are, strictly speaking, tree animals at home only among the twigs and branches; and though the absence of teeth and the protrusile tongue show that their food must be of so soft a nature as not to require any process at all analogous to mastication; yet they differ so much from the great ant-eater, as hardly to admit of a common description. Neither is there any other known species in the same forests with which they can, even with as much propriety, be classed. They are very peculiar animals, and belong to a quarter of the world which has many peculiarities both in its climate and its productions.

ANTELOPES (*Antilopus*). A very numerous and highly interesting genus, or rather, perhaps, family or tribe of animals belonging to the order *Ruminautia*, or those which chew the cud. For the general characters of the order, the most valuable to man in the whole animal kingdom, see "*Ruminantia*."

The species of antelopes are so numerous, and they differ so much from each other, that no popular description could be so framed as equally to apply to and express them all; and yet the family likeness among them is so strong, that no one who has carefully studied even a few of the species can find much difficulty in pronouncing, the very first time that he sees it, whether any new species is or is not an antelope. The other animals to which they have most resemblance, both in structure and in habits, are the goats, though in the shape and covering of their bodies, some of them more resemble deer; but still there is not much danger of mistaking them either for the one or the other.

Yet when we come to state in words what the difference is, we are at a loss. Where both deer and antelopes have horns, the distinction between these is abundantly clear, as the horns of deer are not true horns, but annual appendages to the head, growing at the surface under a skin which remains till they attain their full size, after which it begins to shrivel and they to harden, so as to be in the top of their strength during the pairing season, after which they fall off, sooner or later, according to the climate and the habit of the animal. In all cases they are deciduous; and like the leaves of deciduous plants which drop when mature, they leave a new skin upon the places to which they were attached, or rather it is the formation of that skin which interrupts their connexion and causes them to fall off.

The horns of the antelopes are, on the other hand, true horns; their cores are permanent elongations of the cranial bones, sheathed with real horn, which grows at its inner surface where it is in contact with the core of bone; and although it probably in all cases receives an inner layer of new substance every season, it is in all cases persistent, or remains during the life of the animal, unless destroyed by accident.

The distinction between the antelopes and goats is by no means so clear; as not the goats only, but the sheep and ox tribes have horns of the same general structure, so that in attempting to found a distinction upon the horns of these, we are reduced to some mere difference of form; and though, when we see them together, it is not very difficult to say, either from the shape or the texture, which animals the horns belong to, it is by no means easy to express in words in what the difference consists.

The other characters are not more easily expressed, whether we take the size, the general shape and air of the body, the form of the muzzle, the presence or absence of *lachrymal sinuses* under the orbits, of secreting pores or follicles in the groin, or any other character. The most general popular character is, that every antelope is in its form the type of agility; and in their motions they are as agile as they look.

The period of gestation in many of the species is imperfectly known, but there are some reasons for thinking that it varies considerably, being about eight months in some of the larger species, and not more than five or six in the smaller. Their young are never understood to be more than two at a birth, and seldom more than one; but the females are generally, though not invariably, furnished with four teats, which are *inguinal*, or in the groin. The number of teats, however, proves nothing as to the number of young; for the cow, which has four, has twins less frequently than the ewe, which has only two.

In general, the limbs of the antelope are very clean in their make, firm in their joints, elastic in their tendons, and powerful in their muscles. The hoofs, of which there are two walking ones on each foot, are neat in their form and very firm in their texture. The general covering of the body is hair, short and smooth, but not silky or woolly. In some, however, there is harder and more produced hair in the form of manes, beards, elongations on the throat, *scopæ*, or knee tufts on the fore-legs, just below the carpal joints, and other appendages.

In general the sexes are both of nearly the same colour; and when they differ they follow the general law, in the change being in the adult male; for the young males are like the females. Colour in animals has, however, so little to do with original difference of species, and depends so much on circumstances, that nothing useful can be founded upon it.

The ears of the antelopes are in general long, rather narrow and pointed. The tails vary considerably in different species, being very short in some, moderately long in others; in some with a brush at the point, in others with short hair on all their length, and in others again entirely covered with long coarse hair.

But though it is difficult to select any characters by which the antelopes may be systematically described as one tribe, or even as several subordinate groups, they have at least one character in common, which cannot fail to recommend them to the student of natural history: they are the children of wild nature, and of wild nature in those places which lie the most remote from the culture and the cognisance of man. The cliffs and ledges of mountain rocks, the bush-tangled wastes on the tropical plains and the margins of the arid wildernesses, are the native habitats of the antelopes. There they bound, and spring, and career, fleet as the winds; now balancing themselves where one would hardly imagine there were foot-fall for a bird; now clearing the jungle as if they were winged creatures; and now bounding along the arid plain as if they were actually endowed with a principle of levity. To those who have been accustomed only to the motions of the more sober animals, to the heavy tread of the ox, or the pattering trot of the sheep, the antelopes present something truly novel. From some unseen hollow among the cliffs, one of these animals will vault up perpendicularly, and alight upon all-fours on a pinnacle only a few inches in breadth, and on which any animal with which we are familiar in England would empale itself if it attempted to descend. There it will stand in perfect security with the feet all touching each other and the spine bent upwards like a bow, surveying at its leisure the new horizon of which its elevation has given it command. And it not only seems a bow, but it is one—a bow fully bent and itself the arrow; for no sooner has it espied a new footing to its mind than it bounds off again though the distance be many fathoms. Nor, if it is upon a journey of some length, can it be contented with walking or even with running along the plain; but proceeds by a few fleet steps and a still fleeter bound alternately, as if it were utterly unable to keep its own energy within limits.

From the great diversities of size, power, and appearance, which are observable among antelopes, we may naturally look for corresponding differences of habit. Some accordingly are highly gregarious, and assemble in very numerous herds, especially at particular seasons; others are found in small packs, and others again solitary, or at most in pairs among the rocks. Every where, however, they have to bear great extremes of climate; and thus, in no instance has their great energy been given to them in vain.

Some species may be more localised and permanent in their dwellings than others; but the general habit of the animals is migrant, and there is probably not one district which they inhabit, in which antelopes are not at some season of the year compelled to travel in quest of food. It is this tendency to seasonal mobility which forms the grand and distinguishing character of the race, and the one upon which, in a useful point of view, it is best to describe them. No doubt, in some of their localities, they approach pretty closely to some of the goats, as they also do in structure and appearance; so that there the line of distinction between the two races is not very definite, but that is only at particular points.

Of the other Ruminantia, the buffalo keeps his savannah, and the wild ox his dell or his forest, and only shifts a little way with the seasons. The sheep and the deer too, in the state of nature, have no very strong migratory habits; and though the mountain goat is sometimes forced to descend in the inclement season, his seasonal journeys are not to any very great distance. These races, in general, inhabit the regions where upon the average they can find food during the greater part of the year; and, therefore, there are large tracts of the world which, though seasonally rich in food for ruminating animals, are not adapted for them.

These are chiefly those regions which during the dry season are parched and foodless, but which are speedily covered with luxurious herbage as soon as the rains set in; the greater part of Africa, many portions of Asia, and some of America. In Europe they are comparatively few, and confined to the Alps, the Pyrenees, and other mountain ridges. The species on these mountains is the chamois; and although it has many of the appearances of the antelopes, it has many of the habits of the goats. The same may perhaps be said of the American species, of which the one best known is also a mountaineer: and indeed it is in the mountain species where it is difficult to draw the line, and say with certainty what is an antelope and what a goat. The common distinction that antelopes have the section of the horns round, and goats have it angular, is arbitrary, proves nothing, and is not to be depended upon.

In giving some notice of at least the more remarkable species of these very interesting animals, we shall not pay much attention to system. There is merit no doubt in many of the systems; but from the very nature of the case not one of them can be regarded as any thing like perfect. New species are often occurring; and the classification is chiefly founded upon the form of the horns, which, though it may serve to distinguish one individual or species from another, is connected with no other known character or habit. Hence our plan, as the only popular one, must be to notice the appearance and habits of the several species as briefly and clearly as possible.

The Prong-horned Antelope (*A. furcifer*). This species is an American, inhabiting the northern part of that continent; but migrating a little to the southward in the winter. It is a very handsome, beautiful, and agile animal, measuring nearly four feet and a half from the nose to the insertion of the tail, and standing three feet in the height of its back, which is a straight line and equally high at the shoulders and the croup. The line of the abdomen is also nearly straight, the chest full, the body compact and firmly set on the legs, which are finely formed. The tail is very short. The neck is "at gaze," carried at right angles to the line of the body; the ears are large, and the eyes prominent and bright; the hair on the head and neck, except a rudimental mane on the latter, is short; but that on the body is matted, and the hairs are tubular, or rather in the form of hollow cones, of small diameter as compared with their length. These tubular hairs stand out and give the animal a shaggy appearance. The tubular hair appears to be a defence against the snow and cold in winter, for it does not come on till the end of the season, and it is shed in the beginning of the next. This is a curious winter change in the covering of an animal; but as these tubular hairs contain air, they form an excellent protection against the very low temperatures to which the animal is exposed in its more northerly haunts. The colour of the points on the upper part is fawn; and that of the roots pale blue with a reddish blush. The interior of the fore legs and thighs is white; and there is a white disc surrounding the insertion of the tail. In summer the general tint has more of the reddish blue, but as it passes gradually into the fawn colour, the different individuals are differently tinted at that season. As the hair elongates and becomes tubular it loses its gloss, and no doubt also much of its vital action.

Prong-horned Antelope.

The greatest peculiarity, and the one in which it differs from all other known species with persistent horns, is in the form of these appendages. They are branched, or have a little prong or antler projecting forward from each. This prong is not far from the root, and the part below it is rough, knobby, and of a whitish colour, while that toward the tip is round, polished and black, though curved forwards and inwards. Those naturalists who have written on this animal do not mention whether the bony core has the prong and the irregularities on the basal part, or whether these are confined wholly to the horny sheath. Pronged horns, somewhat different in form, and especially more compressed laterally in the basal part, have been brought from America, from the same regions that are inhabited by this animal; but whether they belong to the same species or to a different one, has not been made out. The males only of this species have horns.

The range and also the numbers of these animals are considerable. They are not found in the very extreme north, nor on the summits of the Stony Mountains; but they range along the secondary hills from the neighbourhood of Hudson's Bay, as far south as the confines of Mexico, and westward nearly to the shores of the Pacific. They migrate southward as the cold sets in, and prefer the open plains and slopes to the woodlands. They are gregarious, and associate and migrate in considerable flocks. The females produce one or at most two at a birth. Their flesh has a rank and "goaty" flavour, and is not very much esteemed even by the Indians, unless when they are very much in want of food.

The Chamois (*A. rupicapra*). As the *prong-horned* is the only American species which has hitherto been made out in a manner perfectly satisfactory, so the *chamois* is the only one which extends into Western Europe, and has its principal locality in that quarter of the world. It is not however confined to Europe, but is found in the mountainous parts of Western Asia, although, hitherto, it has not been seen to the eastward of the Caspian sea. It follows the line of the European mountains, both on the right and the left of the valley of the Danube; but it affects the most lofty and inaccessible situations, never descends into the lower plains, and is perhaps more abundant in the Alps than in any other locality.

The body of the chamois is that of a goat, and the legs also have the firmness of those of that animal rather than the airy lightness of those of the true antelopes. The neck is more slender than that of the goat, and the head, only that the horns are different, and the tips more produced, has much of the air of that of the furcifer. The horns are black in the colour, perfectly smooth, erect for about two-thirds of their length, and then turned back into hooks, very sharp at the tips. The horns are not above six or seven inches long, and they are smaller and less hooked in the females than in the males. The hair on the body is shaggy, deep fawn colour in summer, fading brown in winter, and bleaching into a sort of straw colour before that season is over. The females drop their kids in March or April, after a gestation of five months; they rarely have two at a birth, and, contrary to many of the family, they have only two teats. They continue to suckle their young till about October.

There are few who have not heard of the daring and the perils of chamois hunters in the Alps; and the animal itself is truly a wonderful creature among the crags and precipices. It is not very large, only between three and four feet, and about two feet in height at the shoulders; the croup is as high; and indeed leaping animals, which leap in any other way than to pounce upon their prey, in general stand about equally high on both pairs of legs. But the chamois appears as if it were wholly made of elastic springs, and it absolutely gets up precipices that have very little slope, and down those which are quite perpendicular, by playing at "ducks and drakes" against the rocks, as a stone does upon the water when projected nearly parallel to the surface. In ascending, it contrives so to strike the rock as that the force of the rebound projects it upwards, and it can repeat those rebounds, rising several feet at each. When it descends it is just as adroit in breaking its fall; and if it requires a rest, the smallest ledge, or even a pinnacle will afford it a secure footing. It seems indeed to be as much made for the mountains as the mountains are for it, and one almost regrets that the chamois should ever be hunted.

But the hunting of it is no holiday sport. Its senses are keen and its vigilance great, so that to come upon it requires both silence and patience; and as, when alarmed, it speeds like the wind, the hunter of the Alps dearly wins his game. After all, the prey which he takes is in all probability taken only from the birds of prey or from famine. The pastures on the Alps at chamois height are but scanty, and could not, in all probability, admit of any increase of numbers; and notwithstanding the hardihood of the hunters, their hunting ground is so extensive, their paths are so difficult, and they are for great part of the year so inaccessible, that it is very probable they do little more (if as much) than capture those individuals which would otherwise perish from casualties.

The SAIGA (*A. colus*). Though this species must be considered as originally and properly Asiatic, yet it not only straggles in considerable numbers into those portions of the middle latitudes of Europe which may be said to have an Asiatic character, but remains in them all the year round, shifting its locality with the seasons. It frequents the arid plains or *steppes*, which, interrupted only by the valleys of the rivers, extend from the Danube to the Don; and it reaches eastward into Asia, as far as the same climate and character of land continue. Its food is the saline and other pungent plants which are found in these arid tracts; and it never resorts to the marshes, the woods, or the mountains. It is a true antelope, having none of the climbing habits of the goats, and none of their peculiar odour; but still, from the nature of its food, its flesh is unpalatable.

They have poves or follicles in the groin, lachrymal sinuses under the orbits of the eyes, and (the males only) have the horns round in their section, annulated, and spiral. The horns are semi-transparent, of an amber colour, and much esteemed in the arts. The size is about equal to that of the fallow deer, but the body is thick, bunchy, and not so compact. The head also is large, and the nose prominent and cartilaginous. The legs are long but disproportionally slender, considering the thickness of the body; and though the animal runs fast for a little distance, it soon loses wind, and is not difficult to capture. In the covering of its body, it is tempered to the plains which it inhabits, its hair being long and flowing, white on the under part, and yellowish grey on the upper in summer, but fading into dirty white in the winter. When the latter season begins to set in in the northern parts of their haunts, they assemble in numerous flocks, and migrate southward, and when spring returns they break into small parties and retrace their steps northward. The period of gestation is six months, and the kids are not dropped before the end of May, against which time the plants by the margins of the little streams on the steppes are in full verdure; so that, living dispersedly, they find plenty of food till their young are able to follow them on a wider range, when the saline plants appear, farther into the wilds. They are much hunted for their horns and skins, but their flesh is but little esteemed.

The antelopes of Asia and Africa are far more numerous than those of America and Europe; and as there are extensive regions in both those quarters of the world, yet in a great measure unexplored, it is probable that future observation may increase the number in both. On the confines of those two portions of the globe we may suppose that some of the antelopes will pass from the one to the other, and thus be the same in both; but in proportion as their principal localities lie farther apart, we may, from the climatal and other differences, conclude that the antelopes will not have exactly the same characters in both. This is the more likely from the different structures of their other animals. The elephants of the two are distinct species, having peculiar structural differences; and although the point has not been so well made out, it is probable that the lion also is not quite the same.

The CHIRU (*A. Hodgsonii*). This is a mountaineer, or, at all events, an upland inhabitant, though it prefers the wide plains to the forests or the rocks. Its native locality is on the elevated plains which stretch along the northern side of the Himalaya mountains, in Thibet, and probably in countries farther to the north; but it has not been found on the Indian side of the mountains. The plains which these animals inhabit are very peculiar in their character; for though they are near the perpetual snow on the loftiest mountain tops in the world, their climate is in general mild, though seasonally the snow storms are very violent. The animals of such regions, especially those that keep the open plains during the storms, have their covering adapted to ther locality. They have a coat of long and strong hair which throws off the snow, and a short and soft under garment of wool, which keeps them warm. This is the case with the chiru, which, though it comes further down in winter, braves the weather in the open plains all the year round.

The chirus have no lachrymal sinuses, no poves in the groin, and no knee tufts, and the females have no horns. They are rather large animals. From the muzzle to the horns measures nine inches, from thence to the tail four feet three, and the tail is about eight inches long. The height of the back is about three feet, and the animal stands nearly equally high on all its legs. The lips are hairy, the nose enlarged, with a knob on each side; and the horns of the male are about two feet long, lyrated in their curve, and annulated to within five or six inches of their points by about twenty projecting rings which are most prominent in front. The belly and inner surfaces of the legs are white, the fine wool over the body grayish-blue, the coarser hair fawn-coloured at the points, and bleaching to a paler shade in the winter. The face, the muzzle, and a streak down the front of each leg are dark brown or black. The females have only two teats, and they are understood to produce but one young one at a birth.

They are social at all seasons, living in considerable herds, being under leaders and posting sentinels like deer. If danger approaches, or an alarm is given by the sentinels, they make off with much speed; but if the males are so surrounded that they cannot retreat, they stand at bay, and defend themselves with great courage.

The COMMON ANTELOPE, or SASIN (*A. cervicapra*). This is another species which is properly Asiatic; and though it has been *said* to exist also in some parts of Africa, the fact has not been satisfactorily made out. Its principal locality is India, over the whole of which it is distributed in all places that are adapted to its habits. It shuns equally the desert, the forest, and the mountain, taking up its abode in the rocky plains, where it bounds along with great agility and grace. In its leaps, which appear to it mere play rather than exertion, it is said to rise at least twelve feet from the ground, and clear a horizontal distance of thirty feet.

And its form is as graceful as its bound is fleet. It is not a very large animal; but it is remarkable for the symmetry of its proportions and the liveliness of its expression: round and firm in the body, elegantly formed in the haunches, clean and elastic in the limbs, and bearing the head and neck with singular grace. Its length is about four feet, and its height to the back two and a half; the tail is about half a foot long and nearly naked; the ears are nearly the same length, narrow and pointed; and the forehead to the base of the horns is an inch more. The eyes are large, prominent, and bright; the lachrymal sinuses are much developed; and the horns are peculiarly elegant. In the mature males they are spiral, and a little divergent, closely ridged at their base, annulated in the middle, and smooth toward the points. Their average length in the full-grown animal is about a foot and a half, though in very old specimens they are often nearly two feet. Their size and also their spiral curvatures increase with the age of the animal.

Their colours vary considerably with age. When young, they are of a brownish ochre yellow on the upper part, with a narrow white band on the middle of each flank, and the muzzle, inside of the ears, breast, belly, part of the thighs, part of the buttocks, insides of the legs and cannons, except the knee tufts, which are brown, are also white. As they advance in age, the upper part of the face, the back, and outside of the ears, become rich deep brown; and the markings upon the flanks and other places black; and in some of the finest specimens the colours are almost wholly black and white. These dark-coloured ones are the patriarchs or champions of the race; and each of them has a small flock of females and younger males under his command and protection. The final change of colour takes place about the fifth year, and the females change as well as the males, but they never become darker than a tawny yellow, and are marked with a white streak along each side of the spine. The females have no horns; their time of gestation is nine months, and the produce is only one. When suckled, that one is said to be driven from the herd by the leader or patriarch, in which expatriated state it either falls a prey to enemies, or survives and becomes bold and courageous. This appears rather harsh schooling in a country abounding with beasts of prey as India does; but the antelopes defy the chace of most predatory animals, and their crouching and springing foes are chiefly in the jungles, and not in the ordinary haunts of the antelopes. The chutah, or hunting leopard, is sometimes used to catch them by springing, and they are also flown at by hawks; but their flesh is dry and not much esteemed.

The elegant form and graceful motions of the antelope have, however, found it a place in the Hindû mythology. That is not indeed much honour, considering that these people hold sacred, and build palaces for, animals which most nations find it their interest to destroy: but the antelope has particular honours: it enters into the zodiac as their capricorn, and particular rites are directed to be paid to it. These circumstances prove how early and forcibly it must have attracted the attention of mankind; and certainly, in so far as beauty is concerned, few animals are more worthy of attention.

The Thar (*A. Thar.*) This is also an Asiatic species, and inhabits between the localities of the two last mentioned. It inhabits the southern slopes of the Himalaya, not approaching the snows of those mountains or descending into the plains of India. The species has not hitherto been met with in any other part of the world, but it is plentiful in the region that has been mentioned; not living in herds, or even in small flocks, but solitary, except in the pairing season, and thickly scattered along the whole length of the mountain range. Animals which live solitary are often more easily killed or captured than those which are gregarious; and this is the case with the thar, which is more easily obtained than either the chiru or the common antelope. The gregarious ones keep sentinels always on the watch, whether the majority of the herd are feeding or reposing, and these give the alarm; but as the solitary animal has none to watch for it at such times, it is more easily surprised.

These animals are peculiar in their structure as well as their habits. Both sexes have short horns, slightly curved backward, channelled in their length, and furrowed across. They have the lachrymal sinuses of the true antelopes; but they have no knee bouches or bones in the groin; their muzzles are destitute of hair, and the females have four teats. The make is heavy, and the limbs thick, so that the animal is but a slow walker, and is soon run down upon level ground. The rugged places are its proper haunts, and among these it is quite at home, leaping and bounding along with ease and safety, where few animals can follow it.

The Dzeren (*A. gutturoso*). This is another Asiatic species, inhabiting the wilds of the middle latitudes in that part of the world, and called by the Chinese the "yellow goat." It is about four feet and a half in length, and stands about two and a half high at the shoulder. The body is thick and fleshy, the legs rather short and stout, the horns lyrated, annulated, and of a black colour; the lachrymal sinuses are small; and in the male the larynx is very much enlarged, and forms a prominent lump on the throat, from which the animal gets the name of gutturoso. In the female that enlargement and the horns are wanting. The female has but two teats. The colour of the under part is white at all seasons, and so is the upper part during the winter, but in summer that part is grayish-yellow.

Though far from being the most elegant of the tribe, there are many interesting points about the species. They are not only social among themselves, but they seek the society of other animals, and join domestic herds very readily. They are orderly in their motions, and always advance or retreat in line. They are remarkably fleet and sure-footed, and contrive to find food where few other animals could subsist. Those rocky deserts in the west of China, and between that country and the central mountains, which the continued action of the weather has reduced in great part to sand, or rocks quickly mouldering into that substance, and on which the few patches of vegetation that do occur can hardly be seen by the traveller, are its pastures; and such is its fleetness and inexhaustible vigour, that it appears to fare as well in these wild places as the common ox does in the richest pastures. The females bring forth about midsummer.

The dzeren appears to border on its western confines with the saiga, and to be found wherever the general character of the country becomes too wild and fatiguing for the latter. It probably also meets the chiru on the south of the central wilds; and thus, in so far as our present information extends, it appears to be the peculiar ruminating animal of a singular district, of which we have very little modern knowledge, or indeed knowledge of any kind, upon which we can depend. In the central ridges, however, which give rise to the Indus and the great rivers of China, there may be other species more adapted to rocks and precipices; for, from the volume of waters which some of these rivers (especially the Indus) roll along, at the highest points to which their courses have been explored, we may conclude that somewhere in those unknown central parts of Asia, there must fall much rain, and vegetation must be proportionally luxuriant. The antelopes are, in a geographical point of view, perhaps the most important of all animals; and if as much attention were paid to the *habits* of the migrant species, as has been paid to specific characters which have no application, and consequently no meaning, they might probably have, ere now, in so far been made keys to the unexplored parts both of Asia and of Africa.

The Chickara (*A. quadricornis*). This species, as its trivial names implies, has four horns. It is an Asiatic, and an inhabitant of India; but its appearance. habits, and haunts, are very different from any of those which have been hitherto described. These have all been tenants of the plain, the rock, or the mountains, but the chickara is an inhabitant of the forests. Forest ruminantia, as well as those which reside chiefly among ravines and small broken rocks, where there is no breadth of pasturage, live solitary, or at most in pairs, and the males are monogamous. In such situations they cannot, of course, keep watch; and as their enemies are more numerous and can attack with more certainty than in the plains, a numerous herd browsing near each other in the jungle, would be but the means of betraying each other to the tigers. Accordingly, this species, which is comparatively small and feeble, as well as the next to be mentioned, which is one of the largest, boldest, and most powerful of the tribe, always live apart from each other.

Four-horned Antelope.

The chickara is common in most of the wooded parts of India; its whole length is about three feet two, of which the tail occupies five inches, and the head seven inches and a half. The height is about one foot nine; the first pair of horns, which rise between the orbits of the eyes, are about three quarters of an inch long; the second pair, which rise immediately above the first, are three inches long, and straight, but inclining outwards and a little forward, and all the four are black and smooth, without any channeling or annular markings. The females have no horns. The colours are, bright bay on the upper part, silvery white on the under, and the lips black. The young males are like the females, of which the colour on the upper part is considerably paler. They are wild and restless animals, and impatient of confinement unless taken very young. The male in the pairing season is very pugnacious.

The Nyl-ghau (*A. picta*). The name *picta* (painted) is not very descriptive of this species, as the only peculiar appearance of painting about it are some white spots on the pastern joints. This species is, like the former, an inhabitant of the Indian forests; but it frequents richer places, more closely adjoining the cultivated grounds, and not unfrequently, in the cool of the mornings and evenings, approaches the plantations, and levies contributions on the crops of the cultivators. It is a large animal, standing more than four feet at the shoulders, though less elevated at the croup. The shoulders appear to be elevated by a hump, owing to the produced processes of the vertebræ at that part of the spine. The body is strongly made rather than handsome, and the limbs have a slight resemblance to those of a poney. The hoofs are much longer and flatter on the under parts than in most of the species, indicating that the animal is fitted for walking upon softer ground. The neck is compressed laterally, and furnished with a rudimental mane, which extends as far as the hump on the shoulders; and on the lower part of the neck there is a pendent tuft of long and shaggy hair. The tail is moderately long, rather flattened, and covered with short hair except at the point, where there is a brush. The face is long and straight in the outline; the muzzle large and naked; the lachrymal sinuses much developed, the ears long, broad, and rounded. The horns are scarcely longer than the ears; they are smooth, angular at the bases, tapering, sharp at the tips, and very formidable for their size. Excepting the mane and the tufts on the throat and tail, the hair all over the body is short, smooth, and close. The under parts of both sexes are white; the upper parts of the males are usually of a dull grayish-blue, and those of the females tawny; but the colours are subject to considerable variations. The bluish colour is that of the mature male, the young male being of the tint of the female. The nyl-ghau will breed in confinement, and the females are gentle animals, but the males are vicious, and, in the season, it is dangerous to approach them. Their mode of attack is both singular and formidable; they crouch on their fore-knees, bring their hind and fore feet together, and then dart forward with great velocity, delivering their whole impetus upon the horns. The force would be sufficient to transfix even the tiger; and it is probable that no beast of prey will attack the nyl-ghau openly. But tigers, and even leopards, often leap upon them from their covert, and then easily despatch them; so that in the neighbourhood of the jungles nyl-ghaus form a staple article of the tigers' food. The female goes eight months with young, and generally produces two.

The Ahu (*A. subgutturoso*). This species is described as inhabiting the middle latitudes of western Asia, from the mountainous or semi-desert parts of Asia Minor, by the north of Persia, and through Bukharia, toward Daouria, and on the north bordering with the saiga. In its character and habits it has a very considerable resemblance to the gazelle which inhabits north of the African desert; and as the Isthmus of Suez is the point at which the wild parts of Africa and Asia run into each other both geographically and physically, on that account it is natural to expect that many of their productions, even their characteristic ones, should be specifically the same, though, of course, with climatal differences or varieties increasing as the physical circumstances of the countries differ more and more from each other.

For these reasons, but chiefly because, excepting in the locality they are found, they present no very remarkable differences that can be made the foundation of popular descriptions, we shall refer at least all the northern varieties of what is sometimes termed the gazelline group to the gazelle itself. The chief of these are, the Kalseepee, "black tail" (*A. Bennettii*), of the rocky parts of southern India, which is formed like the gazelle, only a little longer on the legs; the Ariel (*A. Arabica*), seen in the southern parts of Arabia, generally like the gazelle, only more elegant and darker in the colour; the Abu, and perhaps a few more. The Kevel (*A. Kevella*) should, perhaps, be included; but as it is found in Senegal, south of the great desert, that may seem to involve a little difficulty. The difficulty in a great measure vanishes when we consider that in ancient times there was fertile land all the way from the mouth of the Nile to Senegal, without any known interruption of more than a few hours' march for a gazelle; and that, in the parts of the line which have now become barren, the gazelle is among the animals most frequently sculptured upon the ancient monuments. That gazelles should migrate when the countries over which they pass are in progress toward the desert state, is neither improbable nor unlikely. When the desert begins to be formed, the surface, and of course the vegetation upon it, becomes saline; all the antelopes are fond of salt, which seems to be one of the chief inducements which draws them to desert places. The chamois hunters know that they will find their game where the rocks are saline, or salt water oozes out of the ground; and the antelopes in India lick the efflorescence of saltpetre, with which the naked soil there is often covered.

The Cambing Outang (*A. Sumatrensis*), is a native of the island of Sumatra, is called the wild goat there, lives on the rocky mountains, and has many of the habits of the goats. It is about four feet and a half in length, and half the same in height to the shoulder; the back is a little rounded, but, as is the case with all the mountaineers, it stands nearly equal on all the legs; the forehead is straight, the muzzle well formed, the ears are of moderate length, the horns about six inches, stout at their bases, but tapering to the points, and slightly curved backwards. The body is stout, the legs muscular, and the hoofs rather large. The hair is long, generally of a blackish brown colour; but white on the nape, and partially on the shoulders, and the insides of the ears; and straw-coloured on the chin. They are said to live in small flocks, and to be very shy and difficult to come at.

Those which have been slightly noticed are all the leading, and indeed all the well-established, species of antelopes in America, Europe, and Asia. It is not improbable that there may be other species in them all, except Europe; and indeed other species have been named and described; but as that has been done from fragments, and sometimes from small and mutilated fragments, and as the living animals are not known, they do not at present belong to popular natural history.

It now only remains, therefore, to take some notice of the antelopes of Africa, which may be regarded as the grand home and head quarters of the tribe; and were we in possession of data, by means of which we could trace and follow them in all their varieties and migrations, from the shores of the Mediterranean to the Cape of Good Hope; and from Cape Guardafui on the east to Cape Verd on the west, we should no doubt find the antelopes of Africa, with their accompanying animals, and other associated circumstances, one of the brightest as well as the most instructive pages in the book of natural history.

The subject, (though much has been attempted and done of late years,) is one which we know only at a few points. But we know enough to convince us how interesting the whole must be, and also to give us the hope that the channels of general knowledge may soon be opened through that wide and wonderful country. The termination of the Niger, the proximity of some of its branches to those of the Nile, and of its sources to those of the Senegal and the Gambia, render it not unreasonable to conclude that ere very long navigations may be opened from Alexandria to the Gulf of Guinea and to Senegambia; and when this is accomplished, we shall be able to take the lion in his den, and give the whole wealth of Africa, scientific and possessional, to civilisation and enjoyment; and for the mutual benefit of the people of Africa, and of all the other parts of the world, of which Africa forms the centre, and should be the point of connexion. At present we can only "hope and inquire on;" and it is cheering to reflect that the field is rich and ample; and that they who observe the details on the spot, and they who generalise those details, are equally, though in different ways, speeding the grand result.

Antelopes are not the only ruminantia of Africa; but they are by far the most numerous both in species and in individuals. They are not now so numerous in the colony at the Cape, or upon its confines, as they are represented to have been in former times, when swarms of lions toiled in vain to keep down their numbers; and the depredations committed by the prey were more formidable in the eyes of the more distant settlers than the power and ferocity of the preyer. Still they are very numerous, and many of them flit *en masse* from where the drought parches to where the rain brings vegetation; and from what has already been said of the habits of antelopes, it will be borne in mind that those which congregate in such numbers, must, at all points and stages of their migrations, be inhabitants of the plains; for animals do not change their habits when they migrate, they migrate because they cannot change them. Here, therefore, is one point in African geography, as clearly demonstrated as if eye-witnesses had been on the spot. "There are, throughout a great range of latitude in central Africa, plains which are capable of supporting countless millions of grazing animals,—numbers, in short, vastly greater than we know or ever heard of in a state of nature, in any other region of the globe." It, in fact, resembles the fertility of the sea more than the comparative sterility of the rest of the land: the antelopes, and some accompanying animals, arrive like shoals of herrings; and the lions follow, as the predatory fishes do those shoals, and appear not to make much more impression. The conclusion is irresistible: "There must be in central Africa immense tracts of land, which would better repay skilful culture than any other land on the face of the globe." The "passenger pigeons" of North America, though probably more numerous, though not so extended in their part, are not a parallel case; they only prove the vast abundance of wild berries; and where these are superabundant, the land is never either the most kindly for grazing, or the most valuable under the plough.

This instance is given to show the reader, who is not accustomed to reflect upon such matters, the vast importance, in an economical sense, of clear and comprehensive views in natural history. The notices of the African antelopes must be mere matters of detail, for to that only the information reaches; and, in many instances, it is most imperfect even there.

The Gazelle (*A. dorcas*). This is rather a small, but a very beautiful species, and one which has been long known, and much celebrated. Its principal locality at present is the north of Africa, between the cultivated country along the shore of the Mediterranean and on the banks of the Nile, and the Great Desert; but it has been already noticed, that other species are probably only climatal varieties of this one. The specific name *dorcas*, literally means "bright-eye;" and we accordingly find that, in the poetry of the Arabs and its imitations, the eye of the gazelle is the type and standard of beauty in that organ; and, it must be admitted, that the comparison is much finer than any of those in which inanimate substances are introduced as expressive of the lustre of eyes. But the name has other meanings, and alludes to the keen sight of the animal, and also to its darting along like a thrown spear or djerrid.

The gazelle is a very beautiful animal, the most gracefully formed of all the antelopes, indeed of all the mammalia. It is light and slender, and yet its structure is such as to indicate the very maximum of agility and strength which can exist in the same weight of body. In form it is the beau ideal of a deer, bearing about the same relation to the finest roebuck as the Belvidere Apollo does to man. If any of its proportions had been thicker, the impression would have been that it had weight to carry; and if thinner, that it was liable to fatigue. But so perfectly is the gazelle formed, that it gives no impression either of burden or of fatigue. Imagination cannot limit the extent of its bound, or the number of them that it can take in succession.

It is rather less than a roebuck, being about three feet and a half in length, one foot nine at the shoulder, and a little higher at the croup. The head and neck are beautifully formed; the forehead slightly rounded; the eyes large, prominent, dark, and expressive; the muzzle rather slender; the ears long, narrow, and pointed; the horns between nine and ten inches long, gently rounded and lyrated. They are much annulated at their bases, but the annuli disappear on the posterior surfaces about the middle of the length, and a portion at the tips is quite plain. The females are provided with horns as well as the males; but in them they are smaller, and hence some of those who have followed the trade (rather a common one with regard to this race of animals) of manufacturing an antelope out of a pair of horns, have made a species of the female gazelle, and called it *corinne*, and other names. With the exception of the knee tufts, and the tail, which is covered with stiff black hair, and ends in a brush, the whole covering of the gazelle is close and smooth; the anterior part of the head is a reddish fawn-colour, with a dark-brown streak on the nose, and a white one downwards from the root of each horn, over the eye, and along the side of the face. The contrast of these last gives peculiar brilliancy to the dark eyes. The general colour of the upper part is dun, that of the under white, and the two colours are separated by marginal belts of brown, more or less conspicuous. The tints of colour are, however, subject to much difference, both in different individuals, and in the same individual at different ages; so that, in this species particularly, colour cannot be made a character.

Gazelles keep the open plains, and browse upon the saline and other pungent plants which they meet with there. They are gregarious, living in considerable herds; placing sentinels when they graze, and bounding off apparently in different directions when an alarm is given, but making for a more commanding ground, and forming a square there, with the females and young in the centre, and the bucks outside on the defensive. The lion and even the panther will, however, attack these squares, crouching forward till within his distance, and then springing upon one with certain aim, upon which the others move off. It is when they resort to the water, however, which is generally in the morning, that antelopes generally, and gazelles among the rest, suffer most from the ravages of beasts of prey. The gazelle is the species which, geographically at least, connects the antelopes of Asia and Africa.

The Addax (*A. addax*) may be said to inhabit between the gazelle and the African deserts, and probably to follow that line of country through all its bendings and irregularities; the country near the sources of the Nile appears indeed to be a sort of centre, at which antelopes from the different parts of Africa meet, and possibly form hybrids; so that single specimens, and especially fragments, from that part of the world, should be received with the greatest caution.

Addax.

In point of locality the addax bears nearly the same relation to the gazelle in Africa as the common antelope does in Asia to those species which we have said may perhaps be considered as climatal varieties of the gazelle; and it is not a little curious, that the addax resembles the common antelope in many of its external characters, though it is larger in size, and differs from it in other particulars. It stands three feet seven inches at the shoulders, and an inch or two more at the croup. Its aspect is fleet and vigorous; its horns are large, spiral, and much annulated. They stand rather wider at the base, and are not quite so thick at the base in proportion to their length; but still they might readily bo mistaken for those of the Indian antelopes. The addax, however, has a tuft on the throat, immediately below the chin; the tail is much more produced, naked for the greater part of its length, and ending in a bunch. The outline of the buttock is also less rounded, and the insertion of the tail is farther down: it is, as one would say, "droop-rumped." The most remarkable difference is in the habit. The common antelope is gregarious, and the old males are rulers. The addax, on the other hand, lives solitary, or in pairs, and the males do not appear to interfere with each other. This agrees with the character of the localities in which the addax is understood chiefly to reside. These are not arid plains, half desert all over, but still having a breadth of vegetation, such as it is, upon which a herd can browse. They are little patches in the desert; and where these have supply enough of water to resist being changed into sand, they are usually covered with thickets of some sort or other. Thus the addax has, in part at least, the solitary habit of the bush antelopes, rather than the social one of those of the plains. The hoofs of this species are much broader than those of the majority of antelopes, which enables it to move more easily over the loose sands which often lie between its pastures. The general colour of the addax is grayish-white; the head and neck reddish-brown, with a white bar on the forehead, and some black round the bases of the horns.

It is on the south and south-east margins of the desert chiefly that the addax is found; and as these places come within the action of the periodical rains, it follows, almost as a matter of course, that the addax, and all the antelopes which inhabit there, must be migrants. Every one knows that the surface of naked sand must be hotter than that which is covered by any sort of vegetable; and that therefore the natural current of the air must be toward the desert. That current always carries with it germs of life of some sort or other, and when it blows a wind it can carry the seeds of moderately large vegetables. There is thus, therefore, a constant sowing of the desert; and if but one week of heavy rain fall upon it, Sahara itself cannot maintain its sterility. The rains on its margin are heavy and of some continuance; and therefore when these fall the fertile land invades the desert for many miles: and after the rain has ceased, and all the moisture is evaporated, the desert resumes its sway. These alternations play backwards and forwards every year, and over greater or smaller spaces, according to the annual proportions of wet and drought, which vary, of course, as they do in all countries. A season of great drought may thus send the antelopes of the desert's margin to Abyssinia, on the one hand, or to Senegal or the coast of Guinea, on the other; and a season of uncommon humidity may keep them in the interior. We cannot, therefore, say distinctly that they inhabit any particular locality, for they inhabit according to the season. This is another point in the natural history of central Africa which is well worthy of attention.

The Abu-harb (*A. leucoryx*) is the next south-eastern neighbour of the addax. It is, in all probability, the oryx of the ancients, and may (indeed must) in their days have been much more widely distributed than it is now. It is said still to exist not only in that part of Africa which lies opposite the south of Arabia, but in the latter country, and in Persia, as far as the Indies, being, in all its localities, the southern neighbour of the gazelle and its varieties. The data are not complete enough for certainty; but this is probable, as the *isothermal* line does *tend* in that direction; and it is all, partially at least, within the action of the rains. In former times it must, from the extent of plain which has been converted into desert, have extended much farther, and it is not possible to suppose that any one acquainted with Egypt could have been ignorant of it. It is a gregarious animal, and an inhabitant of the plains; but it browses on the leaves of trees, principally those of the acacias, and not the saline plants, like the gazelle; and therefore when, in its progress towards the desert, the country came to produce only gazelle's food, the abu-harb (the *oryx*) must have departed or perished. As its general habits resemble those of the gazelle, it is highly probable that there are, as in that animal, many climatal varieties; and that what have been sometimes described as different species are the same. It must not be forgotten that, as the progress of cultivation has broken the domesticated ruminantia of Europe into many varieties, the progress towards desolation has done the same with the wild ruminantia of the districts under notice.

Oryx.

This species is about the same size as the addax, but rather stouter in the body, and having the hoofs narrower, and not so well fitted for walking over loose sand. The general colour is white, variously marked with black on the forehead and brush in which the tail terminates, with brown on the legs, and with rust-colour between the brown and white. The horns are long, slender, and very slightly bent from the curve of the forehead throughout their length. This is the animal, the profile of which with the horns seen as one, is supposed to have suggested the notion of the fabled unicorn; and the robust make, the long tail with a brush, the mane, though that is much exaggerated, and all the characters of the animal, give some probability to a conjecture which can neither be established nor refuted. The animal which has been described as the Algazel (*A. Algazella*) is a mere variety of this one, and from the same regions—that is, from the south-east or south of the Great Desert; and till we know something of the country immediately to the south, and of the species and habits of the ruminantia there, any information which rests upon a single specimen, of which the general native habitat is not known, must be received with caution.

The Bekr-el-wash (*A. Bubalus*). This is another species of the margin of the desert, inhabiting perhaps nearer to the cultivated lands than those which have been already described. There is a slight trace of resemblance to the ox tribe in the abu-harb and the algazel, and the likeness is still more decided in the present species, which, for that reason, gets its Arabic name of Bekr-el-wash, or the "wild cow." The general air of the head, and the shape of the muzzle, ears, and horns, is bovine; but the horns are annulated to within a short distance of their points. The neck, shoulders, and outline of the croup are also modelled like those of the ox, and there is a sort of rudimental dew-lap between the fore-legs; but the animal is more clean and compact in the body, and the legs are larger in proportion. The proper locality of this species appears to be to the north of the Great Desert, but, like the other inhabitants of the plains bordering upon that, it appears to have been much more numerous in former times than at present.

Though several of the more delicately formed antelopes which are met with in the countries about the sources of the Nile, are probably varieties of the gazelle, yet there are others, which, though they have some analogy to that species, have very marked differences.

Sœmmering's Antelope. (*A. Sœmmeringii*) is a very beautiful species from the eastern parts of Abyssinia. They live in pairs upon the low hills, and partially in the bushes, so that their habit does not agree with that of the gazelles. They have very long and slender limbs; their necks, heads, bodies, ears, and, indeed, horns and tails are so light and slender as to give the impression of feebleness; and though there is an enlargement of the haunch, which indicates that they can leap with some alacrity, there is no indication of their being able to scour the open waste like the gazelle. The throat, belly, and insides of the thighs and legs are pure white, the whole of the upper part cream yellow, and the face variously marked with black, brown, and rust colour, but with a white stroke down each side, as in the gazelle, though in front of the eye rather than across it. The muzzle and crown are both narrow, which gives a lozenge shape to the face; the horns rise parallel and near each other at their bases, then they bend outwards till they are nearly horizontal, and again inwards at the points. They are annulated to near the points. The females have the horns rather smaller and smoother, but in other respects they are like the males in appearance. The hair upon the body is very short and glossy, and turned many ways, so that though really all one colour, the animal appears shaded in stripes.

It is possible that some of the small and lightly formed antelopes, of which menagerie or museum specimens have at different times been brought from the zone between the 10th and 15th degrees of north latitude in Africa, and which have never been seen in a state of nature, are varieties of the species now mentioned. There seems at least some probability of such being the case with those which have been called *A. forfex* and *A. adenota*. The shape and size of horns are, at all events, very unsafe grounds of distinction. It is true that the effect of climate upon the horns of ruminantia has been no more studied than its effect on their colour; but there *are* effects, even within small geographical limits; and they are so strong, that they suffice to distinguish the cattle and sheep of the different districts of Britain.

The Madoqua (*A. Saltiana*). This is a neighbour of the former, and is said to have nearly the same habits; but it is very different in size and in many of its appearances. It is not above two feet long; only fifteen or sixteen inches in height; its body, head, and neck are slender, and the cannon bones of the legs are hardly thicker than a goose-quill. The horns are slender, annulated, in the plane of the face with a very slight bend forward, and they are about three inches in length. Between them there is a pointed tuft of hair, about half their length, which at a distance has something the appearance of a third horn. The female has the tuft, but wants the horns.

This delicate little creature (certainly the smallest and by much the lightest of horned mammalia) is as beautiful in its colours as it is delicate in its form. The face, forehead, coronal tuft and legs are deep red, not so rich and glowing as many of the reds in the feathers of birds, but more so than in the hair of any other of the mammalia. The rest of the upper part to the haunches is squirrel-gray, or gray produced by alternate portions of bluish-black and white in the single hairs, excepting the middle of the back, which is reddish-brown. The posterior part of the haunches round the tail is white, the hair rather produced and radiating from the tail as a centre. All the rest of the under part is white. [In describing the under part of a quadruped, whether one of the mammalia or not, it is understood to mean the throat, breast, belly, and *insides* of the legs. The *outsides* of the legs belong to the upper part.]

There is still another antelope, differing with the locality, or there are two or three species of antelopes, agreeing in almost every thing except size and colour, and not differing more in these respects than some other varieties of the same species do, inhabiting the southern skirts of the great African desert, probably the whole way from the Red Sea to the Atlantic. These animals extending, as they do, over a range of nearly two thousand miles, may be supposed, even though identical in all their characters, to get different names in different places; and indeed, with the exception of those species which, from their resemblance to these animals are called wild oxen, or wild goats, it is probable that the names of all the gregarious antelopes on the borders of the desert, have the same meaning as "gazelle." The species in question is

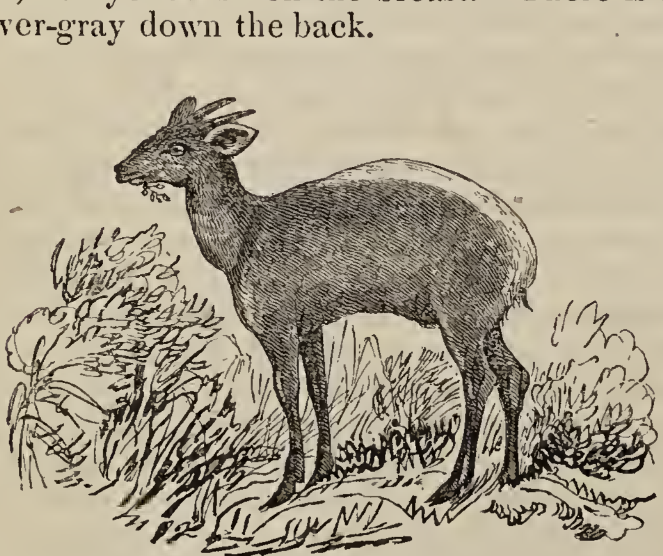
The Dama (*A. dama*), which certainly has been found of larger size and different in colour in the eastern part of the range than in the western. The former, found in Upper Egypt and Nubia, has been called Addra (*A. addra*); and the latter, from the country farther west M'horr (*A. m'horr*). There was indeed a third account anterior to these two, founded upon an immature specimen brought from Senegal by Adanson. These animals are gregarious in their habits, fleet in their motions, and firm and elegant in their shape. The legs are long; the neck long and curved, with a contrary flexure; and there is a white spot at the most prominent part of the curve on the throat. The horns are very peculiar; they are strong at their bases, inclined slightly back, and annulated; and in the remainder of their length are smooth, and recurved forward so as to form complete hooks.

The *m'horr* is about four feet in length, and stands about two feet and a half, the hind legs being a little longer than the fore ones. The length of the horns is about nine inches, including the hooks. The colour of the under part, from the neck to round the insertion of the tail, is white, and there is an oblique band of white across the hip. The head is bright fawn-colour, with some black hairs at the bases of the horns, more produced than the rest. The remainder of the upper part is of a rich reddish-brown.

The *addra* is fully a foot longer and half a foot higher than the *m'horr*. Its proportions and the form of its horns are exactly the same. It does not appear that there is more difference in the colours than is to be met with in the gazelle and in other species. There does not appear to be half the difference between the two, which may be seen in the cattle of the uplands and lowlands of any county in England, having considerable diversity of surface.

The Koba, or Kob (*A. Koba*), is another species, or probably two species, inhabiting to the westward of the former, in the interior of the country upon the Senegal and Gambia. One, the *Grande vache brune* of the French settlers in that part of Africa, is known as a menagerie animal; but of the other, which the same settlers call the *Petite vache brune*, we have not even that knowledge; and we know little or nothing of the *natural* history of the first. The "great brown cow" (*koba*) is almost five feet long; the head is long, the ears long, the horns are said to be twenty inches long, annulated and lyrated. The legs are shorter than in most of the antelopes, and stout. The hair on the body is shaggy. The general colour on the upper part of the body is dull purplish-red, the face and legs (which have the hair shorter) dark brown; the nose, and a streak in front of each eye, white. Its manners and mode of living are unknown. Analogy would lead us to suppose that it lives in the small fertile plains which alternate with wood and bush, and that it is not much of a migrant.

The Bush Antelope (*A. sylvicultrix*), is found in the woods or bushes in the vicinity of Sierra Leone, and by the English residents there called "bush goat." It is a dull heavy animal, lurking in the thickets during the day, and resorting to the open spaces in the mornings to feed. Its back is arched, its legs short, and it has altogether a "pig-like" shape; but its flesh is much better than that of the more handsome antelopes. The length is about five feet, and the height three. The horns are not longer than the ears, nearly straight, divergent, and slightly turned back. The hair is smooth and glossy, dark brown on the back, paler on the neck and flanks, gray on the thighs, and yellowish on the breast. There is a line of silver-gray down the back.



The Bush Antelope.

The Guib (*A. scripta*). This is another species of Western Africa, and, from the little that is known of it, it appears to inhabit still nearer the coast than the former; and, by inference, in pastures still more broken by wood and brush. The guib is of the mean dimensions, or four feet and a half in total length, and two and a half high at the shoulders, but rather higher at the croup. The horns are straight, but wreathed with two prominent ridges in the form of a double screw, prominent at the base, but becoming obliterated near the tip. The general colours are fawn and white variously marked. In general, the head is reddish-fawn, with a darker spot on the forehead, and three white spots on each side of the face, diverging from the bases of the horns, so that one is in front of the eye, the next under it, and the last farther back on the cheek. The fawn colour on the neck and body is darkest in the middle, becomes paler as it descends, and on the breast ends in white. The ridge of the back is marked with a longitudinal stripe of white and black mixed. From this, a greater or smaller number of white streaks pass herring-bone ways backwards and downwards, and they are crossed by longitudinal ones of the same colour, nearly parallel to the ridge of the back. The parts which these stripes do not reach are marked with white spots. The insides of the legs are white; but excepting part of the breast, the rest of the under side is brown. Both sexes have these markings; but it would be contrary to our experience in the case of all other animals to suppose that, when the colours are so much broken, there should not be great differences between one individual and another.

The writer of this article once saw a stuffed skin of a very small specimen from that part of Africa. It was without horns, had the shape and general colours of the guib, but it was dappled with white spots on the fawn-colour, not above twenty inches long, and small in proportion in all its other dimensions. As there was merely the skin, it is impossible to say whether it was a young guib or some other species. The probability is that it was a specimen of the guevi, or huebi (*A. pygmæa*), of which there are certainly varieties differing much in size. As is the case in Abyssinia at the eastern part of the line, these small antelopes of Senegal appear to keep much more in the hilly grounds than the larger ones; and if the accounts can be relied on, they are as numerous in some places as hares in a preserve. The place wants thoroughly exploring however, and for various reasons, physical and others, that is no easy or safe matter.

The guibs associate in small flocks, in the openings of the woods near the larger rivers; and they are, of course, not migratory to any distant part of the country. Indeed, the discovery of the course and termination of the Niger, has taken the district which it and the Senegal circumscribe, and also as much of the country on the outside as their influence keeps in a state of continual verdure, out of the range of those general causes which may affect the rest of the continent. This portion of Africa, which may, as respects the rest of the continent, be regarded as peninsular, is of a lozenge form, extending on the average about 1500 miles from east to west, and half as much from north to south. This large and important tract has its own central mountains, from which streams descend in all directions. There is to be sure, a summit level or "water shed" inosculating with the desert toward the north, between the sources of the Senegal and those of the Niger; but the sources of the most northerly branch of the Senegal, which flows parallel to the line of the desert, are understood not to be twenty miles distant from the Niger, after it has descended from the mountains, and is flowing slowly through the plains of Nigritia. Therefore, the migration of any animals, except birds, must be very limited in this district, and must be confined to the seasonal movement of the tribes in the northern parts into the desert and back again. The great body of its mammalia must be resident; from its productiveness, arising from the hottest climate and plenty of rain, they must be numerous; and the probability is, that antelopes are the most numerous of all, and that many new species and varieties may yet be discovered. As in this part of Africa the grasses are too coarse and reed-like for the food of the ox-tribe, and in the dry season, they in many places wither, and the remaining verdure is too much scattered for these comparatively slow-moving animals, antelopes and other swift and light-made, or long-limbed creatures, which can bound rapidly from place to place, or leap up and seize the pendent foliage of acacias and other trees, which retain their verdure in the severest drought, are much better suited to the country. Africa is thus, in an eminent degree, the land of antelopes; and the natural history of these animals, if complete, would be a key to much of the natural history of Africa.

When however we approach within about five degrees of the equator, our knowledge of the interior wholly fails, and even the coasts are known at particular points only; so that we can no longer make the country and the animals reciprocally illustrate each other, but must confine ourselves to detached notices of the individuals at those places where they are found. It is worthy of notice, however, that though there are in Southern Africa antelopes resembling all or most of the species of the north and the centre, there are none which can be regarded as exactly the same species; and there are some to which no nearly-approximating types have been found in any other part of the world. It is different with some of the other ruminantia; the *giraffe*, for instance, is the very same from Senegal to the most southerly point at which it occurs.

The known species which are first met with in our progress southward, form a distinct group. They are of large size, bold and courageous, inhabit rich pastures, and do not associate in large flocks, or migrate, at least to great distances. The first of these is,—

STEEDMAN'S ANTELOPE (*A. ellipsiprymnus*). (See plate "Antelopes.") This is a large and handsome species, and the most northerly one known inhabiting Southern Africa. The specimen from which our figure is taken, and which is the only one which has yet come to Europe, was obtained near the west coast, and to the northward of Orange River, in about twenty-eight degrees south latitude. The dimensions are seven feet three from the muzzle to the insertion of the tail; the tail to the extremity of the hair, one foot nine; height at the shoulder, three feet ten; at the croup, two inches less; length of the horns along the curve, three feet and a half. It is said that specimens considerably larger occur in the district from which the one in question was obtained, and that they are daring and even ferocious animals, which, excepting in cases of surprise, defy both the native hunter and the lion. The prevailing colour is rusty brown and grey, the brown nearly entire on the back and the lower parts of the legs. The face deep blackish-brown. The interior of the ears, the lips, a streak down each side of the upper part of the face, and an obscure band on the throat, immediately under the jaw, are white. There is also an ellipse of white, very conspicuous and well-defined, passing from the croup across the hips, and meeting below. This mark is equally well-defined and striking. The hair is not very long, but coarse and in clotted tufts, turning in all directions from a whirl on the middle of the loins, and reversed on the anterior part of the body, under as well as upper. The hair on the neck is also clotted, but there is no produced mane or beard. The horns are very strong as well as long; they rise in the line of the forehead, and gradually bend outwards and forwards, but not to any great extent of curvature, and they incline inwards at the tips. For two feet next the base they are annulated, the annuli prominent and distinct, twenty-four in number. The annulated part is also striated longitudinally, and of a light brown colour. The six inches at the points, which are smooth, are black. The section is not round, but has a groove, becoming gradually obliterated toward the points; and contrary to what appears in many other species, the groove is in front. All the characters are expressive of great energy and strength, and, in its native wilds, this antelope must be a noble creature, seen at a safe distance.

The EQUINE ANTELOPE (*A. equina*) inhabits nearly the same places as the last-mentioned species, though perhaps a little nearer to the sources of the rivers. At all events it has been more frequently seen. Its habits appear to be similar, living in pairs or very small flocks, keeping near the perennial streams, and not migrating. It is nearly of the same size, but is not quite so compact in the body, and has more elevation in the shoulders. The horns are not quite so long, and they are thicker, more closely annulated, and curved backwards. The ears are longer, narrower, and more pointed; the hair also is different both in colour and in texture. It is long, open, of a mixture of reddish and grey on the upper parts, and chestnut on the face and outsides of the ears, but variously mixed and marked with white. There is a white patch round each eye, ending in a streak downwards at the anterior angle; a short round white mane on the neck, a white fringe along the throat, and the belly is white. It seems subject to varieties both in colour and in size.

The TAKHAITZE (*A. barbata*) inhabits nearly the same places, but still more mountain-ward than the former. It is not quite so large, but remarkably fleet and daring. It has a long beard and mane. This species do not flock, but alternate between the small open places and the thickets on the hills, feeding upon the leaves of the acacia. Their manners are not very much known, but the natives say it is dangerous to attack them.

The BLAUBOK, "blue buck," (*A. leucophæa*,) is another species agreeing in several particulars with the three last mentioned, but smaller in size, inhabiting still nearer the sources of the streams, and being more discursive in its range, though not gregarious, or, strictly speaking, migratory. It is six feet in length, three feet and a half high to the back, and very compactly made. The horns are more than two feet in length, round, closely annulated to within six inches of the tips, bent back in a uniform but moderate curve, and very sharp at the points. The general colour of the hair is grey, with the insides of the ears, a streak before each eye, the insides of the legs, and a few hairs along the ridge of the neck, white. The hair on the body divides on the line of the back, and is rather coarse and open. The skin under it on the upper part of the living animal, is a black, which, shining through the grey, produces a sort of raven-blue tint. It is the epidermis only and not the mucous tissue which has this black colour, otherwise the hair would have it; and it fades when the animal is dead, as is the case with a highly-coloured epidermis in almost all animals. This species was, in former times, met with as a rare straggler within the limits of the colony at the Cape of Good Hope, but it has not been seen there for many years, and indeed it appears to be of even more rare occurrence than the former three species, of which the discovery is much more recent. All these antelopes appear to be peculiar to the Orange or Gareep river, which flows westward through the greater part of the breadth of the continent, about latitude twenty-eight degrees south.

The Springbok (*A. euchore*). This is the species which, in Southern Africa, corresponds to the gazelle of the north, and it is by far the more abundant and more beautiful animal of the two. In size it is about one-third larger than the gazelle, and it is more symmetrical than even that singularly graceful animal; so that if it had belonged to the country of the Arabs instead of that of the Hottentots, there is no question that the springbok would have been the most poetical of animals. Its colouring is equally fine in gloss and in tint. The general colour on the upper part is a delicate cinnamon-brown, and that on the under part pure white, and on the flanks these two are separated by well-defined bands of venous red. The head, face, cheeks, and chin are white, with a brown band on each side from the eyes to the corner of the mouth, and a mark of the same colour, beginning in a small point over the muzzle, and gradually widening, till it merges in the general

The Springbok.

colour of the upper part. At the loins there begin two duplicatures or folds of the skin, which run parallel to each other to the insertion of the tail. These folds are lined with long hair of the most delicate whiteness, and the animal displays or conceals that hair at pleasure. When the animal is in a state of repose, the folds are close, and nothing but the cinnamon-colour appears; but when it bounds and leaps, they open and the display of white has a very singular appearance. The horns of the springbok are black, round, finely annulated for about half their length, lyrated with bold flexures, and altogether very handsome. Both sexes have horns, though those of the female are smaller: in fact, their general characters are very similar to those of the gazelle. They, however, associate in much more numerous herds, are far more migrant, and do not form into such regular squares for their defence; and although their forward motions are perhaps not more fleet, their upward leaps are more conspicuous.

As they are the most beautiful antelopes of Southern Africa, so also are they the most numerous, though, as is the case with all the species, they are not now so numerous within the Colony as they were formerly. Indeed, so indefatigable do the colonists appear to have been in destroying every production of wild nature that when the country became a province of science, it was in a great measure one of ruins and memorials; and it does not appear that the climate or the fertility is at all improved by these labours of extirpation.

Springboks are migrants over an unknown range of country, flitting with the monsoons, and when they do so, flitting *en masse*. Formerly the numbers that appeared in the colony when the rains brought vegetation upon the open plains or *karroos*, are represented as having been immense; and they still come to the northern parts in very large flocks, though not regularly, every year. Where they come they clear every green thing before them; and it is said that on their marches, those in advance are fat, and those in the rear lean; and when they turn and move back in the opposite direction, the lean ones fatten and the fat ones fall off. This however is not the way in which browsing animals usually pass over an extensive pasture: as they feed themselves full they linger, and others get a-head of them. When herds of animals scour a pasture, they proceed in a manner somewhat different from this, and one of which some idea may be formed by any one who has seen a numerous flock of dottrels scouring the downs in the autumn, or of flocking birds ranging a stubble field in winter. The birds, no doubt, have the advantage of the wing, and so can come at once from the rear to the front; and when the pasture is an unproductive one, the whole roll along like a hollow cylinder. Grazing animals cannot, of course, change their place in the column so rapidly, but antelopes, especially the karroo-ranging antelopes, are very fleet animals, and in leaping over those in advance the springboks are perhaps the fleetest of any. As those that are in front begin to get full they linger, and the others get a head of them, partly by walking and partly by leaping. All grazing animals follow a course nearly similar. The front rank, or even fifty ranks, do not eat the pasture bare; they take but a mouthful or two and pass on. This may be seen in the case of a single cow (which is one of the slowest animals that are gregarious when they graze) when she breaks into the preserved hay-paddock or the corn-field: she does not eat all bare before her, but luxuriates along, trampling down much more than she eats. This leaving of something for the rest of the flock or herd is not only a general law in the economy of gregarious grazers, but those who choose to examine into nature will find that it varies with the power which the rest of the flock have of coming up: not, of course, with the condition of the particular individuals, for gregarious animals often expel the diseased and the weakly, but with the average powers of the species. What has been now stated is the true theory of gregarious grazing; and the story of the herds of springboks, which is repeated in even the most recent compilations upon the subject, must have been introduced by some one who had never examined the animals, and was otherwise very ignorant of the most obvious and general principles of natural history.

So well are the springboks, in particular, fitted for thus changing from the rear to the front, even by bounding over each other, that it is from their constant practice of the upward leap, even when there does not appear to be much occasion for it, that the Dutch boors have given them their vulgar name. It is said that they appear to take these upward bounds for mere amusement; but an animal never uses for amusement any action which is not given to it for some important purpose in its economy. The frisk of the lamb becomes the power of leaping the fence in the sheep; the gambol of the kid, the faculty of bounding from ledge to ledge of the cliff in the goat; and, in like manner, as the springbok does not inhabit the cliffs or the thickets, we may conclude that it leaps in advance so as to get its share of the food.

The Blissbok, or Blaesbok, from its white mark on the face (*A. pygargu*), is another species of the plains, which, like the springbok, was once very numerous, but it is now rare, even in the northern parts of the colony. This species bears some resemblance to the springbok in its form, but it is larger and more stoutly made. The full-grown specimens are rather more than five feet and a half in length, and stand fully three and a half at the shoulders. The horns are lyrated, annulated to very near the tips, and about a foot and a quarter long in the male; in the female they are shorter, and not so stout, but they are of the same form.

The Blissbok.

The colours are so strikingly contrasted, that the animal is sometimes called by the epithet "painted." The face, from the muzzle to the eyes, is white, from the top of which there is a narrow stripe of the same, continued to between the bases of the horns. The rest of the head and the neck are a deep reddish-chestnut, and so are the bases of the hairs on the back; but the points of these are of a dull whitish straw-colour, which, with the chestnut below, produces a mixed and very peculiar tint. This colour is bordered on each side by a broad band of brownish purple, which is continued over the lower part of the haunches; behind that there is a patch of white passing up the posterior sides of the hips, and encircling the root of the tail. The tail is dark coloured, nearly naked for eight inches from the root, and there ending in a thick tuft of black hair, about four inches in length. The whole extends along the belly and breast, and the insides of the fore-legs; the outsides of the legs are blackish or purplish-brown, and there are no knee tufts. The head of the animal thus shows two strongly contrasted colours, and the body three, all well defined, and not blending with each other.

These are the colours of the adults; but the young are so different, that they have sometimes been described as another species; and as we are not well acquainted with the changes of colour with age in any of those antelopes, of which a specimen is seen only now and then, the mistake in this species renders it possible that there may have been similar mistakes in others; and that those described species, between which the only or the chief distinction are differences in size and in colour, are, in reality, the mature and the young of the very same species. Great caution, at least, is necessary in speaking of animals, the numbers of which are very great, but of which only a straggling specimen is found now and then, the more so, that some gregarious animals have a disposition to expel from the herd any individual that is peculiar in appearance. If there is but one black sheep in a flock, it is generally found at the outside, or even at a little distance; and if there are a few such they are usually found together. This may, to a certain extent, account for the origin of coloured varieties in gregarious animals.

In former times the blissboks were much more resident within the colony at the Cape than the springboks; and though they are now more restricted to the interior than they were formerly, they still come more to the south than that species. They are more showy in their colours, but not nearly so lively in their motions; and they are not now found in such large flocks as the springboks are when they do make their appearance. They do not appear to have the same sensibility to the weather as the springboks; and indeed it is a general law of nature that the more migrant any animal is, it is the more sensitive to changes of the weather. This might be inferred from the fact of migration, without any observation to confirm it; because it is sensitiveness to the weather which is the immediate cause of migration; but observation confirms this theory. The springboks, even in a state of domestication and confinement, show great restlessness, and frisk about when the south wind blows; and in the country of the Cape, the south wind is the dry wind, so dry as to wither the vegetation in a very short time; and therefore it is the signal for the migrant antelopes generally, and especially for that, apparently the most migrant of all the species, to escape to more northerly regions, where there is still verdure on the face of the country. How far this dry wind of the southern monsoon may extend into the interior of the country, has not been stated, and indeed the country has not been sufficiently explored for that purpose; but there is no doubt that, to the full extent of its range, it carries the drought along with it, and renders the migrations of the grazing animals necessary. On the other hand, when the monsoon turns, which it does as soon as the southern parts become intensely dry, the rains begin; and as the south wind is first contended with in the interior, and so gradually more and more southerly, and as the rain always falls at the place of contention between the two winds, the progress of the rain, and of the vegetation and consequent migration of the animals, is towards the south, and terminates in the territory of the Cape. The most probable theory in a case like this, where, though there are analogies there are no facts, is, that the plains which are ranged by the migrant antelopes extend to the mountains south of Abyssinia, usually called the Mountains of the Moon; and that the wind from them to the plain at their base, when that begins to get dry and heated, is the turning of the season of the monsoon. See ATMOSPHERE and MONSOON.

The GEMSBOK (*A. oryx*) is another inhabitant of the plains of Southern Africa, but differing considerably both in its appearance and its habits from the two species last mentioned. These antelopes live in pairs, or at most in very small herds, and, as is the case with most grazing animals which have that habit, they do not migrate much or far, but rather shift from place to place within the same locality. They are not, indeed, so well fitted for long journeys as the springboks and other more elegantly formed antelopes; but in proportion as they are less fitted for shifting their quarters they are more capable of endurance, being much more robust and stoutly made.

Their linear dimensions are inferior to those of some of the lighter species, being only about five feet in length, and a little more than three in height at the shoulder; but their legs are stout, their bodies firm and compact, their horns very formidable, and they are endowed with no inconsiderable share of courage and determination. The horns are in the plane of the forehead, nearly straight, inclining very little from each other at the tips, stout and more than two feet in length. In colour they are black, firm in substance, very slightly annulated, rather blunt at the tips in the male, but sharp in the female. The animal charges with them like spears; and as it stands firm upon its well-knit limbs, none of the smaller carnivora can venture to spring upon it with impunity. It keeps clear of those places in which the lion crouches ready to spring, and when he is ranging or prowling it is said to dart in upon him, and either put him to flight or transfix him with its powerful horns. That is probable, inasmuch as the lion, assailed on the flank, or any way behind, is by no means so formidable as when he can spring, or even when he can strike with the paw.

Though not so grey as the blissbok, this species is rather handsomely marked. The head is white, with two bands of black extending from the bases of the horns to the eyes, which they encircle; they are then deflected obliquely backwards and meet under the under jaw, continuing in one black stripe down the middle of the throat to the fore-legs, then it again divides into two, first encircling each fore-leg with a ring of considerable breadth, then passing backward along the flanks and encircling the thighs in a similar manner. The tail also, which is bushy, the greater part of its length is black, and there is a black spot upon the cannons. The body above the black is reddish grey, and below white, as are also the legs with the exceptions that have been mentioned. The hair on the upper part of the shoulders is rough, and from being turned forward it has a good deal of a shaggy appearance. The hunting of this antelope is a matter of considerable danger, because when wounded it is apt to turn upon its enemies with great boldness and effect. It is said to get much fatter towards the close of the season of plenty than the more migrating antelopes, which agrees with the analogy of other animals in other places; but it is still sufficiently fleet and capable of flitting from place to place, to render the possession of a store hump unnecessary.

The CANNA (*A. orcas*). This is the largest and heaviest of all the species in Southern Africa; and as it is not more migratory than the gemsbok, and much more gregarious, it is furnished with certain provisions against the season of scarcity which that species is without. Toward the end of the season of plenty it gets very fat, and it has also a sort of hump upon the shoulders, which is most prominent when the animal is in the best condition.

In countries where the contrast of the season of rain and plenty, and that of drought and want is very great, the hump appears to be an important organ in the economy of these grazing animals, which from structure or habit (the two generally go together) do not migrate. We have striking instances of it in the camels, and in many of the ox tribe, and some of the sheep have a substitute in the tail. All these protuberances get large and firm when the animals are in good condition; with scanty feeding they become soft and flabby, and before the animal perishes of hunger they disappear. As that provision, in a great measure, disappears in those climates where the pastures are perennial, and appears again, either in the form of a hump or dewlap in the colder latitudes, no doubt of its purpose is left; and there is a farther corroboration in those animals which live upon mosses and lichens, and can scrape their food from under the snow, being without any such provision. See HYBERNATION.

The canna is not less than eight feet in length; and it stands fully five feet high at the shoulder, so that, in as far as is known, it is considerably the largest of the whole genus. Its legs are thick and strong, clumsy as compared with those of many other antelopes; and its hoofs are broader and not so much pointed. The haunches are large and thick; the body heavy, the neck much bent down at its articulation; a slight hump behind the shoulders, and a tolerably large goitre on the throat; the muzzle is more square and ox-like than in most of the antelopes; the horns of the male are very thick and strong, but tapering to the tips, and instead of being annulated, they are wreathed with a spiral projection; and in the female the horns are more slender, and the spiral is not so conspicuous. In the male they are about two feet in length, and in the female a few inches less. From between the horns, all along the neck and back to the rump, there is a short erect mane, from which the hair, on the upper part to about the middle of the loins, is shaggy, completely hiding the dewlap and goitre of the throat; and the upper part of it concealing the hump on the shoulders. It is necessary to mention that the hump on this animal differs from that on the camels and humped oxen. The processes of the vertebræ penetrate its substance nearly to the skin, and are of course accompanied by muscles, so that the deposit which is made in it is simply fat; and when it is exhausted it does not sink down but shrinks laterally. The head and neck are quite grey, the upper part of the body reddish-fawn, and the under part white; but the colours, especially that of the upper part, are subject to considerable variations.

Both the disposition and the flesh of this animal correspond with its habits. It is mild, and confiding rather than timid, so that it can be approached much more readily and closely than any of the rest. A few hunters can indeed drive the herd as if they were domestic animals; and one regrets that, in the cultivated parts of the country, they have not been tamed rather than extirpated. But, as already noticed, the instinct has been to kill every living thing which was native in Southern Africa, and a mean course is now too late. These animals are now to be found only in the more remote and wilder parts, and they are not very plentiful even there. Report says that nature, as is usual in all cases of ignorant and wanton destruction, is taking her revenge, and that the karroos, which once afforded seasonal pasture to so many antelopes, are fast passing into perennial and irreclaimable deserts. This is exactly what might have been expected; the grazing animals are just as necessary to the plants on which they feed as the plants are to the animals, so that the destruction of the one, where cultivation comes not instead, always involves the destruction of the other. But these animals are large; their flesh is far more tender and juicy, and of finer flavour than that of any of the other antelopes; and when in season they are very plump and fat. Thus, as has often been the case in other matters, the superiority of their usefulness to man has been the cause of their destruction.

The Caama (*A. caama*) has, in some of its habits, and in the flavour of its flesh, more resemblance to the ox tribe than even the canna. The species of antelope to which the caama has the closest likeness is the beker-el-wosh (wild cow of northern Africa), which at a distance has no inconsiderable resemblance to a cow with a thin body and long legs. The dimensions are large, the full grown male being at least seven feet in length, and standing five at the shoulder; but the dimensions of the female are considerably less. The body is strong and compact, especially about the haunches; the neck has none of the ox character, but is round, and has a contrary flexure. The muzzle is much produced, slender and rather pointed; the ears are large; and the horns are not far out of the plane of the forehead, though inclining a little forwards during the basal half of their length. The surface of that half, especially on the anterior side, is very rough and knobby, while the remaining half, which is nearly parallel to the line of the face, is smooth. The tail is of moderate length, slender, and with a brush at the end. The general colour of the upper part in this species is yellowish-rusty, darkest on the shoulders and ridge of the back. The general colour below is white; and there is a large triangular white spot upon each hip. A spot before the base of each horn, another on the terminal part of the under jaw, and the brush of the tail are black.

These animals are found on the dry plains of Southern Africa, in little parties of from a dozen to twenty, but keeping close to each other, and apparently much attached. The party is generally under the leadership of one old buck, who exercises pretty severe and constant discipline; but is just as ready to defend his charge when danger appears. The Dutch boors call him the "hartebeest," that is, the buck ox or the stag ox; and though, in his more essential characters, he is a true antelope, he certainly has some of the appearances of the ox and some of the habits of the stag. One of the most remarkable of the latter is, that of "standing at gaze," that is, taking a long, steady, and determined look, full faced, at any thing suspicious, in order to deliberate, as it should seem, whether to fight or to fly be the better alternative. If the former is the conclusion, attack is the mode of warfare; and though the mode of attack is not peculiar to this species of antelope, but common to most of the larger ones which inhabit open places, it is still both curious, and, to an unwary enemy, most formidable. He marches toward the enemy, snuffing the air and menacing a little with his horns till he succeeds in arresting his enemy's fixed attention. Then he drops on the knees of the fore-legs, and brings the muzzle backwards till the horns are charging in front like spears or bayonets. In this way he shuffles forward till he judges his distance to be the proper one for the spring; and then he bounds forward as if discharged from a bow, delivering the whole weight and impetus of his body upon the horns, in such a manner as would transfix a lion, were even that powerful beast to abide the collision. By a steady eye he, and all others that have this habit, are, however, easily avoided; as one step taken hastily aside after they are in the air, is sure to cause them to miss their aim. Though the caama has been much thinned by that indiscriminate slaughter which has been practised against all wild creatures in southern Africa, it is still the most numerous and also the most resident of all the larger antelopes; and considering the very hard pasture on which it can subsist, compared with that upon which beef and mutton can be rendered any thing like tolerable, and considering also the hints which, so to speak, the animal itself has absolutely given to that effect, it is really astonishing that it has not been added to the list of domestic animals. The young, of which the female produces a single one in the year, in September or in April, according to circumstances, are very easily domesticated; and as the flesh of the animals is abundantly sweet, and improvable with improved pasture, they might be made valuable.

The Ourebi, the bleekbok of the Dutch (*A. scoparia*, from its large knee brushes), is a much smaller species than the former, but inhabits nearly the same places, but is perhaps not quite so gregarious. In some of its characters it has a resemblance to the nyl-ghau of India, but it is considerably smaller. In the Cape Colony it is much more numerous toward the east and north-east, and beyond the British frontier; and it is sometimes supposed to extend along the whole eastern side of Africa, as far as at least the remoter sources of the Nile, if not farther. Its flesh is held in considerable estimation; but from the peculiar character of its pastures it is very dry to Europeans. It is said, however, when cured, to support the strength for a long time.

These animals are numerous, and they feed near each other, so much so, that all those which are found on the same pasture appear to be acquainted with each other. But they are merely acquaintance upon good terms, but doing nothing in concert. If one is taken the rest show no alarm; and if an alarm is given to the herd, each one seeks safety in its own independent course. Their associating in numbers without any principle of society, leader or rallying point, puts one much more in mind of the flocking of birds than of the usual associating of gregarious mammalia.

The dimensions of the Ourebi are, from the muzzle to the insertion of the horns, about seven and a half inches, the neck and body thence to the tail about three feet, and the tail about three inches and a half. The height at the shoulder is about one foot ten inches, and that at the croup fully two inches more. The horns are five or six inches long, rather slender, but firm, nearly straight, and very sharp at the points. They have a few wrinkles at the base, and then five or six well-marked rings; but these do not occupy altogether above an inch and a half at the base, so that more than four inches are black, smooth, very firm, and keen pointed. The position of the horns inclines a very little forward from the plane of the forehead.

The colours, especially on the upper part, vary in tint in different individuals; but the general colour is pale yellowish-brown. The under part, the posterior surface of the hips surrounding the base of the tail, the chin, the lips, and a bar over each eye are white; and the hair on the tail, which is rather thick and bushy, is jet black, which contrasts strikingly with the white around it. The fact of being higher at the croup than the shoulder shows that this animal is a leaper; and another consequence of its erratic habits is said to be that at no season is there any accumulation of fat upon any part of its body.

The plains of Southern Africa, in which the greater part of the antelopes of that country which have been noticed, find their food and take up their abodes periodically or habitually in flocks, in packs or in a more solitary state, terminate in three different ways, and each of these is marked on the boundary by antelopes of a character somewhat peculiar, or at least different from those found on the others. These are: first, evergreen forests by the banks of the large rivers, and the antelopes which inhabit there are, generally speaking, of tall stature, with produced, and often elegantly twisted horns, and they feed in part upon the green leaves and branches of trees. Secondly, "the bush," that is underwood or shrubs, which for part of the year are without green leaves; but among which there is even then dry vegetable food of some description to be picked up. The antelopes which inhabit these places are better formed for leaping and of smaller size; and thirdly, rocks, which are often very abrupt and wild, and the antelopes which inhabit them have a power of bounding and also of balancing themselves upon narrow ledges and sharp pinnacles which is truly astonishing, and leaves them, unless taken by surprise, pretty safe from wild beasts, as none of these can follow them in their boundings from rock to rock; and it is doubtful whether a cat, with all the flexibility of her spine, could remain for one second upon a point on which one of these wonderful creatures can not only balance itself for several minutes, but from which it can take a new spring, upwards, downwards, or laterally, as may be required.

But besides the species which have been enumerated, and some additional species which have been omitted because the accounts of them are not satisfactorily made out, there are certain other antelopes of the South African plains which, in some of their external appearances, and even some of their actions, appear to connect the antelopes with the horse which, as every body knows, is a solid-hoofed animal not ruminant. At first this seems something of an anomaly in nature; but when we consider that antelopes are the predominant grazing animals of that country, and that where they cease to come their place is taken up by many races, and among the rest by some of the horse genus, as the zebra, the dow, and quagga, we begin to discover that an approximation to these, as well as to the ox and the goat tribes, is necessary to adapt the whole of the races to each other and to their localities, so that no pasture may be unoccupied. Of those antelopes which have a slight trace of the horse in their form, the best known certainly, and probably the most abundant, as well as the most interesting, is

The Gnu (*A. Gnu*). This species, which some systematists make the type of a separate genus, and others include in the great genus *antilope*, is by no means so large in size as some of the species which have been mentioned; but in restless activity and in disposition to do mischief, it is the most conspicuous of the whole. They seem to be continually using their formidable horns, either in butting against each other, which they do playfully, or in attempting to root up trees and bushes, and gore or fight any other animals that come in their way. The height both at the shoulder and the croup is an inch or two under four feet, and the length from the muzzle to the tail is about six feet and a half. The form of the neck, body, tail and legs, with the exception of the feet, is exactly that of a small, compact, fleet, and strong horse; the feet are those of an antelope, the head and muzzle have a good deal of resemblance to those of the ox; and the horns, though somewhat intermediate between those of the buffalo and some other of the antelopes, have so many peculiarities that they cannot be described by comparison. The head is square, the muzzle broad, the neck rather short, but beautifully arched like that of a fine horse, compressed throughout its length, deep at its union with the body, but much less so at the head; the shoulders are deep, and the chest ample and muscular; the body is short, but straight, cylindrical, and very firm; the croup is remarkably broad, and the breadth is farther increased by a hump of fat on each hip; the tail is much longer in proportion than that of most antelopes, and it is covered with long hair throughout the greater part of its length, and borne flowing, like that of a high mettled horse; the legs are long and peculiarly handsome, but at the same time expressive of great strength as well as fleetness; even the ears have a considerable resemblance to those of a horse, which is increased from the peculiar bend of the horns not interfering with them; the neck and upper part of the back for a short distance are furnished with an erect mane of very hard hairs from four to five inches in length; there is also some long hair on the under part of the neck, and a large bunch of the same along the sternum, upon which there is a small dewlap.

The horns originate very near each other in the forehead, a little before the line of the ears. They adhere to that for a considerable part of their length, forming a strong bony frontlet, the two divisions of which diverge till they nearly reach the orbits of the eyes. Just at the orbits they become smooth and form their curvature downward till within a short distance of the nose, and then upwards again till the points are nearly on a level with the roots of the ears. This curved portion, which forms nearly a semicircle, has a bend outwards, so that when the animal is seen directly in front, the eyes appear in the bend of the horns, very bright and glaring. The head, which is so peculiar in form, is rendered still more warlike by a great beard on the chin, mustachios on the upper lip, and a sort of whiskers on the cheeks.

The females are pretty similar to the males, only the horns are perhaps not quite so large, and the general disposition not quite so mischievous. The females have two mammæ, and it is understood that they have not more than one young at a birth.

The general colour of the male is deep brown; and that of the female paler, with an ashen shade; the hair on the bodies of both being short and smooth, and thus allowing their symmetrical forms, and also the ornamental hair of their manes, tufts, and tails to appear to the greatest advantage. In the young animals the bristles round the eyes and mouth are almost entirely white; and so are the lateral and shorter rows of stiff hair in the mane, but the centre and longer ones are black, which gives the mane the appearance of being white, with a black border along the distal edge. In young specimens too the greater part of the produced hairs of the tail are white; but as they get older the white hairs diminish in number; and the old males which lead the herds in the karroos or dry plains, are said to be almost, if not altogether, without white. The young, on the other hand, are nearly white all over, and gradually deepen in colour as they approach maturity.

The gnu is not found at present nearer to Cape Town than the grand karroo in the interior of the colony; and it is so wild, that probably its numbers have been less diminished by the left-handed zeal of the boors than those of the other antelopes. The name given to it by the Dutch is "wilde beest," which means wild ox. These animals appear in considerable flocks; and from their manes and tails, the manner of carrying the head, which partially conceals the horns, and also from many of their paces, they might be mistaken, even at a moderate distance, for troops of wild horses; when advanced upon, they begin to fling with their heels, to butt laterally with their horns, and to play a number of antics as if they were practising a species of energetic and not inelegant military exercise. If advanced upon by numbers, they do not show battle, but retreat in regular order and with great rapidity; halting and forming again, after they have escaped to a certain distance. If, however, they are wounded, they become dangerous, because they turn upon their pursuers, and fight with great courage and desperation to the very last effort. Single males will sometimes, it is said, also advance upon a single enemy, while the rest of the herd remain at gaze watching the issue. In these cases, the general mode of fighting is that which has been described as practised by other species; but the gnu comes more briskly and rapidly to the ground, on which he kneels; his plunge on the enemy is also more headlong and desperate; and he falls more on his feet, and uses his horns with more execution. Gnus are indeed animals with which it is by no means safe to tamper; their strength and speed are both very great for their dimensions, and they appear to be irritated to pugnacity by the merest trifles. In these respects they bear a considerable resemblance to the nyl-ghau; and though as, like that, they are hardy animals, they would no doubt breed in ornamental grounds in England, yet both are somewhat dangerous either for the other ruminant inhabitants or for human visiters. In its native wilds, the gnu is a most interesting animal, lively, brave, handsome, and capable of bearing great extremes of temperature and humidity; but it is not an animal which can be profitably tamed, or even shown to advantage in confinement.

Two or three other species have been mentioned as classible with propriety along with the gnu, into a separate genus; these are represented as being all rather larger in size and not quite so singular in their combination of appearances as the gnu; but all of them are little known, and some rest upon single and not very well authenticated specimens. That there are considerable diversities of size, colour, and even shape and development of the horns in the same species is tolerably well ascertained; and there is another point which, though it has not been often adverted to, is worthy of being taken into account before a genus, a species, or even a variety is founded upon a single individual, or even upon one or two seen at different times, or even several individuals, seen occasionally and distant from each other. Though the fact has not been put to the test, there is little doubt that most of the animals, and probably all of them, are capable of breeding with each other; some resemble each other so nearly that the cross breeds may be fertile; and it is not unusual, or rather it is the general law of cross breeds among other races, readily to breed back to the pure blood. Now the different parts of antelopes often correspond in one part between two species, while they are very different in another part; as, for example, the horns are alike, the bodies are alike, or the limbs are alike; but each of the other two are different; and it is natural to suppose that a hybrid between these might agree with both in the common part, and with one of its parents in one of the others, and with the other parent in the other one. This, of course, would, to those who do not study the manners of the animals, or pay much attention to their anatomy, but simply kill them, and fetch away the skin and horns for the purposes of exhibition, constitute a new antelope. This doctrine cannot be pleaded in positive opposition to any thing which has been alleged concerning the species of antelopes, because it has not been investigated; but still it deserves to be mentioned as a ground of caution, and one the extent of which can be determined only after the facts are sufficiently known.

The Kokoon (*A. taurina*—bull antelope) is described as inhabiting places farther into the interior than the gnu; and, like that, assembling in large herds, but not associating with gnus, or mixing with them on the same pastures. It is much larger than the gnu, but stands very differently on its legs, being considerably lower at the croup, with the hinder parts rather feeble, but the anterior ones, the head, neck, and shoulders, are very powerful. It is, however, said to be a dull and timid animal in comparison with the gnu; and the elevation of its fore-legs, as compared with its hind ones, would lead one to suppose that during part of the year it must feed on the pendent branches of trees and on shrubs. The horns are rather more slender than in the gnu, and instead of passing down between the eyes, they pass on the outside, and then are recurved upwards, but very little forwards. The colour of this animal is described as being of a dark ashen-grey, that is, as having a slight resemblance to the female gnu. The *brindled gnu*, and one or two other species, have been described as differing from this one in the shape of the horns and the colour of the body, but too little is known of them for the purposes of popular natural history, or even for establishing the fact of their being distinct species.

The Pallah (*A. melampus*). This species, which is the *rodebok*, or redbuck, of the Dutch colonists, though it comes not much within their territory, is an animal of light and graceful figure, and is swift in its motions, resembling in many respects the common antelope of Asia, only it is a little larger. The head is small, the muzzle rounded, the eyes prominent, the ears rather large, the neck long and beautifully formed, the chest and belly rather slender, but the hips stout and finely rounded, indicating a leaping animal. The males only have horns, which for the last third are black and smooth, with sharp tips; the remaining two-thirds are distinctly annulated; and the horns are lyrated, and rather slender throughout. Lightness and grace appear indeed to be the leading characters of these very lively animals. The general colour on the upper part is a rich reddish-brown, with a definite jet black line down the ridge of the back, separating into two near the tail, and proceeding down so as to form a sort of oval round the insertion of that member. The under part, including of course the insides of the legs and thighs, is white, and so also are the lips, a spot or line over each eye, and the interior of the ears.

The length is fully four feet and a half, the height at the shoulder three feet, and that of the croup perhaps an inch or two more. In the full-grown animals the horns are about twenty inches long, and the tips are not more than three or four inches apart, although at the middle of their length they are more than a foot apart.

Though not seen within the Cape colony, they are described as being very numerous on the plains further to the north, especially those on the north or right hand bank of the Orange river, near the tropic of Capricorn. They are described not as gregarious, but as living in families of about five or six each; and they are said to display nearly equal leaping powers with the springboks, but they live in a rather more westerly situation, and do not appear to be so migratory as that species. They are eagerly hunted by the natives, who prize their flesh highly; but its quality is a point upon which Europeans have had but few opportunities of giving an opinion: they are, however, one of the species of whose characters and habits it would be desirable to know a good deal more.

The Steenbok (*A. tragulus*). As its Dutch name *Steenbok*, that is, stonebuck, implies, this species is found chiefly in stony places, not among the mountain crags, or indeed living rocks of any kind, but rather upon those upper plains or flats near the rocky hills or mountains, which are interspersed with large fragments and bowlder-stones. Such places, though the pasturage which they afford is generally sweet, and the shelter of the stones in so far protects it from the action both of the drought and of violent winds, so that it lasts for a longer period of the year than the pasturage of the more level and exposed plains, is yet at all times both scanty and scattered, and requires great powers of locomotion in any animal which has to find the greater part of its food there. The steenbok is in consequence an antelope of peculiarly light and buoyant form, remarkable for the length, slenderness, symmetry, and graceful motion of its limbs.

The steenbok is but a small animal; the length of the head to the horns being four inches, and two inches more to the ears, the length thence to the tail is rather less than three feet, and the tail is a mere lump or tubercle not easily perceptible. The height at the shoulder is about one foot seven, and that of the croup two inches more, indicating a leaping animal; and it clears the larger stones on its pastures with wonderful agility. The male only has horns, small, round, slightly furrowed at the bases, very smooth in the rest of their length, and sharp pointed. In many positions of the ears, the horns are concealed by these organs, which are double the length and broad in proportion. It is worthy of remark that, generally speaking, in the same genus of animals the species which find their food in the hardest and most arid pastures have the largest ears, and, it is presumed, the most acute sense of hearing.

The Steenbok.

The head is oval, and tapering to the muzzle which is round, small, and black. The eyes are high in the head, with black sinuses under them. The forehead and nose are pale chocolate-red; the sides of the face and chin, fawn-colour; the neck from the nape and all the rest of the upper part from the croup chocolate-red, passing into deeper red on the sides of the neck, the flanks and the thighs. The breast and under part generally, including the inner sides of the thighs, are white, with the exception of the groin, which is black, and nearly or all together destitute of hair, the lower part of the legs is dun or dark buff. There are no knee brushes, but the knees of the fore legs have small callosities. The pasterns are very short, the hoofs are also short but rather high, black, and firm in their texture. There are no false hoofs on the legs. There is one peculiarity in the colouring which deserves to be mentioned: a black line proceeds from the root of each horn in the male, and the two meet between the ears, forming a very blunt angle. This marking is more conspicuous in the harmless females than in the males; for in them the stripes begin and terminate in the same way, and there are no horns to conceal them.

The steenbok is a native of those places of the Cape which are not far from Cape Town; and it is generally scattered over all the stony flats which are found immediately below the sides and also in the gorges of the mountain ridges. Those haunts expose the animals, especially the young, to great depredations from birds of prey, eagles in a particular manner. They are also met with in more localities than most of the other species; and hence they are very generally hunted as game. They are timid and fleet, and when pursued can take such bounds as to clear obstacles of from twelve to fifteen feet in breadth; but they are mild and gentle, and not only do not turn upon their pursuers, but when pushed to extremities, they conceal their heads in holes or in bushes, and suffer themselves to be taken. Their flesh is held in considerable estimation.

The Grysbok (*A. melanotis*). This species has a very considerable resemblance to the steenbok both in its structure and its habits; but it is more stoutly made, and the legs in particular are both shorter and stouter. It is altogether four or five inches shorter, and stands about two inches and a half lower both at the shoulders and at the croup. The horns and ears are also much shorter: the former being only about two and a half inches, and the latter five. The horns stand immediately over the orbits; they are straight and smooth, and shining, except a few small annuli at the bases. The tail is merely rudimental, and does not appear beyond the hair. The upper part is of a moderately intense crimson colour, and consists of rather long hair, as indeed does the whole covering of the animal. But the red hairs are uniformly mixed with a thin sprinkling of longer white ones, which give the upper part a hoary aspect, and it is for this reason that it is called the grysbok or grisly-buck. The head and the lower parts of the legs are fawn-colour, and the rest of the under parts light sandy-brown. The muzzle, the openings of the sinuses, a small circle round each eye, and the backs of the ears are black; but the latter are thinly powdered with white hairs, being otherwise almost naked.

Its pastures are not exactly the same as those of the steenbok; for while that resorts to places near the mountain rocks, this rather frequents those which border upon the mountain bushes and mountain forests,—the scrubby places which are scattered with low bushes, in nearly the same manner as the haunts of the steenbok are with stones. Like that species it is not gregarious, but found in pairs, which, though similarity of haunt brings them into each other's locality, appear to take no interest in each other. It is not nearly so fleet as the steenbok, and therefore in open places it is much more easily caught; but its bushy pastures afford it cover in which it conceals itself very adroitly, and is not easily driven out. It is, perhaps, more common in its proper localities in most parts of the Cape than the steenbok; and its numbers are much less liable to be thinned by the eagles, as the young are concealed under the bushes, which shield them equally from the vision and the pounce of their winged foes. The bushes in such places are generally hard and stiff, and not unfrequently beset with strong prickles; so that though an eagle were to espy a young grysbok under one of those bushes, and stoop at it, she would gain nothing but a thorough scratching, and the animal would escape to a place of safety before she could possibly disentangle herself. The flesh of the grysbok, like that of the former species is, though at all times destitute of fat, held in considerable estimation by the colonists.

The Koodoo (*A. strepsiceros*). This splendid animal gets the name strepsiceros from the numerous and graceful turns or flexures of its magnificent horns. These horns are among the most showy borne by any animal. They rise together from the crown, bend gradually outwards, then inwards and outwards again, with several flexures which have in each horn the character of a very peculiar spiral; and their remarkable curvature is rendered more striking by a projecting ridge which winds very gently round them, so as always to keep on the convex side of the curve. They are very thick and strong at the bases, from which for a considerable distance they are wrinkled but not annulated. The basal part, as far as the wrinkles, is brownish horn-colour, the middle part of the horn black, and the tip white; each horn is, measured along the windings, not less than four feet in length; and as the animal which carries them is large, they have a very showy appearance. The length of the full-grown koodoo is not less than eight feet; it stands fully four feet at the shoulder; and when the head is carried erect, the points of the horns are at least four feet more. There is a good deal of sheeplike expression in the animal; and from the account given, it will be seen that the horns are something intermediate between those of the sheep and the antelopes. The ears, face, and muzzle are broad; the neck and body are heavily and rather loosely made; and the legs are thick, without many indications of agility. The general colour on the upper part is light greyish-brown, with a white line down the back, and a number of small bars descending thence over the sides and flanks; the lower parts are whitish-brown. Along the neck and on part of the back there is a sort of straggling mane; and there is also a beard on the chin, which is continued along the neck, and as far as the posterior edge of the sternum.

Though from its size, the form of its horns, and the contrast of its colours, the koodoo is an animal well calculated to arrest the attention; yet it has none of the wonderfully buoyant characters, which are so remarkable in those smaller creatures, which scour along the deserts like the wind. The koodoo is an animal of richer pastures, and less laborious pursuits. It lives in the thick forests near the perennial rivers, where, when the grass happens to fail, abundant food may still be had in the leaves and young shoots of trees. It does not, therefore, require to migrate; neither has it any masses of stone to overleap, any rocks to climb, or any deserts to traverse. Its greatest annoyance is water, when its pastures are partially inundated or divided into islands during the rains. On these occasions koodoos readily betake themselves to the water, and swim with considerable ease, their heavy horns resting partially on the back, assisting them in keeping the muzzle elevated above the water. In their ordinary ramblings through the forests, which are usually not at a very quick pace, the horns seem a sort of lumber to them, and they then, in some measure, carry them on their backs. It is possible that this may assist them in respiration, as the direction which that gives to the muzzle brings the nostrils into purer air than can be expected nearer the surface, where so many substances, both animal and vegetable, are in a state of putrefaction. Indeed, unless they serve some purpose of this kind it is not easy to see why many of the sylvan antelopes are furnished with even larger horns than those of the open plains, horns which can be of little service either as a means of defence, or as auxiliaries in finding their food in dense forests. The uses of horns in those animals which have them is, however, a point to which much philosophical attention has not been paid, though it is certainly one well worthy of investigation. The koodoo is not a swift animal, because swift marches would be but of little value in a forest; but it can endure much fatigue, and it leaps with great power and energy, so as to clear readily a bush or other obstacle ten or twelve feet high. The female has but one young at a birth; and the young are gentle creatures, domesticated without any trouble, and never attempt to regain the wilds, so that they might be rendered highly ornamental in Europe as park animals. The males too, though they stand at bay with sufficient boldness and resolution when attacked, are not understood to be in any degree vicious or disposed to act on the offensive. From the nature of their haunts they are animals which are not very much seen by Europeans. They are said to live in small packs.

The Boshbok (*A. sylvatica*) is another inhabitant of the forests, smaller in size, more active in habit, and more generally distributed than the koodoo. This animal is found in most of the wooded districts of the Cape, to which it keeps close during the day, but comes out early in the mornings and during moonlight nights, and not only grazes in the adjoining pastures, but makes free with the corn-fields and even the gardens of the settlers. Its voice is said to resemble the barking of a dog; and on that account it is said often to mislead travellers in the forests. Hearing its bark, they proceed upon it, never doubting that they shall come upon a house-dog in a cottage; but when they approach it, so that it hears the rustling of the branches, it immediately becomes close and silent; and of course neither dog nor human dwelling is found. The deception is not, however, at an end; for instantly another begins to bark at some distance in advance, and continues till approached in the same manner. After that a third, and so on, so that the forest may be ranged from morning till night with the apparent bark of the dog still near, but neither dog nor cottage ever seen. The habit of the animals renders this species of deception very perplexing. They are not gregarious, or reposing in a herd at one quarter of the forest, and again in another quarter. They live solitary, or at most in pairs; and when the female has young ones following her, of which there are often two, the male lives apart, so that they are dispersed over the whole forest. Their flesh is much esteemed, and they are hunted with considerable avidity; but still their numbers have been much less thinned than those of many other species; and they appear better calculated for being game animals in coppice preserves than almost any other of the antelopes.

This species measures about four feet from the muzzle to the tail, and stands about two feet and a half high at the shoulder. The horns are about a foot long, thick at the bases and tapering to the points, which, however, are rather blunt. They are twisted, or rather wreathed spirally by two prominent ridges for the first two-thirds of their length, the third next the tips being smooth. The ears are large and rounded; the fur thick but not shaggy; and, the horns excepted, many of the characters of the animal resemble those of the fallow deer. The male has the ground colours dark sooty-brown on the upper part, and white on the under; the cheeks bright reddish-brown, and the legs yellowish-brown, passing into grey in very old specimens. The lips and chin are white, a white spot surrounds each eye, there is a white band round each extremity of the neck, white spots in the cheeks, and some dappling with white on the haunches, but the white markings are subject to variety in different individuals, and also in different ages. The markings of the females are nearly the same as those in the males, only those on the upper part are less conspicuous, because the ground-colour of the female is reddish-fawn, of rather a pale tint. The difference of colour in the males and females appears before they reach full maturity; but the brown, and also the white in the males, become more conspicuous with age.

The Duikerbok (*A. mergens*) is another inhabitant of the bushes or copses, and also of the taller forests in which there is much underwood. It is equally numerous with the last mentioned species, and though not quite so familiar in its manners, it occasionally pays nocturnal visits to the corn-fields and gardens.

In its native woods it is even more difficult to be seen, because it plunges under the bushes, instead of leaping over them; and it is on this account that it is called the duikerbok, which means, the diving or plunging buck. They live dispersedly, or in pairs; and that farther diminishes the opportunities of observing it in its native haunts. In appearance, and also in manners, it bears a considerable resemblance to the bush antelope of western Africa, only it is more elegantly made, and more lively in its motions. The length of the body is about four feet, the height at the shoulder about two. The horns, with which the males only are provided, are rather small, straight, upright, very sharp at the tips, of a black colour, and altogether smooth, except two or three annuli at the base. The ears are rather long; and between the roots of the horns there is a coronal tuft of hair, which spreads round in all directions, and partly conceals those appendages, and also the ears. This tuft is common to both males and females; and it may serve (as the crests of some birds do) to render the outline of the animal's head less perceptible to enemies while it is raised over the bushes for the purpose of reconnoitring. The general covering of the body is long, but smooth and close. The prevailing colour is light-brown, with a trace of yellowish on the back, and one of greyish-ash on the under part. The centre of the face is dark-brown, the lower portions of the legs and the hair on the tail are black; there is not much difference in the appearance of the male and female, except the absence of horns in the latter.

The Kleenebok (*A. perpusilla*) is a very small and slender-limbed species, which has sometimes been confounded with the guevi of tropical Africa, though they are perfectly distinct, and no one of them has been hitherto found in the other's locality. The Dutch name means the little buck; and the epithet *blauw* (blue) is sometimes added as expressive of its colour. These animals are not gregarious or migrant, but live in pairs among the short bushes. They are exceedingly lively and playful; but at the same time so timid and prone to hide themselves in the bushes that they are seldom seen, even in those parts of the colony where they are known to be very abundant. They are very gentle in their manners, easily tamed, and docile, and soon taught to distinguish and go to those that are kind to them. The neck is very slender, the head pear-shaped, tapering much to the muzzle, which is slender; the ears placed far backwards, rounded at the tips, and nearly naked within. The horns are very small, being only an inch and a half in length in the male, and three quarters of an inch in the female. They are black, nearly erect, but with a slight inclination backwards, marked with seven or eight very minute annuli at the bases, but smooth and very sharp at the tips. The tail is about two inches and a half long, but very conspicuous from the rapid inward curvature of the outline of the hips. The general colour of the upper part is slate-grey, and that of the under ash-grey, but much paler and inclining to white in the young specimens. The forehead and nose are brown; but on each side a narrow line of a brownish-red colour proceeds from the roots of the horns towards the nose, and is met by an oblique one of the same colour under the eye. The legs are of a reddish-brown colour, very delicately made, and the hoofs are black, small, narrow, and pointed. It is altogether a very beautiful and very interesting little creature.

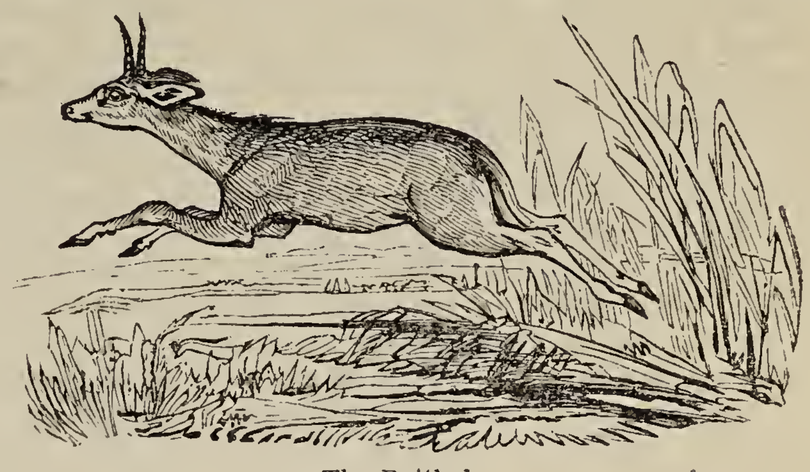
The Rheebok (*A. capreolus*) is of considerably larger size than the species last mentioned, and its haunts are different. It is a hill animal, frequenting the lower slopes of the mountains, especially when these are spotted with trees, and containing underwood between. It appears to be partial to water, as it is found in the vicinity of those places where pools stagnate after the rains; and as these dry up in one locality it shifts to another, never inhabiting at any great distance from the water. These animals are not gregarious, but they associate in packs or families, consisting of about half a dozen on the average; and made up of one male and two or three females with their young. The males fight battles of gallantry, as is the case with most polygamous animals, and the old males, as is the case among deer, drive off the young ones from the family as soon as they are full grown. In other respects they are gentle animals, and the young are easily tamed; they also come very frequently to maturity.

The form of the rheebok is graceful; both body and neck are small, and stretched for rapid running rather than for leaping, and its legs are slender, but finely formed. When stretching itself to its full speed its body is near the ground; and yet it glides along as if it were scarcely touching, and without any apparent leaping or exertion. As its flesh is very dry and insipid, it is very little hunted, and therefore it is plentiful in many parts of the colony.

The length of the full-grown animal is about five feet, and the height both at shoulder and croup about half that measure. The horns of the male are from nine inches to a foot in length, with a few obscure wrinkles or annuli on the basal third, but exceedingly smooth, and tapering finely to keen points throughout the remainder of their length. They are indeed so sharp, so firm in their substance, and taper so gradually, that the natives use them for bodkins and even for needles.

The ears and tail, both of which are nearly naked, are about six inches in length, the head from the horns to the muzzle is about the same, gradually tapering, and the muzzle is small and black. The hair is of a soft woolly texture, approaching the nature of fur, beautifully formed into distinct curly locks in the young animals, but less so in the mature ones. The general colour in the upper part is reddish-ash, of varying tint as the light plays upon it, which is found to be produced by the individual fibres being coloured with a series of wings of ashen-grey and reddish-brown. The prevailing colour on all the under part is white, and so also are the chin and the margin of the lips, but the nose is brown, and the forehead and chin light fawn-colour. This species exhibits considerable varieties of colour, which may have led authors to describe different specimens of it under different names. It is questionable indeed whether it is not subject to a seasonal change of colour; and it is certain that while the legs of the adults have short smooth fur, those of the young have it reduced and curled into small locks.

The Reitbok (*A. eleotragus*). This species, as its name of reedbuck implies, frequents places which abound with reeds, such as the banks of streams and torrents when these contain water, and the beds of them after they have become dry. It is not common in the immediate neighbourhood of Cape Town, but in the interior it is not rare, though it shifts about and is never met with at any great distance from water. These antelopes do not flock, but they are sometimes met with in small packs, though more generally in single pairs; and as they are generally concealed



The Reitbok.

among reeds and other tall herbage, whether green or withered, they are not often seen in proportion to their numbers. Whether it be owing to difference of exposure to the weather or to some other cause has not been clearly ascertained; but it is generally agreed that these animals differ more in the general tints of their covering than any other of the antelopes. On that account they have received different names, but without any other foundation than mere differences of colour.

The reitbok is rather a short than tall animal, being half a foot shorter than the rheebok, but standing three or four inches higher on the legs. The head and tail are both long for the size of the animal, the former being ten inches from the muzzle to the roots of the horns, and the latter an inch more. The horns are peculiar, and at the same time very elegant. They are round, have prominent annuli toward the bases, the hollows between which are beautifully striated. They rise and continue, for the annulated portion, nearly in the line of the forehead, or with a very slight inclination forwards. The remaining or smooth portions bend forwards and a little downwards at the tips, so as to form hooks directed to the front, and it is probable that the animal makes use of those hooks in pulling down the tall reeds and other plants by the margins of the waters, so as to enable it to feed on their tender tops. The general colour of the body is a uniform dull ash-grey, but after red, and sometimes inclining to silvery. The throat and some of the under parts are generally silver-grey, and there are generally some spots or markings of black on the head. The hair on the lower part of the neck, the sides, and the tail, is long and somewhat shaggy. The females are of smaller size than the males, and without horns, but they are very little different in colour.

The Klipspringer (*A. oreotragus*) is a small and wonderfully fleet species, equally remarkable for the boldness of its adventures and the inaccessibility of its haunts. A figure of it is given in the background of the plate "Antelopes," in the attitude of taking a bound from one cliff to another, which it often does to great distances, and over the most frightful chasms. Its feet are so sure, that it can either spring from or alight upon a point of rock which does not appear as if it could afford footing even for a bird. It is the only antelope hitherto discovered in any other part of the world which rivals in command of the rocks the chamois of the Alps.

The entire length of the klipspringer is rather more than three feet; the height at the shoulder, twenty-one inches, and rather more than two and twenty at the croup. The head is small, narrow or compressed laterally, and the front is depressed immediately below the orbits, and terminates in a very slender naked muzzle of a black colour. The body is very compact and round, and the muscles of the shoulders, and especially of the haunches, are very vigorous and strongly marked. The legs are clean made, but much more robust than those of the majority of antelopes of the same size. The hoofs are singular, unlike those of any other animal. They are perfect cylinders, and the pastern joints are so rigid, that cannons, pasterns, and hoofs appear as if they were one continued straight line. There is thus no sort of lateral strain upon any of the joints of the feet, and wherever the foot catches, it holds on the point of the hoof, like a spiked pole. The prints of the hoofs on the ground, when it does walk on surfaces so soft as to receive that impression, are unlike those of any other cloven-footed animal. But it seldom quits its native rocks, as its powers of walking are very inferior to its powers of leaping.

The general colour of the upper part is yellow and green, each fibre partaking of the two colours in different portions of its length. On the sides the hair is long, thick, and standing out, so as to defend the animal from the collision of hard points. On the upper part of the head and neck it is very singular, each hair being a hollow tube, and the whole so fragile, that it breaks with a very slight touch. The general colour of the under part is brownish-yellow or yellowish-red, and that on the legs and head is brownish and short and smooth. The horns of the male are about three inches and a half in length, with small annuli at the base, and smooth for the rest of their lengths. The haunts of klipspringers necessarily expose them to the depredations of the larger birds of prey, though for the same reason they are safe from beasts of prey. Its flesh is much esteemed, and also its hair for stuffing cushions of various kinds. For these reasons it is much hunted; and though it sets dogs at defiance, it forms a conspicuous mark for the musket. It was once abundant in the rocky wilds of the colony, but it is now comparatively rare.

Such is a short outline of the principal species of antelopes, of which satisfactory accounts are to be met with; many more have been mentioned by authors, some upon questionable, and all upon rather imperfect authority. These have in general been omitted as of little use for popular purposes; and it may be added, that it is by no means probable that all the antelopes of central Asia and of Africa have been discovered, or that all which are now described as separate species deserve to retain that character.

As the article has extended to considerable length, some advantage in the way of reference may be derived from the following

ALPHABETICAL INDEX.

ANTENNÆ (literally what is borne in advance and crosswise). Certain appendages attached to the heads of many articulated animals, especially the insects and crustacea. In insects they are generally two in number; but the crustacea often have four. They vary much in their forms, and also in the proportions which they bear to the size of the animals; but they are symmetrical, that is to say, those on the one side of the head are always counterparts of those on the other; and when there are more than two, each pair is symmetrical; and wherever they are situated, they are equally distant from the mesial plane of the animal. They often differ in the two sexes; but among insects, at least, their form is pretty constant in the same species, so that they are much employed as a means of specific distinction; and some naturalists have proposed to make them the basis of larger divisions. As characteristic of species they are very convenient, because they are easily seen, and scarcely two species have them exactly alike. But the characters founded on them are purely artificial; the uses of the antennæ being very little known, or rather not known at all with anything like certainty. Still, from their universality among animals so very numerous, and their always being in a state of repose when the animal reposes, and of excitement when the animal is excited, they must answer some very important purpose in the economy of those creatures to which they belong.

In general they are susceptible of a considerable degree of motion, and of motion which is peculiar to themselves, and internally they are furnished with a considerable portion both of muscular fibres and of nervous tissue. In some insects they are flexible in their general external covering; but they more frequently are jointed, or consist of a number of pieces, stiff throughout their length, but moving freely upon each other and also upon their articulations with the head. Those joints or pieces vary very considerably in number, and also in form. Sometimes they are cylinders, and the whole of each antenna is nearly of uniform thickness. Sometimes they increase in thickness towards the points, and in other cases they diminish. In some again, each joint is swelled out in the middle, so that the antenna appears like a chain of little balls. In other instances again, they have projecting processes which give them a comb-like appearance, and in others they are beset with small bristles or with little feathery appendages. In short, their forms are so various that a large volume would be requisite for giving even the slightest account of them all; and though such a volume were written, it would be of no value, inasmuch as, not knowing the use of antennæ in any one of their forms, it is impossible even to guess at the different uses of the differently formed ones. We have already said that they are largely employed for specific distinction; and in the present state of our knowledge they are of no farther importance as a portion of the history of living creatures.

They are sometimes popularly called "horns," and also "feelers;" but the use of both these terms is objectionable, as both of them tend to give a wrong meaning; while the word antennæ has the advantage of having no meaning at all, and is of course the very best kind of name for any thing of the uses of which we are ignorant.

The projecting appendages to the heads of many of the mollusca are called horns, and they have probably some uses similar to those of antennæ; but they are retractile, and antennæ are not. The notion generally attached to horns, however, is that they are in some way weapons of offence or defence, purposes to which no antennæ are applied or capable of being applied; and indeed, whatever may be the real use of these organs, it is certainly not, in any way, mechanical.

The term "feelers" is still more objectionable than "horns," because it involves a theory of the use of the antennæ, and a theory for which there is no foundation whatever in nature. That theory of course is, that they are organs of feeling, and that those animals which have antennæ examine and know objects by means of them.

There is a double error in this gratuitous theory: in the first place, a direct faculty is given to the antennæ, which there are no means of proving that they possess; and in the second place, it is assumed that feeling is a direct and original means of knowing external objects, which is a very doubtful, or, in truth, a very erroneous supposition, even in the case of man, and in the case of other animals of course still more perplexing.

That sense, or faculty, or feeling in man, to which the common writers on physiology usually give the name of touch, and describe as residing in the papillæ of the skin, especially of the fingers and palms, is not a simple sense, at least when we consider it as a means by which the knowledge of external things, or of what we call their tangible qualities, is acquired. As a mere sense, it could communicate to us the knowledge of nothing but a peculiar kind of feeling, and the ascertaining of what that feeling was would be a mental process, consequent to the feeling, but not arising out of it or in any way dependent upon it as a mere animal sensation. If this were not the case we should be able, of our animal nature alone, and without the slightest effort or application of mind, to feel ourselves into the perfect knowledge of figure and magnitude, that is, of the whole science of Geometry. Now so far is this from being the case, that we may continue touching and fumbling at bodies of all sizes and forms for the whole length of our lives, and not only so, but we may in every case exercise the common act of thought which is exercised by the ignorant about every thing they handle, without ariving at the knowledge of a single geometrical truth. But if our sense of touch, as we call it, cannot convey to us a knowledge of the figure and magnitude of that which we touch, it is difficult to see what knowledge it can communicate. It may be said that it communicates the knowledge of heat and cold, of roughness and smoothness, and a few other states or qualities of matter which we very erroneously ascribe to it. But when we come to analyse them, even in the slightest manner, we find that the knowledge of heat and cold, roughness and smoothness, and all those other states and properties of bodies of which we are in the every day habit of saying we acquire a knowledge at once by touch, are, in truth, not sensations of any kind, but the results of mental comparisons, either of the state of a thing with the part of the body with which the thing comes in contact or comparisons of one thing with another. In us therefore the sense which we call feeling or touch, considered as a mere affection, or change of state (for that is all which it amounts to) in the animal organ really gives us no information whatever, until the intellectual part of our system takes it up, and by analogy, that is, by comparing it with our past experiences, elaborates it into knowledge; and if we had not the intellectual system thus to take it up and render it useful, the animal feeling would be a property given in vain—generally speaking, a source of pain and torture to us, and therefore quite inconsistent with that wisdom and goodness of which we find the traces so visible in every part of nature.

Now, even those who have a lingering desire to take chimpansees and ourang outangs into the pale of rational nature, never go so far as to bestow that "inferior sort of reason," of which they are so charitable to their favourite beasts, upon a black-beetle or a cabbage-butterfly. It is true that they who are thus votive of the sort of demi-rationality, or whatever other fraction it may be, do not thereby squander the property of others; because that which they give is wholly of their own invention and making, and therefore they have a right to bestow it as they list; and it is probable that the showman, who exhibits the "industrious fleas" for his bread, is just as ready to ascribe intellect to them as the man who exhibits an elephant for the same purpose, whether in a den or on a stage, is to ascribe it to the beast of his choice. We laugh at the recollection of the ancient Egyptians, and at the accounts of those castes in India, who made or make a sort of inferior divinities of animals without much regard either to their sagacity or their other good qualities. But truly the great majority of our writers do the very same in almost every page of the treatises on natural history.

But to return to the apes and the insects, in order to see clearly the absurdity of regarding antennæ as organs of feeling. The apes, and indeed all the vertebrated, or, as we call them, the more perfect animals, have no antennæ—no organs appropriated for the express exercise of feeling or touch; and thus, in the implements with which mind should work, we find the butterfly and the black-beetle much better furnished than the chimpansee; that is, we find those animals to which nobody thinks of attributing mind, furnished with specific organs that have been shown to be of no use without mind; while those again to which many are so prone to concede the inferior sort of reason, have no such organs—nothing which can be regarded as expressly and exclusively the seat of touch, inasmuch as all their organs answer other and well-known purposes. Nay, even in man, where we readily admit the existence of mind, there is no separate organ of touch; and that which is called the tactual sensibility of the hands and fingers, appears to be, in truth, nothing more than one of those properties which, combined, render a man's hands so efficient to him in the earning of his bread. The notion of feeling (that is, touch, so as in any way to know the thing touched) must therefore be abandoned in the case of antennæ, otherwise the greatest absurdity and inconsistence must be admitted to exist in nature, which would be equally inconsistent with the analogy and the fact.

The other conjectures as to the specific use of those organs are equally destitute of foundation; and if it were not that they get repeated by ignorant compilers, and thus spoil the philosophy of natural history, the great beauty and the supreme utility of the whole, they would be very ludicrous. They put one very much in mind of the arguments of the two rustics at the fair, when the one laboured to convince the other that the proboscis of the elephant was a nose, and the other strove as zealously to convince him that it was a tail.

The younger Huber (whose father made some important additions to the natural history of insects) fancied that the antennæ, at least those of ants, were a sort of telegraphs, by which these insects could communicate with each other at a distance. To this assertion, in the case of the ants, there is only one little objection—the utter impossibility of knowing whether it is or is not the fact; but then there are very many species of insects furnished with proportionally larger and more elaborately formed antennæ, which spend the greater part of their time under stones, below the surface of the ground, or otherwise in concealment; and of these not a few come abroad only in the dark, so they could not by possibility make the least use of their telegraphs. The telegraph system must therefore be given up, not as so faulty in philosophy as that of the feelers, but as being very palpably absurd in fact.

There is a third conjecture, which, though it has been made, and is sometimes still supported by learned professors, seems very fit company for the other two. The gist of it is, that the antennæ are organs of hearing, a curious sort of ears as it were. But, truly, organs consisting of a series of horny tubes, jointed together, even though abundantly furnished with muscles and nerves, and susceptible of much motion, are so unlike any organs which are *known* to be ears, that the assumption seems at first sight almost as ludicrous as if one were to maintain that the pincher claws of crabs and lobsters are wings. But attempts have been made to demonstrate the assumption by observations. A certain learned Swede was one day examining through a small telescope a nut-weevil, which was in a state of repose, with the antennæ flaccid and drooping. The professor made "a loud sound," and the weevil pricked up its antennæ, and was off in an instant. How loud a sound, or of what particular tone or intonance, the professor was capable of giving out, is not recorded; but the writer of this article has again and again observed insects during very loud peals of thunder remain perfectly quiescent, and never once prick up their antennæ, or give the least sign of hearing by means of these organs. When a musket is fired, too, it raises all the birds which are in the tree or the coppice, as it may be; but nobody ever heard of the mere report of a musket raising all the butterflies, or especially bringing out all the moths. But the external ears of birds are small, and sound may be regarded as in some sort deadened to them by the feathers of the ear coverts; therefore if antennæ *were* ears, in the common acceptation of the term—and if that is not made out there is really nothing made out—the moths, as having proportionally the largest ones, should be the first to start at the noise, and all the butterflies and beetles should be on the move long before a single bird moves a wing. The other supposed proofs of the hearing faculty of the antennæ which have been adduced are not better than that of the Swedish professor, but it is only justice to the parties to say that they are not worse.

It may seem trifling to enter into any thing like a refutation of assertions which are so completely without foundation, and in the judgment of common sense so ludicrously absurd; but they originate with those who, upon other points, claim the confidence of mankind, and thus they come in for their share of that confidence; and so, upon the strength of the other parts of the characters of their abettors, they do their full share of mischief to the young and the ignorant; hence, upon all subjects of which we are totally ignorant the greatest service that can be done, both to the unwary and to those who are seeking for knowledge, is to clear away the rubbish.

Under this impression, the writer of this article has observed and examined, with perhaps more care and attention than the subject deserves, to ascertain whether there is any invariable connection between sound and the excitement of the antennæ of insects, apart from or preceding the excitement of the insects themselves; and though, not knowing what it was, he cannot say positively that he has tested the talismanic sound made by the Swedish professor, yet he must say, that in all his observations there has not appeared the smallest tittle, even of presumptive evidence, that antennæ are ears. They are excitable organs certainly; but by what they are excited, and for what purposes, are points yet to be ascertained.

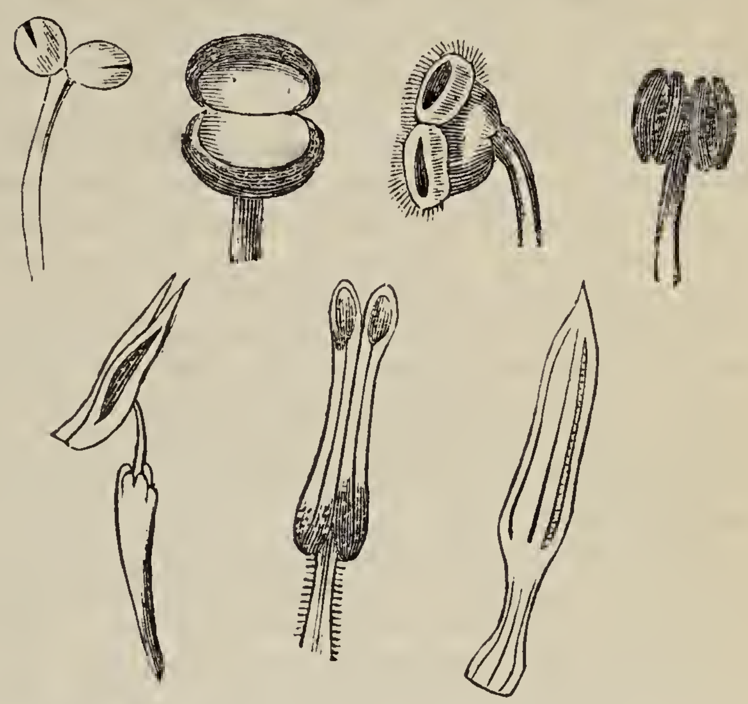
There is another argument which bears strongly against the hearing faculty of those organs; and that is, that many of the crustacea which are furnished with them are inhabitants of the water, of which even the vertebrated inhabitants are generally without any external ears, and such as have them have very small openings without any projecting organ; and it seems doubtful whether those openings are the inlets of what we call sound or not. It is true that fishes are provided with certain porcelainous bodies which have been supposed to be in some way connected with a sense so far resembling that of hearing as it is possible for a sense acting in water to resemble one of which air is the direct and proper medium. But these bodies in fishes are internal, and that they are connected with any kind of sensation is an assumption and not a fact; and though it were the latter, that would not establish any necessary correspondence in use; the truth is that the senses of the invertebrated animals, with the exception of sight, of which the organs, though often peculiar, are not easily mistaken, is one of the most obscure portions of natural history. See INSECTS, and the other divisions.

Various forms of Antennæ.

The above figures show the leading forms of antennæ.

ANTHER (the fertiliser) is the name given to that part of the stamens of flowers which first contains, and afterwards discharges the fertilising dust or pollen necessary for perfecting the ovulæ in the germen or seed-vessel. The anthers are generally supported by slender thread-like bodies, hence called filaments, to which they are attached, either by their base, or back, or by a single point at the centre. They differ very much in form; on some plants they are globular, oval, or hemispherical; on others arrow-shaped, cruciform, horned, or twinned. In colour they are mostly yellow, though often partaking of the general colour of the flower; blue, or red, or purple, and frequently of pearly white. The manner of their dehiscence, or opening to allow the escape of their contents, varies in different plants. Sometimes the anther bursts by a longitudinal suture, the skin or cuticle being rolled back; in other cases the pollen escapes by pores at the base, or at the apex of the cells; or is thence discharged at a lateral opening with some force and to considerable distance. In all unisexual flowers it is worthy of remark that the anthers are commonly placed above, or nearly equal in height with the stigma; and that these two essential organs of the flower become simultaneously perfect, so that their functions respectively may not be neutralised. In bisexual flowers it is also observable that the males have a higher station, or precede the females in development. In the larch and some others of the coniferæ, and among amentaceæ, it is seen that while the female catkins are erect, the males are pendent: so wisely has nature provided that her purposes of reproduction may not be defeated. How conspicuously is this circumstance shown in the zea mays, or Indian wheat? The male panicles are profusely covered with perfect anthers occupying the summit of the plant, before the tuft of thread-like stigmas come forth below. Indeed, the sexes are so distant, or rather the one comes forth so long before the other, as to induce the idea that the pollen finds its way to the stigmas through the vascular structure of the intervening stem. However this may be, the influence of the pollen is duly received, as is evinced by the regerminating powers of the produce.

Flowers are said to be not only robbed by bees of the honey exuded from the bottom of the corolla, but also of the pollen of the anthers, which they knead into wax for the construction of their combs. These thefts may be well excused, because, while these industrious insects are extracting honey and pollen, they are at the same time distributing the latter to accidentally misplaced or distant flowers which, without their bustling visits, might remain unfertile.



Differently formed Anthers, some of them magnified.

The above figures are some of the most common forms of anthers, and which will sufficiently identify these organs to the uninitiated in botanical knowledge; more especially when connected with the descriptions of the other parts of flowers with which the anthers are united. See STAMENS, POLLEN, &c.

ANTHERICUM (Linnæus). A large family of herbaceous plants, chiefly natives of the Cape of Good Hope. Linnæan class and order, *Hexandria Monogynia;* natural order, *Asphodeleæ.* Generic character: perianthium of many parts; corolla of six spreading petals; stamens below the germen; filaments awl-shaped, glossy; anthers leaning, two-celled; germen with three nectariferous glands; style awl-shaped; stigma somewhat clubbed; capsule three-celled; seeds three-sided.

The anthericums are greenhouse plants, and are readily flowered, but possess no great beauty.

ANTHOCERSIS (Labillardière). A family consisting of three species of evergreen shrubs, from New Holland. Linnæan class and order, *Didynamia Angiospermia.* Natural order, *Solaneæ.* Generic character: calyx five-cleft; corolla bell-shaped, but pressed together at the base, throat ribbed, limb in five equal parts; stamens included, with five rudiments; filaments flat at the base; anthers ovular and two-celled; style with a two-lobed stigma; capsule two-celled, two-valved; seeds netted.

ANTHOLYZA (Linnæus). A small, but an exceedingly beautiful genus of Cape of Good Hope bulbs. Linnæan class and order, *Triandria Monogynia.* Natural order, *Irideæ.* Generic character: spatha, of two valves, somewhat convolute; corolla, tubular, elegant, limb gaping, upper lip elongated, the lower cut into five segments; side ones reflexed; stigma undivided; capsule globular, leathery; seeds round, barked. This is one of the most interesting of the Cape bulbs, and is usually treated as a frame plant, and kept in pots. Like other bulbous and tuberous plants, they require to be kept very dry when in a dormant state. There are three species.

ANTHOPHYLLITE. A massive mineral of a brownish colour; sometimes also crystallised, in thin, flat six-sided prisms, streaked lengthwise. It has a false metallic lustre, glistening and pearly. Its crystals are transparent, but not sufficiently hard to scratch glass.

ANTHOXANTHUM—spring grass. One of the most useful of our pasture grasses, belonging to the Linnæan class and order, *Diandria Digynia*. Natural order, *Gramineæ*. Generic character: panicle formed like a spike; calyx, two-valved, three-flowered; corolla two inferior one-valved bristles; middle two-valved perfect, valves unequally acute; stamina, filaments like hairs; anthers, two-celled; styles, two, hairy. The sweet scent of hay is attributed to the presence of this grass; but although this is not entirely the case, it is certainly one of our sweetest grasses. There are four species all cultivated; but the difficulty of cultivating the seeds renders it rather costly for extensive use. It is one of the most early grasses, flowering early in April, and hence its name.

ANTHRACIDÆ (Leach). A family of insects of the order *Diptera;* the characters of which are, body short; wings spreading widely out; antennæ distant, and two sometimes three-jointed; the head as high as the thorax. Stephens, in his Catalogue of British Insects, enumerates two genera as belonging to this family, and found in England. The *Lomatia* of Meigen and the *Anthrax* of Fabricius; to the accurate pen and pencil of Curtis we are indebted for the natural characters of Anthrax, which illustrates the 9th plate of his "Illustrations of British Entomology"—antennæ projecting, remote three-jointed, the first joint cylindrical, and club-shaped, twice the length of the second, with long and thick tufts of hair; the second is nearly globular and hairy; and the third nearly naked, somewhat pear-shaped, with a long style terminated by a tuft of hair, the style being one or two-jointed; maxilla horny and acute, nearly as long as the labrum; palpi two, which are received into the cavity of the mouth, simple, cylindric, hairy, attached to the side of the maxilla near the base, half their length; mentum cylindrical, hollow above, to receive the tongue and labrum. The lips fleshy, oblong, and extend as far as the tongue.

The A. *ornata* (Hoffmansegg) is black and shining; the head covered with black hair between the eyes, silvery behind, clypeus and under side of head with golden hair; thorax covered with ochreous coloured hair before, nearly naked in the centre; scutellum brownish; abdomen covered with short golden hair, the sides being surrounded with alternate fasciculi of fine white and black hair; third and fourth segments with white fasciæ interrupted in the middle; sixth with a white spot in the centre; last joint very white with hair; wings transparent, with numerous nerves, and having a brunneous cloud extending two-thirds the length, situated at the posterior margin, with a transverse transparent spot near the base, a larger one in the centre, and two others near the margin at the union of the nerves. This species was first discovered by J. C. Dale, Esq. at Parley Heath, on the borders of Dorset and Hants, in July 1821, and afterwards in September 1823. It was found settling upon heath, banks, and on the ground where the turf had been pared off; it has also been captured by Mr. Bentley in the same neighbourhood. Another species, *A. flava* (Hoffmansegg) was also captured in the beginning of July 1822, flying amongst rushes, and alighting upon the sand near the sea-shore at Covehithe, Suffolk, and *A. circumdata* of Hoffmansegg has been taken in Devon on the borders of woods in June; they are all very rare, and the only species known to inhabit Britain.

The anthracidæ fly in the sunshine and subsist on the juices of flowers.

ANTHRACITE. This mineral, which is now employed to a considerable extent as a substitute for common fuel, especially in the burning of lime, very much resembles coal in its external appearance. It is sometimes called glance-coal, from the German word *glanz*, which it derives from its glistening lustrous character. Anthracite burns without flame, and contains more than ninety per cent. of pure carbon, so that it may in fact be considered as mineral charcoal..

Mr. Weaver, in a paper on the geology of the south of Ireland, has described vast beds of anthracite occurring in clay-slate and grey-wacke. He says that the most considerable collieries have yielded 25,000 tons annually, and adds, that all the coal of the province of Munster, with the exception of that of the county of Clare, is of the same sort. It is remarkable, too, that the anthracite, and a slate highly charged with pyrites, which accompanies it, are full of impressions of plants of the fern tribe, such as *equiseta* and *calamites*, analogous to those found in the true coal formations; this is an important circumstance with reference to the history of anthracite, and gives strong countenance to the opinion that this substance, even in the oldest of the stratified rocks, is of vegetable origin.

That species of anthracite termed slaty glance-coal, is found in several floetz districts in Scotland, especially in West Lothian, Fifeshire, and Ayrshire, and in the island of Arran. In similar rocks in England, as in the southern parts of Brecknock, Caermarthen, and Pembroke; and near Walsal, in Staffordshire: also at several places in Ireland. On the continent it is met with at Kongsberg in Norway, where it is associated with native silver, in veins that traverse mica-slate: in the Hartz, in veins of red and brown iron-ore, which traverse grey-wacke; and in mineral veins at Schemnitz in Hungary. It also occurs abundantly in the United States of America.

ANTHROCOTHERIUM. A genus of fossil, extinct, *Pachydermata*, for the discovery of the existence of which we are indebted to the researches of the baron Cuvier. This genus appears to have held an intermediate place between the *palæotheria*, *anoplotheria*, and swine. The teeth exhibit many points of agreement with the *anoplotherium;* but the large and projecting canine teeth leave no doubt of its having been a perfectly distinct genus. Two species were found in the lignites of Cadibone, near Savone, and a third in the fresh-water formation in the environs of Agen. The first approached the rhinoceros in size, the second was considerably smaller, and the third rests upon the fragment of a jaw exhibiting certain peculiarities, which was found in the department of Lot et Garonne.

ANTHUS—Pipit. A genus of insectivorous birds, having in their general characters no inconsiderable resemblance to the wagtails; but not being so exclusively insectivorous in their feeding as these, and not so aquatic in their habits. Their haunts are various, some of them resorting to the open fields, others to the vicinity of woods, and others again to the shores of the sea; but in all their differences of locality they are ground birds, nestling upon the surface of the earth, and finding the greater part of their food there. They are not migrants, but they live dispersedly in the summer and the breeding season, retiring at that time to a distance from the habitations of man and the cultivated grounds. When their broods are fully fledged, and the old ones have undergone the moult, during which they lose the peculiar colours of the breeding time, they flock to the cultivated fields; and they have, under these circumstances, sometimes been confounded with the larks, a genus of the distinguishing characters of which they possess none. The larks have the claw upon the hind toe very long and nearly straight; the pipits have the same claw, but shorter and crooked. The following are the generic characters of the pipits: the bill straight and slender, slightly conical in the basal part, but compressed laterally about the middle of its length by a slight turning inwards of the tomia or cutting edges, and awl-shaped toward the tip. The upper mandible has a ridge or keel along the middle, is slightly turned downwards at the point, margined, and with a mere rudiment of a notch. It is thus less insectivorous than the bills of most of the order, but still it has neither the form nor the strength of a seed-eating bill. The nostrils are lateral at the base of the bill, and in part covered by membrane. The feet have three toes before and one behind, the outer one of the first joined to the middle as far as the first joint, and the claw on the hind one more or less produced according to the species, but always considerably hooked. The wings are of moderate length and rounded, the first quill being very short, and the second shorter than the third or fourth. In the closed wing, some of the greater coverts are as long as the quills. For an account of the more interesting species, especially the British ones (of which there are three), see the article Pipit.

ANTIMONY. This metallic body, in a native state, is usually divided into two species, the dodecahedral and the octohedral. The first of these is of a white colour, occurs massive, and is found in argentiferous veins in the gneiss mountain of Chalanches in Dauphiny, where it is accompanied with grey antimony, white antimony, red antimony, &c.; at Andreasberg, in the Hartz, associated with red silver, calcareous spar, and quartz; at Sahlberg, in Sweden, disseminated in calcareous spar. It is also found at Cuencamé, in Mexico.

The octohedral antimony is sometimes divided into antimonial silver and arsenical silver; but by chemical analysis it is found that the antimony really forms but a very small proportion of the entire mass in either case.

Antimony-glance (*speizglas*, Mohs) contains three species, prismatoidal antimony-glance, axifrangible antimony-glance, and prismatic antimony-glance. The first of these is divided into two sub-species, the common grey antimony and plumose antimony. The axifrangible antimony-glance is of a blackish lead grey colour. See BOURNONITE.

The prismatic antimony-glance is of a similar colour to the preceding, and possesses a metallic lustre.

Antimonial ochre is found in Cornwall, and in several places on the continent of Europe.

Antimony-blende, or red antimony. The species best known of this form of antimony is of a cherry-red colour; the primitive form is an oblique four-sided prism. It occurs in veins in primitive rocks, generally along with native antimony, grey antimony, and ores of arsenic.

Berzelius places antimony amongst the electro-negative metals, that is, metals whose oxides rather act as acids than bases in the compounds they form with other oxidated bodies.

The sulphuret of antimony is the only abundant ore of the metal. When this is heated in contact with iron, the sulphur, on account of its greater affinity for that metal, is separated by it from the antimony, which is consequently reduced to the metallic state.

ANTIPATHES (Ellis, Lamouroux). A fixed sub-dendroidal polypidom, composed of a central axis, and a corticiform crust, the axis is flattened and fixed at the base; it is subramose, horny, solid, flexible, rather fragile, and mostly set with small spines.

The cortical crust is gelatinous and polypiferous, covering the living axis and branches, and falling off on the removal of the specimen from the water. They are found in the European seas.

AOTUS (Smith). A genus of three species of greenhouse evergreen shrubs, from New Holland. Linnæan class and order, *Decandria Monogynia*, natural order, *Leguminosæ*. Generic character: calyx ebracteated, five cleft; corolla of nearly equal petals; stamina, subject to fall; style erect, thread-formed, enlarging above; pod two-seeded.

APARGIA (Scobel). A genus, consisting of nineteen species of herbaceous plants, natives of Europe. Three of them are found in Britain, known by the name of Hawkbit, and easily detected by the hairs of the receptacle rising conspicuously out of the top of each plant, they belong to *Syngenesia æqualis* Linnæus; and to the natural order, *Compositæ* of Jussieu.

APE—*Pithecus*. A genus of quadrumana, or four-handed mammalia, and the one which, in its structure, both external and internal, is described as making the nearest approach to the human subject. *Pithecus* is certainly less objectionable for the systematic name of the genus than the Latin *Simia*, because it was applied only to the tailless apes by the Greeks, whereas *Simia* was applied to all apes, or to all the quadrumana known to the Romans, whether they were destitute of tails or not. The other and probably original meaning of the Greek word (*pithecus*) is also less objectionable. It signified "a dwarf," without any allusion to character, whereas *simia* was applied to persons who had more of the trifling mischief of the monkey in them than of the demure gravity of the ape. Both names are, however, thus far exceptionable, that they point to a comparison between these animals and man; and, in consequence of that, the natural history of apes has continued, up to the present time, to involve more absurdity, even in the hands of scientific naturalists, than that of any other genus of animals.

The structure of the different species of apes has indeed been examined with the minutest attention, whenever that could be done; and the conduct of the animals has been observed with much attention, and recorded at great and sometimes ludicrous length; and yet, though Europeans have captured or endeavoured to capture every ape they have seen in those countries where apes reside, there are very few animals of the habits of which in a state of nature we know so little. The fault has lain in the structure of apes not being studied with reference to their own haunts and habits in a state of nature, but to find out what species has the greatest resemblance to man. This is trifling, certainly; but it is any thing but philosophic trifling. Structural resemblances to man can be traced in many animals—in the sloths, for instance, and the bats—nay, even in the whales, the bones of whose swimming paws have a very considerable resemblance to those of the human arm and hand.

At best, the tracing of such analogies is waste of time; and at worst it leads, almost as a matter of necessity, the ignorant to materialism, inasmuch as it tends to show that the only superiority of man over the other animals is what the parties in question call a superior organisation. Now, in the rational view of the matter, there is no superior organisation. Each animal has to perform certain functions specifically different, if the animals can be considered as different species; and in each the organisation is better fitted for the performance of its own function than that of any other animal; and therefore as regards that function, which may be considered as the purpose of the animal in nature, its organisation is higher than that of any other. What the animal does, and how it is organised for the doing of it, are the valuable points in the natural history of any one animal, be it of what class, order, family, genus, or species it may; and to find out how the function and the organisation vary together, as we pass from species to species, is the valuable point in the comparison of one with another.

When we pursue our observations and analogies in this way, the conclusions at which we arrive are of the greatest practical utility. In one respect, we find out the means which are best adapted for the accomplishment of purposes; and as the purposes of animals, that is the actions which they perform, are absolutely countless, there is not a difficulty we can meet with in any mechanical art, in which we shall not get assistance from the structure and functions of animals, if we seek it with due knowledge and without prejudice. Again, if, along with the organisation, and the functions which that organisation performs, we take the dispositions of the animals, and the circumstances which promote most their health and duration, we ascertain the capabilities of the animals, the uses to which we may apply them, as their flesh for food, their skins or the appendages of them for clothing, their strength for labour, and their docility for other services. Such are the practical results of the proper study of animals; and when arrived at by proper means, that is by careful observation and unbiassed inference, no results can be more valuable.

But when, as has been very generally done in the case of the apes, we quit the proper ground of natural history, and seek for analogies where, in the nature of things, no analogy can possibly be found, we not only destroy the proper usefulness of natural history, but we turn it into a source of the most pernicious error, because it is error which leads us to a misunderstanding of our own nature.

If, in proportion as the apes approximate to man in the structure of their bodies, they also approximate to man in the actions which *of themselves* they are capable of performing, then it is impossible to prevent this question from arising to all persons, especially young persons, who are in the anxious pursuit of knowledge and truth:—"If other animals approximate to man in capacity, in proportion as they approximate to him in organic structure, and if the superiority of man depends on his organisation, what possible use can there be for *mind* in man—for an immortal spirit totally and essentially different from all else in the animated creation?" And if the premises are admitted, the answer is irresistible:—"There is no use for such a mind; and by the received law of nature that 'nothing is made in vain,' no such mind can by possibility exist." Such is the doctrine even now broached under the real or pretended authority of names, sounding enough to give currency, and, among the ignorant, reception as truth, to any error! This, however, is a cruel deception, and the responsibility cannot be got rid of by that "easy virtue," whose plea of justification may be that it is "feeding the hungry and clothing the naked."

The grand natural history argument for mind in man, and when properly stated it is quite conclusive, is, that of itself and without the mind to guide it, his organisation does not appear fit for any one thing. Go to the whole of the animal tribes, from the ape to the animalcule, and say whose place, if he had no mental resource, man could supply. Make yourself master of all his anatomy, understand the motions of every bone, and the action of every muscle, then say in what part of wild nature you would place him, so that he would, without mental resource, act his part better than any other creature which is there already, or even half as well as some one or other of them? You find all the animals allocated and peculiar, the best fitted for their localities, and fitted for them without any instruction: man is fit for nothing till he is taught; but with teaching he becomes equally fit for all things. This is a difference not of degree only but of kind; and it bars all useful comparison between man and the other animals. The length of the Thames to the length of a summer's day is not a more absurd comparison than that of man to an ape.

The group at the bottom of plate Apes, in which the burin of Thomas Landseer has brought out the form and the expression with equal force and truth, contains the two species with which the description of naturalists above alluded to have shown the greatest disposition to claim kindred. Some have preferred the metaphysical cut of the chimpansee, others the demure looks of the orang-utan; and from the attitude in which the artist has placed him, as if he were the judge in a cause or the arbiter in a dispute, he looks very wise; though others again may prefer the grave and wigged visage of the black gibbon. But all these differences of appearance are indications of differences in the habits and haunts of the animals, and of *nothing more*.

The distinguishing characters of the true apes are, having neither tails nor cheek pouches. Their teeth are the same in number as in man, and their incisive and grinding both resemble those of man in form, but the canines are large and prominent, and in the full-grown animals scarcely less formidable than the corresponding teeth of beasts of prey. All the paws (for it is incorrect to call them hands) consist of four fingers and a thumb. The latter member is, however, very small, sometimes without a nail, and cannot, in all of the species, be said to perform the functions of a true thumb; but often more resembles the callous pad, which forms a point of resistance against the fingers in several other climbing animals. The anterior extremities are long, but much longer in some of the species than in others; the fingers are also long, the bones of some of the phalanges are often curved toward the palms, and the muscular power in grasping or pulling is much greater than, from the size of the animal or of the parts, one would be led to suppose. Similar grasping powers, in proportion to their size, are, however, common to all the quadrumana, and to all climbing animals. The joints of the elbows, shoulders, and wrists, also admit of more motion than in man, and the grasping power of the fingers can be strongly exerted with the arm in many more positions, especially positions that are wide or outwards. The whole structure of the anterior extremities indicates that they are instruments for grasping in all directions round the animal, and to the greatest distance possible.

The posterior extremities are proportionally much shorter, but they admit of perhaps a greater range of motion, especially at the hip and ankle joints. The knee joints are naturally what are called "bowed," or bent outwards; but such is the motion of the hip joint that the thighs can be plaited across each other, or they can be widely extended, and at the same time rolled so far outwards that the toes (or fingers rather) are behind the line of the heels. The ankle joint is a ball and socket, only its motion is nearly confined to the inner semicircle. The sole of the foot cannot be turned outwards, and in some of the species it is, as in the sloths, not capable of being planted level on the ground; but it can turn inward till it is above the natural plane, backward till it is beyond the line of the leg, and upward till the whole upper part of the foot bears against the shin. The thumb upon these is usually short, articulated far behind the basal phalanx of the toes, and when not in action standing nearly at right angles to the axis of the foot. The toes of these extremities generally have the bones of the phalanges more or less bent; and in some of the species the first and second are united together, as if to give greater steadiness in grasping. The toes on the hind feet, even when they are all free, do not admit of separate motions; and that those of the fore feet can so move is alleged rather than proved. They cannot spread out their hands as man does, or even as is done by dogs and various other digitigrade animals.

Both anterior and posterior extremities are therefore grasping instruments, and proportionally ill adapted for walking; and though, where they do walk, some of them generally, and all of them occasionally, walk on the hind extremities only, they are unsteady and hobbling, and those species which are understood to be the best climbers, have the anterior extremities always ready to balance, support, or assist them as they wriggle along.

Apes, though any thing but handsome to look at, are still interesting animals, both on account of the peculiarity of their structure, and of all that has been said about their resemblance to man; and therefore it is to be regretted that little is known of their habits in their native localities.

They are confined to the eastern continent and its islands, and their haunts, even there, are limited and peculiar. One species only has been hitherto observed in Africa; and the others are confined to the south-east of Asia to Sumatra, Java, Borneo, and some of the other islands, but probably they extend to those portions of the Eastern or Malay peninsula which have a climate similar to that of the islands. They are not found in any of those parts which have the broad extremes of tropical climate, long droughts alternating with heavy rains. This appears to be the case both in Asia and in Africa, and furnishes us with, at least, one little point in their natural history: they are not migrants, but remain in the same locality all the year round, and that locality must, of course, be such as to supply them with a constant succession of food.

The animals of the American continent to which they bear the greatest analogy in their habits are the sloths; but the manners and food of the two differ, so that the climate, or, which is the same thing, the season, must differ in proportion. The sloths are organised for horizontal locomotion along the twigs, with their backs underneath, and they feed on the leaves above them, and repose hanging suspended under the branches; they cannot walk, sit, run, or lie upon the ground with comfort; the action of their extremities is powerful only when exerted towards the mesial line of the body. The apes, on the other hand, grasp all round them; they sit, they lie, and they can walk a little—some of them tolerably well. They are, therefore, not adapted for grazing on the leaves of trees as the sloths do, though admirably so for finding their way from branch to branch, and gathering fruits.

And the localities which the apes inhabit are exactly those in which there are always fruits upon the trees; where the same tree brings forward a succession of crops, and where the productive season of one species falls so well upon the unproductive season of another, that there is an abundant supply of food all the year round.

In this way, the ape, like the sloth, and indeed most localised animals, which naturally inhabit particular districts of the world only, becomes a key to the general character of those places where it is found; such places are never burnt up by tropical droughts, neither are they, for any length of time at least, deluged by tropical rains, because both of these are incompatible with perpetual fruitage. The Oriental islands, to which the greater part of the apes are generally, if not exclusively, confined, are nearly out of the range of the monsoons, which are taken in flank by the trade winds of the Pacific, so that they have a wonderful uniformity of climate, and part of the Malay peninsula has so much the same character, that the fruits of the Molucca islands are found in the woods of that portion of the coast which was ceded to the East India Company at the close of the Burmese war. One species of ape, the chimpansee, has been found in the woods of Africa, and from near the mouth of the Gambia to Angola, or along all that part of the coast which has permanent foliage and fruit; but most abundantly in the lower parts of the Congo and the Niger. From the comparative shortness of its arms, and its greater facility in walking, it is reasonable to suppose that this species climbs less, or at all events travels more, than the long-armed ones, which are such bad walkers. Hence it is probable that the permanently fertile zone of tropical Africa is inferior in productiveness to the Oriental isles.

But still it is by no means an unimportant point to ascertain that there is in Africa, near the parallel of the equator, a zone of perennial fertility, in which the chimpansee can find food all the year round ; and that there must be is corroborated by other circumstances. The river Congo discharges a very great volume of water; it never falls very low, and it never rises above nine feet, so that it must flow, in great part at least, through a country where the rains are comparatively frequent and moderate—a country desirable to inhabit and profitable to cultivate ; and one, by means of the waters of which a communication may at some period of time be established between the sides of Africa. Thus, imperfect as it is, there is some utility in the general natural history of apes.

It is tolerably well ascertained that the apes are all inhabitants of the forest, that they climb trees with great dexterity, and live upon fruits ; and, that they may examine all above and around them for these, is probably the original use of that habit of apparent observation of all that is going on which they have in a state of confinement. They are not understood to sleep clinging, but to make a sort of rude nests for themselves in the forks of trees, where they sleep during the night, and recline during the heat of the day, the morning and evening being, as with most animals of warm climates, their chief feeding times.

No very satisfactory conclusions with regard to their manners in a state of nature can be drawn from the few specimens which have been brought to Europe. These have generally been taken young, trained differently from what they are in a state of nature, and rendered dull and sickly by climatal and other causes. The inference from the character of all the rest of the order is, that they are mischievous, and their strong hands and formidable canine teeth certainly render them capable of much mischief. The data are too scanty for any positive general conclusion ; but it seems certain that they cannot be trained for any useful purpose ; and that, much as their resemblance to man is dwelt upon, they are far behind many other animals in that which is called animal sagacity. We shall now very briefly advert to the species.

1. Chimpansee (*Pithecus troglodytes*). Baron Cuvier gives the preference to the orang-utan ; and, in point of climbing, certainly in point of size, and, for any thing that we know to the contrary, in point of sagacity, it may deserve the preference ; but the matter is one of mere opinion. The chimpansee is, as has been said, found both in the Asiatic isles and in Africa ; and it is said to be of larger size and more handsome form in the latter country than in the former—that it has the arms shorter, walks more erect, and has the neck longer. These differences tend to show that the trees which have apes' food are of smaller growth and further apart from each other than in Asia ; and that, also, in part explains why none of the long-armed climbing apes are found in Africa, but have their place supplied by the baboons, which run well upon all fours, and are more ferocious in their dispositions. The very few specimens of the chimpansee which have been seen in this country have been all of small stature ; but they have been young, and we neither know the period which these animals require to attain their full stature, nor the circumstances by which their growth may be retarded or stopped. Travellers say that they attain the height of an ordinary man ; but there is reason to suspect that in that, as well as in some other points, their history has been confounded with that of the larger baboons. It is said that they live in small bands, and construct a series of huts for their common residence. The former is likely, as all apes are, to a certain degree, social ; but the construction of the huts is doubtful, as it has not been borne out by what has been observed of other apes, or even of the same species in the East. Nor do the tales of their running away with negro girls, for the purpose of stocking their seraglios, appear to be better founded ; and they are certainly against the general analogy of animated nature. The fact is, that the comparisons which have constantly been made between these animals and man, render it no easy matter to determine what portion of the reports which are given of them should be received and what rejected : and the chimpansee is not so very like man after all. The flat top of the head, the great round ears, and the short and scanty hair on the head, have nothing very human in their aspect. There is a ridge over the eyes, but it is not like an eye brow ; and the eyes have nothing human in their enfoncement or their expression. The nose is merely a ridge on the muzzle ; and the mouth, from the manner of its opening, as well as the extent to which it opens, is evidently intended for no purpose save that of biting. The lower jaw is not a chin either, in its anterior part, but merely a deep jaw, to afford insertion to the large teeth and the powerful muscles.

That the females have pectoral mammæ is no proof of approximation to man, because almost all animals which carry their young with them when they ascend trees have the same—invariably if they carry the young in the arms.

It does not appear that the differences which have been mentioned as existing between the chimpansees of Africa and of the Oriental isles are sufficient to constitute a difference or even a variety ; the more so that we are but little acquainted with the appearance and habits of the adult animals in either region. All that can be inferred is, that they have to climb more and walk less, and their arms are lengthened and their legs shortened and weakened in proportion. Even those chimpansees which are the best walkers, do not walk as man does, by advancing the leg while the body remains square to the front; they roll the pelvis, and the feet, instead of moving over straight lines, move over arches of circles, of each of which the opposite hip joint is the centre ; and even in them the feet are far more efficient in climbing and grasping than in walking, which shows that climbing is the grand motion for which they are organised ; and that just as much of the power of walking is added, as enables them to be the passing feeders upon fruits in those parts of the forests where the fruit-bearing trees are too small and far asunder for suiting the organisation of the long-armed apes.

The face and ears of the chimpansee are of a brown colour, and naked ; but the skin of the face, especially, is withered and leather-like, and has no resemblance to the human skin in texture and gloss ; it more resembles the naked parts of some reptiles, or those of the bats. The head, back of the neck, shoulders, and back, are covered with coarse black hair, rather long, and forming a sort of whiskers or tufts on the cheeks, but otherwise longest on the upper parts of the back. The arms have the hair inclining downwards from the shoulder to the elbow, and upwards from the wrist to the same, and these form a sort of ruff at the point of meeting. This position of the hair enables the fore-arm to be more readily thrust among the leaves, to pull the fruit. When there are hairs on the human fore-arm, they are not turned toward the elbow, but outwards, and inclining to the wrist. So that, down to the very minutest particular, we find in the ape adaptations to peculiar localities and habits, not one of which can be traced in man.

Even the trivial name of this species (*troglodytes*) is in some sort connected with gratuitous analogies, and as such calculated to mislead. In ancient times there was a race of people known by the name of *troglodytes*, or "dwellers in caves," said to inhabit somewhere in the vicinity of the Red Sea, and to be of small stature and deformed outline; and so strong was the prejudice, arising probably from this similarity of name, that Linnæus himself made man one species of the genus *homo*, and the chimpansee, which, of course, was not so well known to Europeans in his time as it is now, another, under the name of *homo troglodytes*. Now it does not appear that the chimpansee is *troglodytes* at all, inasmuch as it does not dwell in caves. It does not inhabit those regions in which the *troglodytes* of the ancients are said to have resided, and it is rather improbable that the ancients had any accurate knowledge of the places in which it is now found.

Orang-utan (*Pithecus satyris*). This animal, though more of a climber and woodsman, and more adroit among the branches than the chimpansee, has been much better known and understood. It is the one which the late Baron Cuvier preferred for taking the lead as next to man; and the chief difference is, that it is a much worse walker and more efficient climber than the chimpansee. It is found only in the deep and dense forests of the Eastern isles, and probably in that part of the Malay peninsula which has been described as having the same climate and the same natural character. It will be seen from the plate, to which we again refer as a faithful and characteristic likeness, that there is not a great deal of human character in this animal. The forehead is flat, the eye little enfonced, the muzzle much produced, the gape wide, the canine teeth (in the old animal) very large, the under-jaw without any form of a chin, the ears short, and with few convolutions in the concha, the neck very short, thick, and rendered apparently thicker by a pouch of skin on each side, which the animal distends when it screams or yells, or whatever else the noise it utters may be called. The anterior extremities are very long, so much so that when the animal stands or walks on the hind ones (such standing or walking as it can accomplish upon them), the points of the fingers touch the ground, and a very little bending enables it to walk upon all fours. The posterior extremities are just as disproportionally short, and they are so ill-adapted for walking that it is compelled to walk on their outer edges as the sloth does, because the sole cannot be so turned as to be planted on the ground; the leg and thigh bones are both very short; but with the exception of the incapacity for turning the sole of the foot to the ground, the motions of all the joints of the leg are remarkably true, and the muscles by which the bones are moved are very powerful. The ankle joints move like a wrist joint, and the foot is much more like a hand than in the chimpansee. They are still however hands, of which the chief power of grasping is in the fingers, for the thumbs are very short, and in some individuals they are without nails. The body is not so compact as that of the chimpansee, and the abdomen is larger in proportion. The face, ears, and hands are naked, not so dark, and more inclining to a dull red than in the chimpansee. The hair, too, which is long and coarse on the head, neck, and back, is of a deep purplish red, and so is that on the fore part of the body, which is but thinly covered.

In his native forests, and under what may be perhaps considered as the most genial climate in the world to all vegetables that are grown and all animals that are produced under it, the orang-utan becomes a very large and formidable animal. His height is not less than seven feet; his muscular strength great in proportion; and his bite, from the strength of his teeth and the depth of his gape, is very formidable. He leaps from the ground to the branches, and so from branch to branch, with great agility; and by the power which he has of grasping by the feet, swinging and balancing the body, and extending his long arms, he gets on from tree to tree with great ease and quickness. If, indeed, he ever gains the forest, and he is never found at any great distance from it, it is impossible to catch, and difficult to shoot him; and when wounded and irritated he makes a desperate resistance. It does not appear, however, that he is, in any case, the first to attack, neither does he stand on the defensive, till flight is no longer availing. He remains in his forest, and gathers his wild fruits in peace with all the less powerful inhabitants.

From the specimens recently brought to Europe no correct idea can be formed of the stature, the strength, or the energy of this animal in his native East. Nature has fitted him only for finding his food in the forests there, and also suited his constitution to that climate only. The young ones which are brought to Europe linger a while in a sickly state; but their powers are never developed, and they soon perish of disease.

It does not appear that this species, or indeed any of the true apes except the chimpansee, is found any where but in the south-east of Asia, which would lead to the supposition that the African forests are not so shadowy or so abundant in fruits as those of the Oriental islands. In those islands, the general habit of the orang-utan appears to be to conceal himself in the depths of the woods; but the following account by Dr. Abel shows that, while at home, or even while in health, these animals are social, and even playful. On his return from the East, Dr. Abel brought with him one which he had kept for some time in the island of Java; and the account cannot be better given than in his own words:—"While in Java," says Dr. A., "he lodged in a large tamarind-tree near my dwelling, and formed a bed by intertwining the small branches and covering them with leaves. During the day, he would lie with his head projecting beyond his nest, watching whoever might pass under; and when he saw any one with fruit, would descend to obtain a share of it. He always retired for the night at sunset, or sooner if he had been well fed, and rose with the sun, and visited those from whom he habitually received food. On board ship he generally slept at the mast-head, after wrapping himself up in a sail. Sometimes I pre-occupied his bed, and teased him by refusing to give it up. On these occasions he would endeavour to pull the sail from under me or force me to quit it, and would not rest till I had resigned it. If all the sails happened to be set, he would hunt about for some other covering, and either steal one of the sailor's jackets, or empty a hammock of its blankets. His favourite amusement in Java was in swinging from the branches of trees, or climbing over the roofs of houses; on board, in hanging by the ropes, or romping with the boys of the ship. He would entice them to play by striking them with his hand as they passed, and then bounding from them; but allowing them to overtake him, and engaging in a mock scuffle. Of some small monkeys on board he took little notice, whilst under the observation of the persons of the ship. Once, indeed, he openly attempted to throw a small cage, containing three of them, overboard; but I have reason to believe that he was not so indifferent to their society when free from observation. On one occasion I observed him lying on his back, partially covered with a sail, contemplating with great gravity the gambols of a young monkey which was bounding over him; at length he caught him by the tail, and tried to envelope him in his covering. The monkey seemed to dislike the confinement and broke from him, but again renewed its gambols; and though frequently caught, always escaped. The intercourse, however, did not seem to be that of equals, for the orang-utan never condescended to romp with the monkeys as he did with the boys of the ship; yet the monkeys had evidently a great predilection for his company, for whenever they broke loose they took their way to his resting-place.

"But though so gentle when not exceedingly irritated, the orang-utan could be excited to violent rage, and on one or two occasions committed an act which, in a rational being, would have been called the threatening of suicide. If repeatedly refused an orange when he attempted to take it, he would shriek violently and swing furiously about the ropes, then return and endeavour to obtain it; if again refused, he would roll for some time like an angry child upon the deck, uttering the most piercing screams, and then suddenly starting up, rush furiously over the sides of the ship and disappear. On first witnessing this act, we thought that he had thrown himself into the sea; but on searching, found him concealed under the chains."

There is every reason to believe, from the well-known character of the narrator, that this account is as true as it is graphic; but still it throws little light upon the character of the animal in a state of nature. Dr. Abel does not say how he obtained this specimen, at what age it was caught, or what training it underwent before it came into his possession; though, from its conduct in Java, it is quite clear that it must have been a tamed animal, and not "a wild man of the woods" when there; for all the accounts, (scanty as they are) represent the wild animal as not courting the society of mankind, but hiding himself from them in the woods, with far more solicitude than the monkey race. An account of another one, inserted by the same observer in the fifteenth volume of the Asiatic Researches, throws a little light upon the native character of the animal; but it is only a little, inasmuch as it shows only the efforts of the orang-utan to escape from those who were pursuing him to the death. This specimen was of large size, at least seven feet in height, and when first observed he appeared to be fatigued with a journey of some distance, as his legs were covered with mud up to the knees; and he had taken to a solitary tree in order to rest himself. The place where he was observed was on the north coast of Sumatra, out of the thick forest, and with only a few clumps and straggling trees. As the boat's-crew approached him, he seemed apprehensive of danger and aware that the single tree did not afford him an adequate means of safety; so he descended and made for a clump of trees which was at some distance. On the ground his motion was slow and wriggling, and apparently performed with much effort. He had always now and then to steady it by bringing his hands to the assistance of his feet; and he would even deviate a little from the straight course, in order to lay hold of a tall bush or branch, to enable him to swing himself forward; and it is probable that had he found a sufficient succession of these, he would have been able to elude his pursuers by speed; but on the bare places where there was nothing that he could grasp, he made comparatively but little way, and seemed to be out of his element. The rest of the adventure will, however, tell better in Dr. Abel's own words:—

"On being driven to a small clump, he gained, by one spring, a very lofty branch, and bounded from one branch to another with the swiftness of a common monkey, his progress being as rapid as that of a swift horse. After receiving five balls, his exertions relaxed, and reclining overpowered against a branch he vomited a quantity of blood. The ammunition of the hunters being by this time exhausted, they were obliged to fell the tree in order to obtain him; but what was their surprise to see him, as the tree was falling, effect his retreat to another, with seemingly undiminished vigour! In fact, they were obliged to cut down all the trees before they could force him to combat his enemies on the ground; and when finally overpowered by numbers and nearly in a dying state, he seized a spear made of a supple wood, which would have withstood the strength of the stoutest man, and broke it like a reed. It was stated by those who aided in his death, that the human-like expression of his countenance, and his piteous manner of placing his hands over his wounds, distressed their feelings so as almost to make them question the nature of the act they were committing. He was seven feet high, with a broad expanded chest and narrow waist. His chin was fringed with a beard that curled neatly on each side, and formed an ornamental rather than a frightful appendage to his visage. His arms were long even in proportion to his height; but his legs were much shorter. Upon the whole, he was a wonderful beast to behold, and there was more about him to excite amazement than fear. His hair was smooth and glossy, and his whole appearance showed him to be in the full vigour of youth and strength."

In all this, there is still not the slightest relation to human action or resource. When the animal found that he was pursued, he did what all animals, whose nature it is not to stand and face their enemies, do upon like occasions,—he sought that place where he could use his powers to the greatest advantage; and thus he took to the clump, upon an instinct exactly similar to that which makes the chased badger seek his "earth." As to the "piteous cries," uttered by those animals when wounded, they are no proof of reason, or of "intellectual acquirements," as is sometimes most absurdly said. Of all our domestic mammalia, the pig complains the most loudly and piteously, even when but slightly annoyed, and yet we never think of boasting of the "intellectual acquirements" of the pig; and when we apply metaphorically, as is sometimes coarsely done, to a human being the epithet "piggish," or "pig-headed" we certainly do not thereby mean to imply a more than ordinary share of "intellectual acquirements." Yet in his internal organisation, which is really most important in a physiological point of view, the pig resembles man more than any other domestic mammalia do. The pointing to the wounds, is a natural, and almost a necessary act of all handed animals, because they use these organs, as well in endeavouring to rid themselves of every bodily uneasiness and annoyance, as in making way among the branches, seizing their food, and holding it while they eat it. We have as piteous accounts of the apparent reproach of those who wounded them, by monkeys, and monkeys formed very unlike men, and with goodly swinging tails, as that which Dr. Abel relates of the wounded orang-utan. Therefore, in the whole conduct of the animal there does not appear to be even the slightest approach to human action; and consequently we are to regard the whole of the alleged mental acquirements, as gratuitous fancies, founded on the mere fact of the slight structural resemblance. When we apply analysis to that, we find, as has been already mentioned, that the ape is incapable of in any way taking man's place, and man just as incapable of taking the ape's place. The ape is a climbing animal, fitted for residing in thick forests, and collecting wild fruits as his food; and for these purposes his structure is probably the best that can be imagined. His hands can grasp powerfully, and by means of them he can either pull himself up, or, grasping with his hinder paws, he can pull down that which he wishes. He is also said sometimes to use a stick or even two sticks to help him on his way, when he is forced to walk for any considerable distance on his ill adapted feet. But there, or nearly there, the functions of his hands stop; and there is at least no account of his holding a cocoa-nut upon a stone with one hand, and breaking the shell by battering it with another stone held in the other, which is almost the first act of the very rudest savage in those places where cocoa-nuts grow. As is the case with all other animals, his organs of mastication are fitted for the division of his food into swallowable portions; so that, when he has to crack a hard shell, he does it by means of the large and powerful canine teeth with which he is furnished. This, rather than a means either of attack or defence, appears to be the use of those formidable teeth in the apes; and, indeed, feeding seems to be the grand use of all the furnishing of the mouths of animals in what manner soever they are furnished.

The two species which have been mentioned are probably the only true apes, at least they are the only known ones that have neither tails nor callosities on the buttocks. The remainder of the genus *pithecus*, are tail-less; but they have the callosities in a greater or less state of developement. They are sometimes styled *gibbons*.

The SIAMANG (*P. syndactylus.*) This species is known only as an inhabitant of Sumatra, though the probability is that it exists also in the neighbouring islands. It has not been long known to Europeans. It was first observed in the forests of Sumatra, by the late sir Stamford Raffles (who set a most noble example to governors of colonies where the natural history is little known,) and the two French naturalists

P. syndactylus.

Duvaucelle and Diard. The only account, or at least the most satisfactory one, which we have of the manners of the animal in its native forests, is in a letter from the former of these two naturalists to M. F. Cuvier. After mentioning that the Siamangs are very common in the Sumatran forests, that they are often tamed by the natives, and that he had consequently many opportunities of observing the animal both in its wild state and in confinement;—M. Duvaucelle proceeds:—"The siamangs generally assemble in numerous troops, conducted, it is said, by a chief, whom the Malays believe to be invulnerable, probably because he is more agile, powerful, and difficult to obtain than the rest. Thus united, they salute the rising and the setting sun with the most terrific cries, which may be heard at the distance of many miles, and which, when near, stun when they do not frighten. This is the morning call of the mountain Malays, but to the inhabitants of the town, who are unaccustomed to it, it is a most insupportable annoyance. By way of compensation, they keep a profound silence during the day, unless when interrupted in their repose or their sleep. These animals are slow and heavy in their gait; they want confidence when they climb, and agility when they leap, so that they may be easily caught, when they can be surprised. But nature, in depriving them of the means of readily escaping danger, has endowed them with a vigilance which rarely fails them; and if they hear a noise which is unknown to them, even at the distance of a mile, fright seizes them, and they immediately take flight. When surprised on the ground, however, they may be captured without resistance, either overwhelmed with fear, or conscious of their weakness and the impossibility of escaping. At first, indeed, they endeavour to avoid their pursuers by flight, and it is then that their mal-address in this exercise becomes most apparent. Their body, too tall and heavy for their short and slender thighs, inclines forward, and availing themselves of their long arms as crutches, they thus advance by jerks, which resemble the hobbling of a lame man whom fear compels to make an extraordinary effort.

"However numerous the troop may be, if one is wounded it is immediately abandoned by the rest, unless, indeed, it happen to be a young one; then the mother, who either carries it or follows close behind, stops and falls with it, and uttering the most frightful cries, precipitates herself upon the common enemy with open mouth and arms extended. But it is manifest that these animals are not made for combat; they neither know how to deal nor to shun a blow. Nor is their maternal affection displayed only in moments of danger: the care which the females bestow upon their offspring is so tender, and even refined, that one would be almost tempted to attribute the sentiment to a rational rather than an intuitive process. It is a curious and interesting spectacle, which a little precaution has sometimes enabled me to witness, to see these females carry their young to the river, wash their faces in spite of their outcries, wipe and dry them, and altogether bestow upon their cleanliness a time and attention that in many cases the children of our own species might well envy. The Malays related a fact to me, which I doubted at first but which I believe to be in a great measure confirmed by my own subsequent observations: it is that the young siamangs, whilst yet too weak to go alone, are always carried by individuals of their own sex, by their fathers if they are males, and by their mothers if females. I have also been assured that these animals frequently become the prey of the tiger from the same species of fascination which serpents are related to exercise over birds, squirrels, and other small animals.

"Servitude, however long, seems to have no effect in modifying the characteristic defects of this ape: his stupidity, his sluggishness, and his awkwardness. It is true that a few days suffice to make him as gentle and contented as he was before wild and distrustful; but, constitutionally timid, he never acquires the familiarity of other apes, and even his submission appears to be rather the result of extreme apathy than of any degree of confidence or affection. He is almost equally insensible to good or bad treatment; gratitude and revenge are sentiments equally strange to him. All his senses are dull and imperfect; if he regards an object, it is manifestly without any intention—if he touches it, it is involuntarily. In a word, the siamang exhibits an absence of all intellectual faculty; and if animals were to be classed according to their mental capacities, he would certainly occupy a very inferior station. Most commonly squatted on his hams, with his long arms twined round him, and his head concealed between his legs, a position which he also occupies whilst sleeping, he is seldom roused from his lethargy, nor does he break silence unless at intervals to utter a disagreeable cry, which in sound approaches to that of a turkey-cock, but which appears to be expressive of no sentiment, nor to declare any want, and which in reality expresses nothing: hunger itself is insufficient to excite, or divest him of his natural lethargy; he takes his food with indifference, carries it to his mouth without avidity, and sees himself deprived of it without testifying either surprise or resentment."

Perhaps this statement is, in some of the points, a little coloured; but there is an air of graphic truth about it which leaves no doubt of its being accurate in the main; and, altogether, it is perhaps the best account of any of the genus in a state of nature which has hitherto appeared. The sluggish motions and passive character of these animals no doubt render them much more easily observed than their more energetic congeners; and probably the same circumstances cause them to appear more numerous than they are. Their more social disposition with each other, no doubt, also renders them more easily tamed.

Their appearance accords well with their habits, as described by M. Duvaucelle. None of the genus are handsome; but these are peculiarly clumsy and ungainly. The forehead is low, and partly covered by the hair of the crown, which is reflected forward upon it; and the same long hair descends by the sides of the head, and hides the ears. The eyes are shaded under projecting brows, and they are remarkably close together, a circumstance which never fails in giving a mean and ape-like expression to the human countenance, more especially if it is, as in these animals, accompanied by flatness of the nose, lateral, and rather upward, opening of the nostrils, a long upper lip, and great width of gape in the mouth. The uncouth expression of the face is increased by a greasy pouch or sac, under the lower jaw, bearing a considerable resemblance to that in the orang-utan, but rather larger in proportion to the size of the animal. What other purposes these distendable pouches may serve in the economy of the animals which possess them is not known; but in the siamang they are brought into action when the animal howls. The pouch completely hides the chin, or rather there is no chin to be hidden, as the lower jaw is rounded away from the gape, as in the carnivorous animals, and the gape, which is a mere line when closed, opens backward, nearly the whole length of the jaws. The face is farther deformed by high cheek bones; its colour is black; its texture like that of the naked part of a dog's nose; and it is destitute of hair, except a very few straggling red ones, at the upper and under part. The hair on the body is rather long, thick and close, and generally of a black colour. The body is clumsy; the hind legs, out of proportion, small; and the fore ones, though long, are ill put together. One peculiarity of the hinder paws is the adhesion of the first and second fingers, as far as the last joint, or that which bears the nail. It is on this account that it has received the specific name of *syndactylus*, which means, one toe "with," that is, "united with" another. The siamang is inferior in size to the orang-utan; but it is the largest of the gibbons.

The Wouwou, or nimble gibbon (*P. agilis*), is a smaller but far more active species. It inhabits the same forests, but is much less frequently seen. The height of the full-grown male does not exceed two feet eight; and the female is shorter. The arms are long, easily reaching the ground when the animal stands erect. The fingers on the fore-feet are long and clean made, but the thumbs are very short. The thumbs on the hind feet are longer in proportion, and act more directly in opposition to the fingers, than those of any other of the genus. From the structure of the extremities, and the lightness of its body, as well as of the ready and willing use to which it appears to put its powers upon all occasions, the wouwou well deserves the trivial name of *agilis;* for it skips up the trees, and from one tree to another, more like a winged creature than one which depends solely upon grasping. The following figure will give some idea of its climbing attitude:

The Wouwou.

But though this animal is so fleet in its motions, it is by no means handsome in proportion. It has scarcely any forehead, except a projecting ridge, which overshadows and enfonces the eyes. These organs are closer together than even those of the siamang; and though its nose is not quite so flat as the nose of that animal, the nostrils, which are oblique lateral slits, give the termination of it a deformed and mutilated appearance. The face of the male is bluish black, and that of the female has a tinge of brown. The male has long white whiskers, which conceal the ears, meet in a narrow band over the eyes, and give the head a wigged appearance. The female is without these appendages. The covering approaches more nearly to the texture of fur than that of any of the apes that have been hitherto noticed; and the colours are more variable, not only on different parts of the same animal, but at different ages, and in the different sexes. The young are all over straw colour. The adults are generally dark brown on the head and the under part, and very dark on the backs of the hands; but the neck and shoulders are lighter, and the colour passes into dull whitish on the loins and hips.

This species is not so social as the siamang, being found only solitary or in pairs; and from the rapidity of its motions it very speedily gets out of sight. Few animals gain the top of a tree with more celerity; and it appears to make use of the elastic branches in giving effect to its leaps, as, by the help of these, after it has once brought them into proper swing, and itself into proper balance, it can contrive to project itself to the distance of forty feet, and seize the branches after its spring with the most unerring certainty. M. Duvaucelle, to whom we are indebted for almost all that we know respecting it, does not seem disposed to give it much credit for "intellect;" but, as even he seems to ground his opinions of this matter upon the form of the skull rather than the displayed sagacity of the animal, his opinion is, of course, mingled with a portion of that prejudice which some consider inseparable from the whole doctrines of phrenology. It appears that this animal is not difficult to tame; and though, like all apes, it is perfectly useless in a domesticated state, it is playful and active. We omitted to mention, in its proper place, that it is without the pouch or sac on the under jaw, which gives so goitered an appearance to the orang-utan and the siamang; but the absence of that unseemly appendage does not appear to prevent it from crying as lustily in proportion to its size as either of those animals.

The Ounko (*P. Rafflesii*), is another species, the knowledge of which we owe to the same observers. It is more rare than even the wouwou, or if not, it is at all events more rarely seen; and M. Duvancelle remained among its haunts, and even crossed the woods in all directions, for fifteen months, without being aware of its existence. In its form and manners it has a considerable resemblance to the wouwou; but it is smaller, and the colour inclines more to black. There is no pouch, or dilatable skin, under the chin of the ounko; and otherwise its external characters are a sort of combination of those of the siamang and the wouwou. The colour approaches that of the siamang, except on the loins and some other parts, where the points of the hairs are glossed with brown. The texture of its covering more resembles that of the wouwou; but the hair is more produced on the back and shoulders, forming a sort of mane. The male has the same white whiskers as the wouwou, and, as in that animal, they unite and form a white band over the eyes. The female is without these appendages, and has only two slight brownish marks over the eyes. It is smaller than the male, and according to the accounts it has the first and second toes of the hind feet united as in the siamang, while those of the male are free. This species has, however, been so rarely seen that its history is far from perfect.

The Black Gibbon (*P. lar.*). The darkness of its general covering, the white round the face, and the demure look of this animal, give it a more solemn appearance than most of the other apes. It is about the same size with the ounko, and has sometimes been confounded with that animal; but in its internal structure it has a rib fewer on each side, and externally the paws and fingers are grey, while those in the ounko are black. The manners of the two species, from what is known of them, appear to be similar. They inhabit the close forests; and as they are lighter they resort more to the extreme branches than the larger apes, and make considerable use of the more flexible ones in swinging themselves from tree to tree. Though gloomy in its looks, the black gibbon is said to be gentle in its manners, and slow in its motions, as compared with some of its congeners. None of the toes on its hind feet are united.

The Ash-coloured Gibbon (*P. leuciscus*) is a much more energetic animal than the former, and bears some resemblance to the wouwou, which name is sometimes given to it by the Malays, no doubt in imitation of its cry. Its general colour is ashen grey, lighter round the face, and with the ears at top of the head, and all the feet dark brown. The callosities and buttocks are much larger than in any other of the gibbons; and the walk along the ground is said to be generally erect. In that posture of the spine, it is described as being capable of using all the four feet with equal effect, the fore ones being considerably longer in proportion than in any other of the genus. It is described as being a very adroit climber, and as showing great address while balancing itself on the tops of bamboos and other tall and flexible stems. In maintaining its balance in such situations, it uses its long arms something in the same manner as a rope-walker uses his pole; but still the action is very different, for the rope-walker balances himself on points of support, without any thing that can be called grasping, whereas the ash-coloured gibbon merely balances itself upon the powerful grasp of its hind feet. Those feet have all the toes true as in the black gibbon, and therefore they suit better for grasping small stems and twigs than those which have them partially united.

Such are at least the principal species of the ape genus, so far as at present known; but it is highly probable that more intimate research in the Oriental isles, and the analogous portion of the Malay peninsula, may farther increase the numbers. There is no well-authenticated account of their appearance in any other part of the world than the south-east of Asia, where, as has been hinted, the weather is pretty nearly uniform all the year round, the soil uniformly fertile, the forests thick and tangled, and the trees abounding in fruit, some species of which is almost always in season. Those forests are close and luxuriant; but they are not so tangled and interlaced with creeping plants as the forests of the humid parts of tropical America. They seem to differ also from the forests of tropical Africa, in which, with the exception of the baobab and a few others, which grow straggling and generally alone on the rich plains and bottoms, the trees are thin topped, and do not form a canopy. Few of them, in proportion, too, bear fruit fit even for ape's food; and therefore they are not proper localities for animals whose march is almost exclusively among the branches. They suit better with the baboons, which can walk upon all fours with considerable rapidity.

APEIBA (Marcgraav). A genus of four species of ornamental timber trees from South America. Linnæan class and order, *Polyandria Monogynia.* Natural order, *Tiliaceæ.* Generic characters: calyx five-cleft, coloured within, deciduous; corolla, petals five, somewhat clawed smaller than the calyx; stamens very short; anthers long egg-shaped, outside swollen, with two leafy lobes at top, exterior ones sterile; style elongated, dilated at the top into a funnel-shaped toothed stigma; capsule round, depressed, leathery, many celled; seed small, roundish, and nestling in the pulp. Some botanists describe this genus under *Aubletia.*

APETALOUS PLANTS are (otherwise called monochlamideous) all such as bear flowers having a calyx but no corolla. Of these there are twenty-seven orders, containing two hundred and fifty-six genera, and two thousand six hundred and twenty-eight species. Young botanists are often puzzled in applying the proper terms to the parts of apetalous flowers; but they may be guided by this rule, viz., whenever there appears only one floral envelope or outer expansion round the central members of the flower, that envelope is to be considered as the calyx, whatever may be its form or colour. Such a member is called perianthium (round the flower), and is, in this sub-class of the Jussienan arrangement, generally simple. As instances of this mode of florescence the mezerion and marvel of Peru have the calyx highly coloured, and bearing the semblance of a corolla, though, according to the above rule, these coloured parts are calyces and not corollæ.

This circumstance shows that the corolla is not an essential part of a flower, nor when present, is its use or function in the economy of the plant very apparent. It is generally the most delicate and fugitive member of the flower; and neither from texture or position can it afford much protection to the more essential and reproductive organs. Still, however ignorant we may be of the real use of the corolla, we may rest assured that it answers some important purpose; its delicacy of texture, and powerfully reflective surface of every ray of light, is not merely ornamental: they are at least attractive to the honey-seeking insect, which

> "———transports the fertilising meal
> From flower to flower—
> Then act in nature's office, bring to pass
> The glad espousals, and ensure the crop."—THOMSON

In this view the high colours of the corolla are of the greatest importance even more than we are aware of; for who can estimate the good performed by the unconscious bee flitting from flower to flower, who can fully appreciate how much man is beholden to their interference in perfecting the fruits of the earth?

Other circumstances deserve remark: where colour is wanting in the flowers we often see it bestowed on the foliage: example, *amarantus tricolor*; and where flowers are inconspicuous they are often highly odorous: instance, mignonette.

APHANIPTERA (Kirby). *Aptera* (Linnæus Lamarck). *Rhyngota* (Fabricius). *Suctoria* (Latreille). An order of insects including the common bed-flea and the fleas of various animals. This is an osculant order, and is distinguished from the other *Aptera* of Linnæus in undergoing a regular metamorphosis. The larva is vermiform, the pupa incomplete, and inclosed in a coccoon. Probably the common flea and chigoe would form distinct genera; there are many species belonging both to birds and quadrupeds; amongst the latter the squirrel, the mole, and soft haired animals appear subject to them.

Besides their metamorphosis, they are distinguished from the *Aptera* by the number of segments into which their body is divided, and by their pentamerous tarsi. The following are the characters as given by Messrs. Kirby and Spence:—

Metamorphosis incomplete.

Body apterous, compressed.

Mouth rostrulate, the labium and palpi being elongated.

Tarsi pentamerous, or five-jointed.

Under the head of FLEA, we shall give its popular and natural history; and under the head PULEX, we shall give all the genera as described by the latest authors.

APHANOCHILUS (Bentham). An herbaceous perennial, introduced from Nepaul, belonging to the order *Labiatæ.* It is the same plant called mentha blanda by Mr. Lindley.

APHELEXIS (D. Don). A genus of ornamental green-house under-shrubs, introduced from the Cape of Good Hope. Linnæan class and order, *Syngenesia superflua.* Natural order, *Compositæ.* There are four species, and they were formerly supposed to be either elichrysums or xeranthimums by other botanists.

APHIDÆ (Leach). An extensive family of insects of the order *Homoptera,* and embracing the genus *Aphis* (Linnæus). This family has the tarsi two-jointed, the first joint very short: rostrum in both sexes; antennæ with six, seven, or eight joints; females generally apterous; tarsi with the last joint vesiculous; upper wings in the males larger than the lower; head transverse.

This family contains the genus *Aphis*, of Linnæus. Antennæ setaceous or filiform, seven jointed; elytra larger than the wings, elongate, triangulate; abdomen towards the apex generally tuberculate or horned; eyes entire. Several other genera have recently been added to the family.

The animals of this genus are very numerous, and destructive at times to almost every species of plant. There is a difficulty in preserving the species from their being minute and soft, but we should recommend the entomologist who would wish to make himself acquainted with the numerous species already described to attach to each specimen the name of the plant on which it was found. The most familiar name by which they are generally known in this country, is *plant lice*, the French call them *pucerons*. The minute animals of this genus live entirely on vegetables, and the loftiest tree is as liable to their attacks as the most humble plant. Their numbers are often incalculably great. They prefer the young shoots, on account of their tenderness, and frequently insinuate themselves into the very hearts of the plants, doing irreparable mischief even before they are discovered. But for the most part they beset the foliage, and are always found on the under side of the leaf. This they prefer, not only on account of its being the most tender, but because it affords them protection from the weather, and from various injuries to which they would be otherwise exposed. Sometimes, though very rarely, the root is the object of their choice, and the roots of lettuces have been observed so thickly beset with one of the species that the whole crop has been rendered sickly and of little value. They are rarely, except one species (*aphis salicis*, which is larger and much stronger than the others), to be found on the bark of trees.

These insects are sometimes winged, and sometimes destitute of wings, this variation not depending upon the distinction of sex. In the spring they are viviparous, producing the young alive; and in the autumn they are oviparous, depositing their eggs, like most other insects, in places where they remain secured through the winter till the ensuing spring, when they are hatched. The aphides afford also another surprising deviation from the general laws of nature; one impregnation of the female is sufficient for nine generations. Their beak, the sheath of which is composed of five joints, is inflected. The antennæ are tapering, and longer than the thorax. They have either four wings, or are entirely destitute of them. At the extremity of the abdomen there are two obtuse erect horns; and the tail is sometimes terminated by a small style.

The larvæ and perfect insects are said to have so little difference in external appearance that they cannot be distinguished from each other, except by size.

Aphis Rosæ.—This insect, which is well known by the name of rose louse, is generally of a green colour; with the tip of the antennæ and horns black. The tail is pointed and without a style. Towards the beginning of February, if the weather be sufficiently warm to make the buds of the rose tree swell and appear green, this species of aphis will be found on them in considerable abundance. They are produced from small black oval eggs, which were deposited in autumn on the last year's shoots. If after their appearance the weather become cold, almost the whole of them suffer, and the trees are, for that year, in a great measure freed from them.

Those that withstand the severity of the weather, seldom arrive at their full growth before April, when, after twice casting their skins, they usually begin to breed. It then appears that they are *all females*, and each of them produces a very numerous progeny, and that without any intercourse with a male insect. These, though themselves produced from eggs, are viviparous. Their young, when they first come from the parent insects, are each enveloped in a thin membrane that has the appearance of an oval egg. This apparent egg adheres by one extremity to the mother, while the young aphis proceeding from it extends the other, by this means gradually drawing the ruptured membrane over the head and body to the hind feet. During the operation, and for some time afterwards, the forepart of the head adheres, by the viscous matter about it, to the tail of the parent. Thus suspended, it soon entirely frees itself from its former envelopement; and when its limbs become a little strengthened, it is set down on some tender shoot, and there left to provide for itself.

In the spring months there appear but these two generations of the aphis: the warmth of summer, however, produces no less than five. One of these comes forth in May, and the months of June and July supply each two more. The insects of the May breed cast their skins twice, and the others three or four times, according to the warmth of the season. When the heat has been sufficiently great, and the food in tolerable plenty, the first change has been observed to take place in about ten days after their production.

Early in June some of the third generation, which were produced about the middle of May, after casting their last covering, exhibit four erect wings much longer than their bodies. The possession of the wings seems to depend not on sexual distinction, nor even on the original structure of the insects, so much as on the quantity and quality of the nourishment with which they are supplied. Few of those on succulent shoots have wings, while those of the same generation on the less tender branches are most of them winged. Some time before they come to their full growth, it is easy to discern which of them will have wings, from a remarkable fulness of the breast. When the last covering is thrown off the wings, which were before folded in a very narrow compass, gradually extend in a most beautiful manner to their proper size and dimensions. All the following breeds are winged. In the autumn, the eighth, ninth, and tenth generations are produced; two in August, and the last about the middle of September. The two first resemble the summer breeds, but the third differs very greatly from all the rest. Though all the aphides which have hitherto appeared have been females, in this tenth generation several *male* insects are found. The females have at first the appearance of the summer insects, but in a few days their colour changes from green to yellow, and gradually, before their full growth, to orange. These yellow females are destitute of wings. The males, when they first appear, are of a reddish-brown, but have afterwards, when they begin to thicken about the breast, a dark line along the middle of the back. They come to their full growth in about three weeks, and then, casting their last skin, appear in every part, except the wings, of a bright yellow. They soon, however, become dark brown; the wings become transparent, and at length are in appearance not unlike very fine black gauze. The females soon begin to deposit their eggs, which, if possible, is always done near the buds of the branches, that the future young may be the more easily supplied with nourishment. Some of them continue laying their eggs till the beginning of November: these are oval, and when first protruded are green, but they soon become perfectly black. They adhere to the branches on which they are deposited, by the viscous matter that at first surrounds them. These eggs remain through the winter till the ensuing spring before they are hatched.

If the aphides had not many enemies, their increase in summer would be so great as, by wounding and exhausting the tender shoots of the trees, sometimes to suppress their vegetation. Among their enemies, one of the principal is a small black species of ichneumon fly, which darts its pointed tail into the bodies of the aphides, and at the same time deposits in each an egg. This egg afterwards produces a grub, which feeds within the body of the insect till it has acquired its full growth, when it undergoes its change, and entirely destroys its living nidus.

After a mild spring, most of the species of aphis become so numerous as to do considerable injury to the trees on which they are found. The best mode of remedying this evil is to lop off the infected shoots before the insects are greatly multiplied, repeating the same operation before the time that the eggs are deposited. By the first pruning a very numerous present increase will be prevented; and by the second, the following year's supply may in a great measure be cut off.

Aphis Humuli.—As illustrative of the vast importance of this insect to the British treasury, the following observations by Rusticus may give our readers some idea. "In the year 1802, on the 14th of May, the old hop duty was laid at 100,000*l.*; the fly, however, appearing pretty plentifully towards the end of the month it sunk to 80,000*l.*; the fly increased, and, by the end of June, the duty had gone down to 60,000*l.*, by the end of July to 30,000*l.*, by the end of August to 22,000*l.*, and by the end of December to 14,000*l.*; the duty actually paid this year was 15,463*l.* 10*s.* 5*d.* In 1825, the duty commenced at 130,000*l.*, but owing to the excessive increase of the fly, had in July fallen to 16,000*l.*; at the beginning of September it rose to 29,000*l.*, but towards the end fell again to 22,000*l.*: the amount paid was 24,317*l.* 0*s.* 11*d.* In the following year the summer was remarkably dry and hot; we could hardly sleep of nights with the sheets on; the thermometer for several nights continued above 70° all the night through: the crop of hops was immense, scarcely a fly was to be found, and the betted duty, which began in May at 120,000*l.*, rose to 265,000*l.*; the old duty actually paid was 262,331*l.* 0*s.* 9*d.*; the gross duty, 468,401*l.* 16*s.* 1*d.*, being the largest amount ever known. From this it will appear that, in duty alone, a little insignificant-looking fly has a controul over 450,000*l.* annual income to the British Treasury; and supposing the hop-grounds of England capable of paying this duty annually, which they certainly are, it is very manifest that in 1825 these creatures were the means of robbing the treasury of 426,000*l.*; this seems a large sum, but it is not one-twentieth part of the sums gained and lost by dealers during the two years in question."

APHODIIDÆ. A family of *Coleopterous* insects proposed by Mr. Macay in the Horæ Entomologicæ, for the reception of two genera, *Aphodius* and *Psammodius*, separated from the Linnæan genus, *Scarabæus*, and forming part of the modern group termed *Lamellicorns.* These insects are amongst the smallest of the *Scarabæi* of Linnæus. Their bodies are of an elongated form, their legs inserted at equal distances from each other; they are furnished with a visible scutellum, and their palpi are smooth. They subsist for the most part upon the excrements of various animals, over which they may be constantly observed flying, and in which the sluggish larvæ reside. Of the genus *Aphodius* of Illiger (distinguished by the cylindric palpi and unarmed lower jaws) about sixty species have been observed in Great Britain; of which the *Scarabæus fossor* of Linnæus is the most common; it is about one third of an inch long, of a shining black colour; the shield of the head (clypeus) with three tubercles, the central one being the longest. The other genus, *Psammodius*, of Gyllenhal, evidently approaches some of the *Trogidæ* in its characters; it is distinguished by its thickened palpi and armed lower jaws. The *Scarabæus sulcicollis*, of Fabricius, may be considered as the type. The number of species of this genus is small, and the insects are generally found in sandy situatians, in the neighbourhood of the sea coast.

APHYLLÆ. The second class of the grand division *Cellulares*, containing all those vegetables which have no leaves. It includes the orders *Algæ*, *Lichenes*, and *Fungi*, of which there are 273 genera and 2022 species, many of which will be noticed under their proper names. The accompanying vignette will convey a good idea of plants which form this class.

Aphyllæ.—*Fungi: a*, Phallus indusiatus; *Algæ: b*, Dumontia interrupta; *Lichens: c*, Squamaria Smithii; *d*, Imbricaria cærulescens; *e*, Collema nigrescens; *f*, Imbricaria grisea; *g*, Urceolaria occellata.

APIDÆ (Leach). One of the two families of bees, of far greater extent than the andrenidæ, and, as noticed under the article Apis in the next page, at once distinguished by the length of the terminal parts of the lower organs of the mouth, which form a trunk, folded beneath the head and breast when at rest, but stretched forward when the insect is employed in ravaging the flowers of their nectar. The construction of the mouths of these insects is exceedingly curious, and will be detailed under the article Bee.

From their habits the insects of the family are divisible into two groups; 1st, the solitary, and 2nd, the social bees. In the former the shank of the hind legs of the females is clothed with hairs, whilst in the latter, this portion of the leg is broad and concave, forming a shallow trough for the carrying of pollen. The solitary bees in the recent distributions of Latreille form four sub-families; 1st, the *Andrenoides*, a group of small extent, consisting of the genera, *Systropha*, *Rophites*, and *Panurgus;* 2nd, the *Dasygastres*, or woolly-bellied bees. consisting of the leaf cutters (*Megachile*), upholsterer bees (*Osmia*), some of the mason bees, and others: 3rd, the *Cuculinæ*, or cuckoo-bees, including the genera, *Epeolus*, *Nomada*, *Melecta*, &c.; and 4th, the *Scopulipedes*, or brush-legged bees, including the mason bees, *Anthophora*, and some others. The social bees consist of the genera of humble bees (*Bombus*), hive bees (*Apis*), with several other allied exotic genera. It must be evident that in a work of this kind it will be impossible to enter into the details of the structure and habits of all the various kinds of bees, since volumes would not contain a complete account even of the hive bee alone. We shall, therefore, under the article Bee, give a short notice of the hive bees, and shall detail the economy of the other groups under their respective heads.

APION. A very extensive genus of minute beetles (*Coleoptera*), belonging to the family of the weevils (*Curculionidæ*), established by Herbst, and distinguished by the elegant pear-shaped form, the protruded snout, and the straight antennæ of the species. About ninety species have been found in England. They subsist upon vegetable productions, occasionally doing much mischief. The yellow-thighed apion (*A. flavifemoratum*), feeding upon the seeds of the purple clover and the yellow-footed apion (*A. flavipes*), upon the Dutch or white clover, the larva feeding upon the heads. Mr. Kirby has made an interesting observation respecting an insect of this genus, with reference to the supposed uses of the antennæ; whilst examining it under a lens, its antennæ started upon his making a slight but distinct noise, and which it repeated as often as the noise was renewed. This circumstance has been regarded as affording a proof that the antennæ are organs of hearing (Insect Miscell., p. 107); but from the extreme sensibility of these portions of the body, we should rather be inclined to refer their starting to the operation upon them of the vibrations in the atmosphere, caused by the production of such noise. One of the handsomest, and at the same time commonest species of the genus is the *Curculio frumentarius* of Linnæus; it is about one-sixth of an inch long, of a bright red colour, and is generally found upon the dock.

APIOS (Borelli). A single genus of tuberous-rooted plants, native of North America, belonging to the Linnæan class and order, *Diadelphia decandria*. Natural order, *Leguminosæ*. Generic character: calyx bell-shaped, limb oblique, three teeth short, the fourth or inferior one elongated; keel bent like a sickle, standards bent back at the top; tube notched and fixed below the germen; pod leathery, two-celled, the cells interrupted. This plant is closely allied to *glycine* or *wisteria*.

APIS—the bee. In the Linnæan system of insects this name was employed to designate all those hymenopterous insects which have the lower parts of the mouth formed into a trunk, and bent downwards, the antennæ elbowed in the middle, the wings smooth, and body generally hairy. It included, therefore, not only the honey bee, humble bees, mason bees, leaf-cutter bees, carpenter bees, &c., but also a great number of other species, whose habits were and still are unknown. On more minutely examining the characters possessed by some of them, it was found that the trunk was very short, whilst on the others it often attained a very considerable length, being sometimes as long as the whole body; hence, by Reaumur and De Geer, the latter were regarded as the true bees (forming the genus *Apis*, in Mr. Kirby's admirable *Monographia Apum Angliæ*), whilst to the latter they gave the name of pro-abeilles, which are the andrenæ of Fabricius and the melittæ of Mr. Kirby. On reviewing the whole order of hymenopterous insects, however, these two groups still possess characters in common of such importance as to warrant their formation into a separate section, which has been termed Anthophila (lovers of flowers), or Mellifera (gatherers of honey, or rather of pollen); indeed the latter peculiarity is supported by that singularity of structure which distinguishes the group, namely, the large and dilated size of the basal joint of the posterior tarsi. The two groups above noticed constitute the two families of which, in the modern classification, this section mellifera is composed, namely, first, the Andrenidæ (which see *), and second the Apidæ.

APISTES—treacherous, a genus of Acanthopterygeous, or spinous-finned fishes, belonging to Cuvier's second family of the order, or those which have armed cheeks (*joues cuirassées*); they have teeth in the palate, and only one dorsal fin. Their peculiar character is a strong suborbital spine, with which they are very apt to inflict wounds in the hands of those who incautiously touch the sides of their heads. They are fishes of rather small size, and inhabiting chiefly the warmest seas. One subdivision have the body scaly, with large pectoral fins and one free spinous ray; another have the pectoral fins of moderate size and without any free rays; and a third have the body free from scales, and free rays under the pectorals. Some of the species are found on the coast of Australia; but the habits of all of them are very little known.

APLYSIA-LAPLYSIA (Linnæus, Lamarck). A molluscous animal, belonging to the class *Paracephalophora;* order, *Monopleurobranchiata;* and to the family of *Aplysiacea*.

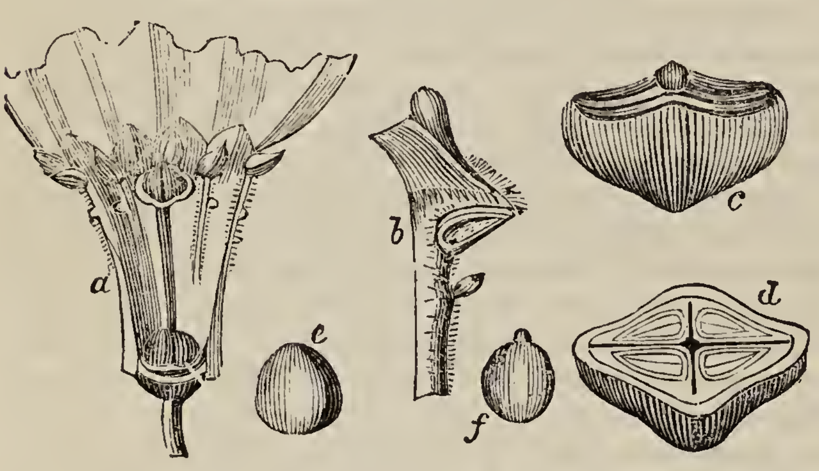
The body of this animal is thick, fleshy, and oval,

---

* It has been inadvertently stated in this article, that although the species of Andrenidæ consist only of two kinds of individuals, males and females, yet that they live in societies. Now it is a physiological circumstance of much interest that all social hymenopterous insects are provided with neuters, for the due support of the community. Neuters are accordingly found amongst the ants, the true wasps, the hive bees, and the humble bees. When, therefore, no neuter individuals exist we may be certain that the insects are not social; now this is precisely the case with the burrowing wasps (*Odynerus*), with many of the Apidæ and with the Andrenidæ. It is true that the latter are often found congregated thickly about some sunny bank, or other convenient place, but their sociality is of no higher order than that which exists amongst the inhabitants of the same street in large towns, where one person scarcely knows his next door neighbour.

provided beneath with a rather thin flat foot; on each side there is a natatory appendage; above and posteriorly there is a kind of operculated buckler, internally solidified by a rudiment of shell, more or less calcareous and regular, covering the cavity of the bronchiæ; two pair of slit auriculated tentacula, the one occipital, the other labial, with very small sessile eyes, placed between these two. Lamarck enumerates three species. Gmelin corrected the name of this genus from *Laplysia*, to the present one, which is more correct, the other having probably originated in a typographical error, overlooked by subsequent authors.

APOCYNEÆ. A natural order of dicotyledonous plants allied to the asclepias, a family. It constitutes the hundred and twenty-eight order of the Jussieuan system (Loudon), and comprises upwards of forty genera and a hundred and sixty species. The following are the botanical characters of the family:—Calyx, consisting of five divisions; corolla monopetalous, regular, five-lobed, and contorted; stamens, five, arising from the corolla; anthers, two-celled, opening longitudinally; one or two superior ovaries, and the same number of styles; fruit, a capsule, a drupe, or a berry. The twisted or contorted segments of the corolla, resembling a catherine-wheel, may be looked upon as a characteristic mark of the family, and on this account the term *contortæ* was applied to it by Linnæus.



APOCYNEÆ (*Cerbera thevetia*).—*a*, portion of the corolla opened to show the stamens and pistil; *b*, stamen, with a portion of the corolla; *c*, fruit; *d*, transverse section of the same; *e*, seed; *f*, embryo.

The plants included under the order are trees or shrubs, principally natives of the tropical regions of Asia, Africa, and America. A few of them are hardy, and grow in the colder zones of the earth.

They are acrid, stimulating, and slightly astringent. These properties, when existing in a weak degree, may be turned to useful account; but when concentrated and powerful, they form active and dangerous poisons. The apocyneæ also possesses narcotic qualities. Most of them yield a milky juice, remarkable for its bitterness and acrimony.

This is a very important order, and furnishes many substances which deserve attention, both in a toxicological and medicinal point of view.

Among the poisonous plants included under the apocyneæ, we may particularly notice the *cerbera tanghin* or *tanghinia venenifera*, the poison tanghin, formerly used in Madagascar as an ordeal for the conviction of criminals. The kernel of the fruit of this plant, although not much larger than an almond, is sufficient to destroy upwards of twenty individuals. In Madagascar, portions of the poisonous kernel used to be administered by persons denominated *skids* (who united the offices of priests and physicians) to those who denied the crime of which they were accused. The poison was considered an unerring means of revealing guilt and clearing innocence. It began generally to take effect within half an hour after its administration. Particular notice was taken of the mode in which the wretched victims fell, whether on their face, back, or side, inasmuch as different shades of guilt were supposed to be indicated by these positions. Convulsions came on, accompanied with efforts to vomit. If vomiting took place early, the person generally recovered; if not, insensibility ensued, and death speedily followed. Those who recovered were looked upon as beings of a superior order, and as the peculiar favourites of heaven. It was with great difficulty that the chieftains of Madagascar were persuaded to abolish this ordeal, which had been in existence among them from time immemorial, and was considered of such importance in the detection and punishment of guilt.

Under a subdivision of the apocyneæ, to which the name of *strychneæ* has been applied, we find the genus *strychnos*, some of the species of which have long been noted for their active poisonous properties. The *nux vomica* which has long been used as a poison for rats, is the seed of one of the species of this genus, viz., the *strychnos nux vomica*, poison-nut, or rat's-bane. From this species, as well as the *strychnos sancti Ignatii*, *colubrina*, and *ticuté*, a peculiar crystalline, alkaline substance, called strychnia, or strychnine, is procured by chemical means. It is one of the most destructive and violent poisons which has been hitherto discovered. A dog has been killed in two minutes by injecting into its chest a sixth of a grain of strychnia dissolved in spirit; and a wild boar has been killed in the same way with a third of a grain, in ten minutes. Half a grain introduced into a wound, Dr. Christison says, would kill a man in less than a quarter of an hour. Strychnia has a peculiar action on the animal frame: it produces tremblings, stiffness, and startings of the limbs, lock-jaw, general rigidity, and difficulty of breathing. If the dose is very small these symptoms pass off, or may be removed by the use of brandy and other stimulants; but if the dose is large, the spasms become violent and succeed each other rapidly, and death soon takes place from suffocation, which is induced by the spasms affecting the muscles of respiration. The brain is not affected, and the mental faculties remain unimpaired. From these symptoms it is concluded that strychnia acts on the spinal marrow alone. Notwithstanding its powerful effects, this substance has been used with considerable success in various diseases, more especially palsy, dysentery, and cholera.

From the *Strychnos ticuté* there is procured a poisonous juice, well known under the name of upas. This famous Javanese poison owes its virulence to the presence of strychnia, and is employed to cover the ends of arrows and other instruments of warfare. Concerning the upas-tree, or poison-tree of Java, many marvellous stories were formerly propagated. It was stated that no plant could live within the distance of a stone-cast round it—that if birds happened to alight on its branches they instantly dropped down dead, and that in order to procure the poisonous juice without endangering life, it was necessary to have the whole body covered with a strong cotton cloth. The recent researches of botanists have proved these accounts to be fabulous and exaggerated. The upas-tree is found in India, growing along with many pleasant aromatic plants, such as the pepper, the clove, and the nutmeg ; and we thus find the same heats of a vertical sun giving energy to the juices of the most fatal as well as the most salubrious species.

The bark of the *Strychnos colubrina* has been used as an antidote against the bite of the snake called cobra de capella (*Coluber major*). There are several species of strychnos, such as the *potatorum*, *brachiata*, and *pseudoquina*, which do not possess poisonous properties. The bark of the last-mentioned species is employed in Brazil, under the name of quina do campo, as a substitute for Peruvian bark, in the cure of intermittent fever.

The bark of the *Cerbera manghas*, one of the apocyneæ, is purgative. The root of the *Ophioxylon* possesses similar properties ; it is used in India under the name of snake-root, as an antidote to the bites of serpents. The root of the *Neicum odoratum* is poisonous, while its sweet-scented leaves are employed externally to dispel inflammatory swellings. The leaves of the periwinkle or hinca are astringent, and have been used successfully in tanning. The *Wrightia tinctoria* yields a beautiful blue dye.

Some of the apocyneæ possesses nutritive qualities. Among these may be noticed the cream-fruit of Sierra Leone, and the *Tabernæmontana utilis*, the hya-hya, or milk-tree of Demerara. The milk-like fluid which is obtained in great abundance from the latter plant, has been used as an article of diet. It is thicker than cow's milk, is destitute of all acrimony, and resembles in appearance the vegetable milk of the palo de vaca, or cow-tree of the Caraccas. The fruit of the *Carissa edulis* is eaten in Nubia. The young shoots of the *Apocynum Indicum* are also employed dietetically, as it is said the pulp surrounding the seeds of most of the apocyneæ, whether poisonous or not, is innocuous, and may be eaten as food.

Caoutchouc, or Indian-rubber, is procured from the *Urceola elastica*, a climbing plant of Sumatra, as well as from various other plants belonging to this family. The milky juice of these plants is smeared over moulds of clay made in the form of bottles, and is afterwards dried in the smoke. After the first layer is dried another is added, until the necessary thickness is obtained. In this way bottles of Indian-rubber are prepared. The black colour of the caoutchouc is owing to the smoke in which it is dried.

There are many other plants included under this interesting order, which possess properties rendering them useful in a medical and economical point of view ; but those alluded to are sufficient to show the general properties of the order, and the important place which it holds in the vegetable world.

APOGON—beardless. A genus of spinous-finned fishes belonging to the perch family, and so much resembling the mullets as sometimes to be called the beardless mullet, and at other times the king of the mullets. They are fishes of small size, and remarkable for the brightness of their red colour. They have two dorsal fins, and the ventral fins are situated immediately under the pectorals. Their bodies are short and covered with large scales, which are understood to be shed and reproduced once a year, or even oftener. They are without the beard or cirrhi, which fringe the under lip in the true mullets ; and it is on this circumstance that the generic name apogon is founded.

APONOGETON (Thunberg). A family of four species, stove and greenhouse perennial aquatics, natives of India and the Cape of Good Hope. Linnæan class and order, *Hexandria Trigynia ;* natural order, *Fluviales.* Generic character : flowers on spikes arranged on one side, bracteas distinctly coloured ; calyx none ; corolla none ; stamens inserted on the common receptacle ; filaments dilated at the base, awl-shaped ; anthers roundish ; stigmas three or four, awl-shaped, turned back ; capsule one-celled, three-seeded.

APPLE. Although this is a general name for many different kinds of fruit, it is more especially applied to the common orchard-tree, called by botanists *Pyrus malus.* Of the pyrus, or pear family, there are forty-six distinct species ; and of two of these, viz., *Pyrus communis*, the pear ; and *Pyrus malus*, the apple ; there are innumerable varieties. Linnæan class and order, *Icosandria Di Pentagynia ;* natural order, *Rosaceæ.* Generic character : calyx five-cleft, persisting ; corolla five petaled, petals rounded ; stamens inserted on a raised ring on the throat of the calyx ; filaments awl-shaped ; anthers two-celled ; styles less than five ; apple five-celled ; each cell two-seeded ; partitions of the cells cartilaginous, as are also the coats of the seeds.

The common apple is decidedly the most useful fruit in cultivation. Its characteristics of hardiness of the tree, beauty of its flowers, and wholesomeness of its fruit, whether the pulp be used as food, or its juice as drink ; whether immediately from the tree, or from the fruit-room six months after gathering, the apple is one of the choicest gifts of nature.

Notwithstanding the great variety of our orchard apples, it is more than probable that the wild crab of our woods and hedges is the common ancestor. The first accidental variation of the crab no doubt occurred in the woods, as we see is the case at the present day. Such would naturally attract the notice of the planter. The stranger would be transplanted to the garden, where its peculiar properties would be in time imperceptably diffused among congenial neighbours. Hence a collection of *wildings* would be brought together ; and from among them a higher grade would originate, and henceforward take the name of apple. But as these new favourites could not be propagated by their seeds (except by accident, as they themselves had been), the arts of layering, grafting, &c., were had recourse to, for the purpose of perpetuating the kinds. By these means the new varieties were continued by cultivators ; and it appears that from the great number of excellent sorts possessed by our forefathers, as good sorts were obtained by accident in those days, as we now procure from the best practice assisted by science. The old golden pippin, golden russet, and rennette, nonpareil, and several others, still rank as high in public estimation as any of the new sorts lately brought into notice by the ingenious device of artificial impregnation.

The method of obtaining new varieties by impregnating the female organs of an inferior sort by the pollen or male dust of a superior kind, is only performed by curious cultivators, either in the cider districts or by nurserymen. The more simple and easy way of raising young trees, is by grafting the desired kinds upon crab-stocks raised from seeds collected in the woods. The seeds or pips are, when fully ripe, taken from the capsules, dried, and kept in dry sand till March, then sowed in rich, well-broken soil, in drills an inch and a half deep. When the seedlings are two inches high, they are thinned, kept free from weeds, and transplanted at the end of the second year into nursery rows, thirty inches apart, and at eighteen-inch distances plant from plant, there to stand till they are fit to receive grafts.

According to the management they receive, or to the suitableness of the soil on which they are grown, stocks may be ready for the graft in the second or third year after being planted out. In the next season after the operation of grafting is performed, it should be determined for what purpose and in what form the young tree is wanted. Apple-trees are required for walls, or espaliers, or for dwarf standards. For all these purposes the graft should be inserted as close to the ground as possible; and this to allow the production of branches below, in order that the trainer may have a choice to give the tree the required form. But for orchard planting tall standards are requisite, in order that the branches may be out of the reach of cattle, or not encumber the surface where under-crops are raised. For this purpose the nursery practice is to choose the leading shoot of the graft, pruning off all laterals, and leading this upright with a clear stem, and only stopping or beheading it when it has risen six feet and a half or seven feet high. At this height the tree is permitted to branch out with three, four, or more arms as the manager thinks best. Obtaining a like length of clear stem is sometimes accomplished in another way; stocks are trained upright, and the graft or bud is afterwards put in at the proper height. This is often done in the case of plums or cherries, where tall stocks can be drawn from the woods in the neighbourhood.

A fresh, loamy, well-trenched soil is most suitable to the apple when planted in an orchard; no pruning is required after the first and second year, and then only to regulate the first branching. In such situation the trees are required to grow to their natural size as soon as possible; and they will, without assistance, assume their specific form. But when introduced into a garden, and where they are compelled to take some unnatural shape, or be cramped in a limited space, no fruit tree requires more attention from the manager than the apple. In its utmost volume it is only a small tree; but when trained to a wall or espalier, or confined to the form of a bush on a narrow border, no tree struggles more to fly away from the artificial form imposed. Hence much pruning is required to keep it symmetrical; and so sure and so long as this struggle continues, few fruit will be seen. And the reason is, the tree is in a constant state of barren excitement. The fructiferous gems inherent in the system require to be moderately developed. In their progress from incipient existence in the bosom of a bud, until they are mature as a visible flower-bud, the process must be slow; otherwise strong flowerless shoots will only be put forth instead of flowers. And these strong shoots producing irregularity, and an appearance of wildness, must be pruned away only to excite a new growth of others of the same kind to come forth. Thus a tree so managed can neither be kept in a neat form or be at all fruitful. What adds to this luxuriance is, that while the head is annually reduced, the roots are annually extending; and instead of these two principal parts being equally balanced (as they always are in a natural state of a tree), they are not so; but, like a basket-maker's willow, the more it is cut the more it grows.

But this state of an apple-tree is not necessarily so: by skilful treatment the tree may be so managed as that not only moderate, but even diminutive growth may be induced, and thereby gain not only the desired form in a small space, but, when the seasons allow, abundant fertility.

The whole secret lies in preventing unnecessary growth. Instead of allowing a tree to bring forth a great number of rampant shoots, which must ultimately be cut away, stop every excess of the kind. Every bud threatening to push in a wrong place, should be rubbed off; and every shoot not wanted to complete the form, should be stopped when not more than three inches long. The month of May is the proper time for this indispensable work in the garden; sooner or later, however, according to the season. By stopping all the unnecessary growth of the head, the roots are also moderated, and send up no more nutriment than what is absolutely necessary for the demands of the head: thus inducing an equable condition of the system, producing the desired results. Moderate growth induces the maturation of flower-buds; and though these may become too numerous for the strength of the tree, it need not suffer, while thinning the flowers and fruit is so easy a task.

There are other modes of checking the too luxuriant growth of a tree sometimes had recourse to by orchardists: viz. taking up and immediately planting it in the same place; or cutting out a hoop of the bark of the stem to partially stop the ascent of the sap; or, which has a similar effect, tying a band of tape or string very tightly round the stem to produce strangulation. These expedients may answer the purpose; but the most natural is disbudding.

Apple-trees may be unproductive and unthrifty through extreme weakness. This is often witnessed in old orchards, or in the case of very old trees; and is usually attributed to the cold wetness of the subsoil. If the stem be not hollow, the tree may be renovated by digging-in fresh soil, or well rotted manure, about the roots to a considerable distance round the trunk; and by scraping or drawshaving off all the dead outside bark (even down to the liber) from the stem and large branches; or, as a last resource, taking off the head of the tree altogether, to cause the production of a new set of branches. Such treatment may be worth the trouble to save the life of an old favourite; but planting young trees to succeed the old is the best management.

The following are a few of the most esteemed sorts:—

For the table.—White Astracan; Beachamwell; Borsdoffer; Borovitsky; Breedon pippin; Bringewood pippin; white Calville; Cambusrethan pippin; Cockle pippin; cole, or scarlet perfume; court pendu plat; court of Wick; Downton; Dutch mignonne; Essex pippin; Cornish gillyflower; golden drop; golden Harvey; golden pippin; Grise; Ingestrie; Juncating, red and white; Margil; Newtown pippin; nonpareil; Oslin; scarlet and winter pearmain; pomeroy; golden rennette.

For the kitchen.—Baldwin's Suffolk Beaufin; belle bonne; burr knot; Caroline; Carlisle codlin; Dutch codlin, English codlin; Fearn's pippin; gloria mundi; Gravenstein; Hawthornden; Lucombe's seedling; Minshal crab; royal russet.

For cider.—Coccagee; Cyder sop; Damelot; yellow eyelet; Glasbury; Gregoire; hard pippin; Hogshead; House; John apple; Norman styre.

APPLE BERRY (Smith). Otherwise called by botanists *Billardiera scandens*, a genus of climbing plants introduced from Australia. Linnæan class and order *Pentandria Monogynia;* natural order *Pittosporeæ.* Generic character: calyx five-cleft, coloured; corolla connivent, forming a tube; stigma, two-lobed; berry, two-celled with many seeds; seed smooth.

APRICOT. A well known wall fruit. Linnæan class and order, *Icosandria Monogynia;* natural order *Rosaceæ.* Generic character: calyx somewhat bell-shaped, five-cleft, deciduous; corolla five-petaled, roundish, inserted in the calyx; stamens attached to the opening of calyx; filaments like threads; anthers erect, egg-rounded, two-celled; style simple; stigma headed; drupe roundish, smooth, with a longitudinal furrow; nut compressed, suture prominent, smooth; embryo inverted, seed leaves fleshy.

The fruit has its name (*A. præcox*) from the circumstance of its ripening early in summer. It is one of our earliest flowering trees, and the first wall fruit that comes to table. Although commonly trained to walls, a variety, called the Breda, ripens pretty well, in the latitude of London, on standards in the open ground, if planted in a warm soil and sheltered situation. The necessity, as well as the custom, of making the apricot a wall tree, is attended with two disadvantages, viz. the heat and shelter of the wall brings out the flowers so early that they are in jeopardy from night frosts; and the branches being all trained on a vertical plane, induces an inconvenient growth of breastwood, which, without constant attention of the manager, is a waste of vigour, and injurious to the regular form of the tree.

To secure, however, the health and beauty and fruitfulness of this tree, moderate growth must be induced by the system of disbudding, as recommended in treating of dwarf-apple trees. The habit of the tree is to produce strong shoots from the stem and lower parts of the branches. This, though a lucky circumstance in a tree trained in the fan manner, occasions constant inspection and labour to prevent them shooting into large unfertile branchlets, which must be, either in the summer or winter pruning, cut away. If moderate growth be obtained by stopping irregular growth, the roots will never become too powerful for the head; and the well-placed summer shoots being carefully laid-in close to the wall, in every vacant part, abundance of bearing wood will be obtained to give flowers and fruit in every favourable season.

The apricot tree is one of those that produces short shoots, commonly called spurs; those are almost always fruitful; and should be preserved by the pruner, while they are yet but a moderate distance from the face of the wall. When these, however, gain an unsightly length, they should be displaced; because the safety of the flowers and maturity of the fruit, depends on their closeness to the wall. The shoots of the past year, provided they are of moderate size and well ripened, bear in this, the finest fruit: and there is one peculiarity respecting these shoots which deserves attention. If any shoot continues to advance till late in the summer, it is rarely fruitful: but if stopped some time before the growth naturally ceases, the buds on its lower part will be formed into flowers; but if stopped too soon, these same buds will burst into tufts of leaves only.

Except for standards or riders, this tree is usually budded near the surface of the ground, for the purpose of being trained in the fan manner; which, for general purposes, is certainly the most eligible: other modes of training, however, may be adopted, viz. with an upright principal stem and horizontal branches; or with a tall upright stem, with the branches trained downwards. These unnatural positions of the branches, it may be observed, are only means of moderating the growth to induce fertility.

The apricot is commonly budded on plum stocks; some kinds, as the moorpark, are worked on their own stocks, i. e. stocks raised from apricot kernels. If the young trees be intended for riders or standards they should be budded on the Saint Julian plum.

The tree is readily injured by wounds: and therefore the utmost care should be observed that no necessity arise for taking off large limbs. The heartwood is not durable, and if long exposed to air, as in a large wound it must be, it quickly rots and brings on general decay. For this and other reasons, as soon as the tree attains its natural size, or has filled the space assigned to it, every expedient should be practised to keep it stationary; no excess of growth being allowed, except only the ordinary succession of young wood for bearing.

The apricot, like other icosandrious plants, is apt to blossom too early in the spring, and on this account requires at that time some kind of shelter from night frosts. Copings, projecting from four to six inches over the face of the wall, are a great security: or curtains of net, bunting, or light canvass, fixed to the top, and let down every evening, defend the flowers sufficiently; and, moreover, may be used for another purpose, too often neglected, viz. for *shading* the flowers in the middle of the day from hot sunshine, which very frequently destroys many more flowers than are killed by frost in ordinary seasons. It is on this principle that the old common custom of protecting the flowers with small twigs of evergreen trees is so effectual. These twigs being regularly stuck in between the upper branches and the wall, hang drooping over the lower parts of the tree; and remaining throughout the flowering and setting season, act both as a shelter and a shade.

This treatment is required by all early flowering fruit trees, apricots, peaches, nectarines, and particularly plums and cherries, on south walls. Retarding the flowering by every possible means is also a good plan: and it may be observed of the apricot (as well as morella cherries, plums, &c.), that, in the latitude of London they do better on an eastern or western aspect, than on one due south; not only because the flowering is retarded, but also because the ripening fruit become too soon mealy on a south wall.

The best varieties of the apricot are the Moorpark, Breda, Masculine, and Brussels; all which ripen in the months of August and September. Besides their value in the dessert, they are convertible into many descriptions of confectionary; and the green fruit (necessarily thinned from the tree before stoning), is useful for tarts.

APSEUDES (Leach, Eupheus, Risso). A small but remarkable British genus of *Crustacea*, belonging to the order, *Isopoda*, and section, *Heteropoda*, having seven pairs of legs, of which the second pair is very large, dilated, and notched, somewhat like the fore legs of a mole; whence the species has been termed *Cancer gammarus talpa* by Montague. The tail is terminated by two long filaments. It is found amongst marine plants. This genus may be regarded as the type of the family *Apseudidæ*.

APTENODYTES—the Patagonian penguin. A genus of aquatic birds inhabiting the sea, and the last of a very peculiar and well marked family, which are closely allied to the divers, but yet differ from them in some particulars. The first of that family may be considered as the common auk, or razor bill, or perhaps the puffin, as both of these are excellent divers, but have their legs placed far backwards, are very bad walkers, and cannot stand but in an erect position, supported on the whole length of the tarsi. After the auk there is an intermediate genus, which used to be classed along with this one, and of course called by the same name; but there are differences, especially in the structure of the bill, which render it more advisable to separate them in a systematic arrangement, though they are all popularly known by the name of penguins.

The generic characters of the Patagonian penguin are, the bill longer than the head, slender, straight, a little curved at the tip; the upper mandible furrowed throughout its length; the under one wider than the upper at the base, and covered with a smooth skin; the nostrils in the upper part of the bill concealed in front by feathers; the legs very short, thick, placed far backwards; four toes on each foot, all turned forwards, three of them of considerable length and completely webbed, the fourth one very short; wings merely rudimental, quite unadapted for flying, and the feathers on them having nearly as much resemblance to scales as to ordinary feathers.

These birds can swim and dive well, but they are rather the inhabitants of the lonely shores, than discursive over the sea. Indeed, none of the wingless birds have the habit of making long excursions. That they should not, is a wise provision of nature; because they are mostly inhabitants of seas liable to be agitated by violent tempests; and as they are in general heavy birds, they would be ill able for contending with the agitation of the water produced during these. This genus is found on the Antarctic shores, most abundantly in the creeks of the southern part of the American continent, and of the island of Terra del Fuego; but they are also met with in various others of the southern islands. They do not move equatorially, or appear to leave their localities at any season; and they are so unsuspecting, that they may be taken with the hand, or knocked down by a stick. For particulars of this and an allied genus, see PENGUIN.

APTERA—wings wanting. A name first employed by Aristotle, and subsequently by the early systematists, and adopted by Linnæus to designate all those species of articulated animals furnished with articulated legs, which are destitute of wings during the whole period of their existence; another peculiarity exhibited by these animals being that, unlike the winged insects, nearly the whole of them acquire their perfect form, on escaping from the egg, the only change which they undergo consisting of an increase of their size, as in quadrupeds, or more properly, resulting from a series of moultings, as in the serpent tribes. In the system of Linnæus this order contained 290 speices, distributed in the following manner:—

A. with six legs, and the head distinct from the thorax, containing the genera, *Lepisma*, three species; and *Podura* (or spring tails), fourteen species; *Termes* (or white ants), three species; *Pediculus* (or the lice), forty species; *Pulex* (the flea), two species.

B. with fourteen legs, and the head united to the thorax. *Acarus* (or the mites), thirty-five species; *Phalangium* (or the harvest spiders), nine species; *Aranea* (the spiders), forty-seven species; *Scorpio* (the scorpion), six species; *Cancer* (the crabs and lobsters), eighty-two species; *Monoculus* (the water fleas), nine species; *Oniscus* (the wood lice), fifteen species.

C. with numerous legs, and the head separate from the thorax. *Scolopendra* (or centipedes), eleven species; and *Julus* (or the millepedes), eight species.

In the days of Linnæus, however, the structure, and more especially the internal organisation of these apterous insects had been so little attended to, that we can scarcely but feel surprised, whilst considering that the formation of these different generic groups presented modifications of far higher rank than those by which the genera of the beetles or other winged orders were distinguished from each other, that in so imperfect a sketch as the above, the traces of those higher distributions should be observed which the more minute investigations of modern naturalists have rendered necessary; thus, if from the first division A. we remove the genera *Termes* and *Pulex* which undergo transformations, we shall have a division corresponding with the sub-class *Ametabola* of Leach, which see; the genera *Acarus* and *Aranea* constitute the modern class *Arachnida*, which see; and *Cancer monoculus* and *oniscus*, that of the *Crustacea*, whilst the two genera composing the section C. are formed into the modern division *Myriapoda*, each being the type of an order, namely, the *Chilognatha* and *Chilopoda* of Latreille and Leach.

The original name of the order thus separated into so many other divisions, has been employed by entomologists in various manners, so that unless the student be put upon his guard he would be greatly perplexed in consulting the valuable works in which such variations occur. Thus Lamarck, having established the class of arachnida, and removed all the other genera to different classes, with the exception of the *flea*, retained the original name of *aptera* for the order established for the reception of that insect, in which respect he has been followed by Mr. Macleay. Messrs. Kirby and Spence, on the contrary, proposed the name of *aphaniptera* for the order of the fleas, and applied the term *aptera* for the spring tails, the mites and harvest spiders, the centipedes and millepedes, all of which they introduced into the class insecta, retaining the spiders alone in the class *Arachnida*, whilst Latreille, considering the arachnidæ in a wider extent, and the *Myriapoda* as distinct classes, has employed, in some of his later works, the term *aptera* as a primary section of the true insects consisting of the Linnæan genera, *Lepisma* and *podura*, *pediculus* and *pulex*.

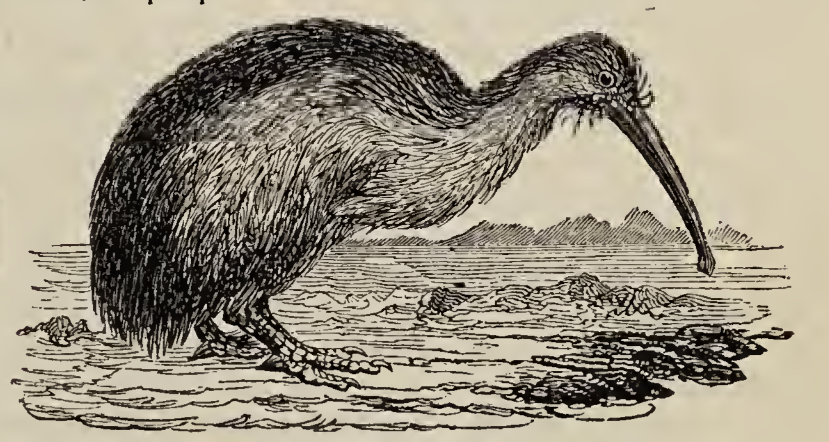
As, however, the group, which it was originally proposed to designate by the name of *aptera*, has been broken up into so many different sections, it would certainly seem to be a matter of convenience that the name by which, as a whole, these groups were known should be no longer employed; if, moreover, no other motive existed than that of removing all the confusion above detailed, by the employment of a more restricted nomenclature, we should feel but little hesitation in rejecting the term *aptera* altogether; but as the occasion for its employment is no longer requisite, we shall regard the order, containing the genus *pulex*, as entitled to the term *aphaniptera* (which see), as proposed by Messrs. Kirby and Spence; whilst with Mr. Macleay we shall regard the centipedes, millepedes, spring tails, and lice, as the types of so many orders in the class of *ametabolia* in a more extended sense than as defined in p. 91, whilst, with Latreille, we shall regard the *arachnida* as containing not only the spiders and scorpions, but also the mites which Dr. Leach regarded as forming a class by themselves.

APTERYX—the wingless bird of New Zealand. A most extraordinary species, genus, family, and—as one may almost say—order of winged creature, of which the characters, so far as they are known, clearly enough demonstrate that it is a bird, but they as clearly demonstrate that it does not come within any of the orders into which other birds are arranged in the systems. All that is known of it is a single skin, with the bill and feet attached, unmutilated, and in a good state of preservation. This skin was brought from New Zealand in 1812, by Captain Barcley of the ship Providence, from whom it passed into the hands of the late Dr. Shaw, and after the doctor's death it was purchased by Lord Stanley, in whose possession it now remains. Dr. Shaw described it in the 24th volume of the Naturalist's Miscellany, and accompanied the description by a figure; and that description and figure form the only sources whence Temminck, and some other foreign naturalists, who have noticed the bird, obtained their information. But Dr. Shaw, though a laborious collector, and voluminous compiler, was by no means a philosophic naturalist, and therefore his figure was not very accurate, and his description by no means calculated either to draw much attention to the bird, or to put inquirers in the right way of discovering its natural relations or affinities. Some foreign naturalists went even so far as to question the existence of the bird, though in the same work, and in the adjoining page, the very same author mentions it, under its New Zealand name of *Kivi Kivi* (most likely an imitation of its cry), as being abundant in the forests of that country. Of course, no characters are described along with the mention of the Kivi Kivi, because, though many of the voyagers frequenting New Zealand have often heard the natives mention the name of the bird, the places where it is found, and some of them have seen the chiefs with cloaks ornamented with the skins, so as to leave no doubt of the identity of the Stanley specimen, yet it does not appear that any European has seen either bill or foot, except in that specimen.

Lord Stanley sent the specimen to the Zoological Society, where the skin was so carefully examined as to ascertain with certainty that there is no deception in it; and a new figure and description, more in accordance with the analogies of the bird, were drawn up by Mr. Yarrell, with his usual accuracy. Of this figure, prepared under the directions of Mr. Yarrell, we give an accurate view in the next column; and we cannot convey a clearer idea of the appearance of this extraordinary creature than in that gentleman's words.

"The whole length of the bird," says Mr. Yarrell, "from the point of the beak to the end of the body (for there is no tail), is 32 inches; the beak is of a light yellow brown colour, long, slender, smooth, and polished, in form resembling that of an ibis, but rather more straight, and depressed at the base; length from the gape to the point, six inches and three quarters; the upper mandible is grooved in each outer side, near the margin, throughout its whole length; at the end of this groove, at each side, the nostrils are pierced, the apertures elongated and covered by a membrane, so suspended on the outside of each of these like a valve, that the slightest pressure against the outer surface when flexible, as during life, would render the nostrils impervious, and effectually defend and cover them. A bristle introduced into the nostril, under and behind this defending membrane, passes up the whole length of the beak. The upper mandible terminates in a blunt truncated knob, projecting a little downwards, behind which, on its under surface, the end of the lower mandible ranges when both are closed. The lower mandible is also grooved slightly near the outer edges throughout its whole length. Both mandibles are broad and flat at the base, measuring full one inch across at the gape, and only seven lines in height. The breadth of the upper mandible at the point is two lines, under mandible still more narrow.

"Throughout the whole length of the upper mandible and the distal three-fourths of the under one, the inner or opposed surfaces of both are perfectly flat, producing, when pressed together, uniform and entire contact, and well adapted for compressing or crushing such substances as may be selected for food. The proximal fourth of the lower mandible is concave on its inner surface, affording space for the tongue, which must, in proportion to the beak, be small and short.



Apteryx.

"The form of the body in this preserved specimen is that of an elongated cone placed nearly upright over a pair of short and stout legs, and the bird is thus made to resemble a penguin. In the figure annexed to the present description, the position and character assumed for it is that of the *Struthious* birds, in accordance with its real systematic relations.

"From the crown of the head to the lower end of the body, the length is twenty-four inches; and the circumference at the lower part eighteen inches. The feathers on the top of the head and forehead are short, and the skin carried forwards over the base of the beak to the extent of an inch, is covered by a mixture of dark feathers, bristles, and hair. About the gape on each side are also several long black bristles. The feathers of the neck are somewhat longer than those on the head, and they increase in length generally in proceeding downwards over the body. Those of the head and neck are of a hair brown colour, with the shafts lighter; on the back, sides, and rump, the shafts and inner portions of the webs are reddish, yellow, brown, and the edges dark brown, producing an agreeably variegated appearance. On the lower part of the neck in front, the breast, and the belly, the feathers are lighter in colour than on any other part of the body; the shafts still lighter than the webs, and greyish white. The feathers generally are uniform in structure, and resemble those of the *emu;* but each feather is much shorter, the longest (those hanging over the rudimentary wings) not exceeding four inches and a half. The webs are of greatest extent, most flocculent and silky at the base of each feather, and become more linear and shorter towards the end; the whole of the fibres forming the web are disunited, and the shaft has no secondary or accessory plume.

"On each side, about midway between the head and lower end of the bird, is a rudimentary wing consisting of three distinct portions.

"The part of the *humerus* that remains is about one inch in length; and from the appearance of the fractured end of the bone within the skin, was broken off clear below the head; the radial portion, figured by Shaw, appears to be made up, as far as can be ascertained by present examination, of two distinct bones, each about one inch and three-eighths in length, covered with a corrugated skin, and ending at the carpal extremity in a small horny claw, supported on a short ungual (heel) bone, the two portions in conjunction measuring about three-eighths of an inch.

"To the radial portion of the wing several feathers are attached of the same character as those of the other parts of the body; but the feathers above and behind this rudimentary wing are longer than those of any other part of the body, and, being directed forwards and downwards, entirely cover and conceal this small and useless wing.

"As far as I am able to judge by the preserved skin, the *femur* was probably three inches in length, the tibia about five inches; the articulation of the tibia with the *tarsus* is one inch and three-quarters below the end of the body, and on a line with the pendent ends of the plumage of that part. The *tarsus* is three inches in length, and measures two inches and an eighth in circumference. The other bones of the leg appear to have been like the tarsal bones thick and strong. The tarsi are covered with hard and dense reticulated scales, larger in size, and arranged in transverse lines in the front and behind, but smaller and more irregularly distributed on the sides.

"The toes are four in number on each foot, the three anterior toes entirely unconnected. The middle toe is two inches and three-eighths in length; the claw one inch; the inner and outer toes on each side are equal, and measure one inch and three-eighths; the claws very nearly as large and as long as that of the middle toe.

"On their upper surface, these toes are covered with a series of broad imbricated scales, arranged in succession transversely; the under surface is defended by very small reticulated scales, and the lateral linear junction of these two coverings is marked by a well-defined but slightly prominent ridge, which appears to have been mistaken for the remains of an interdigital connecting membrane.

"The claws are slightly curved, and taper gradually to a point; those of the middle toes are convex above, concave beneath; those of the inner and outer toes are also convex above; but the worn edges of the under sides give them a convex form beneath also, and they resemble a spur curved downwards. The hind toe is placed on the inner flattened surface of the *tarsus;* it is directed backwards, and almost perpendicularly downwards. The connecting bones are articulated so high up on the *tarsus*, that the extreme point of the claw scarcely reaches the ground. The whole length of the hind toe is but one inch and an eighth, of which the claw measures three-quarters of an inch. In form it is nearly straight, round, tapering, and pointed, and has much more the appearance of the spur of a *gallinaceous* bird than the claw of a hind toe. The *tarsi* and toes are yellowish brown, all the claws of a shining whitish horn colour.

"The decided rotarial nature of the legs and feet, with the very elongated form of beak common to a different order of birds thus combined in the apteryx, present considerations of the highest interest to the ornithologist; and it is to be regretted that little or nothing is known of the habits of a bird possessing parts and peculiarities of such distinct and different character. Its short legs and divided toes prevent progression in water, and equally deny compensation for the want of the power of flight. It is obvious that it possesses no efficient means either of escape or defence. Its food is unknown; but Colonel Sykes having found beetles, grasshoppers, worms, seeds, and vegetable fibres in the stomachs of some of the Indian species of *ibis*, I am induced to conjecture that the food of the apteryx is probably similar, or perhaps even still more exclusively insectorial.

"No public or private collection is understood to possess another specimen of this singular bird; and it might reasonably be expected that so defenceless an animal must soon fall, even to extermination, when assailed by powerful and ingenious enemies."

The apteryx is not represented as being generally distributed over either of the two islands of which New Zealand is composed, but to be found chiefly in the mountainous, dry, and stony tract near Cape East, on the eastern side of the northern island. The mountains there are not nearly so high as in the southern island; their climate is warmer, and they are interspersed by rich grounds, though without those forests of large trees which are found on the slopes of the more alpine places and in the morasses between. The climate is rather humid, and that, with other circumstances, leads to the conclusion that, under small stones and in the shallow crevices of rocks, there should be an abundant, and, generally speaking, a perennial supply of insect food; and it is probable that such is the principal subsistence of the apteryx.

Voyagers, who have seen the feathers adorning the mantles of the chiefs, have considered them as belonging to a species of emu, smaller and brighter in the colour than the emu of Australia; and the feathers are certainly very much of the same structure. But it must be borne in mind that neither the emu nor the apteryx has any of what may be called working feathers, conducive either to motion through the air, or to the direction of motion along the ground. The whole of their feathers, except in so far as, in the apteryx especially, the bristle-like ones may protect the eyes and the proximal part of the gape from injury, are wholly clothing feathers; and therefore the only inference than can be drawn from the similarity of structure is, that the two birds are exposed to pretty nearly the same kind of weather. Their feathers are a sort of pendent thatch, well calculated for throwing off the heavy rains which fall in those countries, and their loose and flocculent nature makes them also a good protection against the heat of the sun during the dry season. Thus far there is a resemblance between the two birds; and thus far we can see the necessity for that resemblance, in the analogy of the climates. But here the parallel ends; and in the present state of our knowledge, we are not able satisfactorily to continue it by a reference to any other known species of bird.

The grand deficiency is our total ignorance of the internal structure, because from that alone we could ascertain whether the bird feeds wholly upon insects and other small animals, or whether it occasionally has recourse to vegetable food. That its food is not the same as the food of the emu, or the other struthiones is evident from the form of the bill; and though reference has been made to the probability of its feeding on the same substances as some of the species of ibex, the difference of the bills is so great, and that of the apteryx is so peculiar and unique as to forbid any satisfactory analogy. The feet too forbid any comparison with the struthiones, or with the grallidæ, as they are neither adapted for swift marches nor for wading. They are, as Mr. Yarrell justly observes, rasorial, or scraping feet, bearing more resemblance to those of some of the gallinaceous birds, than to any others. They are strictly dry land feet; very robust and powerful, apparently capable of scratching up earth and gravel with considerable effect, and also forming a firm base either stationary or during slow motion. The bird cannot from its structure be a traveller, but must find its food within a limited range; but whether it seeks its food during the heat of the day, or in the twilight or moonlight, is not ascertained. Neither is it ascertained whether it nestles in the holes of the rocks, or squats upon the open surface. The New Zealanders are indeed said to hunt it during the night with torches and dogs, which would lead one to suppose that it remains hiding during the day. The information is so scanty however, that not even a satisfactory guess can be hazarded respecting its habits.

From the familiarity of the natives with its name of *Kivi Kivi*, it is natural enough to suppose that it is not very rare in those localities which are suitable to its habits. From this it may seem strange that, considering the number of Europeans who have visited New Zealand, and the length of time that some of them have resided there, and the familiar terms on which (while they conducted themselves properly) they have been with the natives, none of them should have once seen the bird in the living state. But it must be borne in mind that the New Zealanders are rather a shrewd and sagacious people, and do not very readily point out to foreigners those productions of their country upon which they themselves set the highest value. We had an instance of this when a ship was fitted out to fetch home, for naval purposes in this country, a load of that excellent and durable timber of which their war canoes are constructed. There is a much more showy tree than the valuable one; and they readily conducted our people to where that grew, and a load of handsome spars, and even masts, was procured with no great labour, and in a short time; but, unfortunately, when the vessel arrived in the Thames, the whole cargo was rotten, and good for nothing. The skin of the apteryx seems to be held in even more estimation than the canoe timber, and therefore the probability is that they are more jealous in keeping strangers from its haunts. So that the only way of arriving at the natural history of the bird seems to be by an independent excursion; and that, armed as the New Zealanders now are, would be a matter of no inconsiderable hazard.

APTINUS (Borelli). A genus of the bombardier-beetles, belonging to the great family *Carabidæ*, and sub-family *Brachinidæ*, separated by Bonelli from the genus *Brachinus*, to which the species are very nearly related, on account of their being destitute of wings—a character indicated by the name. In their habits they resemble the *Brachini*, but they are generally found in mountainous districts in warm climates, as in the south of Europe, the Cape of Good Hope, &c. Dejean, in his new catalogue, gives fifteen species belonging to this genus, none of which are found in England. A memoir, by M. Solier, upon this and the allied genera, has just been published in the Transactions of the French Entomological Society, from which it would appear that the absence of wings is not an exclusive character of the genus, but that the species are sufficiently distinguished from the *Brachini* by the presence of a tooth in the centre of the chin (mentum).

APUS (Scopoli). A very curious genus of *Entomostracous* (or soft shelled) crustaceous animals, belonging to the order *Branchiopoda*, section *Phyllopoda*. The body of these singular insects is covered by a large and flattened membranous plate of an oval form, with a deep cleft at its hinder extremity, and bearing in front two large eyes, placed close together, with a smaller one behind; the tail is terminated by two long threads; the first pair of legs, or antennæ as they have been considered by some authors, are very long, thread-like, and branched; but all the rest, of which there are about sixty pairs, are short, compressed, and of a complicated structure, serving as a branchial apparatus.

These animals are occasionally found, in considerable numbers, in fresh water, particularly such as is stationary; in which situations they are sometimes observed to be produced in so instantaneous a manner that it is difficult to conceive whence they could have been brought, this is more especially the case in puddles of water caused by heavy rains: it is evident, however, that the eggs of these animals must be endowed with great powers of vitality, by which means alone, as in the genus *Anabas*, which is occasionally observed under the same circumstances, we are able to account for their sudden appearance. They subsist chiefly upon tadpoles. The distinction of the sexes has not been observed, some naturalists even supposing them to be hermaphrodite. When full grown they are about an inch and a half long. The species are very few in number, and of rare occurrence. The type of the genus is the *Apus cancriformis* of Latreille, or " le binocle à queue en filets" of Geoffroy's History of the Insects of the Neighbourhood of Paris, pl. 21, fig. 4.; Scopoli's name for this genus has been generally adopted, instead of that of *Binoculus* of Geoffroy, although the latter has clearly the priority in date. Hence, in order to avoid confusion in the family name of these insects with the bees, *Apidæ*, in case we were to form it from the name of the present genus *Apus*, *Apidæ*, we have deemed it advisable to adopt Dr. Leach's name of *Lepidurus*, the other genus, as the foundation for the name by which we propose to designate the family, namely, *Lepiduridæ*.

AQUAMARINE. A stone bearing this name is much prized by jewellers for its beautiful green colour. In a classified collection of minerals it is placed with the topaz; and under this title are included the mountain-green varieties of that mineral found in the soft rocks of Eibenstock, in veins and cavities in

Siberia, and we may add in alluvial soils, in the upper parts of Aberdeenshire. A variety of the beryl is sometimes called by the same name.

AQUARIUS (Schellenberg). A name proposed for some of the water-bugs. See HYDROMETRIDÆ, and synonymous with the genus *Hydrometra* of Fabricius.

AQUILA—Eagle. A genus of accipitrous or rapacious birds, belonging to the division of diurnal feeders, and to the natural family of the *Falconidæ.* In their general characters they may be described as intermediate between the falcons properly so called and the vultures; and, in their specific characters, some of them approach more nearly to the first of these groups, and others to the second.

Their general characters are: the beak very strong, nearly straight in the basal part, but much hooked toward the tip, without any trenchant tooth and corresponding notch as in the falcons, but with a flexure or deviation from the straight line, near the middle of the tomia. The nearer the species approximate to the falcons in their habits, this deviation from the straight line is the more conspicuous, and the curvature of the beak begins the nearer to the base; and on the other hand, the nearer that their manners approximate to those of the vultures, the tomia and also the greater length of the beak are straight. The tarsi are in general short and very robust, the tendons which they contain being among the most firm and rigid of animal substances. The toes are three before and one in the rear, firm and elastic, and armed with large and powerful crooked claws or talons. Those talons are very sharp at the points; and they are partially retractile, or rather they rise by the action of elastic ligaments as soon as the feet of the birds come in contact with a pinnacle of rock, or other perch; so that the whole base on which the bird rests is the padded parts of the toes, and the talons are reserved for their proper purpose in the economy of the bird—that of clutching and killing prey. The claws on the hind toe and exterior one in front are usually the largest. In all the species the toes are perfectly free in their lateral motions, so that they can clutch at four nearly equidistant points. In those which feed exclusively upon land animals, the toes have no other motion than this, and that of clutching together with great power; and they are, strictly speaking, tearing claws, round on their convex sides, but grooved with two sharp edges on their concave ones, so that while they clutch they tear and lacerate with those edges. In the species which subsist chiefly by fishing, the outer toe is reversible, so that the claws grasp two against two; and in these the claws are not grooved, as that would only tend to cut through the hold which the bird gets of the fish that it clutches in the water. The wings of eagles are very powerful both in their form and the strength of their feathers; but they are broad and rounded, and not adapted for so rapid a degree of motion, or such graceful wheeling in the air, as those of the falcons. They are, however, much stronger, and probably the strongest in the whole class of birds. The first quill is very short, and the fourth the longest in the wing; but so many of them are nearly of the same length that the wings have a blunt or truncated appearance. The tails of eagles are large and powerful, and capable of much motion, more especially great extension and breadth. All the feathers on the upper part of eagles, more especially those that approach nearest to the falcons, have a firm and almost metallic appearance; but those which approach the vultures have them rather softer; and in those which fish habitually, the under part of the body and the under sides of the wings are feathered something like those of aquatic birds. In the bolder species the feathers of the neck are long and pointed, and they are erectible when the birds are in a state of great excitement.

The eyes of eagles are proverbially keen and penetrating; and the sight is the chief and indeed the only sense upon which they depend in the finding of their food. Among the many fabulous stories told of eagles, of which there are more both in number and extravagance, than respecting perhaps any other genus of birds, it is reported that the eagle can fly sunward with the open eyes directed full upon that luminary, without any injury to her powers of vision. But the very structure of the bird prevents the possibility of its looking at the sun, or even looking upward to any considerable angle. The eyes are placed laterally, and they are shielded by projecting upper orbits and orbital feathers for the very purpose of defending them from the light from above, and rendering them more keen to that from below.

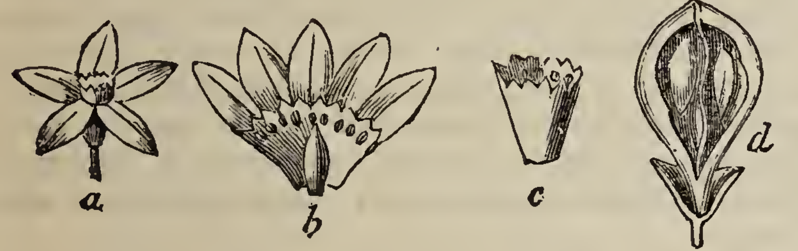
Eagles have indeed no occasion to look upwards, when they are in the air, or generally when they are in their dwelling places among the cliffs; for in both situations they themselves are, generally speaking, above all other living creatures; and though there may be some birds which, in peculiar situations and states of the weather, occasionally soar above the eagles' flight, yet those birds are, at these times at least, not eagles' prey. The power of eagles in seizing their food is in their descent; and they seldom if ever give chace on the wing, but descend or "stoop" upon their prey when it is on the ground. In that case their weight and their muscular energy together conspire to give them effect, and that effect is equally grand, and to the animals on which they prey, irresistible. But if they were to try hawking on the wing after flying game, they would fare but scantily; for their broad wings and tail make them turn so slowly and with so much difficulty that there are very few birds which would not throw them out so repeatedly, as to exhaust even their great strength in a fruitless chace.

The vision of eagles is no doubt wonderfully acute, as appears from the height at which they are found beating their pastures for even comparatively small game, and game which differs not much in colour from the vegetable covering of the ground. In these cases it is probable that their vision commands the whole of a circular horizon two or three miles in diameter, and that they can in a moment scan every point within that wide range. The surface immediately under them appears to be that which they command the least perfectly; and a perfect command of that would be of comparatively little advantage to them, inasmuch as an eagle cannot drop perpendicularly on its prey, but always in an oblique curve, by means of which it both delivers its whole impetus upon the prey, and prevents unpleasant collision with the ground.

Mammalia rather than birds seem to be the favourite prey of the more powerful eagles, either the smaller ones, such as hares or marmots in their full grown state, or the young of mountain goats, mountain antelopes, and other larger species. The eagles which inhabit the mountain ridges where these abound have, however, generally a spice of the vulture in them, and have no objection to feed, occasionally at least, upon those animals which fall a prey to the casualties of the situation or the climate. These species often fly very high, and beat as a pasture the summits of entire mountain ridges, discerning with much readiness the body of even a small animal in the deepest fissure or the darkest ravine. For a particular account of the haunts, habits, and economy of the principal species, we must refer to the article Eagle.

AQUILARINEÆ. A natural order of plants, nearly allied to the *Samydeæ*, *Chailletiaceæ*, and *Thymellæ*, and containing only a few genera and species. The plants included under it are as yet very imperfectly known, and their properties have scarcely been ascertained.

The essential characters of the order are as follows: Calyx turbinate, coriaceous, five-lobed; petals, none; stamens monadelphous, ten fertile, ten sterile; anthers two-celled, bursting longitudinally; ovary superior, one-celled; stigma short and simple; seed-vessel pear-shaped, two-valved, and one-celled, with the valves bearing the seeds; seeds solitary, with an arillus or tail. The plants are generally trees with alternate entire leaves, natives of Asia.



Aquilaria Malaccensis. *a*, Flower; *b*, the same opened to show the phycostoma; *c*, the phycostoma and stamens; *d*, section of the fruit and persistent calyx.

From the inner part of the trunk of the *Aquilaria Malaccensis* is, or *ovata*, and the *Aquilaria agalloch*, there is obtained a fragrant resinous substance called aloes-wood, or calumbac, the *bois d'aigle* of Sonnerat. This substance has a strong aroma, is employed as a cordial, and has been used in gout and rheumatism. The Cochin Chinese are said to manufacture a kind of paper from the bark of these trees.

ARA—maccaw. A genus, or perhaps rather a sub-genus, of *Zygodactylic*, or yoke-footed birds, belonging to the great natural family of the parrots and analogous genera; and in the gracefulness of their forms and the richness of their colours among the most beautiful of these very showy birds. Their principal distinguishing characters are, the cheeks naked of feathers, and the tail very long. Their attitude is graceful, and the colours of their plumage and also of the metallic reflections, are intensely bright. They have nearly the same complication and muscular furnishing at the bronchial end of the windpipe (the real organ of voice in birds) which belong to the rest of the family, but their natural voice is remarkably harsh and croaking, and they are far from sparing in the exercise of it. The word *Ara*, which is their name, they articulate naturally; and they can be taught to articulate other words, though not so easily as the parrots. Screeching is their favourite sound, in the exercise of which they occupy a considerable portion of their time; in other respects they are more sedate, less given to mischief, and do not so habitually tear things to pieces as the parrots; while their large size, handsome form, rich colours and graceful deportment, render them favourites in spite of their noise.

Ara.

They are all inhabitants of the warmer parts of America; and like the rest of the family seek their food and spend most of their time upon trees, in the holes of which the majority of them nestle, and some are said to excavate decaying trunks like the woodpeckers, though one species at least is mentioned as burrowing in the elevated banks of rivers and streams. Their food is the seeds of large forest trees, rather than the succulent pericarps of fruit, whether wild or cultivated; but they attack with great avidity the smaller cultivated fruits, such as coffee. They are not so social as most others of the family; being found in pairs, or at most two or three pairs together, more in juxta position than in society. The pairs are however, much attached to each other, and are said to divide the labours of nest-making and incubation pretty equally between them. They climb with great readiness, using both feet and beak, as is the habit with the whole family. On the ground they have very little command of themselves; for besides the general awkwardness of zygodactylic feet in walking, they seem encumbered by their long tails. When they can take wing from a height, however, they have considerable command of themselves in the air. For an account of the species see Maccaw.

ARACARI—*Pteroglossus*. A genus of *Zygodactylic*, or yoke-toed climbing birds, nearly allied to the Toucans, and sometimes regarded as forming only a section of that singular genus. See Toucan. There are, however, sufficient distinguishing characters to entitle the aracari to the distinction of being a separate genus. The feet are nearly the same, short, rather slender, with the toes grasping two against two, and therefore well adapted for climbing. The wings of moderate length, or rather short, and not fitted for long flight. The tail long, formed like that of the magpie, with the middle feathers much longer than the rest; and, as in the magpie, susceptible of extensive and rapid motion, so as to balance the bird when it shifts into various positions while clinging to a branch. The bill, however, is the grand means of distinction between these birds and the true toucans. The true toucans have the bill invariably thicker than the head, of great length, thin and transparent in the greater part, and often beautifully coloured, the colours fading almost instantly upon the death of the bird. The bill of the aracari is never thicker than the head, and seldom quite so thick, though it is still a bill of very ample dimensions. It is regularly curved in the culmen or ridge of the upper mandible, both mandibles are slightly bent at the tip, which is very sharp, and their tomia or cutting edges are toothed or serrated. The plumage is in general smooth, and the prevailing colours are green, marked with red or yellow on the neck and breast, and the green in some places passing into deep blue, and in others into black. There are several species, but they do not differ very materially in their appearance, and little, if at all, in their manners. The following figure will give a general idea of their form and the manner in which they sit on a branch.

Curl Crested Aracari.

These birds are all natives of the forests in the warmer parts of South America. They extend from Guiana to Paraguay, and also into Brazil; but, except South America, they are not met with in any other part of the world. The British birds which they most nearly resemble in their habits are magpies; but they are much less upon the ground, and more exclusively tree birds. They are, however, about the size of magpies, or, leaving out the great excess of bill, perhaps a little smaller; and they are more beautifully coloured. Though yoke-footed, they do not run along and inhabit the bark of trees, like woodpeckers, they fly with rather fluttering wings from tree to tree, and leap with great adroitness from branch to branch. In some respects they are omnivorous, but, as is the case with most omnivorous birds, they prefer animal food if they can obtain it. They live much upon the larger insects and their larvæ, and they are also great plunderers of the nests of smaller birds, eating with avidity either the eggs or the callow young, though it does not appear that they ever attack full-grown birds if in a state of vigorous health. Their vision is quick, and though, from the great size of the bill, the head cannot be jerked about so rapidly as that of a magpie, they have a good deal of the prying looks and peculiar habits of those thievish birds. They reside more in the wild woods, however, and come not often into the neighbourhood of human dwellings. Their colours are fine, and, though their lives are not very honest, their motions are often graceful; but, like all the rest of the gaudy climbing birds which inhabit the tropical forests, they have little to boast of in their music; their croak, or crash, or whatever else it may be called, is a single screech, something resembling the caw of a rook cut in two in the middle.

ARACHNIDA, Mac Leay (*Arachnides*, Lamarck and Latreille; *Arachnoida*, Leach). A class of articulated animals, the name of which is derived from Arachne, the name by which the spiders, which are the chief species contained in it, were known to the Greeks. The celebrated Cuvier, having by his invaluable discoveries in the comparative anatomy of the invertebrated animals, established the propriety of the removal of the Crustacea, as a *class*, from the apterous insects of Linnæus, *Aranea* and the remaining genera (with the exception of *Pulex*, as already noticed under the article APTERA) were shortly afterwards raised to a similar rank by Lamarck, under the name of Arachnides, having been previously regarded as a distinct *order* by Fabricius, under the name of *Unogata*, and by Latreille under that of *Acephala*. Lamarck, however, introduced into the class the centipedes, millepedes, spring-tails, &c., under the name of *Arachnides antennistes*, in addition to the spiders and scorpions, or *Arachnides palpistes*. The class has, however, been restricted by Latreille, Mac Leay, and most modern entomologists, to the latter, the former composing portion of the class *Ametabola*, or *Myriapoda*. Thus constituted the Arachnida are distinguished by their comparatively small size, their bodies in general being short and rounded. They consist of two parts only, the cephalo-thorax and abdomen, the head being so intimately united to the thorax that scarcely the slightest traces can be perceived of their union: whilst in others even the separation of the cephalo-thorax from the abdomen is almost equally imperceptible. Like the *Crustacea*, they are destitute of wings, and are not subject to those metamorphoses which distinguish the true insects.

The organs of respiration, upon which great stress has been laid as affording some of the primary characters of the group, consist either of internal air gills performing the office of lungs, and enclosed in pouches, or of radiated trachea, the spiracles or passages for the entrance of the air being from two to eight in number, and situated either at the lower part of the abdomen or the sides of the cephalo-thorax.

Messrs. Kirby and Spence have adduced various arguments of considerable weight against the union in the same class of animals whose circulatory system is so distinct as the trachean and pulmonary arachnida, and have considered the latter only as referable to the class, placing the trachean species in the class of insecta. Mr. Mac Leay, however, after a very careful examination of the chief types of the class in a living state, has defended, with his usual ability, the introduction of the trachean species into the class, and observed, that these "most evident arachnida" have no relation with the hexapod ametabola. See Zoological Journal, No. 18.

The anterior part of the cephalo-thorax generally exhibits on its upper surface a certain number of minute shining points, which are the organs of sight; they vary in number from two to eight, and furnish excellent characters for the distinction of the generic groups. Unlike hexapod insects, the animals of this class are furnished with eight very long legs, generally terminated by two small claws; in front of the legs are to be observed a pair of very powerful organs terminated by acute moveable hooks, which, in many cases, afford passages for the discharge of that poisonous fluid with which some of the insects are provided. These organs have been termed chelicera, by Latreille, who considers that they represent the antennæ of insects and the internal antennæ of the decapod crustacea, but so little attention has hitherto been paid to the comparative anatomy of these analogical organs that it is perhaps the safest course to regard such analogies as undetermined. In addition to such organs, the mouth is furnished with a lower lip and a pair of lateral moveable instruments, similar to the lower jaws of the mandibulated insects furnished externally with a pair of jointed appendages or palpi. All the arachnida appear to be earnivorous, but some are parasitic upon the bodies of other animals, and in these the mouth undergoes a considerable change of structure, being composed of an instrument capable of suction, although formed of the same typical number of organs as the mouth of the preceding.

The portion of the body, succeeding the cephalothorax, constitutes the abdomen; in general it is soft, more or less globular; on its under surface are to be observed a certain number of apertures or spiracles, and the anal aperture, as well as the spinnerets, when present, are placed at its posterior extremity.

The external covering of the arachnida may be regarded as of a leathery rather than a horny texture, but in some species it assumes a considerable degree of rigidity; it forms, however, in all cases an external skeleton, to which the muscles are internally affixed as in insects.

Of the senses of the arachnida it may be observed that, according to the best of our necessarily imperfect knowledge of such matters, they appear to possess all the five senses with which the higher animals are endowed; that the minute simple stemmata on the crown of the metathorax are eyes, and that these animals possess the sense of sight cannot be doubted; every body having observed the hunting spider (*salticus*) throw itself to a considerable distance upon its prey. Here it is evident that the instinct of the animal, acting upon the impressions produced by the possession of the sense of sight, induces it to do an act for the gratification of another sense, that of taste. In like manner the sense of touch is possessed in an eminent degree by these animals; and although the accuracy of the poet's observation, that the spider

"Lives in each thread, and feels along the line,"

has been called in question in a very popular work (Insect Miscellanies, p. 5), it is evident, from experiments which we have made for the express purpose of ascertaining the relative powers of the senses of sight and touch, that the latter is much stronger than the former. When a fly is caught in the web of a spider, the latter instantly stretches out its legs in the direction of the captured and struggling fly and feels, for in no other manner can we describe its proceedings, the nature of the disturbance which is taking place in its web. In the work above alluded to, it is stated, "We have tried numerous experiments, by moving and vibrating the lines of the webs of many species, so as to imitate as nearly as possible the entrapment of a fly, but in no case have we succeeded in bringing the spider to the spot, because, as we inferred, her eyes always detected our attempted deception." Now the experiments made by the author of this article have produced a result so contrary to the above, that it is not without a repetition of them that we have ventured to adduce them against the statements in question. These experiments were chiefly made upon the *Epeira diadema*, one of the largest of the British species, which, from its very common occurrence, beautiful markings, and elegantly-constructed web, must have attracted the attention of the most casual observer in the autumn. Now from its size it is evident, that, if the intelligence which these insects obtain respecting the entrapment of a fly, results from the sense of sight, the epeira would make no use of its legs for obtaining such knowledge, and that its eyes alone would be brought into action; but so far is this from being the case, that we have repeatedly disturbed the lines of the web, within an inch of the spider, *and in the direction of its eyes*, but in every instance the legs have been instantly put in motion, which has been continued for a considerable time even after. We have ceased the disturbance, in order that, if possible, the spider, by slightly moving the web itself, might set the fly, which it evidently supposed to have been captured, in motion again, so that, by its repeated struggles, it might ultimately fall an easier prey to the inhabitant of the web. But in addition to this fact, it is to be observed, that the den-like retreats of many spiders are so placed that they cannot possibly see any thing which occurs on the web, and yet no sooner is a fly entrapped in any part of the web than the spider instantaneously acquires a knowledge of the fact, evidently by touch, and darts out of its den upon the luckless captive. Thus we frequently find the spider deeply seated in the aperture of a wall, and the web extended to a considerable distance over its surface; and yet by the tension of the cords composing the net work, the spider is instantly made aware of what occurs on every part of its surface. Two instances are adduced in the work in question in support of the idea, that the eyes, and not the legs, are the instruments of knowledge to the spider. First, the long-bodied spider (*Tetragnatha extensa*) is noticed as having probably given rise to the popular opinion under review, notwithstanding it huddles its legs into a close bundle, and which is evidently done with the view of making them appear motionless, although the insect does not the less obtain information by their assistance; and immediately afterwards the long-legged house-spider (*Pholcus phalangioides*) is referred to, as giving more countenance to the opinion, because it keeps its legs spread out as if to feel the more readily when any thing is caught; although the more than usual prominence of its eyes is mentioned as showing the superiority of its powers of sight. We have noticed these contradictions, because as they occur in a work of great popularity, it is advisable that the erroneous impressions which they must necessarily produce ought to be counteracted as early as possible.

In the majority of the arachnida, a complete and very distinct system of circulation exists. The heart is contained in the abdomen, and in many species of spiders its pulsations are easily to be observed. It consists of a large longitudinal vessel which emits a certain number of arteries, and receives the veins by means of which the sanguineous fluid returns, after having been aerated by the respiratory organs, to be again distributed through the different parts of the body.

In this class, as in the insects, the sexes are constantly distinct, and impregnation is necessary for the fecundation of the eggs. Several striking peculiarities are connected with the act of impregnation, respecting which the most celebrated physiologists are at variance, and though the pages of the present work can hardly be considered a proper field for discussions connected with this subject, it may be proper to state that it was considered one of such importance, that, at the last meeting of the British Association for the Promotion of Science at Cambridge, the inquiry as to the true male organs of generation in the spiders was one of the three questions proposed relative to the annulose animals.

The development of the embryo of the spiders has been traced in a most elaborate manner by M. Heroldt, of which a notice will be found in the Insect Transformations, pp. 123 and 124. (Untersuch ungen über die Bildungs-geschichte dir Wirbellosen Thære im Eie. Marburg, 1824.)

From various observations, it is evident that the limbs of the arachnida are capable of reproduction when mutilated. This faculty, together with the longevity of some species, various peculiarities of structure, and especially the circumstance that some spiders engender more than once during the course of their lives, evidently prove the distance which exists between this class and the insects, and their greater proximity with the crustacea.

The habits of the arachnida exhibit much of popular interest, but as they vary greatly in the different families, it will be more convenient to notice them under the head of each group.

As to the classification of this class, it is to be observed, that we are indebted for the most part to the works of foreigners for those views which have been adopted in the modern arrangements of the annulose animals. In the work of our countryman, Lister, published in 1678, " Historiæ Animalium Angliæ tractatus de Araneis," are, indeed, to be found many very good coloured figures of British spiders, as well as the first attempt at their distribution ; but until within the last few years, arachnology seems to have been banished from the studies of British naturalists, and taken up its abode in France, where, under the hands of Savigny, Latreille, and, above all, the baron Walckenaer, it has arrived at a high state of cultivation. We may now, however, boast of the labours of Blackwall, published in the Linnæan Transactions and the Annals of Philosophy, as well those of an anonymous writer in a late number of the Magazine of Natural History, from whose admirable pencil and pen, British arachnologists may shortly hope to be furnished with a most invaluable series of memoirs.

The class, as at present constituted, has generally been divided into two orders, the pulmonary and the trachean arachnida; but in his last work, Latreille has established a third order, *Aporobranchiæ*, for a very remarkable group of animals, which Leach regarded as possessing so doubtful a situation, that in the Entomologists' Compendium, they were placed at the end of the true insects.

The class may therefore be thus distributed.

SECTION I. *Pulmonaria*, having pulmonary sacs for respiration, with six or eight simple eyes, consisting of two orders.

ORDER 1. The *Dimerosomata* of Leach, or the *Araneides* of Latreille, consisting of the great group of spiders, divisible into various families, having the abdomen attached by a foot-stalk, and not articulated.

ORDER 2. The *Polymerosomata* of Leach, or the *Pedipalpi* of Latreille, consisting of the scorpions, and divisible into two families, *Scorpionidæ* and *Phrynidæ*, having the abdomen attached by its whole breadth, and composed of numerous segments.

SECTION II. *Trachearia*, having tracheæ for respiration, never with more than four eyes, consisting of two orders.

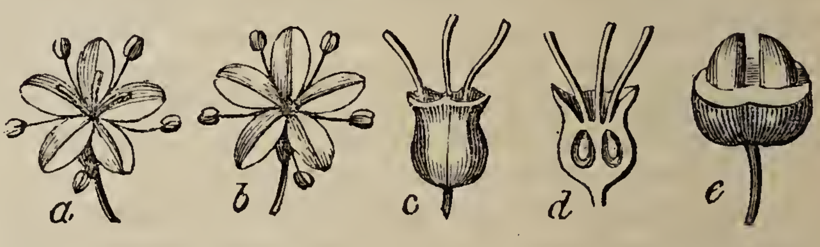
ORDER 3. *Adelarthrosomata**, or those trachean species which have the mouth furnished with visible didactyle chelicera, and the abdomen annulated, although occasionally in an indistinct manner.

Consisting of the families *Solpugidæ*, *Cheliferidæ*, and *Phalangiidæ*, or harvest spiders.

ORDER 4. *Monomerosomata* of Leach, or those trachean species which have the body formed of a single segment, the abdomen presenting no traces of articulation, and the mouth either suctorial or furnished with concealed didactyle chelicera. This order consists of the very extensive Linnæan genus *Acarus*, or mites, divisible into various families. See the article ACARI.

SECTION III. (ORDER 5.) *Podosomata* of Leach, or the *Aporobranchia* of Latreille. These singular insects are marine, they are not furnished with distinct spiracles, so that it is probable that respiration is effected by portions of the external covering of the body possessing the properties of branchiæ. The body is linear, and seems, as it were, to be composed only of the union of the legs; the mouth is tubular and porrected; and the females are furnished with an additional pair of legs, which serve only for carrying the eggs. This order consists of two families, *Pycnogonidæ* and *Nymphonidæ*.

ARALIACEÆ or ARALIÆ. A natural family of plants, the ninety-ninth order of the Jussieuan system, comprising seven or eight genera, and upwards of forty-three species. This family has a considerable resemblance to the umbelliferous tribe, from which it is distinguished by its many-celled fruit, and shrubby habit. The botanical characters of the family are : calyx inferior ; petals five or six ; stamens equal in number to the petals ; anthers two-celled ; ovary two or more celled ; styles many, simple ; berry two to fifteen celled ; generally trees or shrubs, rarely herbaceous plants : flowers small, collected into umbels, and provided with involucres.



PANAX QUINQUEFOLIUM. *a*, hermaphrodite flower; *b*, male flower ; *c*, calyx and pistils ; *d*, section of the ovary ; *e*, section of the fruit, showing the seeds.

This is a small order, containing plants which are not remarkable for the beauty of their flowers, although the foliage of many is extremely fine, as seen in the species of sciadophyllum and ivy The plants of this order are found in India, China, North America, and Europe. In their general properties also they resemble the umbelliferæ, being stimulant, aromatic, and occasionally narcotic. They differ, however, from the umbelliferæ in the qualities of their seeds. The roots of most of the Araliaceæ have a sweet aromatic flavour. Those of the *Aralia racemosa* and *nudicaulis*, resemble the parsnep in taste. The roots of the latter species are brought from North America, and sold as a substitute for sarsaparilla.

* In order to preserve the order of the mites entire, as suggested by Dr. Leach in the Supplement to the Encyclopædia Britannica, we have been compelled to establish a new order for the reception of the remainder of the trachean species, which we have named from the comparatively obscure articulation of the abdomen.

From the *Aralia umbellifera* an aromatic gum-resin is obtained.

Among the plants included under this family, the *Panax quinquefolium*, or American ginseng, particularly demands attention. This plant would appear to resemble closely the celebrated Chinese ginseng, which has been so much praised for its tonic, restorative and invigorating qualities. These qualities are said to be possessed by it only in the fresh state. The roots are washed and prepared in a particular manner by the Chinese. According to Father Huton, who has written a paper on the subject in the Philosophical Transactions, this root gives immediate relief after fatigue, strengthens the stomach, promotes the appetite, and gives a vigorous tone to the body even in extreme old age. The qualities of the ginseng have, however, been much exaggerated, and it is now scarcely ever used in Europe.

The ivy, with its beautiful evergreen foliage, adorning our walls and covering the trunks of trees, belongs to this family. The berries of the ivy were supposed by the ancients to possess purgative qualities; and an extract was made from them which was used in dropsy and jaundice. The leaves have been employed for dressing burns and blisters, and a resin is obtained from the stalk in warm climates, which is used to form a varnish.

ARAUCARIA. The Chilian name (Latinised) of a magnificent genus belonging to *Diœcia monadelphia* of Linnæus, and the order *Coniferæ* of Jussieu. This fine forest tree arrives at the height of one hundred and fifty feet, and with a trunk of proportionate bulk. It was introduced to England as long ago as the year 1796, but it is hardly hardy enough to bear the open air of Britain.

Araucaria imbricata.

In the royal garden at Kew, and at Dropmore, the seat of lady Grenville, there are pretty large specimens of this interesting tree, which require temporary coverings in the depth of winter. It is, however, expected that, as the plants increase in size, and when the growth becomes moderate, they will acquire greater hardihood, so as to be placed among and classed with our natural forest trees. We have as yet no good account of the quality of the timber, but presume that like others of the cone-bearing family, yielding a resinous sap, the wood must be durable. Congenerous species of this tree have been found in other provinces of South America besides Chili, and also in Australia; hence their names are not yet very well defined. The Chilian species now under notice has been called *Colymbca quadrifaria* by Salisbury; but this name has been set aside for the first, given by Ruiz and Pavon, viz. *Araucaria imbricata*, so called from the scale-like position of the leaves on the stem. Another even more majestic species has been found on and introduced from Norfolk Island, and at first was called *A. excelsa* in the Hortus Kewensis. This last, however, has been raised to the dignity of a new genus, under the name of *Altingia* (a German botanist) *excelsa*, by Noronha, the Spanish traveller. To this genus another species, found in New Holland, had been added by Mr. G. Don, which he has called *Altingia Cunninghami*. There is yet another genus of this natural order, found subsequently to the above mentioned in China, and named (in honour of the Messrs. Cunningham) by Dr. Brown, *Cunninghamia lanceolata*, and which is the *Pinus lanceolata* of Lambert, and *Belis jaculifolia* of Salisbury.

The regularity of growth in these genera is one of their most conspicuous characters; the exact symmetry of the Norfolk Island Altingia is peculiar; no other tree is more uniformly tapering from the base to the summit, nor so truly decussated in the branches diverging from the stem at equal intervals, in the most uniform manner. So much does regularity appear in the young trees, that they would be most repulsive objects to a flowing-handed painter if called on to represent them faithfully on canvass, because every one viewing his work would pronounce it to be done by scale and compass.

There is another peculiarity observable among this tribe of plants, viz. the definite constitutional structure and powers or tendencies of their several buds or parts. Their gems or buds are either principal, secondary, or tertiary. Of principals, each tree (if we except accidents) develops but one to form the stem, and which, until it gains its natural altitude, continues to ascend perpendicularly. This cannot be made to do the office or take the direction of a branch; so neither can the secondary order of buds, and which serve to produce branches, take or do the office of a leader. The third order of buds are produced from and along the sides of the branches, and when developed have usually a pendent or hanging character, rendering the tree very graceful, especially as they are again ramified at the points.

These trees have been propagated by layering and grafting; but if the scions or layers be the points of branches, the young plants, even by the most attentive training, cannot form trees of the natural character, they always taking a horizontal direction. If, however, a young perfect tree have its stem forcibly bent down upon the ground, latent gems will be put forth possessing all the properties of principals; and these, either layered or made grafts of, will grow up perfect trees.

Imported seeds, direct from Chili, are often found deficient on their arrival in this country. Lately, however, a collector has discovered a mode of transporting them in the greatest safety and perfection; so that we may hope to see thousands of perfect seedlings in every public nursery.

ARBOR VITÆ. An ornamental evergreen shrub or tree, called by botanists *Thuja*, of which there are ten species, natives of Europe, Asia, and other parts of the world. Linnæan class and order, *Monœcia Monadelphia;* natural order, *Coniferæ.* Generic character: male flower, catkin small and round; anthers four, sitting, somewhat globular and sealy at the base. Female flowers sealy, digynous at the top; embryo having two seed-leaves. These trees are usually planted in pleasure grounds, and answer the purpose of shrubs rather than trees, as they give depth and density to ornamental plantations. Like others of the coniferous tribe, they always add a richness to dressed scenery, whether standing alone on the lawn, or intermixed with other trees. Propagated by seeds.

ARBUTUS (Linnæus). Strawberry-tree. A genus of beautiful evergreen shrubs, natives of Ireland and South America, belonging to the Linnæan class and order, *Decandria Monogynia;* natural order, *Ericeæ.* Generic character: calyx, five cleft; corolla, pitcher-shaped, limb with five reflexed teeth; stamens inserted on the base of the corolla; filaments short, dilated at the base; anthers, two celled, opening by two pores at top, on the back a bristle; germen, disk ten angled; style, simple; stigma obtuse; berry of five cells, containing many seeds. Whether while in flower or in fruit, no shrub is more ornamental than the *Arbutus unedo* being both an elegant and hardy plant, showing to particular advantage in the months of October and November, when it is covered at once with blossoms and fruit. In Ireland it is found wild, growing on limestone rocks in greater luxuriance than in Italy.

ARCA (Linnæus, Lamarck, Cuvier). Fifth family, *Polyodonta;* third order, *Lamellibranchiata;* third class, *Acephalophora;* of De Blainville's System of Malacology. The body of these mollusks is thick, of rather a variable form; the abdomen provided with a pedunculated foot, compressed fitted for adhesion, and divided lengthways; the mantle provided with a single row of cirrhi prolonged rather backward; the buccal tentaculæ very small and very rough.

The Arcaceæ, as they are now established by modern naturalists, present a numerous and well defined genus, easily recognised by their general resemblance to the hull of a ship, whence they have derived their name, and by which they are distinguished from their congeners. The Linnæan genus Arca is very properly subdivided into three, *Arca, Pectunculus,* and *Nucula;* Lamarck made another, which he called *Cucullæa;* but it is restored by De Blainville to the arks; each of these genera possesses a strong distinctive character, fully sanctioning a separation from each other.

The shells of this genus are transverse, subequivalve, inequilateral; the apices distant and separated by the angular area or channel of the ligament, which is always external; the hinge is placed in a right line in most species; they are without ribs and furnished with numerous small sharp teeth, alternately inserted between others in the opposite valve; in many species the valves when shut, gape in the centre, occasioned by the wide flexuous curve of their outer margins, and sometimes one valve overlaps the other. They are said to spin a byssus, and are covered with a lamellar or velvet like epidermis, frequently ending in a deep fringe. The valves are longitudinally ribbed, imbricated, smooth, granulated, or finely striated.

De Blainville has divided the genus into six species; the first navicular with the hinge completely straight, the foot tendinous and adherent, as in the *Arca Noæ,* here figured; the second species is twisted,

Arca Noæ.

close shutting, and the hinge quite linear, as in the *A. tortosa;* the third boat-shaped, with a straight hinge, and the terminal teeth longer and more oblique than the others, *A. auriculifera,* constituting Lamarck's *Cucullæa,* so named from each valve possessing a small chambered portion or hood-like separation; the fourth species has a straight hinge, but it is not notched or gaping beneath, and the muscle of it is not adherent, *A. barbata;* the fifth species is perfectly close, they are of a less elongated shape, more pectiniform, and with a straight hinge; and the last division includes all that are elongated, a little arched lengthways, slightly gaping beneath, the summits much closer, the ligament nearly interior, and the dental line a little arched, *A. mytiloidea.*

Arca Barbata.

Lamarck enumerates thirty-seven recent species and nine fossil. De France mentions twenty-five fossil species, besides three of *Cucullæa.* They inhabit the sea in all parts of the globe, at a short distance from the shore; and, though not particularly distinguished for the richness of their colouring, they are many of them beautifully sculptured and of a very graceful form.

ARCHANGEL. The English name of a family of herbaceous annual and perennial plants, several of them indigenous to Britain, but not in cultivation. They are sometimes called "dead nettle" from their appearance, yet harmless character. Two of them, *Lamium orvala* and *L. flexuosum,* are admitted into the flower borders, but they are exotics.

ARCTOMYS—Marmot. A genus of mammalia belonging to the order of *rodentia* or *gnawers.* Like the rest of the order they are without canine teeth, and in the sharpness of the incisors of the lower jaw they bear some resemblance to the great family of rats and mice, of which perhaps they may be considered a sa subdivision, though, in some respects, they bear at least a slight resemblance to the squirrels, and their external forms and also their manners are peculiar. They have five grinders on each side in the upper jaw, and four in the under, the summits of which have sharp tubercles, so that they seem capable of subsisting on insects, and even on the flesh of larger animals, as well as on vegetables. Their bodies are thick and clumsy, their legs short and thick, their head large and flat, their ears short and blunted, and their tail short and apparently incapable of motion.

The Marmot.

Some of them inhabit the most bleak and dreary situations, the summits of the most elevated mountains, such as the Alps, and near the margin of the region of perpetual snow. The chief food of these is no doubt the hard alpine grasses, and other plants which are found in regions of so scanty vegetation; and these are found only for a part of the year, not more than half of it in the more elevated haunts of the animals. But in their habits they are as seasonal as the places where they reside; for when the cold weather sets in they descend into the depths of their burrows, and there remain in a dormant or hybernating state during the whole of the inclement season. Thus their years of activity are reduced to half years, and during these they are very slow in their motions, and at no time is there such action in their system as to occasion that waste and necessity for food which take place in more active animals. Accordingly, barren as their pastures comparatively are, they get very fat toward autumn; and are covered with lard like little pigs, or perhaps rather stored with grease like bears when they retire to their winter domiciles. Their hybernation, which is not, even in the greatest depth of its quietude, a total cessation of all the animal functions, is gradual at its commencement; and the recovery from it is also gradual. Owing to these circumstances, the fat is wholly absorbed by the time that the animals are able to come abroad; and in the brief space of their short year, they have to recover their strength, rear their broods, and again become fat preparatory to a new hybernation.

At all seasons they are ground animals, and spend the whole of their time, except what is taken up in feeding, in their burrows, which they dig with great ease and rapidity and to a considerable depth, always sloping downwards, so that the dwelling may be beyond the reach of the intense cold of the winter, and yet so contrived as to be in no danger of filling with water during the rains or the melting of the snow.

Some of them are animals of considerable size, not less than the common wild rabbit. But though easily taken, as their progressive motion is slow, and it is not very difficult to dig them out of their burrows they are of little value to mankind as game. In autumn, when they are fat, the mountaineers do eat them, but they are not very palatable to those who have a choice of food. It seems indeed to be a pretty general fact, if not a law, in warm-blooded animals, that the more sluggish the functions of life are, the flesh of the animal is the less palatable and the less stimulant. But though the marmots are thus not hunted with the same daring assiduity as the chamois and some others of their fellow mountaineers, they are still not without their destroyers, for the keen glance of the eagle is upon them as soon as they quit their burrows. There are various species, inhabiting different countries, and having different manners; for the details of which see the article MARMOT.

ARCTOTIS (Linnæus). A numerous family of herbs and under shrubs from the Cape of Good Hope. Linnæan class and order, *Syngenesia necessaria;* natural order, *Compositæ.* Generic character: anthodium scaly, scales squamose; receptacle bristly; pappus chaffy.

This genus of ornamental plants, though agreeing in essential character, are a good deal varied in habit: hence botanists have divided the family into five sections, founded on the different form of the leaves, nature of the stem, or on having no stem. Many of them have handsome star-like flowers, several are splendid; and the metallic tints reflected from the rays of the flowers are, in many of the species, very imposing. Of the shrubby species there are sixteen; and of herbaceous fifteen; some of the latter being annuals.

ARDEA—Heron. A very striking and by no means an uninteresting genus of birds, belonging to the order of *Grallidæ* or waders, and to the natural family of the *Gruidæ* or cranes. By the elder naturalists this genus was made a very extensive one, and species were included in it which had little analogy to each other in their manners, such as the cranes, the storks, the night herons, and the bitterns. There is even still a disposition to retain the bitterns in the genus by those who exclude the cranes and storks. But this is in violation of all natural affinity, because the bitterns really differ more from the herons than the herons do from the cranes and storks. The bitterns, no doubt, breed in marshy places, and spend the greater part of their time there; but in their food and feeding they have some slight analogy to gallinaceous birds, though, as they feed in secret, the precise nature of their food is not accurately known. There is reason to believe, however, that they feed chiefly upon worms, molluscous animals, the young of frogs, and other aquatic reptiles, and very rarely upon vegetable substances. They never migrate but from necessity, and that during the inclement season, and they are not seen on the wing except in the twilight, and then chiefly or exclusively during the breeding season.

The herons, on the other hand, do not breed in marshes, but on trees, near water if they can so obtain them, but on trees, whether very near water or not. They subsist almost exclusively by fishing; and they fish openly in the small streams, ponds, and shallows of lakes, often having to journey for many miles through the air to find food both for themselves and their young. It is true they are not found upon the waters during the heat of clear and sunny days; but then the cause of their not being so is in the prey more than in the birds. The cool of the morning and evening, but more especially the former, are the times at which the little fishes are most easily caught, and on that account the herons then resort to the waters. On dark and gloomy days, which often put herons' food in motion, one cannot always easily tell why, the birds are often by the water all day long. They often frequent the banks after floods to pick up the stranded or migrant fishes; of the latter of which eels form no inconsiderable portion.

In those countries which have dry and rainy seasons alternately, they are much more migrant than in temperate climates where the state of the waters is uniform; and when they are, as one would say, "dried out" in their native haunts, a few of those which belong to countries of the former character often straggle into the latter. The principal distinguishing characters of the herons are the bill long and strong, compressed laterally, and tapering gradually to the point, which is remarkably sharp. The general form is nearly straight, but sometimes a very little arched. The tomia are generally finely toothed or serrated, and the bill is furnished with a notch. The nostrils are lateral near the base of the bill, placed rather obliquely, and half closed by a membrane; from them slight grooves or channels proceed along the upper mandible, and are gradually obliterated towards the tip; and the gape extends as far backward as the eyes, admits of considerable distension, and is opened and closed with great rapidity. The eyes are surrounded by naked skin, which extends to the gape. The head is small but compact, and often furnished with a beautiful flowing crest to the hind head, which appears to guide and steady the stroke of the bill, in the same manner as feathering guides and steadies a dart or arrow. The neck is very long and slender, and remarkable alike for the rapidity and the grace of its flexures. In the true herons the lower part of the neck is surrounded by a sort of ruff or produced and pointed feathers, which appear to regulate the motions of that organ something in the same manner as the crest regulates the motions of the bill. The following figure will give some idea of the head and neck of the common heron, which in Europe may be regarded as the type of the genus.

Head of the Common Heron.

The body is very small for the apparent size of the bird; and in some of the species it is ornamented with very peculiar but very beautiful produced feathers arising from the scapulars or other parts of the back. The tarsi are very long, rather slender, but admirably protected from the decomposing action of water, and from changes of temperature, by the nature of their covering. They are always naked to their articulation with the tibiæ; and in some of the species these parts are also bare of feathers for half their length. The toes are three before and one behind; the hind one articulated on the same level with the others, but turned inward. The middle and outer ones are united by a small membrane at their bases; but it does not in any way approximate to the nature of a web, neither are the birds in any way adapted for swimming. The claw on the middle toe has a sort of prominent tubercle on its inner side; but the claws altogether are nails rather than organs either of prehension or perching. The fact is, that though the birds nestle and also rest themselves on trees, they stand rather than perch; and hence they are always so near the tops, that when they raise themselves on their long legs, they can extend their wings, and take flight without any interruption from the branches. The wings are very long; but they are rather blunt, and adapted more for forward flight than for turning. The second and third quills are the longest, and both of nearly the same length. The wings are hollow and take a great deal of air in their under sides; but though the flight when the bird is high and on a journey is by no means slow, it has a loose appearance, as the body is too light for affording a steady point of rest for the action of the wings, but plays upwards a little with their downward stroke, and downwards with their upward one.

Still, in places where they resort (and the common ones are social), herons are very ornamental birds, and, in all their attitudes when extended, give an idea of magnitide which their weight by no means justifies; and when a heron denuded of its feathers is compared with one of the same size in full plumage, it seems a mere skeleton, and but for the bill and the legs, one could hardly believe that the two birds belong to the same species. If there are fish-ponds near a heronry, the birds levy severe contributions upon the fish. Herons are also said to flatten and stunt the tops of those trees in which they take up their abode, as their mutings are acrid, and destroy both the leaves and the young shoots. Where they do take up their abode, however, they inhabit very pertinaciously; but the beauty, and almost royal character of their plumage, makes ample amends for any inconvenience of this kind. See Heron.

ARDISIA (Swartz). A genus containing twenty-three species of tropical plants chiefly shrubs. Linnæan class and order *Pentandria Monogynia;* natural order *Myrsineæ.* Generic character: calyx five-cleft; corolla, salver-shaped; tube short, segments of the limb spreading and a little reflexed; stamens awl-shaped, inserted in the tube of the corolla: anthers, lance-shaped, connivent; style awl-shaped with a simple stigma; fruit a one-seeded berry. As ornamental plants they deserve a place in stove collections; yielding frequently cymes of showy red or white flowers.

ARDUINA (Linnæus). A single plant and evergreen shrub, introduced from the Cape of Good Hope, and named after Pietro Andruina of Padua, Linnæan class and order *Pentandria Monogynia;* natural order *Apocyneæ.* Generic character: calyx, five-parted, persisting; corolla, somewhat funnel-shaped, limb five-cleft; stamens included; style bifid; fruit a two-seeded berry. This is a beautiful stove plant, somewhat like box, propagated by cuttings under a hand-glass.

ARECA (Linnæus). A family consisting of ten species of palms, common in the East Indies. In the Linnæan system it is placed in *Monœcia Monadelphia*, and in the natural order *Palmæ*. Generic character: flowers seated closely on the spadix, upper ones male, lower ones female; spatha, double, membranous; calyx, three-clefted; corolla three-petaled; stigmas sitting; fruit a fibrous one-seeded drupe; albumen chewable. The areca nut is a necessary of life in India; being chewed with a leaf of the pepper betel, qualified by a little chunam (lime). Its use promotes saliva, exhilarates the nerves, gives a fine colour to the lips, and sweetens the breath. It is universally used, and never omitted to be presented as a sign of welcome at entertainments. The tender heart leaves are sometimes used like those of the cabbage.

ARENARIA—Sanderling. A genus of birds, also described under the name *Calidris*. In their characters they are tolerably distinct, and hold a middle place between the sandpipers and snipes, without having the characters of either. The form of the body resembles that of the sandpipers, though still more slightly made than these birds; the bill, again, has considerable resemblance to the bills of the snipes, only it is shorter in proportion. It is compressed laterally in the basal part, and depressed or flattened towards the tip, where it ends bluntly, but without any nail or other hardened extremity. It is flexible throughout its length, and, as there is reason to believe, sensitive; and therefore the probability is, that the birds find their food by boring into the sand close to the line of the tide, which they follow during the greater part of the year in small flocks, and with shrill and wailing cries. The feet are feeble, and entirely destitute of hind toes, but the birds are powerful on the wing. There is only one British species; but as some points in its history are a little ambiguous, we must refer to the article SANDERLING.

ARETHUSA (Linnæus). A genus of two species, tuberous-rooted herbs, natives of foreign countries. Linnæan class and order *Gynandria Monandria;* natural order, *Orchideæ*. Generic character: sepals five; helmeted, cohering at the base, swelling during growth; labellum united to the base of the column, concave, crested with interior lines; column long-jointed, linear, dilated at top, membranous, somewhat lobed; anthers terminal, without being latticed. These, like almost all the genera of the order, are interesting objects of floral elegance and fine colour. The only drawback on the possession of them is their difficult culture, which is accomplished by planting them in loose wet peaty soil, keeping them in a frame well exposed to the sun.

ARGEMONE (Tournefort). Flower-border annuals, natives of Mexico, and in class and order *Polyandria Monogynia;* natural order *Papaveraceæ*. Generic characters: calyx of two or three sepals, each sharp pointed, deciduous; corolla of four or six petals; stamens below the germen; anthers oblong, two-celled; style or stigma, headed, lobed, persisting; capsule of one cell, opening at top; placenta like a thread, the apex vaulted; stigma cohering and persisting; seeds round and rough with furrows. This genus is very nearly allied to the poppy, flowers as showy, and equally fleeting.

ARGENTINA—Argentine. A genus of *malacopterygeous*, or soft-finned fishes, belonging to the salmon family, and having many of the characters, both external and internal, of the sea trout. It has the same silvery and glistening appearance in the scales as these fishes, and that lustre in them readily distinguishes them from those which inhabit the fresh water. It is remakable that this appearance, even in the salmon, which is a native of the fresh water, is acquired only in the sea, and that it fades during the annual excursions of those fishes up the rivers. So completely, indeed, has the silvery lustre, and even the scales in which it appears, vanished by the time that the spawn is wholly deposited, that salmon are then popularly known by the name of "black fish." In the purchase of salmon, the lustre of the scales is thus a good rule for those who are not otherwise acquainted with the qualities of the fish. A lustreless fish is at all events poor and bad, and if very lustreless it is even unwholesome. On the other hand, if the silvery lustre is brilliant, the fish may be depended on as both wholesome and excellent.

The air-bladders of most fishes have this silvery lustre, but it is more remarkable in the argentine than in any other species; so much so that these vessels in the above genus of fishes are more prized by the manufacturers of artificial pearls than any other substance which they employ. This lustrous substance gives the pearly play of colour, and the isinglass of the vessels form so good a cement, that pearls thus prepared, in substance, and not mere coated glass bubbles as the inferior ones are, are with great difficulty distinguished from real ones.

The argentine has the mouth small, compressed horizontally, and without any teeth in the jaws; but the tongue is furnished with pretty strong recurved teeth, and there is a transverse row of the same on the palate. The gill-flap contains six rays. There are two dorsal fins, the second of which is small and fleshy, without any rays. The stomach is internally black.

There is but one known species, an inhabitant of the Mediterranean, though there are many other fishes which closely resemble it in a variety of their characters. Its food is not very well known; but from the smallness of the mouth, and the absence of teeth in the jaws, it is probable that it feeds on small, soft, and naked marine animals. Its flesh is wholesome, though a little dry and insipid.

ARGONAUTA. (Linnæus, Lamarck). This interesting and elegant shell is generally well known to collectors by its trivial name of the Paper Nautilus; some authors indeed have suggested the propriety of calling it the *Argo nauta papyracea*, as being more descriptive of its delicate paper-like structure; but as this shell was known and described with considerable accuracy by Aristotle, Pliny, and other early writers on natural history, the present name should be preserved, and with the greater reason, as it was given with a classical allusion to the celebrated expedition of Jason in the ship Argo, to recover the golden fleece; in which all those who accompanied him were called Argonauts, and to whom the art of navigation is poetically described as having been pointed out, in the skilful management exhibited by the instinctive little sailor, inhabiting the Argonauta, while steering its frail bark through ocean's trackless paths.

> "For thus to man the voice of nature spake,
> Go, from the creatures thy instruction take,
> Learn of the little Nautilus to sail,
> Spread the thin oar, and catch the driving gale."—Pope.

In fine calm weather when the bosom of the sea is unruffled, the Argonauta is said to have been observed gently rising with the keel of the shell turned upwards, in order, it may be supposed, to present less opposition in its ascent through the water; this may be mechanically effected by the animal ejecting a portion of the water contained in its shell, thereby rendering it specifically more buoyant; but what peculiar organisation enables it either to rise to the surface, or sink into the depths of the ocean, cannot yet be satisfactorily explained. When it has reached the surface, it gradually assumes its sailing position, extending three tentacular appendages, which passing over the thickened auriform notch on either side of the shell, serve as so many oars, while in the centre of these, two spoon-shaped membranes are elevated, acting as sails, to catch the passing breeze; and thus this pretty boat is propelled and guided on its way through the azure main. On the approach of any sudden danger, or of tempestuous weather, the little mariner lowers the sails and withdrawing the oars, retires into the hull of its vessel, again sinking to the bottom of the ocean, undismayed by the perils of the deep, a circumstance elegantly alluded to by Byron, when describing the dangerous vicissitudes of a sailor's life.

> "The tender Nautilus, who steers his prow,
> The sea-born sailor of this shell canoe;
> The ocean Mab, the fairy of the sea,
> Seems far less fragile, and alas! more free!
> He, when the lightning-wing'd tornados sweep
> The surf, is safe, his post is in the deep,
> And triumphs o'er the armadas of mankind,
> Which shake the world, yet crumble in the wind."

Lamarck placed this mollusk in his second order, *Cephalopoda*. Cuvier also considers it properly so classed; but De Blainville, in his system of Malacology, does not admit that the animal belongs naturally to the shell in which it has been constantly found, considering it a parasite, he says the animal of the genus Argonauta is altogether unknown, but a consideration of the form of the shell, induces him to suppose it closely allied to the *Spiratella* and *Atalanota;* he has therefore placed it following these genera, forming the family *Pteropoda*, of the fifth order, *Nucleobranchiata;* second class *Paracephalophora*.

This interesting little animal has perhaps furnished more matter of dispute, a greater diversity of opinion, and, in some instances, more ill-will among naturalists than any other subject in the whole range of animated nature; and during a period of more than two thousand years, the question is not yet decided, nor apparently nearer being so, whether the animal invariably found in the Argonauta is the architect of that shell, or merely a pirate. As it does not however form any part of the object of this work, to take up the dispute on either side; and as we do not arrogate to ourselves the power of elucidating a matter so involved in doubt, we shall only for our part say, that the animal never having been found in any part of the world living *free* from the shell, though certainly not conclusive, is good presumptive, evidence of its being "the lawful owner of its fairy bark." Whether it should be considered one of the genus Ocythoë, or, as others imagine, Octopanus, it appears to us quite certain, that none but a similarly organised animal could have constructed such a dwelling; an opinion we deem to some extent confirmed by an examination of the mollusk, whose smooth thickened auriform processes on either side of the aperture, appear to serve as points d'appui for the tentacular members said to act as oars, and they are therefore wisely so constructed, to prevent the laceration that might otherwise ensue from the constant action of rowing, had those parts been formed thin and cutting, as is the case with the other portion of the aperture.

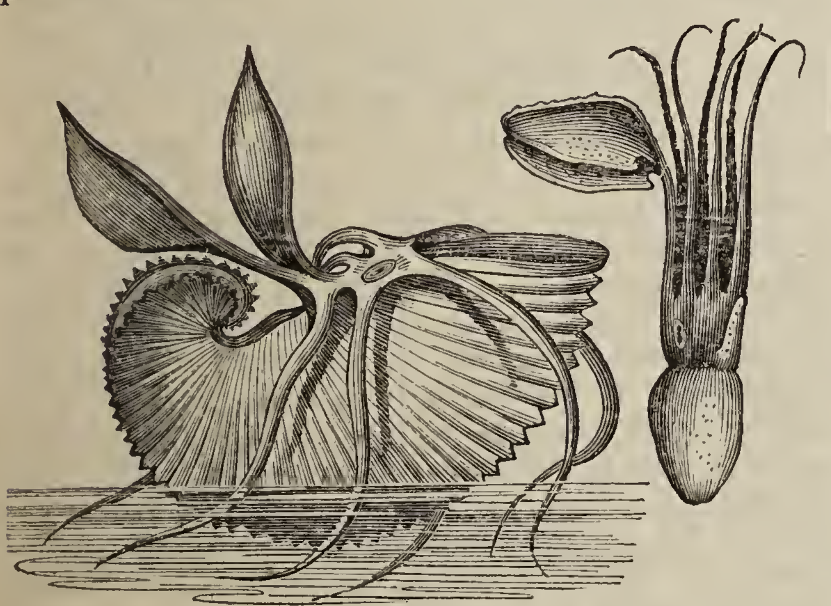
Several scientific naturalists of the present day have published opinions on this subject; to some of which we will briefly allude, leaving our readers to draw their own conclusions. Dr. Leach, in a Memoir published in the Philosophical Transactions, June 5th, 1817, states, that "Pliny, Androvandus, Lister, Rumphius, D'Argenville, Bruguière, Bosc, and Shaw, have described a species of this genus, that is often found in the *Argonauta argo* (common paper nautilus), and which they have regarded as its animal, since no other inhabitant has been observed in it.

"Sir Joseph Banks and some other naturalists have always entertained a contrary opinion, believing it to be no more than a parasitical inhabitant of the argonaut's shell; and Rafinesque (whose situation on the shores of the Mediterranean has afforded him ample opportunities of studying this animal, and of observing its habits), has regarded it as a peculiar genus, allied to the polypus of Aristotle. (*Sepia octopodia* of Linnæus.) De Blainville, ten months since, said 'animal unknown;' and he has lately informed me that he has written a long dissertation to prove that the ocythoë of Rafinesque does not belong to the shell in which it is found, but," continues Dr. Leach, "Mr. John Cranch, zoologist to the unfortunate Congo expedition, has cleared from my mind any doubts on the subject. Having taken several specimens of a new species of *ocythoë*, which were swimming in a small *argonauta*, on the surface of the sea, in the Gulf of Guinea."

W. J. Broderip, Esq., F.R.S., has published a paper on the argonaut in the fourth volume of the Zoological Journal, in which he says, "Is it not strange that it should now be a question whether the animal usually found in the shell popularly called the paper nautilus is the lawful owner of its fairy bark?

"From the time of Aristotle, the delicacy of the bark and the habits of its sailor have afforded a subject to every observer; and we have in addition to the descriptions, a succession of figures by Aldrovandus and others, which though most of them afford proofs of a very lively imagination on the part of the designers, are still evidently figures of a cephalopod, which would in the age of Linnæus have been ranged under the genus *Sepia*, if it had been taken swimming at large and free from any shell. It is curious to observe how assertion upon assertion at last accumulates into something that is taken for positive proof, till at last we have descriptions apparently the result of actual observations. De Ferussac in his "*Notice sur l'Animal du Genre Argonaute*," arguing for the legitimate title of the animal to the shell in which it is found, is of opinion that it is *no parasite*, and in opposition to the opinion of De Blainville considers the question put to rest. Risso who appears to be of the same opinion with De Ferussac, says *Je n'ai jamais vu retirer cet animal de la mer sans être toujours muni de coquille*." Mr. Broderip concludes, by saying "There is not, perhaps, sufficient evidence to convict the subject of our memoir of piracy, but there is quite enough to make us strongly doubt the assertion, that he is his own industrious shipwright."

J. E. Gray, Esq., F.R.S., has also published a paper in the Zoological Journal, from which the following observations are abridged, in illustration of some observations on the disputed question of the molluscous animal (*Ocythoë*), found in the shells of the genus Argonauta, being a parasite or not. He states that he had lately examined ten specimens, four of them referable to *Ocythoë Cranchii*, and the remainder to *Ocythoë antiquorum*, there being but little, however, to distinguish them except their size. All these specimens, as well as those which have been figured, were females, and had eggs enclosed in the hinder part of the shell, in the cavity which is uniformly found behind the body of the animal. Only one or two of these individuals had their bodies marked with the ridges of the shell, the impressions of which were, however, mostly observable upon the arms. The animals all appeared to be retained in the shells by the inflection of the anterior pair of arms. He adds, that he had also lately seen several specimens preserved without shells, and having their bodies shaped exactly like that of the common *Octopus*, without the slightest appearance of having been enclosed in a shell. From these facts Mr. Gray is inclined to regard it as probable that the *Ocythoë* is only parasitic in the shell of the argonauta, and that the shells are only resorted to by females during the breeding season for the protection of their eggs, the chief purpose of the dilated portion of the anterior arms being to retain the animal in the shell. He also states, that he is not aware that any author had distinctly asserted from his own observation, that these parts are expanded into the form of sails before the wind, a service they seem incapable of performing except in poetic fiction.



A. argo.

The genus is divided into three species by Lamarck, the shell of the first, *A. argo*, here figured, has its keel much narrower than the others, and the pointed tuberculations on either side of it very sharp; the sides of the shell are transversely striated, with wrinkles proceeding longitudinally from the recurved spire: the second species, *A. tuberculosa*, is more convex at the sides, having nodulous elevations, the keel much broader, and the points on either side of it more obtuse; the third species, *A. nitida*, is a much smaller shell than the *A. tuberculosa*, and has its aperture very much dilated in proportion to its size: in general appearance it however resembles the latter.

One of the species inhabits the Mediterranean, and the two others the Indian and African seas.

The elegant symmetry and the delicate structure of this mollusk, combined with the doubtful character and habits of its inhabitant, will always render it an object of interest, not only to conchologists, but to all persons who love to look from "nature up to nature's God," and humbly trace the infinite wisdom displayed in all *His* works.

We cannot close this article without briefly adverting to the admirable memoir on this part of the animal kingdom by Mr. Owen; which, for elaborate research and anatomical knowledge, stands superior to any other work on the subject.

ARGUS, or ARGUS PHEASANT (*Phasianus Argus*), a large, beautiful, and very singular species of pheasant, found native in the south-east of Asia, more especially in Sumatra and some of the other islands. Some naturalists have made it the type of a new genus (*Argus*), to include the superb pheasant of China, the existence of which is only known from Chinese paintings, and is on that account a little doubtful. One circumstance would, however, lead us to believe that a bird, which the Chinese represent so often, and always with the same characters, has a real existence in the country. That circumstance is this: the *Camellia japonica*, frequently represented in Chinese paintings, was long regarded as a merely imaginary plant; and yet it is now, perhaps, the leading beauty in the British garden. The same may be the case with the superb pheasant; but we must in the mean time confine ourselves to the argus. This bird, except its superior size, and the singular enlargement of some of its feathers, hereafter to be noticed, is a true pheasant. The bill is as long as the head, compressed, the upper mandible curved, and slightly hooked at the tip. The nostrils are about the middle of the upper mandible, lateral, and half closed by membrane. The tarsi are slender and without any spurs. The three anterior toes are partially united by membrane, and they have *rasorial* or scraping nails like the other gallinæ. The head, cheeks, and part of the neck, are destitute of feathers. The tail is elevated, divided into two compressed planes of six feathers each, and having the two middle feathers much longer than the rest. The wings are singular in their structure. They are short and round, very short, in fact, in proportion to the size of the birds; but in proportion as the primary quills are short, the secondaries are long and broad, being in the male not less than two feet and a half in length. Those produced feathers are thickly studded over with eye spots, which have a very brilliant appearance, and on account of which the bird has been called argus. When the bird displays himself, for it is in the male that the greater splendour appears, the feathers of the tail are spread fan-shape, with the two long feathers in the middle rising high over the rest. The produced secondaries glittering with their multitude of eyes, bear against the lower and lateral parts of the tail, and rising high over these, give the whole display the form of a coronal plume with three points. The colours are beyond description beautiful, as there is no language containing names for a tenth part of the tints. Every colour is there in the perfection of its beauty; and yet the contrasts are so sweetly delicate, that there is not the slightest expression of gaudiness about the whole bird. As is the case among all gallinaceous birds, the female is much less showy than the male, has the secondaries less produced, and without the eyes, which give so much liveliness to the other.

One peculiarity of the colouring of this splendid bird is, that the whole effect is produced with scarcely any assistance from metallic lustres and reflections.

Gigantic Argus.

These birds are very large, far exceeding in size any of the other known pheasants. They are birds of the mountains, and as such may probably be met with along the heights of the eastern peninsula as far as China; though hitherto their localities have not been much examined, and but little is known of them in a state of nature. It is understood, however, that their habits are similar to those of the other pheasants, only that they do not perch in trees—at least not habitually. When marching about on his native pastures, under the brilliant sky, and with the incense-loaded breeze, which plays with perpetual health on the mountain tops of that paradise of the world, the argus-pheasant must be a splendid bird, probably the most splendid of the whole of the feathered race; and as there is heat and light to bring out and display his colours with the utmost perfection, and an atmosphere to stimulate to the utmost, yet without fatigue or exhaustion, he must be seen to greater advantage than any tenant of the woods or of more confined places. He stands nearly five feet in height, and those masses of feathers which are studded with eyes, each present a beam of glories two feet and a half long, and at least nine inches in breadth. The carriage of the head, too, is majestic; and during the breeding season, all the naked skin on the head and throat is a fine pure red, contrasting beautifully with the bright golden yellow of the irides, and the paler yellow of the bill. The bird seems rare; but with proper attention it might, perhaps, be introduced, and made to breed in this country.

ARGYREIOSUS (so named from its silvery colour). A genus of *Acanthopterygous*, or spinous-finned fishes, belonging to the mackerel, and, like the rest of that family, a surface fish, but differing greatly in form and in the structure of its fins. By Linnæus and his followers it was included in the genus *Zeus*, the type of which is the celebrated John dorée, a genus which with them was not a little confused. There is only one known species, which is the *Zeus vomer* of Linnæus. It is a fish of the clear and deep waters on bold shores; and it is not a little singular that the two localities in which it is most abundant, if not the only ones in which it is found, are the shores of Norway and those of Brazil. The body of this fish is greatly compressed and enlarged in the vertical diameter, so that the profile is very much elevated. The first dorsal fin is long, and the second of considerable length, and some of the rays of both are prolonged into filaments. The ventral fins are also very much produced, and the fish can extend them laterally so as to present a sort of broad base, and thereby steady its thin and elevated body. Notwithstanding its ungainly form, it gets through the water with considerable rapidity, but its food and habits generally are little known.

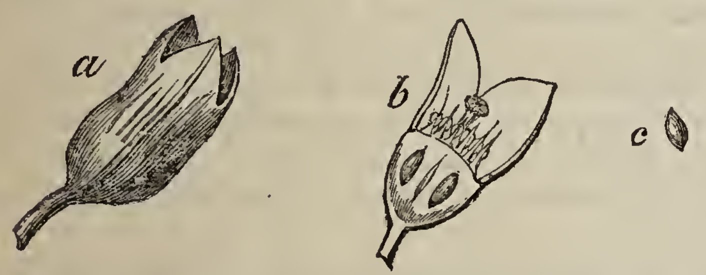
ARISTEA (Linnæus). A family containing five species of handsome blue flowering herbs, natives of the Cape of Good Hope, belonging to the Linnæan class and order *Triandria Monogynia;* natural order *Irideæ.* Generic character: spathas bundled, chaffy, rarely green; corolla of six regular plane petals, with a short tube; stamens erect, fixed to the germen; style cylindrical; stigma in three heads or flattish; capsule prismatical, seeds flat. They are green-house plants.

ARISTOLOCHIÆ—The Birthwort tribe. A natural order of plants containing only two or three genera, and placed upon the limits of the *Monocotyledons* and *Dicotyledons.* The order is nearly allied to the *Cytineæ.* Its essential characters are: flowers hermaphrodite; calyx adherent with the ovary, and divided into three segments; stamens varying from six to ten, sometimes free and distinct, at other times adhering with the style and stigma; ovary three to six-celled; style short; stigma divided; fruit dry or succulent, three to six-celled, many-seeded. Herbaceous plants or shrubs, very abundant in the tropical regions of America. Some of them are climbing. Their general properties are bitter, tonic, and stimulating; these qualities reside chiefly in the roots. None of the aristolochiæ are poisonous. The chief genera in the order are *aristolochia* and *asarum.*

The *Aristolochia clematis, rotunda* and *longa,* are natives of Europe, and have been celebrated from remote antiquity for their stimulating effects on the female constitution. The first of these species is frequently found among the ruins of nunneries in England, and is known by the name of common birthwort. It was formerly recommended in gout, and is one of the ingredients of the Portland powder, so celebrated for the cure of that disease. The other species have been used in ague and catarrh. The root of the *Aristolochia serpentaria,* Virginian snake-root, is an article of the materia medica. It has an aromatic smell like valerian, and a warm pungent taste, somewhat resembling camphor: with alcohol it gives a light green tincture. It is heating and stimulating, owing to the essential oil which it contains, and its action is chiefly on the skin and kidneys. It is used in ague and typhus fever.

The mode in which the seeds of the *Aristolochia clematis,* and of several other species of the genus, are perfected, is singular, and deserves to be noticed. The stamens and pistils are excluded from the influence of the air by being confined in the globular base of the flower, and the stigma being placed above the anthers it is scarcely possible for the pollen to be distributed upon it by the usual means. This, however, is accomplished by means of the *Tipula pennicornis,* a small insect which enters the superior tubular part of the flower, and gets into the lower portion where the stamens and pistils are situated. The tubular part is lined with a number of fine hairs pointing downwards, which allow the insect to enter easily, but completely prevent its return. In these circumstances it moves about in the little chamber, and becomes covered with the pollen, which it thus scatters over the stigma; the flower afterwards withers, and the insect escapes. The plant, however, rarely bears seed in this country. An American species, the *Aristolochia sipho*, which flowers abundantly, probably from want of an insect of this kind, never bears seed.

The leaves of the *Asarum Europæum*, or *Asarabacca*, are officinal in the British pharmacopœias. This plant is indigenous in the north of England, but is not found in Scotland. The roots are brought from the Levant, and are also used medicinally. They are bitter and acrid, have a disagreeable nauseous odour, and possess powerful emetic and purgative properties in the recent state. The powdered leaves are used as an herb snuff to promote sneezing, in cases of drowsiness, headach, sore eyes, and palsy. The root of the *Asarum Canadense* has an aromatic flavour, more agreeable than that of the Virginian snake-root, and is used in America as a warm stimulant to promote perspiration. By the country people it is used instead of ginger, and hence has received the name of wild ginger.



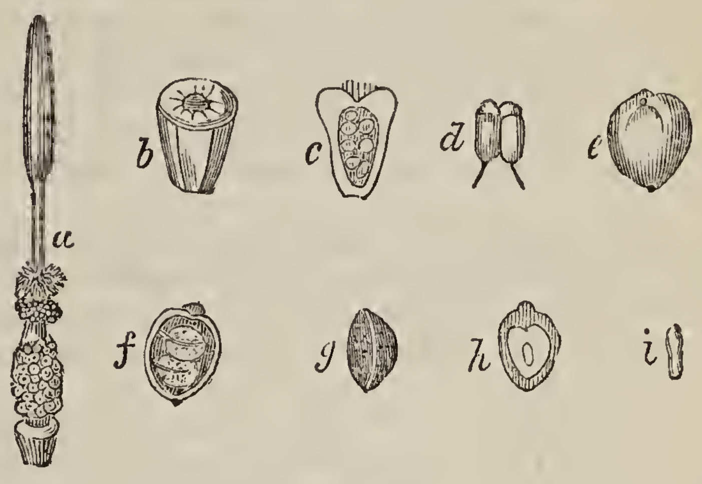
Asarum Europæum. *a*, Flower; *b*, section of the same; *c*, seed.

In consequence of the genus *Asarum* being included in this order, it has sometimes received the name of *Asarineæ*.

ARISTOTELIA (Linnæus). A South American evergreen shrub, named in honour of the Greek philosopher Aristotle, belonging to the Linnæan class and order *Dodecandria Monogynia*, natural order *Homalineæ*. Generic character: calyx five-cleft; corolla five-egged petals, equal to the calyx, inserted on the receptacle; stamens below the seed-vessel; filaments short; anthers linear; style like a thread, protruding; stigma, tripid, reflexed; berry round, three-celled. This shrub is tolerably hardy, growing freely in sheltered situations, and the berries are eatable, of a purple or black colour, and slightly acid. In Chile the inhabitants make a wine from it which is administered in fevers, and which is supposed to cure the plague. It is propagated by layers and cuttings.

AROIDEÆ.—The Arum tribe. A natural family of monocotyledonous plants, the two hundred and fourth order of the system of Jussieu (*Loudon*), containing about twenty genera, and upwards of a hundred and twenty species. The plants included in this order are generally herbaceous and stemless, and are frequently furnished with broad fleshy leaves, somewhat resembling those of dicotyledonous plants. They grow in shady moist places, are found abundantly in tropical climates, though rarely in those which are temperate. In the tropics the aroideæ occasionally become arborescent, and sometimes throw out aërial roots by which they become attached to other trees. Some of the plants of this order, as, for instance, several species of the genus *Pothos*, are truly parasitic. In America some of the aroideæ are found at an elevation of upwards of 8000 feet above the level of the sea.

The essential characters of the family are:—flowers sometimes hermaphrodite, sometimes unisexual, numerous, sessile, growing on a spadix which is sometimes enclosed in a coloured spatha or sheath; the perianth is often wanting; when present, it consists of four or six segments. In the male flowers, the stamens vary in number, and are very short; the anthers are subsessile, ovate and turned outward. In the females, the ovary is superior, and many-seeded; stigma sessile. The fruit is simple, and either succulent or capsular. Seeds vary in number. The order has been divided into three sections; the true *Aroideæ*, the *Dracuntiaceæ*, and the *Arontiaceæ*.



Arum Maculatum. *a*, The spadix, with the male and female organs, and nectaries in their relative situations; *b*, ovary; *c*, the same in section; *d*, anther; *e*, fruit ripe; *f*, the same in section; *g*, seed; *h*, the same in section; *i*, embryo.

In the aroideæ, as in most monocotyledonous orders, the roots are the chief objects of interest, whether we regard them in a medical or economical point of view. In the fresh state they are acrid and stimulating, sometimes possessing purgative and even poisonous qualities. When dried, subjected to heat, or macerated, they lose their acrimony and become mild and nutritive. A good illustration of this may be found in the case of the *Arum maculatum*, the cuckoo-pint or wake-robin, a plant which is pretty common in England, although rare in Scotland and Ireland, and which is well known by its spotted arrow-shaped leaves, and its fine red berries, which remain during the winter. The root of this plant, when fresh, is very acrid and pungent, causing swelling of the tongue, salivation, and a burning sensation in the mouth and throat; but when boiled or macerated it is wholly deprived of its acrimony and may be used as an article of food. It is so employed by the inhabitants of Weymouth, and the island of Portland, and is made by them to yield an amylaceous substance, which is sold in London under the name of Portland sago, and is an excellent substitute for bread-flour. In Sclavonia, after being washed, boiled, and dried, it is preserved as food during the winter.

The plant is retained in the pharmacopœias. The fresh root, when mixed with gum arabic or spermaceti, so as to prevent it exerting its pungency on the mouth, may be administered as a very powerful purgative, in doses of ten or twenty grains. The dried root is quite inert, and the French prepare from it a harmless cosmetic called cypress powder.

The roots of the *Arum colocasia* and *esculentum*, the Indian kale of the West Indies, the tairo of the South Sea Islanders, when roasted or boiled, are deprived of their acrimony and become agreeable and important articles of food. The leaves of the first-mentioned species, when cultivated and duly prepared, are employed as a potherb. The root of the *Arum campanalatum*, which often weighs from four to eight pounds, is cultivated as the potato is in this country, and as the yams in the West Indies. It is said that milk in which the root of the *Arum triphyllum* has been boiled is useful in consumptive cases.

The different species of *Caladium*, a genus belonging to this family, invest the trees in the tropical forests, and from their colour and form constitute a striking feature among the plants of those regions. Some of them are stemless, while others have long climbing stems from which thick roots arise. They all furnish an acrid juice. The *Caladium seguinum* has the property, when chewed, of causing the tongue to swell so as to impede speech. On this account it is called in the West Indies dumb-cane. The *Caladium fragrantissimum*, a native of Demerara, diffuses in its recent state a most powerful and delicious odour.

The *Calla Ethiopica*, a plant included under the aroideæ, is commonly cultivated in green-houses and drawing-rooms on account of the beauty of its flower. The *Calla palustris* is found in the northern parts of Europe, and inhabits the deep stagnant and frozen marshes of Lapland. The fresh leaves of the *Calla pertusa* are used in Demerara as blisters and rubefacients for the cure of dropsy. The root of the *Dracontium polyphyllum* possesses antispasmodic virtues. The root and seeds of the *Symplocarpus fœtidus*, skunk weed or skunk cabbage, a plant found in Canada, and very abundant in the meadows and swamps of the United States, are used in asthma, catarrh, and chronic coughs. The flowers of this plant appear before the leaves, and are so unlike a vegetable production that a person at first sight would take them for something artificial, or for a shell of the cypræa tribe. Their very fetid smell, however, on a near approach, soon dissipates the delusion.

The *Acorus calamus*, common sweet flag, is another interesting plant belonging to the aroideæ. This plant is found in watery places in the south-eastern counties of England. It has an aromatic root or rhizoma, known in commerce under the name of *Calamus aromaticus*. It is stimulant, carminative, and stomachic, and is frequently administered in intermittent fevers and in gout. After being blanched it is mixed with sugar and used in Constantinople as a preventive against epidemic diseases. From its agreeable odour the plant is used for garlands, and is strewed on the floor of the cathedral at Norwich on festival days.

Some of the plants belonging to this order possess a peculiar property of evolving heat at a certain period of their growth. This has been particularly observed in the *Arum maculatum* and *italicum* at the time when the sheath opens. The heat has been observed to be 7° above the temperature of the surrounding air. The rise in temperature begins at three or four o'clock in the afternoon, attains its maximum at six or eight, and finally ceases at ten or eleven at night. During the evolution of heat the spadix becomes of a black colour.

ARMADILLO. The name given by the Spaniards to a very singular genus of mammalia, which are found only in South America, and chiefly in the woods or on the plains of Paraguay, or otherwise in the great valley of La Plata. They are animals of many names, as well as many peculiarities. The name armadillo, which in England has become the common name of the genus, means "clad in armour." The name *encuberto*, by which they are known to the Portuguese, has nearly the same meaning; and they apply it indiscriminately to the whole genus, though in Europe it is often used as denoting only one particular species. *Tatou* is the name given to them by the natives of Brazil, and has been adopted by D'Azzara, the Spanish naturalist, to whom we are indebted for the best account of them in their native localities. The generic name bestowed upon them by Linnæus, and still retained by the majority of systematic writers, is *dasypus* (hairy foot), which is one of the old Greek names for the hare or rabbit, and certainly as little descriptive of the armadillos as can well be imagined; but it has the sanction of custom, and therefore it is not, perhaps, worth while to change it for a better one, the more so that the characters of the animals are so striking, that there is no danger of confounding them with any others. *Dasypus* may also mean "thick foot," or "foot closely put together;" but though that is true of the armadillos, it is not more descriptive of them than of many other animals.

Their most obvious and striking characteristic is the armour, or shield, or shell, or whatever else it may be called, with which the upper part of their bodies is covered, and from which they get the Spanish name that has been adopted as their English one. This covering, taken all together, has a very considerable resemblance to plate armour. It consists of a great number of transverse bands or segments, marked with a succession of studs. These bands are, in some instances, that is, on some parts of the body, completely united into broad bucklers, each consisting of a single piece, and moveable only as a whole, whatever may be the apparent number of bands of which it is made up. Of these broad pieces there are three; the first covering the upper part of the head, as a sort of helmet; the second, which is much larger, covering the neck, shoulders, and more or less of the back; and the third covering the croup from the loins to the tail: between the second and third of these there is a variable number of smaller pieces, united by skin but admitting of very little motion. The number of these intermediate and slightly moveable bands, has been popularly made the foundation of specific distinctions; but it is by no means well adapted for such a purpose, as the number often varies in the same species, and is often the same in different species.

No complete set of observations on the progress of this curious covering during its growth has been made; and therefore it is impossible to say that each transverse band both of the larger and of the intermediate plates is formed separately, with skin intermediate until it is full grown. But this is probable, inasmuch as the anchylosis or immoveable adhesion of these bands together, does not always take place at the same age in the same species; and it is probable, though even that has not been carefully observed, that the skin between the several plates, or the joints of the armour, as we might say, stiffen and approximate to anchyloses as the animal advances in age.

The plate on the head, or helmet, is much narrower than those on the body. It commences not at, but generally near, the muzzle, and passes towards the occiput in such a manner as partially to shadow the eyes from perpendicular light, but not to cover either them or the ears. It is composed of a number of tuberculated pieces, but so closely united together as to form one immoveable covering of very considerable firmness and strength. From the edges of this there generally proceed two rows of hard tubercles, which pass under the eyes, become gradually smaller, and terminate on the cheeks.

The plate or buckler on the neck and shoulders is much larger, and descends laterally so much as to conceal the greater part of the fore legs except the feet.

The intermediate plates and the plate on the crupper descend also far down laterally, so that the last in a great measure conceals the hind legs; and thus the whole animal appears "thatched," so to express it, with transverse bands of shell or crust, which are so thick, firm and hard as to be a perfect defence against the attacks of almost any animal.

The tail also has its armour, which consists of a greater or smaller number of rings, not perhaps absolutely united into a solid, but still usually admitting of little or no motion in that organ.

From this external covering of the armadillo it is the least flexible of all the mammalia; and when it turns, it turns like a block upon legs, without any perceptible bending of the body even at the junctions of the intermediate plates. The head is capable of little elevation, so that, in a lateral or upward direction, the animal is less capable of motion than a tortoise. In the remaining direction, or downwards, the motion is more free, as some species can roll themselves partially, and one of them completely into a ball.

Though the uses of this most singular covering, in the economy of these curious animals, are little understood, yet they must be important, as the organisation, especially that of the spinal column, has reference to it. With respect to their internal structure, however, it is very difficult to speak generally, as there are differences in the species, sufficient almost to call for divisions into different genera; and all the species have not been dissected with equal care. The point of resistance to the general action of the spine, and indeed to that of the whole animal, appears to be the sacral or hinder extremity. The whole thence to the muzzle pushes forward as a stiff and nearly inflexible column, sustained partly on the spine itself, and partly by the armour.

On the frontal bone there are two elevated processes, one object of which is evidently to support the helmet or plate which covers the head; and these differ with the form of the head and relative size of the helmet in the different species. The number of vertebræ in the neck is seven, as in all mammalia; but their structure is very different from that of animals which have free motion in that part of their bodies: very remarkably different from the neck of the tortoise, which, though an animal of a different class, is very apt to occur to one's memory when examining an armadillo. The short neck of that animal has its vertebræ so articulated, as to admit of more motion within a limited compass, than perhaps any other animal structure. The neck of the armadillo is the very reverse: it has little motion in any of the joints, and some of the vertebræ, especially the third and fourth, which being the middle ones, necessarily give stiffness to the whole neck, are anchylosed or united together. In this respect the neck of those animals resembles the neck of the whale, which not admitting of lateral motion, carry the head forward with the same stiffness as if the neck were one solid bone, and yet without the danger of fracture that might result from a structure of that description. The transverse processes of the vertebræ of the neck are very long, and assist in supporting that portion of the buckler by which the neck is covered, so that the spinal structure of the neck and its exernal covering both conduce to the same end, that of giving stiffness; and there is no doubt that the buckler diminishes or destroys any strain upon the cervical spine which might tend to injure the spinal cord.

The dorsal vertebræ, which are represented as being twelve in number, are not anchylosed, but they admit of very little motion; and their spinous processes, which are much produced, are directed backwards, and bear against the buckler like props or stays. The hinder dorsal vertebræ and the lumbar ones, which are three in number, have the processes still more produced, and directed outwards and forwards, so as more completely to support and bear up the heavy armed covering of the animal at that part of the body where there are no ribs. After the spine (which generally consists of eight sacral vertebræ posterior to the lumbar ones) is past, the bones of the pelvis are so formed as to give support to the plate on the crupper. At the anterior edge of the pelvis, the *ilia* rise into two short but thick props; and at the posterior, the tuberosities of the *ischia* rise in the same manner, and by these four bony prominences the plate is completely supported.

In considering this structure, we find two results: in the first place, any pressure which is communicated to the anterior extremity of the spine, or, which is the same in effect, any resistance to the motion of the spine forwards, is so transferred to the plates of the armour, that these divide the strain, and in great part take it off that organ; secondly, from the support given by the extended processes of the posterior vertebræ, and the projecting processes of the bones of the pelvis, the posterior part of the armour is kept wide at the sides, so as not to interfere with the contents or functions of the abdomen or pelvis, the latter of which is large and wide in proportion to the size of the animals. Such is the covering of the upper part of those curious animals, and the means (at least one of the means) by which that covering is turned to account. We shall now briefly notice the appearance and covering of the under side.

The head, except the parts that have been mentioned as covered by the helmet or the hard tubercles under the eyes, is covered with skin, and so is the whole body below the armour, and the legs, with less or more of hair upon it, according to the species. There are also in some species numerous long hairs in the interstices of the plates. The skin on the under part of the body is beset with tubercles, and they get hard and indurated on the legs and feet. There are, however, none upon the soles on which the animals walk, and these are also without hair. The legs are short, and from the portion of them that is covered by the armour, they look much shorter than they really are. They are, however, very thick and strong. The feet are large and flat, and have the toes united by a membrane as far as the last phalanx. There are, in some, five on all the feet, and in others, four on the anterior ones, and five on the posterior. The nails upon these are large and strong, round on their upper surfaces, hollow on their under, and admirably adapted for digging. It would not be altogether consistent with the nature of a popular work to enter minutely into anatomical details; but we may mention generally that the system of apparatus by which the feet and toes of the armadillos are moved is peculiar, very powerful, and fitted alike for vigorous and continued action.

One of the most singular indications in the bones, and consequently in the parts which these bones support, is a resemblance to birds. This resemblance appears in the bones of the lower part of the body only, because the armour on the upper part, and those adaptations of the vertebræ and other bones which have been mentioned, preclude any resemblance in that part. The resemblance is, also, but slight, not so great as in the *Ornithorhynchus* or *Echidna* of New Holland; the one of which is an aquatic animal, and burrows in the ooze and mud, the other a land animal, and burrows in the earth; but still it shows a deviation from the ordinary structure of mammalia, which breathe by expansions and contractions of the chest. In the armadillos there is a rudiment of a furcal bone, or "merry-thought;" and the sternal portions of the ribs are completely ossified. To compensate for this want of mobility in the parietes, or walls of the thorax, and still give the animal freedom in breathing, that cavity is capacious in its dimensions, and each lung of the animal consists of three lobes. These circumstances compensate for the want of a flexible chest, as in the mammalia proper, and also for that of air cells, as in birds. The bones of the pelvis also indicate a slight approach to the structure of the winged tribes. The bones of the pubis do not remain wholly detached from each other, as in these, or in the great ant-eater, or the *Chlamyphorus*, an animal which has some external resemblance to the armadillos (see Chlamyphorus); but they are united by symphosis at their points only. In the remainder of the pelvis the resemblance to birds is still greater; the *sacrum* is very broad posteriorly, and the angles of it are completely anchylosed to the spines of the *ischia*, so that the walls of this cavity are, like those of the chest, in in a very great degree inflexible.

It may seem singular, to those who are not in the habit of tracing analogies in natural history, that animals which live great part of their time under the earth, and have coverings much more solid than the other mammalia, should be the ones which have most resemblance to those animals, the majority of which spend great part of their time in the air; but it is nevertheless true; and, as has been already hinted, they, in some parts of their skeleton, also bear some resemblance to the whales, which spend the greater part of their time in the water. These analogies in structure must be attended with analogies of use, though it is more difficult to understand these, inasmuch as it is not always possible so to analyse the functions of an animal, as to show how they accord with the different parts of its organisation. The stiffness given to the neck by the anchylosis of its central vertebræ, and to the whole spinal column, by the armour, and the bearing of the processes of the vertebræ against that, evidently enables the armadillo to push forward into the earth, so as to keep itself advanced to the full action of the claws in burrowing downwards in an oblique manner, which it does with very great rapidity; so fast indeed as almost to elude pursuit; for as it gets the body buried, it takes so powerful a hold of the earth, that the tail may be pulled away without bringing out the animal. In these cases it is probable that it holds on with the whole body, and not merely with the feet. While digging, the legs are not stretched, so that when it raises itself upon these, the body is brought into firm contact with the upper part of the burrow; and the armour holds like a screw by means of its transverse prominences. The echidna shows the same facility in burrowing, and the same power of adhering to the earth; and it probably is assisted in holding on by its spinous covering.

From the direction in which it descends, which, according to D'Azzara, (whose statements being founded on personal observations are worthy of implicit confidence), is at an angle of forty-five degrees, or exactly midway between the horizontal and the perpendicular directions, it is easy to see the advantages which the armadillo derives from the firm and bird-like structure of the chest. This steep slope of the burrow continues for about three or four feet, or double the length of the average species. It is much steeper than the slope at which loose earth stands; and, therefore, what the animal pushes upward by its action in digging, must have a constant tendency to descend upon it by the force of gravitation; and thus with the pushing of the earth upwards, and the resistance of this tendency to fall down again, there must be considerable pressure on the body of the animal. One can also see the advantage of the armour, and even of the enlarged pelvis in the performance of this operation. The armour bears against the roof and sides of the burrow, nearly as a solid piece, the whole extent of the body of the animal; and its transverse irregularities take such a hold as to form a powerful fulcrum for the digging members, while the breadth of the pelvis prevents the mould from rolling back at the sides, and pressing upon and hampering the anterior part of the animal, the part which has the hardest task to perform.

But the resemblance to birds is not confined to the bones of the under part, it can be traced in the digestive organs. Most of the species, if not all of them, are very miscellaneous in their feeding. Tuberous roots, and other farinaceous vegetable substances, worms, insects, carrion, all things, in short, that constitute what may be called an omnivorous, or, at all events, a very miscellaneous feeder, are greedily sought after by armadilloes. Their teeth are not at all adapted for mastication, as whatever may be their number and their situation in the mouth, they are slender, stand apart from each other, and in the two jaws fall into the intervals of each other when the jaws are closed, so that they do not cut tooth against tooth, in such a way as that they can either cut or bruise. The mouth is thus an instrument for the prehension or taking of the food only, and can assist little, if at all, in preparing it for the stomach. The stomach is partly of a gizzard structure, that is, its coats are thick and muscular toward the pyloric extremity, or that to which the intestinal canal is attached. This structure evidently answers two purposes: first, it prevents the food from getting into the intestines before it is properly comminuted; and secondly, the action of the muscular coat assists in the process of comminution, in the same manner, though probably not to the same extent, as the gizzard of birds. This gizzard structure has not been observed in all the species, because they have not all been dissected with the same care: but it is probable that it may vary—be less in the ones that feed most upon animal substances. Nay, it may vary in the same species, just as the stomachs of birds vary so as to adapt themselves to different kinds of food, when habituated to these exclusively. A certain degree of adaptation in the stomach in this way, is common, if not universal, among animals; and it is one of those wise provisions of nature, by which races are prevented from perishing, when, by any casualty, the supply of their natural food is reduced below the quantity which they require.

Though the head of the armadilloes varies in the different species, it may be considered as in general small, and narrow and produced at the snout. The nostrils are terminal, and the sense of smelling is understood to be very acute. The eyes are small, but perfect in their formation, and, in some of the species at least, furnished with a third eyelid or nictitating membrane. The tongue is soft, and though it is but little extensile, and cannot be projected beyond the mouth, like that of the ant-eater, it may assist in the capture of ants and other small prey, as the saliva is of a peculiarly viscid nature, and obviously better fitted for assisting in the capture of the food than in the preparation of it for the stomach. Indeed, the incapacity of masticating renders saliva unnecessary for the latter purpose. The teeth have been already noticed, they are all of the same character, and cannot be described as answering to any of the three sets of teeth in ordinary mammalia, as they have as much resemblance to the teeth of reptiles or fishes, though they differ also from these. Like these, also, some of them have teeth upon the intermaxillary bones, as well as in the jaws. It has been remarked, that they are not adapted for cutting or bruising, and they are just as unfit for tearing. Hence the animals never, even in defence of their lives, show the least disposition to bite. They do not appear to be capable of dividing any thing but a pulpy substance which has no toughness; and that may be the reason why, though they are fond of the flesh of large animals, they never attempt to eat it till it is putrid. In this respect they bear some analogy to the alligators, which always bury their larger prey till it is softened by putrefaction. But in proportion as the mouth and its furniture are ill adapted for preparing the food for the stomach, the pharynx and gullet are well fitted for conveying it to that organ, the whole swallowing apparatus being furnished with muscular coats capable of very powerful contraction. Cuvier is under a mistake in stating that their intestines are without cœcal appendages; for some of the species have two, though but of small size. One other point may be mentioned in which they have a slight resemblance to the *monotremata*, the ornithorhynchus and the echidna; and that is, that, in the female there is very little distinction between the uterus and the vagina, but both approach the form of a single canal, as in birds. The mammæ are persistent, however, four in some of the species and two in others, and they are furnished with nipples. Of course, from the form of their mouths, the young armadilloes can suck in the same manner as the young of other mammalia; whereas the *bills* of the ornithorhynchus and echidna quite disqualify them for that operation, and the females have, in consequence, no nipples, but the milk comes through the integument of the mammary glands in drops, and the young get it "as they best can," for the process of their suckling has not yet been observed.

It is understood that armadillos breed but once a year, but the brood are often more numerous than the teats of the mother; and as one cannot suppose that the surplus number are regularly produced only to perish for want of maternal nourishment, there is no doubt but what two or more must often be nursed upon one teat. That, however, is not an anomaly in nature; for though the most prolific species generally have the most numerous teats, there is no necessary connexion between them and the number of young: the cow, when she drops but a single calf, has all the four teats equally furnished with milk.

Armadillos are found only in South America, and not in the southern parts or the mountainous parts in any latitude, or in those places which are subject to inundation during the rains. Some of the species are found in Guiana, and others in the pampas to the southward of La Plata; but they are not so numerous in these, which may be considered as the limits of their geographical distribution, as they are in Upper Paraguay and the adjoining parts of Brazil. In these they are very plentiful, and, for reasons which will be pointed out by and by, their numbers are probably increasing rather than diminishing. Some of them confine themselves more to the woods (not the thick and tangled forests or the humid grounds, but the woods on dry land, which are less luxuriant and more open), and others reside more in the open plains. They chiefly live in burrows, descending at first, as already described, at an angle of forty-five degrees, till they gain a depth of about two feet and a half below the surface; they then proceed for four or five feet more without descent, or rather with a little rising, and the dwelling is at the further extremity. By this mode of descent they obtain a roof strong enough not to fall in; and the turn which it afterwards takes secures them from rain, the quantity of which that can enter by the small external opening is not, under ordinary circumstances, very great. Some of the species remain constantly in their burrows during the heat, and even the light of the day, and come abroad to feed only during the night. These species are said to be very timid in their manners. Others come abroad at all times, and are less easily alarmed. They all, however, make for their burrows when pursued; and if they find that they cannot reach those, they set about earthing themselves with great expedition. Notwithstanding the shortness of their legs, the apparent weight of their mailed covering, and its stiffness, which prevents flexure of the spine and those alternate risings of the shoulders and the crupper, which are seen in the ordinary mammalia, their progressive motion in a straight line is by no means slow, for some of them will outrun an ordinary man. They owe this rapid motion entirely to the great muscular power of their legs, and to that concentration of the action of the whole body toward the sacrum as a point of rest, which urges them forward when digging.

Their digging is not confined to the excavation of their dwellings, for they also practise it in the seeking of their food. They thus get at tuberous roots in the ground, and also at worms and other small ground animals. As the structure of their tongues is not so well calculated for the capture of ants as those of the ant-eaters, they do not devour these insects in such numbers; but they are said to exterminate them much more speedily and completely from places where they abound. They effect this by mining obliquely into the ant-hills in all directions, and especially by digging down upon those places where the chrysalids of the young ants are collected, the capture of which annoys the workers more than that of a part of their own numbers. The holes which they make are also too deep and large for being easily filled up by the ants; and as they admit water to the very lowest inhabited part of the hill, the ants are either driven out, or drowned by the first rain that falls. Indeed, the best way of destroying a large ant-hill in any country, is to lay it open by boring in the same manner as is done by the armadillos.

They also bore under or into dead carcases, commencing in the earth at some distance, and going directly to that part of the carcase which pleases their sense of smell the most. They thus continue till they, on repeated visits, eat out the whole of the interior, while the surface, which is exposed to the hot and drying atmosphere, is too hardened for their being able to make any impression upon it; and if they find the putrid interior full of maggots, these and the substance upon which they are feeding are equally welcome as a mess. They often also invade the graves of human subjects, not merely of those who die in the woods or wide plains, and have to be buried there, but in the burying-grounds, and those who are attentive to the mortal remains of their friends, protect them with stones or bricks, as a defence against the armadillos. Unless, however, the place of sepulture is so secured in the bottom, as well as at the sides and on the top, the security is not perfect, as the animals get below, and mine upwards till they come at the body.

It is said that the males, and even the females, evince that desire to devour the young in the early stage, which is sometimes shown by pigs and other animals; and as it may sometimes happen that the female, immediately after littering, has not access to other food, one part of the brood may in this way be sacrificed for the preservation of the remainder; and, if so, the disproportion of the number of young produced above that of the teats of the mother may be in so far accounted for.

They multiply abundantly, however, and when they are so far grown as to be able to take care of themselves, they have few enemies. The shields are proof against the teeth of the puma, or any other of the few beasts of prey that are found in the locality of the armadillos; and, as the feline race never scrape to any extent in the earth, as that would damage their retractile claws, the armadillos soon remove all that part of their bodies upon which teeth or claws would make any impression out of the reach of such foes. The vultures are the rivals of armadillos in the matter of carrion; but the vultures are not much disposed to kill if they can otherwise find food, and while feeding they are too much occupied for interfering with any other creature, even though it is at work close by upon the same subject. Besides, the nocturnal ones are not abroad at those times when the vultures are feeding; for vultures are day feeders; and, therefore, though much is usually said about the acuteness of their sense of smell, it is probable that they depend much more on sight in the finding of their food. Preyers by scent are usually nocturnal, or at least twilight feeders in a state of nature; and therefore the allegations about the sense of smell in the vulture, which have given scope to much ornate expatiation on the part of those who know not very well what they say, demand direct proof before they can be implicitly admitted.

Having thus few enemies, and pastures more ample than almost any other race of land animals that could be named, the armadillos are very abundant, and it is probable that the colonisation by Europeans has tended very considerably to increase their numbers. They are much hunted, and many of them are captured for food, as, when roasted in the shell, some species are reckoned among the most delicious *bonnes bouches* in the country. But still they in some respects resemble *cultivated* animals, of which the numbers are contrived to be increased in proportion to the demand that there is for them. Neither the Spaniards nor the Portuguese, indeed, keep them in a domestic state, excepting a few for curiosity, though it appears that they could easily be domesticated, at least as much so as warren rabbits are, in any climate and soil suitable to their habits. But their flesh, like that of almost all animals, is probably the more racy when they roam in free nature, so that they have plenty of food; and they are so easily captured by flooding or smoking them out of their burrows, that the hunting of them is not a matter of chance, but quite as certain as that of hares or pheasants in a well-stocked preserve. And the colonists, though not intentionally, have supplied them with an abundance of food, and of food much to their liking, to which there could have been nothing comparable previous to the settlement of the Europeans in the country. The cattle which the colonists introduced have multiplied to innumerable herds in those wide and fertile plains; and the slaughter of them for the skins only is largely practised as a regular trade. These cattle, too, appear to have become so numerous, that there is no danger of exterminating them, or even permanently diminishing their numbers, as those which are killed are perhaps even more than replaced by the annual increase. When they are killed for their skins the carcases are left upon the spot, and thus there are thousands all over the country, which, though the sun dries them on the outside, every one becomes armadillos' food in the interior. Into these the mailed fellows burrow, and there wanton in a plenitude of luxury, which must have been quite unknown to them when there were no cattle in the country. To these may be added the bodies of numerous horses and mules, and even those of Indians and Guachos, who are frequently falling in the continued small hostilities between these races. All these must conduce to make the country a land of luxurious plenty to the armadillos of the present time, compared to what it must have been to their remote ancestors in ages long gone by; and as they feed more daintily, as well as more abundantly, than when they were confined to their wild roots, and insects, and worms, with a small lizard or snake now and then, by way of tit-bit, we may conclude that they have not only become more abundant in numbers, but of larger size, and more juicy in flesh. It is on this account also that their stomachs may now have less of the muscular or gizzard structure than when their food was more of a vegetable character.

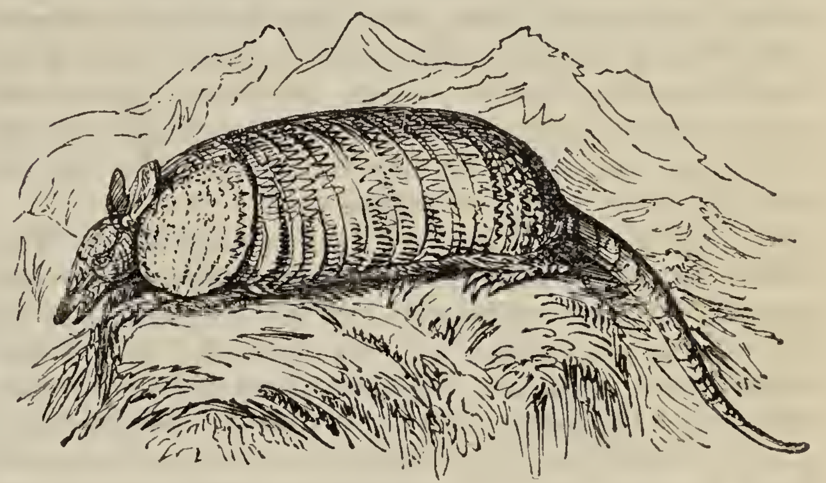
This effect of the colonisation of South America upon the armadillos is probably a greater anomaly in the effect of colonisation upon wild animals generally than the armadillos themselves appear to be in the class mammalia. The bear, the buffalo, and many other of the wild animals of North America, have vanished from great part of the United States; the antelopes of Southern Africa have, many of them, ceased to appear within the territory of the Cape; and even the kangaroo of Australia is a rare animal, compared with what it was when the colony was first established in that part of the world. All these are animals more resembling those which are domesticated and attended to in Europe than the armadillos; and yet these appear to be the only race of living creatures, natives of a colonised land, which have really and substantially benefited by colonisation.

The armadillos are classed in the order of *Edentata*, or toothless animals, and, though they all have teeth, and some of them a greater number than perhaps any other of the mammalia, they are not improperly so classed, as their teeth neither have the structure nor perform the functions of teeth properly so called; whether they should form a sub-order, or group, or only a genus, as at present, is another matter, but not one of very much importance in the *knowledge* or use of natural history. There are points of family likeness among all the *Edentata*, from the sloths to the scaly *pangolins*, though the first of these more resemble the ordinary mammalia, and the last more resemble the *Monotremata*, at least in some points of their structure. Still the edentata, though curious animals, form perhaps as natural an order as any of the others; and were it not for the single structural peculiarity from which they are named, that order might include the monotremata.

For the reason already mentioned, the Linnæan division into species, founded on the number of separate plates between the buckler on the shoulders and that on the crupper, is inapplicable, and though it were applicable, nothing could be founded upon it, and therefore it is useless. Baron Cuvier's five sections or subgenera are perhaps the best arrangement in the present state of our knowledge; but they too are founded chiefly upon external characters, and some of those characters appears a little inconsistent, as, for instance, distinguishing, by the number of their *teeth*, animals of which the general character is that they are *toothless*. Cuvier's sections are *Cachicames*, *Apars*, *Encouberts*, *Cabassous*, and *Priodontes*, the first and third containing three species each, and the remaining three only one each, making in all nine known species. We shall shortly notice the sections in their order.

Cachicames. These have seven or eight teeth in each side of both jaws, the muzzle long and pointed, and the tail also long. They have four toes on the fore feet, and five on the hind ones. The claws on the two middle anterior toes are very large and strong; the lateral ones, especially the inner, are much shorter, but also strong and well adapted for digging. The fore feet thus form pointed spades, which penetrate the earth much better than if the claws were all of equal length. The species included in this section are said to be more vegetable in their feeding than some of the others; some of them come abroad from their burrows during the day, and run with considerable swiftness. The following are the species.

1. *The Peba* (*Dasypus peba*). This is the pig-headed armadillo of Grew, the nine-banded, the eight-banded and the seven-banded of some of the systematists; and they might have added six-banded, for some individuals have that number. It is said that the additional bands are formed by separation from the bucklers, or rather by the production of new matter, as the markings of the bands and bucklers are not the same, and that these take place as the animal increases in age and size.



The Peba.

The usual length of the full-grown peba is about one foot four from the point of the snout to the root of the tail, and the tail is about one foot two, making the total length of the animal two feet and a half. The head is long and slender, the muzzle much produced, and terminating in a snout not very unlike that of a pig. The ears are rather long, and stand close together on the top of the head; and the eyes, which are small, and have the opening of their lids nearly lengthways, are placed in the middle of the sides of the head. The gape extends a considerable way backwards, and there are eight straggling teeth in each side of both jaws. The buckler or helmet on the head extends from the ears to the muzzle, and in breadth to the orbits of the eyes, which it partly overshadows and protects. There are small hard scales on the ears, and partially on the cheeks, throat, and other parts of the under side of the body. The buckler on the shoulders inclines forward on each side of the neck, and reaches down till it completely conceals the elbows; it is made up of a series of united stripes or pieces, increasing in breadth as they advance towards the back, and all of them slightly concave toward the head. These stripes are formed of hexagonal pieces of small size but very closely and firmly united. The buckler on the crupper is of similar structure, only the stripes of it are slightly concave toward the insertion of the tail, which its posterior margin nearly surrounds. The intermediate bands, which vary in number, as already mentioned, are composed of angular pieces, larger in size and different in shape from those which compose the bucklers. The tail is thick at the root, nearly two inches in diameter, and it tapers gradually to a point. It is covered with a number of rings, and admits of considerable flexure. The legs are short and the feet smaller than in some of the other species. A considerable quantity of hair covering the under part appears from below the edges of the armour.

The colour is blackish, and hence it is sometimes styled the black armadillo.

This species is very generally distributed, and also very abundant. It is found from Guiana to pretty far south in Paraguay; it frequents the open fields and not the woods, and it does not quit though man takes possession and cultivates. It is nocturnal in in its habits, very timid, tolerably swift in its pace, and a most expert burrower. Its flesh is more esteemed by persons of European extraction than that of most of the others, partly, no doubt, because it is *understood* to live more upon vegetable matter. But birds which live on vegetable matter are not so highly flavoured as some of those which live upon animal substances, and that may be the case with armadilloes, which, as has been hinted, have some resemblances to birds. It has not been ascertained whether this species has cœcal appendages to its intestines, though these are found in other species said to be more fond of animal food.

2. The Mule Armadillo (*Dasypus hybridus*). The trivial name *hybridus*, given to this species, is rather absurd, because no species can be a hybrid, and no hybrid can originate a species; and the only thing mulish about this one is that the ears stand up something after the fashion of those of the common mule. This species does not appear to have been named from the number of intermediate bands, which are said to be six or seven. It is much smaller than the peba, and has the tail and legs shorter and the ears longer; altogether it is not above eighteen inches in length, of which the head and body occupy two-thirds, and the tail one. The brood of the female are numerous, sometimes as many as a dozen, and it is said that each litter are always all of one sex. D'Azzara found this to be the case in one instance; but in animals so numerous, one instance is not sufficient to establish a general fact. This species extends into more temperate latitudes than the former, and is found abundantly in the pampas, even to the southward of Buenos Ayres. It is diurnal in its habits, and not nearly so dexterous in burrowing as the peba.

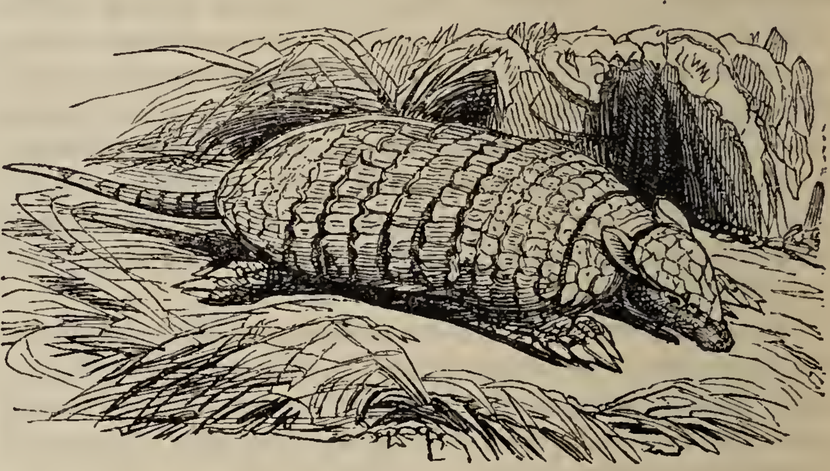
3. *The Totou verdadeiro* (*Dasypus verdadeiro*) is a species resembling the former in many respects, but much less perfectly known. Its chief character is a sort of horn, or single horny sheath on the point of the tail. It has been observed in Brazil, where it inhabits the woods, lives in burrows, and is diurnal in its motions.

Apars. This division resembles the former in the the structure of the feet; but the teeth in each side of both jaws are generally nine or ten. They have the power of forming themselves so completely into a ball, that they may be rolled, tumbled, and thrown about without sustaining any injury. There is but a single known species; and that one, though found in Brazil, in Paraguay, and as far southward as Buenos Ayres, is by no means abundant in any known locality. That species is—

4. The *Mataco* (*Dasypus apar*). This is the three-banded armadillo of Linnæus, and the three bands on it are very conspicuous, more from the larger size of the pieces of which they are made up, than of the pieces which compose the bucklers. The head of this species is about three inches long, and pear-shaped; the body a foot long, and rather lumpy or clumsy; and the tail is not quite two inches long, flattened and blunted at the point. The ears are short, rounded, and wide apart from each other. The bucklers advance very far forward toward the chin, and descend very much at the crupper; and the pieces of which they appear to be made up are so irregular that it is not very easy to trace them in regular transverse rows. The intermediate bands are formed of granulated rectangular pieces, which form a remarkable contrast with the rest of the armour. It is said not to burrow, at least to the same extent, or with the same facility, as most of the other species; but still it is not without its means of defence in the facility and firmness with which it rolls itself into a perfect ball, and thereby presents nothing but armour at all points. Its habits are not very well known.

Encouberts. The animals of this division have nine or ten teeth on each side of both jaws, and also some teeth on the intermaxillary bones of the upper jaw, which may perhaps be considered as a sort of fore-teeth. They are not, however, incisive teeth in any ordinary meaning of the term, but round, standing apart, and fit only for prehension, like the teeth in the jaws, so that the animals of this division have still only the same kind of teeth as the others, though two of them are differently placed. They have five toes on all the extremities. There are three known species.

5. The *Poyou* (*Dasypus encoubert*). This is the six-banded armadillo of the Linnæan arrangement, and the weasel-headed armadillo of Grew, by which name it is still often popularly described in this



The Poyou.

country. Its length is about sixteen inches, and the tail about eight. The head rather large, flat on the forehead, triangular in shape, and blunt at the muzzle. The eyes are rather small, and the ears erect, and wide of each other. The armour does not descend laterally so low, either on the body or the legs, as in the species hitherto described; the legs are also larger, thicker, and stronger; the feet and claws longer; and the whole expression indicative of a more powerful and energetic animal. The armour on the back is very broad, and the breadth of the animal corresponds, so that it appears one of the widest of the mammalia in proportion. The great breadth is particularly conspicuous when it squats down, as it often does, for the purpose of rest, and probably also of concealment; as in these cases it entirely folds up the legs, and the edges of the armour touch the ground. The number of moveable bands is not constantly six, but often seven or eight; and these and the bucklers are of a whitish colour, while the feet, which are covered with scales and tubercles, have a tinge of yellow; from between the bucklers there arise a few greyish bristly hairs; and the under part of the animal is tolerably well supplied with hairy covering.

The intestines of this species is furnished with two small *cœca*.

This is one of the most active of the armadillos; it runs with great swiftness, and even, notwithstanding the little flexibility of its back, makes attempts at a sort of jumping. It is a bustling animal, and appears to wish to know what is going on; for if hallooed to in its burrow it replies by grunting; and if the noise is continued, it comes out to see what is going on. Still it has no means of defence but flight or burrowing, as it does not offer to use either its teeth or its claws when assailed. It has already been mentioned that its pace is rather swift; and in dexterity of burrowing it is perhaps superior to any of the genus. It is particularly fond of carrion; and as it is an active animal, it finds abundance of that description of food, and is in consequence generally fat. The Indians seek after it with considerable avidity; but the descendants of Europeans seem to have a prejudice against its flesh, in consequence of the nature of its food; though it is probable that some of the species which they eat with the greatest relish, and which are night-feeders, and their food imperfectly known, may as frequently regale themselves on putrid bullock as the encoubert. In Paraguay this species is very plentiful. The mammæ in the female are only two in number; the broods, in all probability, exceed that, though their positive number is not very well ascertained.

6. The hairy armadillo (*Dasypus villosus*) resembles the encoubert in many particulars, but it is smaller in size, has the tail shorter in proportion; and the body is much more hairy, as brown hairs appear not only in the joints between the bands and bucklers, but over their surfaces. The length of this one is about fourteen inches, and that of the tail about five.

The hairy armadillo is not found in the tropical parts of South America or even in Paraguay. It resides chiefly in the drier parts of the pampas, never approaches the humid grounds, and lodges and nestles in natural holes in the ground rather than in burrows of its own excavation. It can burrow, however. It is very fond of carrion; and when the surface of the carcase on which it preys is dry and hard, it burrows in below, where the parts in contact of the ground have begun to decay; and feeding away as the carcase putrefies, it hollows out the whole interior, leaving the dry surface like a thin and empty shell. The flesh of this species, notwithstanding its feeding, is said to be very delicious.

7. The *Pichiy* (*Dasypus minutus*). This is the pigmy armadillo of some authors, and the smallest of all the known species. It inhabits the same regions as the one last mentioned, and extends even farther to the southward, being found on the borders of Patagonia. Except that it lives in burrows of its own excavation, its habits very much resemble those of the hairy armadillo. The whole length is only about ten inches, and the tail nearly half as much more. The head is small, the neck short, the buckler on the head shadows the small eyes, and below them there are tufts of hair on the cheek. There is a good deal of hair between the moveable plates, but it is not so much distributed over the body as in the last-mentioned species.

Cabassous. The animals of this division have generally nine or ten teeth in each side of both jaws, though it should seem that the number of teeth, like that of the moveable bands in the armour, is not constant, and therefore not implicitly to be depended upon for the purposes of classification. There are five toes on each of the feet; the first, second, and fifth on the fore feet having the claws moderate, but the third and fourth having them of immense size. There is only one known species.

8. The *Tatouay* (*Dasypus tatouay*). This is the one-banded armadillo, though in fact the number of moveable bands is about twelve. The length is about nineteen inches, and the tail between seven and eight. It is not so much fortified by armour as that organ in the other species, but covered with detached scales or crusts. The head is long and the muzzle pointed, but the forehead round; the ears are large, and at a moderate distance from each other. It is much more tropical than many of the other species, being found in Guiana and Brazil, but rarely indeed even in the upper part of Paraguay. Its habits are very imperfectly known.

Priodontes. The animals of this division have the same large claws on the middle toes of the fore feet, and the teeth in each side of both jaws vary from twenty-four to thirty-six. It is from this great abundance of teeth that the division is named.

The giant armadillo (*Dasypus gigas*). This is the twelve-banded armadillo of some authors, and so far as is known, the number of bands intermediate between the bucklers amounts to twelve or thirteen. It is rather a tropical species, but it is found in Brazil and the northern parts of Paraguay, where it never appears in the plains, but keeps to the great forests, and burrows in the ground with great facility. The head is long and very slender, the ears rather short, the buckler formed of distinct transverse bands very close to the neck, nearly meeting under the throat, and very concave forwards. The buckler on the crupper completely invests the root of the tail, and the concavity of its transverse pieces is turned backwards. The scales on the moveable band and also the markings on the others are rectangular. This is by far the largest of all the armadillos, being three feet three inches in length, with the tail one foot five inches more. The tail is very thick at the root, tapers to the point, and is covered by small plates forming a sort of spiral row.

The habits of the great armadillo are not much known, but observation shows that it is very fond of putrifying animal matter, and that it will dig deep into graves in order to get at the bodies of the dead.

Such is an outline of most that is accurately known of the natural history of these most singular animals.

ARRAGONITE, or prismatic limestone. An earthy mineral which is usually divided into two sub-species. The common Arragonite is of a greenish white tint, in some specimens approaching to a violet blue. It occurs massive, and is frequently crystallised. The primitive form of its crystals is an oblique four-sided prism.

Arragonite is found in the trap-rocks of Bohemia, of the Brisgau, and of Lower Italy. Very beautiful specimens occur at Schwartz in the Tyrol, one of which, preserved in the mineralogical collection at the British Museum, is represented on the next page. It strikingly resembles some portions of the animal viscera, and in fact appears like a part of the human frame petrified. It is there associated with copper-green, grey copper-ore, ochry-brown iron-ore, iron pyrites, quartz, and calcareous spar; in Spain it occurs imbedded in gypsum, along with reddish-brown quartz crystals; near Iglo in Hungary, it is accompanied with calcareous spar, ochry-brown iron-ore, and copper-green; near to Schemnitz in Hungary, its accompanying minerals are brown-spar, silver-ore, and galena; at Salfeldt, the principal mineral with which it is grouped is compact brown iron-ore, along with blue copper, and pyramidal calcareous spar; and it is found in compact lime-stone at Wolfstein in the Upper Palatinate. It is frequently found in Scotland, where it occurs along with galena, and in the secondary trap-rocks.

Arragonite.

The coralloidal arragonite, like the preceding species, is massive in its character, but the fragments have a peculiar wedge-shaped appearance.

ARROW GRASS (*Triglochin* of botanists.) A family of bog plants, mostly natives of Europe. There are six species: three of which are found in Britain.

ARROW HEAD. The Sagittaria of botanists: a genus of fourteen species found in low marshy places in all quarters of the world. Linnæan class and order *Monœcia Polyandria*; natural order, *Alismaceæ*. Generic character: flowers perfect monœcious and diœcious; calyx three sepaled; corolla three petaled; stamens inserted on the receptacle; filaments like threads; anthers ovate, double; cells discretous, opening outwards; styles numerous, very short; stigma acute, persisting; caryopses numerous, hard; seeds albumenous. This genus receives its name from the shape of the leaves being like the head of an arrow; often seen in the shallow parts of lakes and rivers.

ARROW ROOT of the druggists, and MARANTA of botanists. A family containing fourteen species, all considered ornamental: natives of the torrid zone. Linnæan class and order *Monandria Monogynia*; natural order *Canneæ*. Generic character: calyx double, both sides three-parted superior; corolla one petaled, three-cleft, leaning back, segments thrice two-parted; stamens, filaments like petals, two-parted, bearing one anther, style twisted; stigma three-sided. *Maranta arundinacea* yields the nutritive fæcula of the shops.

ARSENIC, a mineral which appears to have been one of the first known in medicine; it was also used to a considerable extent for the purpose of painting, even in the time of Theophrastus. It presents a variety of appearances dependent on the various bodies with which it is combined in its mineral state; but one very marked peculiarity is the strong odour of garlic which results from raising its temperature. This however is a test that should be employed with care, as the arsenical vapour which produces this odour is in the highest degree acrid and poisonous. It is electro-negative, and belongs to that class of metals whose oxides rather act as acids than bases, in the compounds they form with other oxidated bodies.

Native arsenic when fresh fractured is of a whitish grey colour. It occurs massive, and is externally either rough or granulated.

It is generally found in veins in gneiss, micaceous-slate, and clay-slate; and is a frequent precursor of rich masses of silver or cobalt: it is also associated with red silver, sulphuretted silver-ore, and arsenical pyrites. The mines of Kongsberg in Norway produce it in considerable quantities; as also do those of Saxony, Silesia, Suabia, and Hungary. The accompanying sketch is taken from a specimen from Nagyagin, Transylvania.

Arsenic.

We may now enumerate some of the principal mineral combinations of arsenic. Arsenical silver is massive in its character, and has a specific gravity of 9.440. It is found in Germany and Spain.

Arsenical pyrites is usually divided into two species; prismatic arsenical pyrites and di-prismatic arsenical pyrites. The first of these is of a pale steel grey colour, with a metallic and shining lustre: it occurs massive, in the form of oblique four-sided prisms. This species is again sub-divided into common arsenical pyrites, and argentiferous arsenical pyrites; the latter occurs abundantly in Cornwall and Devonshire, as well as in the north of Europe. It is from this one that the white oxide of arsenic is principally obtained, and artificial orpiment is also prepared from it.

Argentiferous arsenical pyrites is distinguished from the last named mineral by its inferior lustre and the smallness of its crystals; it is of rare occurrence, and is almost exclusively confined to the north of Europe.

Arsenic oxide nearly resembles PHARMACOLITH, which see.

ARTABOTRYS (R. Brown). A sweet scented ornamental evergreen shrub, introduced from China. Linnæan class and order *Polyandria Polygynia*; natural order *Anonaceæ*. Generic character: calyx three parted, larger than the corolla; segments lanceolate; corolla six-petaled, alternately roundish and pointed; stamens below the germen; style very short, and simple; berries attenuated on each side, two-seeded.

ARTHROPODIUM (R. Brown). A genus of five species of perennial herbs, chiefly natives of New Holland. Linnæan class and order *Hexandria Monogynia;* natural order *Asphodeleæ.* Generic character: corolla six-petals, spreading; the margin of the inner petals undulating or fringed; pedicles jointed; stamens below the germen; filaments bearded; anthers erect, base with a margin; style like a thread; stigma hairy; capsule three-celled, three-valved; seeds angular. These plants are only seen in botanical collections or herbariums.

ARTICHOKE. The *Cynara scolymus* of botanists. Of this genus there are eight species, two of them cultivated, and long introduced from the south of Europe. Linnæan class and order *Syngenesia Æqualis;* natural order *Compositæ.* Generic character: scales of the anthodium fleshy at the base, armed with spines; receptacle fleshy, chaff cut and defensive; pappus seated, and feeble. This large exotic herb is cultivated for the fleshy receptacle or base of its flowers for the use of the table. It is more a delicacy than a necessary of the kitchen garden, but as it is often partaken of by valetudinarians, who can relish nothing else, and moreover, considered nutritive and not destitute of some valuable medicinal qualities, it is held in high estimation.

Cultivation.—As great bulk in the plant and consequent amplitude in the flower constitutes the principal value of the artichoke, much care is bestowed on the preparation of the soil intended for them, as well by deep trenching or double digging as by enriching with good dung or compost. The favourite soil of these plants is a deep, rich friable loam; and as it has been observed that they grow luxuriantly in the neighbourhood of the sea-shore, a moderate portion of salt is supposed to be necessary to them. Artichokes, however, will succeed anywhere, provided the ground is made deep and rich enough.

New plantations are made in the spring. The ground intended for them should receive a good coat of rotted dung, five or six inches thick. This should be trenched in at least sixteen inches deep, and if it be a clayey subsoil, twenty-four inches will be still better. If the natural soil be considered too heavy and tenacious, a portion of sand, or of some looser description of earth may be incorporated when the trenching is done. This work should be done any time between the first of October and beginning of March, while the weather is dry, in order that the ground may be settled and ready to receive the plants about the middle of April. Previous to planting, say about the middle of March, the ground should receive another coat of well rotted dung, or rich compost: this should be neatly digged in, the surface levelled, and divided into four-feet beds, along the middle of each the rows of plants are to stand.

The root of the plant is large and fleshy, having strong spurs, which descend deeply into the ground. This is the reason why a deeply lying stratum of rich dung is required for the points of the roots. The crown of the roots is compound, that is, composed of one central and many surrounding buds, which shoot up during summer. A root, if left to nature, becomes, in the course of years, very much extended laterally; but as this would yield a great number of heads of too small a size, the proper practice is to reduce the number of suckers, or side branches, in the beginning of April, leaving only four or five of the strongest to form sizeable heads.

It is from this necessary dismemberment of the old stools that young plants are obtained with which to make new plantations. Drawing away the earth from the base of the stool, allows the side shoots to be slipped off with ease, each with a few fibres attached. A lot of the largest and best rooted are chosen to be planted; part of the top of their leaves is cut off; a line is stretched along the middle of each bed on the prepared ground, and the plants introduced at two feet distances apart. The plants should be let in at least eight inches deep, and if the soil be very dry a little water may be given to each. This, together with the manure previously digged in, will expedite their rooting, and ensure a luxuriant growth during the ensuing season.

The summer management only consists in keeping the ground free from weeds by deep hoeing, occasionally; intervals between the rows being usually cropped with some low growing summer plant as lettuce, dwarf beans, or the like.

If the season be favourable and the plants have taken kindly to their new place, they will each produce small heads in the autumn. These, perhaps, may be too small for plain boiling; but they are used in other ways by the cook, or for slicing in salads.

The roots are liable to injury from frost, and therefore, on the approach of winter, the precaution called the *winter dressing* is bestowed. About the 25th of October, the largest dangling leaves are trimmed away from each stool; the central leaves are preserved and loosely tied together with a string of bass, a quantity of loose, dry litter, or fern is brought and piled round the leaves and extending over so as to cover the roots. The whole surface of the ground is then digged over, working the earth towards the rows of plants, so that each row shall stand in a ridge, a graduated hollow being left along the middle of the intervals. This manner of laying the surface secures the plants not only from frost, but also from being soaked and chilled by the winter snow or rains.

Thus secured, the plants remain till winter is past, and until the time arrives when they receive their *spring dressing.* This may be done sooner or later, according as the season is more or less favourable. From the 20th of March to the 10th of April is the usual season for this work. What was done at the winter dressing is reversed at this; the earth is digged away from the rows of plants, exposing the roots sufficiently for the dresser to make a proper selection of the shoots to be left for a crop, and to reject the supernumeraries. Thus, the selection of the shoots, is the only point in which much judgment is required in the cultivation of the artichoke. If the land they grow in be poor, very few heads should be left to be perfected; two or three in this case is enough if large flowers are desired; if the ground be in good heart, and the stools appear strong, five or six of the strongest shoots to yield heads may not be too many; for in proportion to the luxuriance of the stool should it be called on by the manager to yield accordingly. In choosing the shoots the strongest near the centre should be preferred, otherwise the stool becomes irregular in form, by creeping away from its proper station in the row.

The heads are not only enlarged by leaving but a few to be perfected on each plant, but also by divesting them (the principal stems) of their branches, which also bear smaller heads: and these when no larger than a hen's egg are useful in the kitchen. In gathering the principal heads for use, they should not be cut, but wrenched or twisted off; by which many of the strong fibres of the stem which penetrate into the bottom are withdrawn, thereby improving the quality of the latter when brought to table. The stems may be cut down as soon as the flowers are off.

There are two kinds of artichoke in cultivation, viz., the green globe, which is the largest, and the purple globe, which is said to be more delicate and superior in flavour. Either seeds or roots may be purchased at the seedsmen's shops.

A plantation of artichokes, if properly planted at first, and receiving a dressing of good dung every third or fourth year, deeply digged in among the roots, with careful treatment at the spring dressing, and well secured from frost in winter, will continue productive for a considerable period—say ten or twelve years. When a plant is four or five years old, however, it is then at its best.

ARTICULATA—jointed animals. The third of the grand divisions into which Cuvier arranges the animal kingdom, and the second of the invertebrated or spineless animals. The species which it comprehends are exceedingly numerous and varied in their forms and their habits and economy, so that they not only extend to genera, groups, and orders, but admit of division into four classes—*Annellida*, *Crustacea*, *Arachnidæ*, and *Insecta*, all of which have their characters as classes as well defined as those of the four classes of vertebrated animals—*Mammalia*, *Birds*, *Reptiles*, and *Fishes*. But as these, in all their classes, and in all the varieties of each class, preserve the fundamental characters of the grand division—the articulated spine and the other parts of the internal bony skeleton, which gives form and support to their bodies, and affords points of rest, centres of motion, and levers, by means of which the muscles or organs of motion are enabled to act; so the *Articulata*, destitute in every instance of even the slightest vestige of spine or internal skeleton, preserve their fundamental character of a jointed external covering, which in like manner determines their shape, and gives insertion to their organs of motion. In the majority of cases, they are, like the vertebrated animals, furnished with distinct organs of locomotion; with feet, with wings, or with fins (or at least with organs which answer the same purpose), according to the element in, or on, which they move; but there are some which are destitute of such organs, and these crawl or wriggle along by the help of the edges of their rings, or by the flexures of their bodies. Some of the apodal, or footless articulata, as the common earth worm and the leech, appear indeed to derive advantages in their locomotion from the want of an internal spine. Spined animals cannot lengthen their bodies beyond the length of the spine stretched to a straight line; and they cannot shorten them in any way but by bendings or flexures of that organ—at least the changes that can be made in either way are so trifling, that they are not worthy of taking into account. The spine, though it has its advantages, has thus, also, its disadvantages. Its contents, the continuation of the nervous mass, are too essential to the life of the animal, for admitting of alterations by lengthening and thickenings by contraction, as these would disturb, or possibly suspend the functions of those nerves which, originating in the contents of the spine, are essential to the motions of the animal. But the articulated covering of the animals under consideration, has no immediate connexion with their nervous mass; and so when necessary to the habits of the animal, lengthenings and shortenings of the body, by expansions and contractions of the spaces between the rings, may take place without any interruption or injury to the sentient system. When this takes place to a large extent, the rings themselves vary in breadth and diameter, widening and becoming smaller when the animal stretches itself, and narrowing and expanding in diameter when it shortens. Thus we see that every varied structure of the animal frame has its peculiar advantages; so that, however different they may be from each other, we cannot, when we take into consideration the functions which they have to perform, say that one is better than another.

This lengthening and shortening of the body are required only in those species which have not feet, and they are confined to certain species of the annellidæ. The other orders of articulated animals have feet, and have them articulated, or jointed, as well as the vertebrated animals. The only difference, except number, size, and form, are not merely similar to the characteristic distinction of the grand division, but actually part of it. The articulations of the legs are in the covering, and the muscles and all the other organs are within; and though there are in some, as in certain joints of the large lacs of crabs, internal substances of a bony, or rather cartilaginous nature, which in part support the muscles, there are not, in any degree, approximations to an internal skeleton: they are appendages to the external crust, and articulated to that, and to that only.

When we attentively consider legs of this construction, we find that they possess many valuable qualities which cannot be possessed by legs with internal bones, and the muscles and other soft parts on the outside. The external crust is stronger, or, at all events, stiffer than the same quantity of matter in a solid bone, upon the same principle that a hollow cylinder of metal is stronger or stiffer than a solid rod containing the same quantity in an equal length; and the strength is very generally augmented by the different articulated pieces being spindle-shaped, or thicker in the middle than at the ends, and having the longitudinal outlines curved. By this means every part of the surface resists pressure like an arch.

It is also easy to see that, shielded as they are in the crust, or other firm articulated covering, the soft parts are far more safe from injury than if they were external, with the bone inside, against which they might be pressed, and nothing to defend them but the soft integuments. The leg of the articulata thus bears something like the same relation to that of the vertebrated animals, as a leg clad in armour bears to a leg which is naked; only the advantage is greater, because the soft parts of a mailed leg, when pressed by dinting the mail, are resisted and crushed midway by the bone; whereas those in the articulata are resisted only at the opposite surface; and as the pressure there is, as it were, against the under or concave side of the arch, it has a tendency to give way a little, and by its elasticity take off much of the injury of the crush. In consequence of this structure it is demonstrable, upon the most simple and obvious principles of mechanics, that the limbs of the articulata, and their bodies, in so far as these are similarly formed, can, without injury or inconvenience, bear pressures, crushes, or blows, proportional to what would maim or even destroy the stoutest of the vertebrated animals. A beetle, for instance, suffers no injury, by a fall from a height, or the fall of a substance upon it, which, estimating according to the relative weight of the animals, would dash an elephant to pieces, or, at all events, crush it to death; and the tiny leg of an ant can bear, without the least injury, a pressure, the relative effect of which would crush the paw of a lion to jelly. We shall afterwards have occasion to see that very many of the articulata are, not occasionally only, but habitually exposed to such pressures; and that if they had internal bones and the soft parts outside, they could not exist.

But the advantages of this structure are as great in action as they are in endurance. The muscles, inserted as they are in the opposite sides of the two jointed pieces, can exert their contractile force, either in bending or straightening the joint, much more effectively than can be done by external muscles, as they have the advantage of the whole lever power on both sides of the joint, and act in the straight line; while the external muscles very frequently act on the short end of the lever and have, besides, much of their force spent by their acting obliquely, and often through the medium of straps and pulleys, which, smoothly as the working surfaces of animals move upon each other, always destroy some of the power by friction. In the case of the internal muscles (that is, muscles in the inside of the parts which they move), no tendon, pulley, or ligamentous strap, is required. From the one point of insertion to the other the whole can afford to be efficient contractile fibres; and as those fibres are also, from their position, able, in almost every imaginable case, to exert the very maximum of their effect, it is not too much to say, that bulk for bulk, or weight for weight, an internal muscle of one of the articulati can act with twice, nay, with ten times the effect of an external muscle in any skeletoned animal. But bulk for bulk, or weight for weight, is not the means by which to estimate muscular activity, nor even a safe element in that estimate. Both bulk and weight are in themselves obstacles to motion, rather than sources of it; and in a muscle two pounds in weight there must be one pound of the motive energy expended in moving the additional pound more than would be necessary, if the muscle weighed only one pound. Suppose a certain muscle in an elephant to weigh a quarter of a hundred weight, or 28 pounds avoirdupois, and a certain muscle in an ant 1 grain troy; then, estimating in round numbers the pound avoirdupois at 7000 grains, the relative weights of the muscles will be 196,000 for that of the elephant, and 1 for that of the ant. Therefore, the loss of power from the overcoming of the mere inertia in the muscle of the elephant, is nearly two hundred thousand times as great as that in the ant. It must be borne in mind, too, that this overcoming of the inertia of the muscle is not a mere initial resistance, which can be overcome by any momentum after the muscle is in action. The whole body of an animal does acquire a momentum, which, in rapid motion, takes off part of the general weight from the whole organs of motion; but no single muscle can possibly acquire a momentum which can in any way relieve it of the constant dead-weight of its own inertia. The contractions of a muscle are independent and separate efforts, no one of which transfers the least portion of energy or impetus to that which follows; and therefore the inertia, in time, becomes too much for the muscular energy; and the heavy muscle, when the bodies moved are in proportion, is always first exhausted by fatigue. The large, heavy, and handsome horses, employed in the brewers' drays in London, could not get through one day in a coal-wagon, or a common travelling stage, though for short distances, with rests between, they may pull one-half more than the horses employed in these.

Another advantage which the internal muscle has over the external one is, that no part of its energy is ever expended in stretching its antagonist. When, for instance, the muscles which bend the human knee, or the joints of the fingers, are exerted, the *extensor* muscles are pulled in length by the projection of the joint, as it bends, pulling the tendons which pass over it. This, no doubt, keeps the joint steady, but it also diminishes the effect of the *flexor* muscles in bending the joint. But as the internal muscles pass through the centre of motion, the one of them is not pulled in length by the contraction of the other; and therefore the whole energy of that which contracts is effective in bending the joint.

The mere fact of being internal, surrounded with fluids, protected from changes of temperature, and from all atmospheric action, is an advantage to the muscles of the articulated animals, which alone would give them considerable additional strength, and especially additional power of continuing in action without fatigue. It would be no easy matter to estimate exactly the effect of the resistance, the decomposing power, and all the other influences of the atmosphere upon external muscles; and it would, perhaps, not be more easy to reduce to arithmetic the influence of changes of temperature; but we feel both, and especially the latter, so much in our own case, as to leave not a doubt that, but for these, we should be both stronger, and less easily fatigued; and as that is the case with us, we may very safely conclude that it must be the case with all animals which, like us, have external muscles and internal bones.

These considerations, and many others which will readily occur to the reader who carefully examines what has been stated, tend to show the advantage, and not the advantage only, but, if the expression may be admitted, the *necessity*, of the articulated structure in very small animals, which have to make their way along the surface of the ground, or even which sport in the air, as is done by gnats, and many other tiny creatures during almost the whole period of their winged lives. If we were to suppose the mountain rocks shattered into fragments, varying from the size of a haycock to that of our largest buildings, and the whole scattered miscellaneously about, so that in some cases an ox could pass under, and in some others only over them; if we were to suppose this, and that it were the general character of the earth's surface, then it would bear nearly the same ratio, and oppose nearly the same resistance to the progress of the larger mammalia as the common mould of a garden, with its admixture of pebbles, bears to the size, and opposes to the march of garden ants and the smaller beetles. We have ample proofs, in the smaller obstacles, by which their utmost exertions are foiled and defeated, that not even the fleetest of the mammalia, or those which are inured to the most stubborn and stony paths—the mountain-antelopes and mountain-goats—could make the least way over such a surface. It would be equally beyond their strength and their endurance: they could not accomplish it; and even if, in point of strength, they could, their flesh would soon be cut to pieces, and their bones broken to splinters by falls. But the articulated animal, defended by its crust, or other firm-jointed covering, and by the advantage of its internal muscles, performs its analogous, parallel, or even apparently more arduous labour, not only without injury, but without the least appearance of fatigue; for though we often find these little creatures in a state of repose, we can in no instance say that they are resting, because their leap, their march, or their flight, has fatigued them to exhaustion.

Thus we find, in the general structure of articulated animals, a consummate wisdom of design, and the very perfection of adaptation. So perfect and so striking, indeed, are these, that, in the minutest of the animal kingdom, it is difficult to imagine how any others than articulated ones could perform their functions, and preserve their existence; and when we reflect on the almost countless number of the genera, the absolutely countless myriads of some of the species, and how industriously and incessantly they are all at work, we see what a mighty blank there would be in creation—a blank, the occurrence of which would suspend all the other operations—if this division were to cease to exist.

But, while we look with admiration upon one division, and revere to the fullest extent the demonstration of Creative wisdom which it displays, we must not suppose that the special wisdom has been displayed, or the superiority of fatherly care expended upon that; for when we turn our attention to the next, be it what it may, we find that though the mode is different, the demonstration of wisdom, power, and goodness is still the same; and though we follow it to that shadowy boundary, where our knowledge of the creature is in a great measure matter of imagination, we find, even then, that the demonstration of the Creator is subject to no diminution, but that, like His own eternal and immutable essence, it is at all times and in all places exactly the same.

Though the limbs and other moving parts of articulated animals possess what may be considered as the maximum of strength and endurance in the same quantity of matter, they by no means possess the maximum of all advantages; and though we may with propriety reckon theirs the most powerful form of organisation, it is still an inferior form; as the very circumstances which give security and strength to the articulated members, limit them in that higher function which may be called *aptitude*. Every joint of theirs is, necessarily, from the structure of the parts, and especially from the moving power passing through the centre of motion, and being between the points of motion in the hard parts, little else than a common hinge, or *ginglymus*, as it is technically called. Such a joint, when well made (and all the natural joints of animals are well made), is, even in common mechanics, at once the most steady, and the one by means of which the greatest effect can be produced by the same application of force. But the hinge opens and shuts only in one plane; and if it is wished to turn the motion into new directions, there must be an additional hinge for every one of these. It is the same with the joints of the articulata; there must be as many joints as there are directions of motion; and as in any thing which is articulated there is always necessarily one piece more than the number of joints, the limbs in the articulata, to give them the same number of motions of which those of vertebrated animals are susceptible, would require a vast many more pieces and joints; so that to "bring up" the articulated animals even to the common active motions of the vertebrated, would require them to be at once very clumsy and very complicated. The sacrifice of power which arises from the structure of those animals which have internal bones and external organs for moving their bones, is not, therefore, a total sacrifice, it is merely sacrificing the single attribute of strength for the superior advantage of conveniency; and before an articulated animal could have the same conveniency—the same varied use of its members, it probably would have to exert more than a corresponding portion of the greater strength which it possesses in the single joint. The external muscles admit of all sorts of joints, from the hinge in one plane only, to the ball and socket which moves in all directions; and they admit of being so applied as to give to those joints every kind of motion, linear, rotatory and oblique. The human arm and hand, being intended for the most miscellaneous and universal application, are certainly the most perfect instance of articulation. And they are truly wonderful. If we take from the shoulder only, there are not very many joints; and yet the axis of the finger can be brought, without strain or exertion, to every point within a space of not less, even in a short arm, than two cubic feet. The human hand can divide space, and record the division by marks visible with a glass, to less than the 2500th of an inch, but say the 2000th, that makes 8,000,000,000 points in the cubic inch, or 13,824,000,000,000 in the cubic feet. The last is a number, not only beyond all counting, but beyond all ordinary comprehension; and yet it does not express all the positions of the fingers, even if we suppose the shoulder to be immoveable; it only expresses that very limited fraction of them which can be seen by the eye, aided by its glasses. But if we bring into consideration the flexures of the spine, the number becomes so great that instead of understanding it, we have hardly any name by which to call it. There is probably not, in the whole of the vertebrated animals, any organ capable of nearly so many motions as the hand; but in all cases, a much smaller number of joints effects every compound motion in those than in the articulata; and when we consider the state of the earth's surface, we cannot but perceive that the vertebrated animals are those to which it seems especially adapted; and that though the adaptation is equally perfect, the other tribes may rather be said to, be adapted to their particular situations upon it.

The inferior adaptation of the joints of the articulated compared with those of vertebrated animals are shown in many parts of their organisation. Their legs are more numerous, and the increased number appears to be equally necessary for the purposes of stability and of locomotion. They present a wider base both when the animal stands and when it walks; and in some species they spread so wide that the animal stands upon more than ten times as much ground as its body would cover; so that if we were to witness any thing like the same spreading of legs in order to obtain a base to stand on, in vertebrated animals, we should at once set them down as utterly deformed.

Another circumstance which points out the comparatively little freedom and range which there is in the joints of articulated animals, is the way in which the mouth opens. In all the vertebrata, the jaws, or in most cases only the under jaw, open downwards, and the two are always placed horizontally, the one upon the other: the great flexibility of the neck enables a mouth opening in that manner to get at and seize the food better than if it opened in any other; and in those which have the neck rigid, and which are invariably inhabitants of the water, the element in which they move compensates for the rigidity. But in the articulata, there is no motion of the neck by which the mouth can be guided to the food. They must advance upon it by progressive motion of the whole body, and therefore the jaws open laterally, and both mandibles have an equal degree of motion.

The senses of the articulata are not well understood. Many of them have eyes, and these of course have the faculty of sight; but their senses of hearing and smell are very obscure, not only as respects the organs in which they may be understood to reside, but as respects the fact of their being possessed by the animals or not. Their eyes are sometimes placed upon stalks or peduncles. At other times there are two kinds of them in the same animal: one kind simple and usually placed on the top of the head, the other kind compound, often very large in size, and placed at the sides.

The animals in this grand division are, however, so numerous, and differ so much from each other, that no common description can reach the details. The orders are tolerably distinct; and under the names of them will be found the distinguishing characters of each. See Annellidæ, Arachnidæ, Crustacea, and Insecta.

ARTOCARPEÆ — the Bread-fruit Tribe. A natural order of plants, containing many genera and species, which, from their value and importance, demand special attention. This order is by some authors looked upon as a subdivision of the urticeæ, or nettle tribe. The order is thus characterised:—flowers monœcious, in heads or catkins; calyx divided, membranaceous; stamens uncertain in number; ovary free, one or two-celled; style single, thread-like; stigma bifid; fruit usually a fleshy receptacle, covered with numerous pericarps, lying amongst the persistent calyces, or enclosing them within its cavity; occasionally consisting of a single nut, covered by a succulent involucre; seed solitary.

The plants of this order are trees, shrubs, or herbs, inhabiting chiefly tropical regions, more especially the East Indies. In this family, of which the Fig may be looked upon as the type, we meet with plants having very opposite properties, some being nutritious and salutary, as the bread-fruit, fig, and mulberry, while others, like the antiaris, are acrid and poisonous.

Most of the plants yield a milky juice, possessing a considerable degree of acrimony. This juice is, however, occasionally bland, and becomes an article of food. Many of the plants which yield an acrid juice furnish fruit of a mild and nutritive quality, and in some instances the fruit is acrid in its young state, but becomes innocuous when ripe.

We shall illustrate this important order by alluding to several of the genera included under it.

The genus *Artocarpus* (a term derived from two Greek words signifying bread and fruit), whence the name of the order has originated, is one of the most interesting.

Bread Fruit.

The *Artocarpus incisa*, Bread-fruit tree, a native of the Moluccas and the South Sea Islands, attains a height of thirty or forty feet, with a diameter of a foot or a foot and a half. It abounds in a milky viscid juice, and its leaves are two or three feet long, and often a foot and a half broad. Its fruit is fleshy, as large as a good-sized melon, and is used as a substitute for bread. It is baked as bread after the central pith is removed. When roasted or boiled, it is said to taste like the potato. The properties of this tree are summed up by Dr. Hooker in the following manner:—The fruit serves for food; clothes are made from the fibres of the inner bark; the wood is used for building houses and making boats; the male catkins are employed as tinder; the leaves for table-cloths, and for wrapping provisions in; and the viscid milky juice affords bird-lime.

The *Artocarpus integrifolia*, Jack tree, or Entire-leaved Bread-fruit, is found in the East Indies, especially in the Molucca islands, and has, along with the last mentioned species, been introduced into the West Indies. It is a tree about thirty feet high, having leaves from four to six inches long, and producing a fleshy oblong yellow-coloured fruit, which sometimes exceeds seventy or eighty pounds in weight. The fleshy part of the fruit is used for food, and forms a considerable part of the diet of the natives of Ceylon. It has a strong sweetish smell, is not relished by strangers at first, and seems to be difficult of digestion. The seeds resemble chestnuts, and are esteemed excellent.

The *Ficus*, or fig, is another important genus included in this order. This genus is one of the most extensive among plants. Many of the species attain a gigantic height, and are remarkable for their fructification, their milky juice, and the affinity they bear to the bread-fruit. The genus abounds in the tropical parts of Asia. In Dr. Wallich's catalogue, a hundred and five species are enumerated.

The *Ficus carica*, a native of Asia, but cultivated in the south of Europe, furnishes the common esculent fig. Figs are brought to this country from the Levant. They are demulcent and laxative, and enter into the composition of some pharmaceutical preparations. When roasted or boiled, they are used as cataplasms, and are frequently applied to the gums and throat to relieve inflammatory swellings. The milky juice of the *Ficus elastica* and *australis*, when evaporated, constitutes the common Indian-rubber or caoutchouc. Both these species are very tenacious of life, and can exist for months or years suspended in the air without any attachment to the soil. The *Ficus sycamorus* is the sycamore tree mentioned in the Scriptures. It yields an edible fruit. *Ficus religiosa*, the famous banyan tree, or sacred fig of the Hindoos, is one of the many astonishing features of Indian vegetation. Its branches bend towards the ground, take root, and thus form separate trees, which successively cover a vast space of ground, and furnish a most agreeable and extensive shade in warm climates.

> ———————— its wondrous branch,
> Bent down to earth, new stems can launch,
> Which upward spring to bend again,
> And form a forest o'er the plain.

The *Ficus Indica* resembles the last mentioned species in its mode of growth. A tree of this species is mentioned by Marsden as growing in Bengal, which had fifty or sixty stems, with a total diameter of 370 feet, and which afforded at noon a shadow, the circumference of which was 1116 feet. Gum lac is procured from this species. The bark of the *Ficus racemosa*, or red-wooded fig, is used as an astringent. The *Ficus toxicaria*, as its name implies, possesses poisonous properties. The Dorstenias are herbaceous Brazilian plants belonging to this order. The *Dorstenia contrayerva* has an astringent, bitterish, aromatic root, which is used as a stimulant diaphoretic. The *Dorstenia Braziliensis* is employed as an emetic, and its juice is put into poisoned wounds to avert bad consequences.

The morus, or mulberry, is also referred to this order. The black mulberry, originally a native of Persia, produces dark purple fruit, which has acid and purgative properties. It is used to allay thirst, and to act as a refrigerant. The white mulberry is so named from the colour of its fruit. A peculiar acid, denominated moroxylic, is obtained from it. The leaves of both the white and black mulberry are used to feed silk-worms. The *Morus tinctoria* yields the yellow die called fustic. The bark of the morus, or *Broussonnetia papyrifera*, the paper mulberry, a native of China and the Eastern Archipelago, furnishes a kind of paper, as well as a particular sort of cloth. The *Antiaris toxicaria*, or toxicodendron of Leschenault, yields the ipo, or upas-antiar, one of the famous Javanese poisons. It possesses properties similar to those of the upas-tienté, already described under the article Apocyneæ.

The American caoutchouc is obtained from the *Cecupia peltata*, a species of cannon-wood tree.

From the palo da vacca, the cow-tree of the Caraccas (a species of the genus *Brosimum*), a nutritious milky juice is obtained, which is highly prized by the inhabitants of South America.

ARUM (Linnæus). An extensive family of herbaceous perennial herbs, found in every quarter of the world. Linnæan class and order *Monœcia Polyandria;* natural order *Aroideæ*. Spatha of one leaf hollow. Spadix, apex naked, like a lengthened club, the base serving for a germen; anthers attached to the middle; glands of the top thready; anthers superior; filaments none; anthers seated transversely, two-valved; style none; berry one, or many-seeded. Of this genus there are thirty-nine species, which are botanically divided into three sections, founded on the form of the leaves, viz., composite, simple, and arrow-shaped. Many of them have thick tuberous roots. One, the *A. macrorhizon*, is extensively cultivated in China, and answers the same purpose there as the potato in this country. The *A. colocasia* is said to be cultivated in Egypt. The *A. maculatum* is the only British species, called provincially wake-robin, and is a common plant. It presents, however, the general character of the family.

ARVICOLA (the campagnol or meadow-mouse of Pennant). A genus of *Rodentia*, belonging to the very numerous natural family of the rats and mice. The principal difference of appearance between this and some of the other field mice, is that the tail is shorter, and covered with hair. The meadow campagnol (*Arvicola agrestis*) is a well-known and by no means rare British species. It is reddish brown on the upper part and ash-coloured below, with the tail only about one-third the length of the body. It inhabits meadows rather than corn fields, though it is sometimes accused of committing depredations on the latter, and it forms its nest of dried grass. The accusations about plundering the crops appear to be in a great measure disproved, or at all events rendered very doubtful, by the kind of places in which the animal is most generally met with. These are low-lying pastures covered with tall herbage, and, as it appears, the more moist the better they are liked. From this circumstance one would be led to conclude that its food is not entirely vegetable, but that it seeks insects and other small animals among the roots of the grass. Its history appears to be in some way confounded (at least in the books) with that of other field mice, which take up their abodes in drier situations, and more among the fields under crop.

Another species of this genus, new to British natural history, has been discovered by Mr. Yarrell, and was by that gentleman brought before the Committee of Correspondence and Science, of the Zoological Society of London, on the 22nd of May, 1832. This new species the discoverer has named *Arvicola riparia*, the bank campagnol, from the places which it chiefly inhabits, and in which it nestles. These are ditch banks and hedge bottoms, and it is said that the nest, unlike that of the other species, is formed of wool. The body of this species is smaller than that of the other, and the ears do not stand out so prominently. The tail is also longer, consists of four more vertebræ, and has the hair near the tip somewhat elongated. It is altogther a smaller animal than the meadow campagnol, but it has the appearance of greater energy and strength; and from some differences in the internal organisation it probably feeds still more upon animal matter. For an account of the foreign species see Campagnol.

ASARABACCA. The asarum of botanists, a genus of five species of hardy herbaceous perennials, natives of Britain and North America. Linnæan class and order *Dodecandria Monogynia*, natural order *Asarineæ*. Generic character: fruit inferior; calyx corolla-like, joined to the germen, bladder or bell-shaped, limb three-cleft, erect or revolute; stamens situate on the germen; filaments awl-shaped, anthers fixed below the apex of the filaments, two-celled; style thick, short; stigma six-lobed; capsule leathery, six-celled; seeds covered with a glandular substance, which, when off, shows a semilunar spot. This plant is said to grow wild at Rochdale, in Lancashire.

ASBESTOS, or AMIANTHUS, a mineral which derives its latter name from a Greek word signifying *unstained.* This was given to it by the early mineralogists from its power of passing through fire without soil or stain.

Flexible asbestos is of a whitish colour, approaching to green, but in some few cases of a bright red. It occurs in veins in serpentine at St. Keven, in Cornwall; and is found in a number of places in Scotland, especially in veins of micaceous slate at Glenelg in Inverness-shire. On the continent of Europe it is found in the Hartz, in veins of primitive greenstone; in Bohemia, in metalliferous beds, along with magnetic ironstone; in Upper Saxony, in veins of serpentine; and in a similar situation in Silesia and Switzerland. In Dauphiny, and on the St Gothard, it is found in contemporaneous veins in gneiss and mica slate. Uncommonly beautiful white and long fibrous varieties are met with in the Val de Serre in Savoy, at Cogne in Piedmont, and in the island of Corsica. The mineralogist may also readily supply his cabinet with specimens from the Uralian mountains, and from several places, in the United States of America.

Flexible asbestos was employed by the ancients to form a species of incombustible cloth; in which the remains of persons of distinction were consumed on the funeral pile. The cloth was afterwards withdrawn from the fire and inclosed with the ashes in an urn; and it is a curious fact that there now exists in the Vatican an asbestos shroud, containing ashes and burnt bones several thousand years old. The value of the asbestos mainly depends on the length of its fibres, and also on its whiteness and flexibility. In preparing the cloth, the asbestos is first carefully washed to free it from all impurities; and its fibres then laid straight and interwoven with flax. The fabric is then passed through a furnace, by which the flax and oil used in the operation of weaving are consumed, and the process is completed. The natives of Siberia weave gloves, caps, and purses of asbestos; and it is formed into girdles, ribands, and other articles, in the Pyrenees.

Asbestos is a very slow conductor of heat; and the editor of the present work was presented by the Chevalier Aldini with a glove of this mineral, in which the hand was so perfectly protected from the action of fire, that a bar of glowing hot iron might be grasped, and held for some minutes without the slightest inconvenience. This property has suggested the employment of an entire dress for the use of firemen. It has also been employed for an incombustible wick to a spirit lamp.

The *common asbestos* is darker in its colour than the preceding. It occurs massive, and in distinct fibrous concretions. When acted on by the blow pipe it fuses very readily into a slight greyish globule, similar to enamel. This mineral is found in serpentine and in primitive greenstone; it also occurs in metalliferous beds along with ironstone as well as with copper-ore. It is found, though but rarely, in Asia, and the United States of America.—See Rock Cork, and Rock Wood.

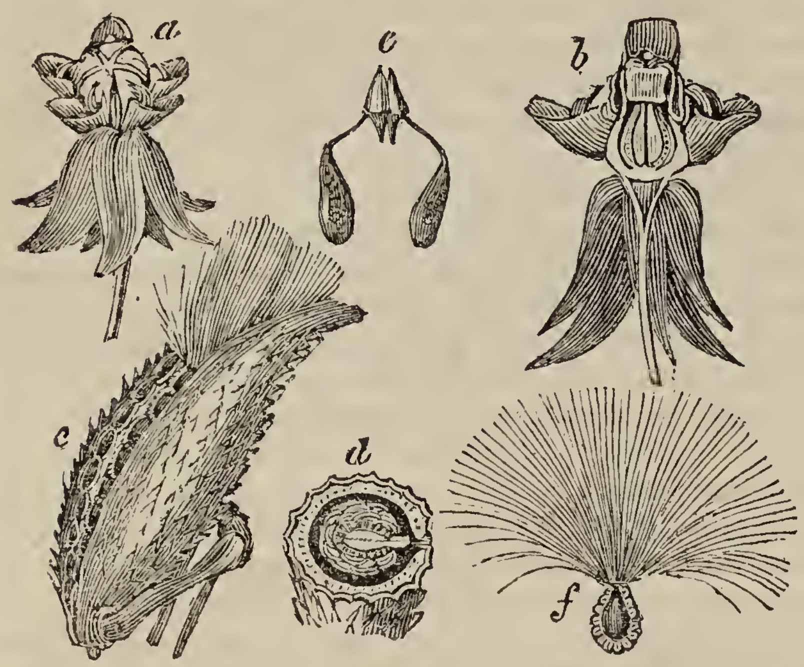
ASCARIS (Lamouroux). A genus of intestinal worms, of the order *Nematoides*, Rudolphi. Cuvier, having for its character, body cylindrical, attenuated at both extremities, the mouth surrounded or preceded by three tubercles. This genus is very numerous, and the animals which compose it are easily distinguished from all others, although the species are often confounded with each other. They appear to acquire their full growth in a very short time; some are scarcely half a line in length, while others attain a considerable size.

These worms are very common; some animals nourish many species, some of them in great numbers; others are solitary or rare, and we only observe them in certain seasons. The greater part of these animals are found in the intestinal canal; others in the interior of the lungs, and various other parts of the body.

There are nearly five hundred species described; about two-thirds are certain, the others still doubtful. It is probable that many remain undescribed, and in many instances the same species has been described under different names, in consequence of their appearance at different stages of their existence. The more remarkable species are the *A. lumbricoides*, Linnæus, which is sometimes found twelve inches long. It is found in the intestines of the human body, the ox, the hog, the horse, and the ass; they sometimes increase so much as to cause serious illness in children. The *A. mystax*, Rudolphi, is found to inhabit the intestines of cats, both in a savage and domestic state. The *A. maculosa*, Rudolphi, is found in the domestic pigeon and the turtle dove. The *A. echinata*, Rudolphi, is a very singular species; the head presents three great tubercles; the body is attenuated behind, and terminated by a tail, long, very slender, turned up at the extremity, and all the surface presents a number of little needles (*aiguillons*) directed backwards, situated in transverse ranges. It lives in the intestines of the gecko.

ASCLEPIADEÆ. A natural family of dicotyledonous plants, containing between forty and fifty genera, and upwards of two hundred and sixty species. They are closely allied to the apocyneæ, but differ from them in having the stamens united together so as to form one body, and the pollen coherent in masses of a waxy substance to the five corners of the flat central stigma. The essential botanical characters are in other respects so similar to those of the apocyneæ already detailed, that it is needless to enumerate them. The plants included in this order are generally shrubby, but occasionally herbaceous, and sometimes climbing. They are found abundantly in Southern Africa, India, New Holland, and the warm regions of America, more rarely in temperate climates. Some of the succulent genera inhabit the dry sterile plains of the African continent.

In their general properties also the asclepiadeæ bear a close resemblance to the apocyneæ. They yield a milky juice, which is acrid, bitter, stimulating, and sometimes poisonous. Many of them are used in medicine, and some are employed as articles of diet. The properties of the order will be best shown by adducing a few examples. The asclepias, one of the genera of this order, furnishes numerous species which are said to be confined to the eastern side of North America. This genus gives origin to the name of the order, and is valued for the beauty and hardiness of most of its species. The infusion of the root of the *Asclepias decumbens* excites a general perspiration without raising the heat of the body much, and it is used in Virginia in cases of pleurisy or inflammation of the membrane lining the chest. It has also purgative properties, and has been administered in dysentery.



ASCLEPIADEÆ. *a*, flower; *b*, vertical section of the same magnified; *c*, fruit; *d*, horizontal section of the same; *e*, apparatus of the pollen; *f*, seed.

The root of *Asclepias tuberosa*, the butterfly-weed, a plant found in the United States, is also used both as a diaphoretic and purgative. The *Asclepias curassavica* acts as an emetic. The root of the *Asclepias gigantea*, or *Calotropis mudarii*, a native of Bengal, when well washed and dried furnishes a substance called mudar, which is a powerful sudorific, and has been used, more especially by the native practitioners in India, in cutaneous and glandular diseases as well as in rheumatism. A peculiar principle, *mudarine*, has been found to exist in it, which differs from other known substances in gelatinising by heat and becoming liquid on cooling. The *Asclepias Syriaca*, Syrian dog's-bane, is poisonous to dogs, and also to man. It yields a resin, and a considerable quantity of caoutchouc. It is furnished with appendages to the flower which act as fly-traps. The young shoots when boiled become esculent, and taste like asparagus. The application of heat in this instance, as in many of the apocyneæ, deprives the plant of its poisonous qualities. The *Asclepias lactifera* furnishes abundantly a sweet milky fluid which is used as food by the Indians. The fibres of the stem of the *Asclepias debilis* are made into a sort of flax, which has a rich gloss and possesses great strength.

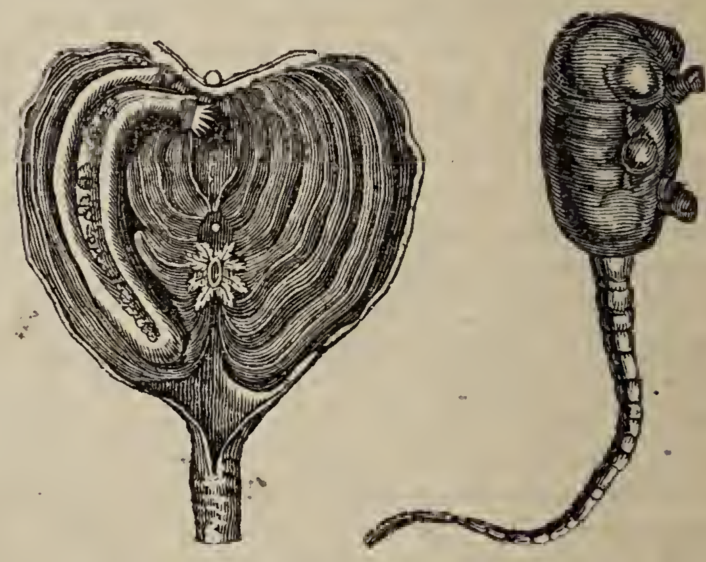
The *Cynanchum*, another important genus of this order, grows in northern latitudes. It is said, however, to extend from 59° north latitude, to 32° south latitude, a wider range than that usually enjoyed by individuals of the vegetable world. The roots of *Cynanchum vincetoxicum*, swallow-wort, tame poison, have a nauseous odour and a bitter acrid taste, which are lost by drying. They excite vomiting and purging. The *Cynanchum monspeliacum* furnishes a strong purgative concrete juice, known in commerce as the scammony of Montpelier; while the Smyrna scammony is furnished by the *Periploca scammonis*, another plant of this order. The leaves of the *Cynanchum oleæfolium*, or argel, found in Nubia and Egypt, are often mixed with those of senna; they possess similar properties with the latter, but are apt to be too powerful and cause colic. The *Cynanchum ipecacuanha*, a native of the Isle of France and Bourbon, and called sometimes, from its properties, *vomitorium*, has an acrid bitter root which is used as a strong and active emetic. It is one of the species of white ipecacuan.

The stapelia is a peculiar and extensive genus found in southern Africa. Its flowers are commonly coloured, and have an offensive odour, while fleshy stems supply the place of leaves.

The *Gymnema lactiferum*, a plant found in Ceylon, called by the natives kiriaghuna (from kiri, milk), yields a nutritious milky juice, like the cow-tree of the Caraccas, or the milk-tree of Demerara.

The genus pagularia is esteemed for the fragrance of its species. The young shoots of *Pagularia edulis*, as well as those of *Periploca esculenta*, and *Asclepias aphylla*, are used for food. *Ceropegia* is valued for its singularity. *Hoya*, is a climbing genus which, from the clustered odoriferous waxy flowers of many of its species, and the honey which they distil, must be familiar to all who are in the habit of visiting green-houses.

ASCIDIA (Linnæus, Lamarck). The body of this molluscous animal is oval, conical, or cylindrical; sometimes club-shaped. It is contained in an external envelope, more or less coriaceous, or subgelatinous, fixed by its enlarged or pedunculated base, and posteriorly terminated by two short siphons, indistinct and unequal, whose orifices are internally furnished with radiated tentacula, but slightly salient. This genus is divided into three :—first, such as have no very definite form—rugose, coriaceous, and but little or not at all extensible, of which the *A. microscomus* is an example; the second possesses a soft skin, flexible, and more or less extensible, *A. intestinalis*; and the third oval, regular, with a more or less elongated peduncle, *A. clavata*.



Ascidia Australis.

The species of this genus amount to thirty-three, according to Gmelin; but Lamarck only enumerates twenty-two. They appear to inhabit every part of the ocean, but particularly the Northern Seas, where they live attached to submarine bodies, frequently at a great depth. It is extremely difficult to distinguish their species.

Their classification, in De Blainville's system of Malacology, is seen by a reference to the article ASCIDIACEA.

ASCIDIACEA (Linnæus and Lamarck). These small marine animals are enveloped in an immoveable gelatinous, or coriaceous case, more or less rough and contractile, adhering or fixed by the reversed buccal extremity, free and terminated at the other extremity by two indistinct mammillary tubes, each pierced with an orifice, often papillary, and more or less approximated ; the larger and most elevated leading into the bronchial cavity, at the bottom of which is placed the mouth, and the other in the common tube at the termination of the intestinal canal, and to that of the other organs, the reticulated branchiæ lining the branchial cavity.

De Blainville forms of the Ascidiacea his first family of the order *Heterobranchiata*, class *Acephalophora ;* he observes, that to understand the relation existing between the animals of this family and the *lamellibranchiata acephalophora*, it is only requisite to compare them with the last genera of that order, which are constantly in a vertical position ; the buccal extremity beneath, and the anal uppermost ; the hard and coriaceous envelope of the ascidia is analogous to that which covers the body, and particularly the tubes of the truncated mya. The two short tubes which terminate it, and even the papillæ, more or less internal and radiated, sometimes observable, are also found in the little bifurcated extremities of the united siphons of the mya and some of its congeners ; the muscular part of the abdominal mass has disappeared, as not being of any more use ; the mouth is in the same position, but without labial appendices, and the branchiæ are, in fact, in the same place as in the last lamellibranchiæ, namely, in the tube itself, but their form is quite different. As to the form of the stomach, liver, heart, and even the other organs, it is evident there is a very great analogy of structure and of position.

ASCOMYS. A genus of *Rodentia*, or gnawing animals, of which there is only one known species. It belongs to the great natural family of rats and mice, and is about the size of the common rat. It has four grinding teeth on each side of both jaws, in the form of compressed prisms, the first double, and all the others single. The incisors in the upper jaw are marked by two furrows in front. There are five toes on all the feet, and the three middle ones in front have very long and crooked claws, flat on their under sides, and well-adapted for digging in the ground. It has large cheek pouches, which give a singularly thickened appearance to the sides of the head and the upper part of the neck ; and on account of these, some authors have called it *mus bursarius*, or the pouched mouse ; but as the term " pouched," when applied as part of the general description of an animal, usually refers to the existence of a *marsupium*, or abdominal pouch, in the female, the general use of the word in any other way is exceptionable. This animal is very low on the legs, but it is an expert digger, and lives in very deep burrows. Its haunts are the uninhabited parts of the interior of North America ; and its food is understood to be vegetable.

ASCYRUM (Linnæus). A genus containing five species of North American, chiefly green-house, shrubs. Linnæan class, and order *Diadelphia pentandria*, natural order, *Hypericineæ*. Generic character : calyx of four sepals, the interior largest ; corolla four-petaled ; stamens variously united at the base ; styles three, sometimes only one or two ; capsule one-celled, three-valved ; valves bearing the placenta on their margins.

ASH-TREE. The *Fraxinus excelsior*. One of our most common and useful trees. Linnæan class and order *Polygamia Diœcia ;* natural order *Oleinæ*. Generic character : flowers polygamous ; calyx four-parted or none ; corolla of four petals, four-parted or not ; stamens short ; anthers ovate, two-celled, opening outwards ; stigma almost sitting, divided ; fruit two-celled, compressed, winged at the top, often one-seeded.

The Ash Tree.

The ash, from its long standing in Britain, may be considered a native. In favourable soils it grows to a large size before it is rotten at the core ; and its timber stands next in value to the oak. For all kinds of agricultural implements it is preferred ; and for every purpose where pliability and toughness are required it is inestimable. Whether grown for timber or underwood, no tree answers the purpose of the planter better than the ash. It is, however, injurious to all undergrowths ; its numerous roots run near the surface, and exhaust the soil so much, that neither corn nor grass prosper under its shade. For this reason the tree is unsuitable for hedge-row timber, and should always be, whether intended for timber or coppice, sown or planted by itself.

Cultivation.—The seeds may be sown on fresh mellow loam, in beds, either in autumn, as soon as they are ripe, or kept in dry sand during winter, and sown in April. Most of the autumn sowed seeds appear in the following summer ; and many seedlings of the spring sowings do not rise till the following spring. After standing twelve months in the seed-bed, the seedlings may be transplanted into nursery rows, twelve inches apart, to gain strength, before being finally put out in plantations. Underwoods may be raised by sowing the seeds on clean, well-prepared ground, like a crop of corn ; by which means they seldom fail to succeed. Ash coppice may be cut every seven years for hoops, hedging stuff, &c. ; and every tenth or twelfth year for hop-poles, hurdles, and other fencing materials.

There are above forty species of this tree; and of the common ash there are ten varieties seen in arboretums, or in ornamental plantations. Among these the *F. excelsior pendula* is one of the most curious, the branches running on the surface of the ground instead of rising in the air; but by grafting a scion of the *pendula* upon a tall stem of the common, the branches from the scion hang downwards: hence it is called the weeping-ash.

The Manna Ash (*Ornus rotundifolia*), a native of Calabria, yields the gum called manna; and is mentioned in this place because the tree is erroneously called an ash, though, in fact, it belongs to another genus, which will be noticed in course.

ASIMINA (Adanson.) A genus of four species of deciduous shrubs, natives of North America. Linnæan class and order *Polyandria Polygynia;* natural order *Anonaceæ.* Generic character: calyx three-cleft; corolla of six petals, the anterior smallest; stamens numerous, inserted on the disk of the germen; anthers somewhat sitting, and nearly united; style somewhat ternate; berry egged, fleshy, sitting closely, and full of seeds. These plants being tender are seldom seen in European collections.

ASIPHONOBRANCHIATA. The second order of the class, *Paracephalophora* of De Blainville's System of Malacology.

In these animals the organs of respiration are constantly formed by one or two pectiniform branchia, obliquely placed on the anterior part of the back, and contained in a cavity, the upper division of which is not prolonged into a tube, but which sometimes presents an appendage, or inferior lobe, performing that office.

The shells of this order vary considerably in form; the aperture is constantly entire, and always completely operculated, that is, closed by a horny, but more frequently a calcareous operculum, proportioned to the size of the opening. The name of the order means literally, not possessing branchial siphons.

ASPALATHUS (Linnæus). A rather extensive family of evergreen shrubs, from the Cape of Good Hope. Linnæan class and order *Monadelphia Decandria;* natural order *Leguminosæ.* Generic character: calyx five-toothed, teeth rather unequal; standard clawed, keel divided; pod oblongly-egged, denuded. There are above thirty species of this genus, all of which are more or less ornamental. They are arranged in two divisions, viz., with leaves in bundles, and leaves trifoliate. The scenery of southern Africa is much enlivened by the flowers of this tribe of plants.

ASPARAGUS (Linnæus). A genus of twenty-six species of herbaceous or low shrubby plants, found in almost all parts of the world. Linnæan class and order *Hexandria Monogynia;* natural order, *Asphodeleæ.* Generic character: corolla somewhat bell-shaped, six-cleft, deciduous; stamens inserted in the base of the corolla; filaments awl-shaped; anthers erect, inversely heart-shaped; style short; stigma three-lobed; berry globular, three-celled, containing seed.

Asparagus has been long in cultivation, and esteemed one of the most delicate productions of the kitchen-garden. In its wild state on the sea shore the whole plant is diminutive, but is capable of considerable amplification by suitable culture.

The physical structure of the plant requires to be well understood, in order to have right ideas of its manner of growth and requisite management. The root, from its peculiar form, affects an open, porous soil; it being a much divided tuber, its divisions extend horizontally, and are furnished with fibres along their whole length. The divisions are attached to and meet together on a collet or crown, whence the shoots arise. The crown is annually enlarged by offsets, which usually proceed from the first in one direction; the first formed crown and appendages consecutively dying off as new divisions are produced. Although the crown, after three or four years, be composed of an aggregation of distinct plants, yet they are not independent of each other, because when united they produce much stronger shoots than any one of the divisions could do if separated; therefore it is a rule in the management of the plant to allow the crown and roots to accumulate and gain strength for three or four years before they are checked by the knife.

To give luxuriance to the whole aggregation is the special object of the cultivator; and whether he sows or plants his asparagus, he must consider that it is not from the seeds or plants which he so carefully puts into drills that he ever should or ever can gather a crop of shoots, but from the new offsets produced from the originals.

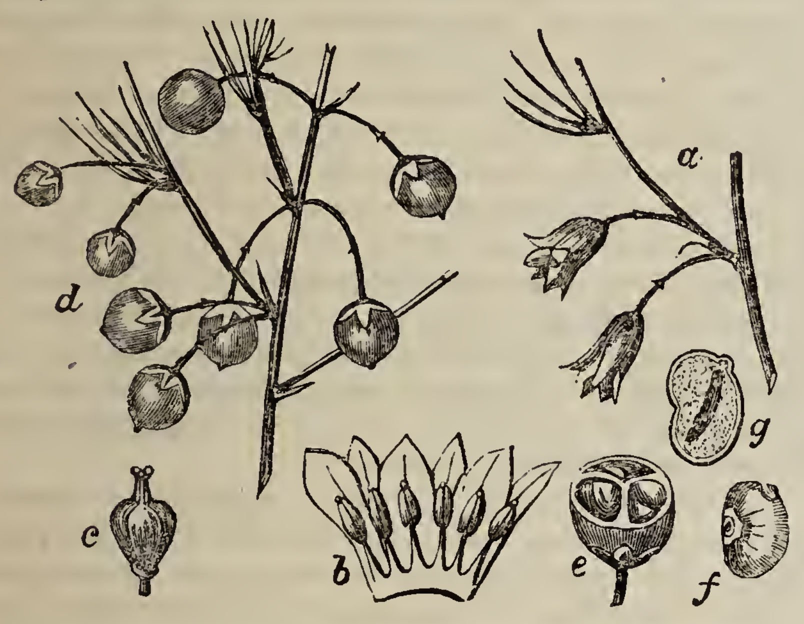
To encourage, and even pamper the plant, by every practicable means, constitutes the art of culture. For this purpose the soil should have a light, friable surface, with a rich substantial bottom, or subsoil. To form such a bed, the usual practice is to bury by trenching (fifteen inches deep) a thick coat of the richest dung that can be procured; not that it is expected the roots will ever descend so deep, but that such a sunken stratum of rich material will be retentive of moisture, and will also be ever evolving a nutritious gas serviceable to the plants. The new surface should also be enriched by a good coat of well-rotted stable dung, leaf-mould, and sea-sand, if it can be conveniently had. All this well incorporated by the spade, and freed from stones, levelled, &c., will be in condition to receive seed or plants.

Although a plantation of asparagus may be laid down by sowing seeds, it is seldom so executed, because much time is lost in waiting till seedlings acquire the necessary strength to produce shoots of a proper size. A better plan is to prepare a seed-bed previously to transplant from, or purchase two-year old plants from a nursery-garden.

The ground should be completely ready for planting any time in the month of March. The first step is to divide the surface into beds of two feet wide, with two-feet alleys between; or three-feet wide beds, with two-feet alleys; or into five-feet wide beds, with two and a half feet wide alleys between. The narrowest beds are intended for single rows; the next for double rows, and the last may have four rows of plants.

All plants rob each other if placed too near together. Of course single plants, or single rows of plants of asparagus particularly, grow more luxuriantly, and yield larger shoots, than when placed in closer order. But as quantity as well as quality are desirable, five-feet beds with four rows, and two and a half feet spaces between, with six-inch margins at the sides, is the disposition most commonly adopted. In first-rate gardens asparagus should always be planted in single rows; not only for the purpose of obtaining superior quality, but for another purpose hereafter to be noticed.

The business of planting is performed in two ways, viz., by drawing drills with the hoe, in which the plants are placed, spreading the roots right and left, the crowns being set against the upright side of the drill, and about two inches deep; the removed earth being afterwards drawn back over them. Another method is to remove two inches of the whole surface of the bed; in this opening the plants are set by line, having their roots spread out in their natural positions, and afterwards covered up with the removed soil. The distance from plant to plant in the rows may be nine, ten, or twelve inches, according to the size of the plants.



Asparagus Officinalis. *a*, flowers; *b*, corolla opened to show the stamens; *c*, pistil and ovary; *d*, fruit; *e*, horizontal section of the fruit; *f*, seed, magnified; *g*, vertical section of the same.

The summer management of such a plantation only consists in keeping the ground free from weeds by frequent hoeings, and paying attention that no deep-rooting perennial weeds, such as docks, dandelion, birdweed, &c., get established among the roots of the crop; for if they do, they are ever after a plague to extirpate.

It may be easily conceived that asparagus plants so treated have every chance of succeeding. The soil being open and rich gives every facility for the range of the roots, and consequent enlargement of the crowns and stems. In soils naturally rich, as the alluvial deposits on the banks of rivers, or on sands impregnated with much vegetable or animal matter, we see asparagus succeed without any other preparation than is made for other garden crops, viz., by a simple digging; and it may be safely averred that this favourite vegetable may be had without half the trouble and expense usually bestowed in laying it down. It is well, however, to err on the safe side; and wherever planted as above directed no fears need be entertained of success.

To protect and strengthen the roots, it is an old custom to cover the beds about the beginning of November with short dung two or three inches thick, above which is laid a coat of earth dug out of the alleys. This is supposed to save the roots from frost, and feed them with the juices washed down from the covering of dung. The latter idea is good; but the former is groundless, because no roots are more hardy than those of asparagus. Still a winter covering is useful, not so much for the defence of the roots, but for another reason not always appreciated. In early spring the temperature of the earth at twelve inches from the surface is always higher by ten or fifteen degrees than the air; consequently, roots lying at that depth are sooner excited into action than such as are just beneath the surface; it follows of course that the shoots are ready to rise as soon as the season permits the removal of the covering, viz., about the 20th of March. In this view, and for the purpose of bringing forth the shoots, a covering is necessary, and the thicker it is, the more care is necessary in forking the beds when they are levelled down at the spring dressing, lest any of the points of the shoots are broken by the fork.

The author of this article has long disapproved of this method of spring dressing asparagus beds. Many of the crowns and roots are injured by the tool even in the most careful hands, if put deep enough; and if it be not allowed to go deep enough to break the old surface, it answers very little purpose doing such work at all. A safer method of winter management is this:—As soon as the stems are dead in the autumn, let them be cut down close to the surface and cleared away. Then let the beds be forked over as deeply as may be without disturbing the roots. At this time there is less danger of damaging the crowns because their places can be seen by the remains of the old stems. The surface being thus sufficiently broken, the beds should be covered with at least four inches of old hot-bed or other exhausted dung. Over this may be laid a couple of inches of mould raised from the alleys, and so to remain during winter. This mould is only to be raked off at the spring dressing, leaving what remains of the dung to form the surface, through which the shoots will easily rise, and which is turned in and mixed with the common soil by the fork at the autumn dressing. Supposing the crowns to be at their natural depth from the surface, viz., two inches, and the covering of decayed dung to be two inches more, these together will be a depth sufficient over the crowns to allow length enough of shoot to be cut for use. The advantage of this annual addition of soft mild dung, is its being gradually reduced to a fine fertile mould, particularly well calculated to allow the shoots to penetrate and to yield suitable nourishment to the roots below.

As asparagus plants are much weakened by cutting the shoots before they are well established in the ground, it has become a rule to reserve a new plantation till the third year after it is laid down before any shoots are cut, and even then it is done but sparingly. One shoot from each plant is considered quite enough to be taken in the third year; on the fourth a fine and plentiful return may be expected; and in every following year, if the cutting be done regularly and moderately, a plantation will continue productive for many years, provided care be taken to fill up any blanks that may occur in the beds by the introduction of fresh plants. The long period that this crop keeps, or may keep possession of the ground, is the reason why so much manure is buried beneath the plants in the first place. Manuring afterward can only be applied in the shape of top dressings; and though this may be administered effectually in the case of many surface rooting plants, it is well to have a rich sub-soil for plants intended to remain many years on the same spot.

It has been before observed, that the natural depth for the crowns of the asparagus plant is two inches; and if two inches more be given of artificial covering, shoots allowed to rise four inches above the surface will be the required length for the table. It is the exposed part of the shoot which is eatable; as the white or bottom part produced within the ground is too tough and stringy for use. The shoots, however, may be drawn to a much greater length by extra coverings of any loose substance, as dry peat earth or leaf mould.

The shoots when ready for use are cut with a saw-edged knife, or broken off from the crown by the finger. When the crowns are deeply covered, the knife must be used; but when they are only hidden by two or three inches of loose and easily removed earth, the shoots may be forced off with the utmost facility. In both ways there is danger of damaging the rising shoots if care be not taken in the execution, and certainly less by the knife than by any other means. When cut, the shoots are tied in bundles of quarter, half, or whole hundreds, before they are carried to market.

Asparagus is extensively forced both in private and market gardens, and usually on dung heat. It may also be forced in glass covered pits, by either hot water, steam, or fire flues.

The principle of forcing such a plant as this, is to do it gradually; because, being taken from their native bed, where they have been for years established, and placed in a situation with which they have no previous connexion, they must depend on their own innate vigour or store of nutriment within themselves, to enable them to produce shoots from their incipient buds. Excitement is almost all they receive in their new place; and, therefore, unless they are substantial and in high health, the shoots produced will be few and diminutive. It is for this reason that full aged plants are chosen for forcing, viz., four or five years old from the seed-bed.

Hot-beds for asparagus are made of well prepared stale dung, and more or less substantial, according to the time of the year in which forcing is begun. If wanted for the table in February and March, the bed should be made about Christmas, and not less than three feet in height. When the heat has risen and become moderate, the frame and lights being put on as soon as the bed is made, the surface should be laid so as to be about one foot from the glass, and covered with about five inches of dry loose earth. On this the plants are laid in rows as closely together as possible, filling the openings between the crowns and roots with light dry compost (sandy loam and leaf mould is the best), and covering the whole therewith to the depth of two inches. The steaming heat from the dung will soon make the compost and roots moist enough; but if very dry, a sprinkling of water may be given at planting.

As soon as the shoots appear through the surface, two more inches of compost must be put on; and after they have risen through this, another covering of the same depth must be added, which finishes the earthing up. The purpose of this gradual earthing up is to accelerate the growth of the shoots, and to prevent burning the roots, which, were the whole covering put on at once, would be likely to happen. After this last addition of compost, the frame and lights will require to be raised three or four inches by placing bricks under the corners, and thick twisted straw bands along between to prevent the earth falling out from under the frame. Some practitioners think it better to fill the frame in the first place, so that the roots should be no more than six inches from the glass, and, as the shoots rise and require earthing up, to raise the frame at the same time, so that the shoots shall always be as near the air and light as possible. After the final earthing, the shoots are allowed to rise towards the glass, and then to have as much air and light as can be with safety admitted, because it is these which give colour and flavour.

In the course of this method of forcing asparagus, care must be taken that the heat is never at any time too intense. If the dung has been duly prepared by repeated turnings before made into a bed, there is less fear that it will heat violently afterwards, unless it be too thickly covered with mats, or not sufficient air be given to allow the heat to escape. Very severe weather may be expected, and attention must be paid lest the bed gets chilled. Sharp frost is kept off by surrounding the bed with dry litter and coverings of mats; and, if needful, by hot dung linings rather than the roots be checked by cold. But at all times a temperate rather than a strong heat is required, because the stronger the heat, the smaller and more worthless are the shoots, and their running spindlingly up can only be checked by admissions of fresh air whenever the weather allows. Such a bed successfully forced, continues to yield moderate dishes of asparagus for three weeks or a month after the first shoots are ready to cut.

Asparagus may be also forced in pits built for the purpose, in which there must be a full command of heat, whether by fermentive substances, as tanners' bark, stable dung, or leaves; or by heat, given out by steam or hot water pipes, or smoke flues. The roots should be planted as near the glass as possible, so as to allow space for earthing up and growth of the shoots.

Asparagus planted in single rows on two-feet wide beds may be forwarded in the open air by having the alleys between dug out to the depth of sixteen or eighteen inches, and filled with hot dung or leaves. For this special purpose the sides of such beds are formed of boarding or open brickwork. By this expedient, fine shoots may be had a fortnight or three weeks sooner than they can be had naturally; and as it is only exciting the growth a little earlier than would happen without the application of the heating substance, there is no destruction of the plants. As the full effect of this mode of forcing cannot be had without some kind of covering on the surface, a rank of hand glasses should be employed, and these covered in the night to protect from frost, are all that is wanted. Such narrow beds can only be forced in this manner; but the same should not be forced two years together, as this would tend to weaken the plants too much. The same beds, however, might be forced every third year without injury; and where such practice is intended to be followed, a sufficient number of such beds should be provided.

ASPERGILLUM (Lamarck). SERPULA AQUARIA (Linnæus). In separating this shell from the Linnæan Serpula, Lamarck has been guided by the presumed distinct organisation of the animal, and though the inhabitant is unknown, the different structure of its shell fully authorises his having distinguished it from the Serpula and his constituting a new genus of it.

This singular formed shell is a testaceous tube (Lamarck calls it a testaceous sheath), somewhat curved, though in most instances nearly straight; it gradually tapers towards, and is open, at the upper extremity, becoming rather club-shaped towards the lower end, which is closed by a convex disk, or cover, perforated by numerous small holes, from whence it derives its trivial name of the *watering pot;* in the centre of these a small lengthened fissure is observable; it has a waved sub-tubular fringe-like border, and occasionally two, projecting beyond the periphery of the outer circle. On the side of the tube, near its extremity, are two permanently fixed valves, leaving an open fissure between them, and the exterior of the tube of some species is incrusted with sand.

Lamarck considers this shell an *equivalve bivalve,* allied to the genus *Fistulana,* in which, however, the shell it includes is detached and free, while in the *Aspergillum* it adheres to the sheath, completing, by the two fixed open valves, a part of the tube that encloses the animal. He remarks that it is, no doubt, an error to imagine the shell ever fixed by the open end, which, like the fistulana and clavagella, must of necessity be open to permit the animal's egress. De Blainville observes, that this mollusk probably covers but a small portion of the animal's back, upon which it is, no doubt, attached: he describes two species: the first, *A. Javanum,* which possesses a fringed disc (we may say sometimes more than one); and the second species, *A. Novæ Zeylandicæ,* which is without that fringe, or frill. He adds that, notwithstanding the resemblance between these two species, it is extremely difficult to form an idea of the inhabitant of the aspergillum, and, above all, of the organs which penetrate and form the tubular spines of the disc, without we assume them to be the filaments of a sort of byssus, or of the foot itself, serving to attach the mollusk to submarine bodies; we might then admit of its existing in the sand, attached to a great number of its grains, in a position more or less vertical, the smaller extremity of its tube uppermost, and the head downwards. In his system of Malacology, he has ranged it in the second section of the family *Pyloridea,* the order *Lamellibranchiata,* and class *Acephalophora,* immediately following the genus *Clavagella.* Recent species inhabit Java and New Zealand. De France also enumerates two fossil species. Though this mollusk does not possess any brilliant hue to attract the eye, or a form particularly symmetrical, it is, nevertheless, highly interesting to the naturalist, and has given rise to much speculative reflection, which time alone will satisfactorily elucidate.

ASPHALTUM, or compact mineral pitch, an inflammable resin, which appears to form one of the connecting links between the vegetable and mineral kingdoms. It is of a shining black colour, and breaks with a conchoidal fracture.

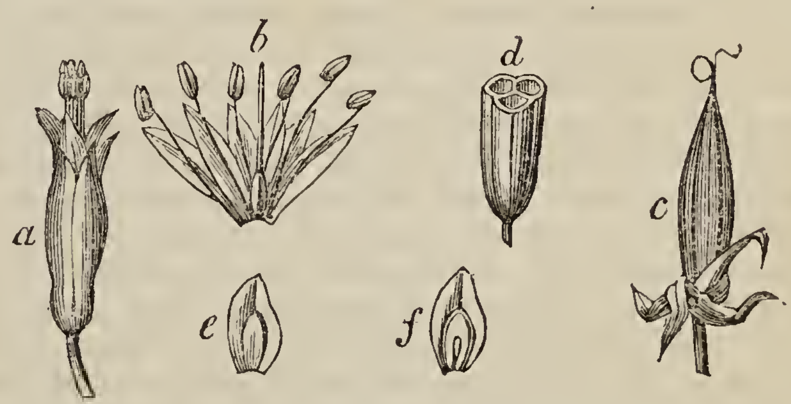
Asphaltum occurs in veins, in secondary limestone, in Fifeshire, and in several other parts of Scotland. The continent of Europe also furnishes great quantities; but Asia and America are the main sources from whence it is derived. It rises in large masses to the surface of the lake Asphaltes, in Judea, and appears to be derived from strata of mineral pitch in the neighbourhood. In the island of Trinidad there is a lake three miles in circumference covered with this mineral, and considerable quantities are brought from Barbadoes. It may be proper to add, that in various parts of the world we find a species of natural unctuous and inflammable substance oozing from the earth, which, under the various names of naphtha, petroleum, earth pitch, and asphaltum, is found of considerable service in the useful arts. The Egyptians formerly employed it for embalming the bodies of the dead; and the Turks still use it, mixed with common resin, for coating the rigging of their ships. The mineral pitch of Trinidad is supposed to have the power of protecting the hulls of vessels from the attacks of the teredo or borer, so frequent in the West Indian seas. See PITCH, MINERAL.

ASPHODELEÆ. A natural order of *Monocotyledonous* plants containing upwards of fifty genera and more than 500 species. It is allied to the lily tribe, but differs from it in its expanded flowers, and dark crustaceous, fragile seed-coat. The essential characters of the order are: calyx and corolla six-parted, or six-cleft regular; stamens six, inserted on the perianth; ovary free, three celled, and generally containing numerous seeds; one style; stigma entire or three-lobed; fruit usually a three-celled capsule.

The plants of this order are generally herbaceous; occasionally, however, they are arborescent. They are all pretty; many of them are showy and ornamental, and as such cultivated in gardens. The flowers are coloured and the roots are bulbous or fasciculated. They are widely diffused over the globe, and are found much more abundantly in temperate than in tropical climates. Some of them grow in the colder regions of the earth. They form a marked feature in the vegetation of New Holland.

Their properties reside in their roots, or bulbs. In general they are bitter and stimulating, sometimes acrid. In many instances they contain much starch, and then are nutritive. None of them are poisonous.

In order more fully to exhibit the properties possessed by the plants of this family, it will be necessary to notice a few of the more important genera included under it.



PHORMIUM TENAX. *a*, flower; *b*, the same opened to show the stamens; and pistils *c*, fruit; *d*, horizontal section of the same; *e*, seed; *f*, the same in section.

From the *Phormium tenax,* represented in the preceding figures, there is prepared the strong fibrous New Zealand flax, which, from its superiority to all other kinds of flax, has now become an important article of commerce.

The genus Asphodelus, whence the order derives its name, contains many showy species which contribute not a little to adorn our flower-gardens, but none of which are put to any particular use.

The extensive genus Aloë is found in this family. It consists of succulent plants provided with thick firm leaves, which absorb powerfully by the surface. The purgative substance commonly known by the name of aloes is obtained from several species of the genus. There are three kinds of aloes imported into this country, viz. the Socotrine, the Barbadoes, and caballine aloes. The first is procured from the *Aloe Socotrina,* or spicate, and was brought formerly from the island of Socotra at the entrance of the Red Sea. It is now procured from the Cape of Good Hope and from the island of Jamaica. The second is called also hepatic aloes, from its resemblance to liver, and is procured from the *Aloe perfoliata*. It is not quite so pure as the first, and is imported from the Levant and the island of Barbadoes. The third variety, called caballine, or horse aloes, differs from the others in being very coarse and impure, and in exhaling a very fetid smell. It is said to be the refuse of the process for making Barbadoes aloes, and is only used in veterinary medicine. Aloes is a stimulant purgative, and acts chiefly on the lower part of the intestines. It is prepared either by cutting the leaves of the plants and allowing the juice to flow out, or by boiling them in water and afterwards evaporating. The purest or Socotrine aloes is got by the former method.

Allium is another important genus of this order. The leek, onion, shallot, chive, rocambolle, and garlic are all species of the genus. In general they are stimulant, and are used as condiments to promote digestion and excite the appetite. Garlic, or the allium sativum, besides being an ingredient in the epicure's sauces, is employed medicinally as a powerful diffusible stimulus. It is also administered in cases of retention of urine. The onion (*Allium cepa*) was worshipped as a divinity by the Egyptians. It contains a volatile oil combined with sulphur, and has been used in dropsy. Most of the alliums act as rubefacients, and some of them as blisters.

The genus *Scilla* possesses properties in many respects similar to those of the allium. From the large scaly root of the *Scilla maritima*, a plant which grows on the sandy shores of the Mediterranean, a medicinal article is procured, known by the name of squills. This is a bitter stimulant substance, which is very extensively used. It acts chiefly on the lungs and kidneys, possessing expectorant and diuretic virtues. It also acts in large doses as an emetic. From its stimulating qualities, it cannot be employed in any active inflammatory complaints. Squill root contains an acrid principle, called scillitine, which is volatile; and hence it loses by keeping or too much drying. The inhabitants of the Pyrenees use the bulb of the *Scilla lilio-hyacinthus* as a purgative. The roots of the *Scilla esculenta*, esculent squill, or camass, are eaten by various Indians on the North-west coast of America; and a kind of cake is made from them.

The common asparagus, which in its young state is a delicate article of food, is used as a diuretic, and is said to exert a peculiar sedative effect on the heart's action. The shoots of most of the species, even of those which afterwards become woody, may be used as food in their young state. The long fleshy roots of the *Asparagus sarmentosus* are eaten with milk by the inhabitants of Ceylon. An extract is procured from the roots of many of the species of asparagus, and a crystalline matter denominated asparagin.

The *Dracæna Draco* yields a concrete juice, called gum dragon, which is used as a styptic, to stop bleedings and discharges. The *Dracæna terminalis* is diaphoretic, and its root is used in Java in dysentery. *Ti*, a favorite spirit of the Sandwich islanders, is prepared from this plant. Several gigantic species of *Dracæna* are found in the Canary Islands.

Xanthorrhœa hastilis yields the yellow gum resin of New South Wales. In consequence of its spiral leaves hanging down on all sides, this tree is called by the English inhabitants of Port Jackson, the grass-tree. It is used as a styptic and anti-dysenteric.

The thick tuberous roots of the *Yucca gloriosa*, Adam's needle, have been used by the Indians in place of bread.

The root of the *Ornithogalum umbellatum*, common star of Bethlehem, which is eaten to the present day in Palestine, is said to be the *dove's dung*, mentioned in the Second Book of Kings, chap. vi., v. 25. The fragrant flowers of *Ornithogalum corymbosum* are used by the Peruvian females as an article of ornament for the hair.

We might have noticed the Hyacinth and several other beautiful genera, belonging to the Asphodel family, were it not that those already alluded to are sufficient to show the properties of the order.

ASPHODELUS—Asphodel (Linnæus). A family of ten species, herbaceous flowing perennials, natives of Europe. Linnæan class and order *Hexandria Monogynia*; natural order *Asphodeliæ*. Generic character: corolla six-petaled, spreading; stamens, filaments form a vault with the base of the petals, connected, arched, awl-shaped; anthers incumbent; style awl-shaped, bending upwards; capsule leathery, three-celled, full of seeds; seeds angular. These plants always find a place in the shrubbery borders, as they are of rapid growth, and flower readily; they are also easy of propagation by division.

ASPIDIUM (Swartz). One of our most numerous and beautiful families of Ferns. It is called the shield fern, from the form of the indusium of the fructification. The genus consists of forty-eight species, of which thirteen are natives. Generic character: sori, roundish and scattered, or deposited in ranks; shields solitary, roundly peltate, or kidney-shaped, fixed by the middle or the edge. Cryptogamists have arranged the genus into five sections, founded on the forms of the fronds, viz. ternate, pinnate, bipinnate, bipinnatifid, and supradecomposite.

ASPIDOPHORUS, a genus of spinous-finned fishes, belonging to Cuvier's family of *Joues cuirassées*, or those which have the cheeks armed with thick and strong scales, or osseous plates. The fishes of this genus have not the cheeks only, but the whole body and tail so armed. They have also the gill-covers bordered with fleshy filaments. The mouth opens under the muzzle. They have not teeth in the *vomer*, and by this they are distinguished from the bull-heads (*cottus*), with which at least some species of the present genus have been confounded. The scales with which the body is covered are large and angular, and thick and tuberculous in the middle. They have in general two dorsal fins.

There is one species which is met with on most of the coasts of Europe, the common pogge, or armed bull-head. It has the head large, the plates upon it also large, forming a complete armour; four small spines on the snout; and the fleshy fibres of the gill-covers so long as to hang like a beard under the throat. It is a small fish, seldom met with more than four or five inches long, and in an economical point of view it is of no value.

There are other species, chiefly in the Pacific Ocean, some of which differ in one respect or other from the pogge; as, some have the mouth in front, and the two jaws of course equally produced; others have the gill-covers smooth; and there is an Indian species with but one dorsal fin, which Lacépède has, apparently without much reason, formed into another genus, *Aspidophoroides*.

ASPLENIUM (Linnæus). A family of ferns consisting of forty-seven species, natives of almost every region of the earth. Generic character: sori in lines along the sides of the veins; indusium, a membranous plane, opening at the side. This tribe is divided into six sections, founded on the form of the fronds.

ASPREDO. A genus of soft-finned fishes, with abdominal fins, belonging to the natural family of the *Siluridæ*, and by the elder ichthyologists included in the genus *Silurus*. They have one remarkable character, not to be met with in any other of the bony fishes, and yet in which they can hardly be said to approach the cartilaginous ones. Their gill-lids are immoveable, and there is merely a slit on each side of the neck, by means of which the water used in respiration is discharged after it has passed through the gills and performed its office there. The gill-lid is incapable of motion; and thus it is a question how they contrive to produce a current of water through the gills when they are at rest, as the motion of the gill-lid is supposed to assist in that operation in all the other bony fishes. Their head is flat, and the eyes very small and placed in the upper part of the head. The anterior part of the body is much enlarged, especially in breadth. They have two teeth or spines upon the first ray of the pectorals, much larger and more formidable than those on any of the siluri. There is but one dorsal fin; but the anal fin is long, extending to the tail, and the tail is slender as well as long. As is the case with that of most of the family, their flesh is little esteemed.

ASPRO. A genus of spinous-finned fishes, so called from the roughness of their scales. They belong to the *Percoidæ* or perch family, and in many of their characters they have a considerable resemblance to the common perch. The leading characters are,—the body elongated, with two dorsal fins considerably apart from each other, and with the ventral fins very large; the head is depressed, and the muzzle projects beyond the mouth, and is rounded at its termination.

Two species are found in some of the rivers of Europe; but so far as observation has gone, they are not generally distributed even where the latitude and climate are nearly the same. The flesh of both is esteemed as pleasant to the taste, and light and easily digestible.

One species, *l'apron* of the French, is found in the Rhone and its branches. It is the *Aspro vulgaris* of Cuvier, and *Perca asper* of Linnæus. It is of a greenish colour, with three or four vertical bands of black upon each side. It grows to about the same size as the common perch, only it is longer in proportion. This species has eight rays in the first dorsal fin.

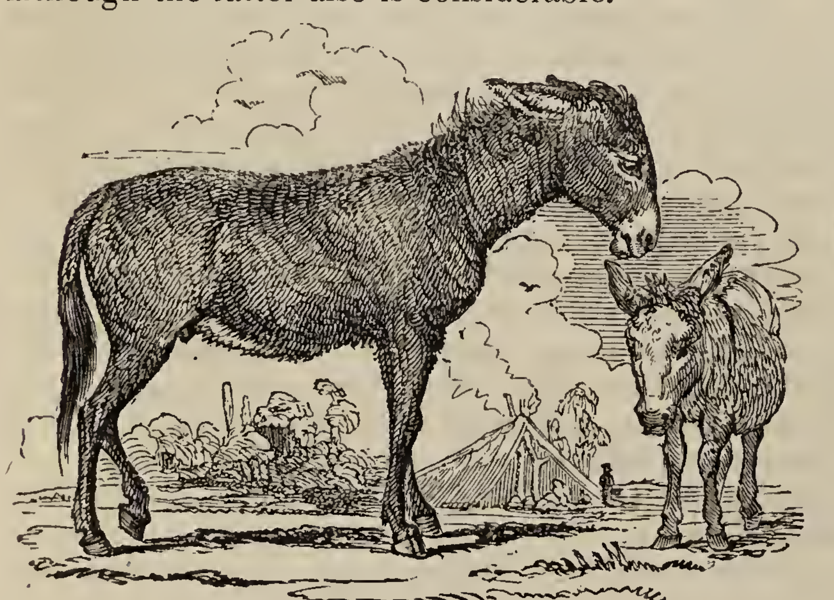
The other European species is found in the Danube; it is the *Zingel* (*Perca zingel*) of Linnæus. It is larger than the other, but coloured nearly in the same manner. It has thirteen rays in the first dorsal fin.

ASS (*Equus asinus*), a well-known, but, in this country at least, not equally well-used animal. It is a species of the genus *equus*, or the horse, and intermediate between the horse, properly so called, and the zebras or striped species of the same genus. The genus forms the third family of Cuvier's *Pachydermatous* animals, the family *Solidungula*, that is one-hoofed or solid hoofed. Attempts have sometimes been made to make the ass a genus separate from the horse, but they have, very properly, not been generally adopted. There are *specific* differences certainly, but there is not one *generic* one: and the same law of subdivision, which would make two genera of the horse and ass, would, if carried generally into natural history, destroy the foundation of all generic classification. The discovery of a new genus is however reckoned so very great an honour among systematic naturalists, that it is no wonder that some of those who have not the opportunity of discovering a new genus, should be occasionally tempted to "do the best they can," by making one. The present instance is, however, far from a happy one for such an experiment.

In this country, the ass is seen under very great disadvantages, and, independently of the climatal deteriorations, and the greater deterioration arising from bad treatment, there is a prejudice attached to the very name. Ironically, it is, in vulgar language, used to express dulness and stupidity in human beings; and this, its metaphorical meaning, is thrown back with additional degradation upon the animal. Why this should be so strongly the fact in the case of the ass, does not appear explainable upon any very rational grounds, as it is not so in the case of some other animals. Thus, to call a man "horse," is neither very consistent with polite speech, nor very complimentary; and yet that does not in the least detract from the character of the horse, which still holds its place, by common consent, and in common parlance, as "the noblest" of domestic animals. Something may depend upon the owners and the usage of the animals, though when the horse is past honourable and respectable service, rating the treatment according to the power of endurance, he is probably the worse used animal of the two. Much as Englishmen boast of their horses, and carefully as they tend and pamper them while handsome, the pathetic ballad of "The High-mettled Racer" is still a faithful biography of perhaps ninety-nine out of every hundred horses in England. A few, no doubt, are allowed to spend their last days in ease and plenty; but they are so few that they form the exception and not the rule. The character of the animals appear, however, to be taken from the condition of their owners, and the treatment which they receive in their best service, and thence may arise the difference.

The ass, from its low price, the cheap rate at which it can be maintained, and its exemption from state imposts is, in an especial manner, the poor man's beast of burden. But the state of modern society in Britain is such, that the more settled, constantly occupied, and, for these reasons, the more respectable of the poor, do not require beasts of burden. They are almost all employed for others; and therefore the ass falls into the hands of persons of another description —those who have no home or no constant employment at home, but who must wander about the country in the profession of the lowest description of huxters, or with no profession at all. Though persons of this description cannot be said to be altogether out of society, they are of necessity deprived of many of its advantages. They get no character from the more regular part of society; and it appears to be a sort of law of human nature, that persons who are too poor to purchase a good character (for, in a mercantile country, that article has its price as well as others), are never able to acquire one, unless the world gives them some little to begin with. Such persons are necessarily without many of the wholesome restraints of regular society; and, which is of far more importance, though but too often overlooked, they are without the incentives to virtue, which are the more pleasing results of an orderly society. They are thus led, or perhaps it is more correct to say driven, to associate with each other; and it seems to be the nature of society to be progressive, whether in the gaining of character or the losing of it. Now it is chiefly to such persons and such societies that the ass belongs; and therefore he suffers, not only by the treatment which he receives from his owners, but from the opinion which, right or wrong, the world has of them. There is, of course, no moral, and except what has been stated, no social necessity, why a man who possesses, or rides, or drives an ass, should either be a man of rough character, or one who will treat the animal with cruelty; but the fact is so general, that very unequivocal proofs are necessary to restrain suspicion, even when there is not otherwise the least ground for suspecting.

These observations may, at first sight, seem to have more connection with the civil history of men than with the natural history of asses; but as we form our opinion of the animals from the condition in which we find them, it is necessary to show how they come into that condition, and that it is neither natural to them nor in any way their fault. It is true, that even the warmest part of England, even with the best treatment, is too cold for the full development of the natural appearance and character of the ass; and that, as the latitude increases, the adaptation becomes worse. But the effects of climate would not alone produce that diminution of the stature and deterioration of appearance which he has in England, as compared with the south of Europe and the isles in the Mediterranean. The contrast between the Maltese ass and the English ass is, in some respects, greater than that between the Arabian horse and the Shetland pony. (See engraving.) The bodily distinction is not so great, certainly; but that of the spirit of the animals is much greater. The pony is small in size and shaggy in covering; but there is still fire in his eye and mettle in his limbs; and small as he is, he is still "every inch a horse." The ass, on the contrary, is more dispirited than dwarfed, although the latter also is considerable.



Maltese and Common Ass.

How much, or whether any of the deterioration of the ass, in point of spirit, depends upon the circumstance about to be stated, has not been investigated; and, indeed, so far as the writer of this article is aware, the question, though it is a curious, and no doubt might prove to be an important one, has never been once mentioned by any one writer on natural history. The point is this, the ass remains far more stubbornly true to its normal type than the horse. The ass, in fact, breaks less into varieties, even varieties of colour, than any other domesticated animal. There is some reason to believe that it was domesticated at an earlier period of human history than the horse; and there is no reason to suppose that its domestication took place later. The Bible is certainly the oldest authentic history that we have; and it shows that in ancient times the ass was the general, if not the universal saddle animal for all who could afford to ride; and that the horse was used, if not exclusively, yet generally for warlike purposes only. It is not our object to institute an inquiry into the history of either animal in a domesticated state, or to trace the means or mode of their distribution from the central parts of Asia, of which it is probable that both are natives, to the several parts of the civilised world, and till the horse, at least, has become wild in the plains of South America, and the hybrid progeny of the two has become the great beast of burden, in the difficult and dangerous passes of the Andes. It is sufficient for our purpose to know that the domestication of the ass is, at least, not later than that of the horse; and that point admits of no dispute or question.

Now the horse has broken into innumerable varieties, not of colour merely, but of size, shape, and spirit; so that, not only has each country its peculiar horse, distinct, and well known to all who are acquainted with the character and points of the animal, but each small district, nay each kind of employer of horses has a marked variety. This is so palpably the case, that even the most common observer in the streets of London, who knows nothing about the economy of horses, or the preservation of the variety by "breeding in and in," or the change of it by "crossing," can at once distinguish a brewer's horse, a coal-merchant's horse, a carrier's horse, a farmer's horse, and so of all the horses which are regularly employed in a particular way, and bred for that employment. In all these, again, there are subordinate varieties, in colour, size, and various other respects; so that the horse appears particularly pliable to circumstances, whether of climate or of treatment. Many other domesticated animals, the ox, for instance, do the same, but none perhaps so readily, or to the same extent, as the horse.

But the ass shows no such varieties. There are trifling changes in the shade of its colour, and some individuals are nearly white; but the last are, from the red colour of their eyes, obviously albinos, and in the other cases, it is a simple change of shade in the colour, and not a breaking by the introduction of a new one. We do not find pied asses, or asses with a white blaze in the forehead, or white feet, neither do we find them dappled; at least if there are any such instances they are exceedingly rare. They also retain the mesial line on the back, and the transverse band which forms the cross upon the shoulders. Its coat may be sleek or it may be shaggy, according to the climate to which it is exposed and the treatment with which it meets; but it so preserves even its external specific characters, that it every where seems the very same ass, without the least tendency to variety. It is highly probable that the diminished size, and increased length and shagginess of the hair, which take place in this and in other species of mammalia, when made to reside in countries much colder than those which are natural to them, are connected with each other; and that that portion of the substance and action of the animal which, in the cold climate, goes to the production of the additional covering, would, in a more genial climate, go to increase the size and flesh of the animal.

To this law the ass yields, but still it yields as a whole; for it preserves its form even more pertinaciously than its colour. It is usually said that the ears of tame asses are longer in proportion than those of wild ones, but the fact is not very fully established. In other respects, however, the former, in all climates and under all modes of treatment, is true to the type. The head never gets disproportionally large, the legs never thicken; and the change falls so equally upon all parts of the animal, that one cannot upon any just grounds consider it as a variety.

There is still another circumstance which is worthy of consideration as tending to show the stubbornness with which the nature of the ass adheres to its normal type, and that is the case of hybrids. Analogy points out as a general law of animated nature—and though it has only very recently, and, as one may say, incidentally, been made a matter of scientific research, observation, so far as it has gone, appears to establish the fact—that in the case of hybrids the external form takes more after the male, and the constistitution and disposition, and where there is a difference in that, the internal organisation, takes more after the female. In the hybrids between the ass and horse, however, the stubbornness of the former animal to its normal type appears to give a predominating character to the hybrid.

There are, of course, two hybrids between these species, the *mule* when the male is an ass, and the *hinney* when the male is a horse. The former has not only much more the external characters of the father than of the mother, but it has many of the constitutional qualities—the patience, the temperance, the hardihood, and, as it is called, the stubbornness. The mule is not nearly so showy, so fleet for a short distance, so dashing, or so headlong as the horse, but, give it its pace, and it can do more, endure more, may be said to be at once the most cautious and the most sure-footed of animals; and for these reasons it is chosen to bear loads along paths where hardly any other animal could maintain its footing, even though unloaded. The hinney has some of the external characters of the horse, but not nearly so many as the mule has of the ass; and those which it does have are more localised and broken, and appear in particular parts rather than in the general aspect of the animal. The ears are proportionally shorter than those of the mule, and the head and tail have some resemblance to those of the horse, but the general aspect of the body is not a little asinine. It has none of the qualities of the horse, and even the better ones of the ass appear to be deteriorated by the cross. There is another point:—the beauty and value of mules depend far more upon the superiority of asses than on that of horses; and therefore mules of the best quality can be bred only in countries where asses are less deteriorated than they are in England, though the horses of that country may be of an inferior description.

There is another point still, which though more vague than any of those that have been stated, is yet worth mentioning, if only for the purpose of calling attention to the subject. Mules, though they do not breed with each other, and preserve the broken race, are yet, generally speaking, perfect or fertile animals, and can breed back to the pure blood of either species; but it is said that they return much sooner and more readily to the normal type of the ass than they do to that of the horse. Thus, in every point of view in which it can be taken, the ass appears to be by far the more stubborn to its specific character; and thus, instead of altering in some respects, so as to adapt itself to difference of climate, and remaining unchanged in others, it alters as a whole. It is very important for breeders and cultivators to know that those species which remain stubborn to the normal type, which they have in their native places, are (whether they be animals or plants) much less profitably cultivated over an extensive range of latitude or climate, than those which are plastic to circumstances.

On this account it is not probable that, though the ass is a strong, hardy, healthy, and economical animal, it could be so improved by training, as to make it fit, in this country, for any but the most common purposes, such as relieving the back of the burden, or the limbs of the fatigue of walking, to those who require no faster progressive motion than they could obtain by the use of their own feet. In all other cases, velocity is so important an element, in the saving of time and thereby adding to the efficient length of life, that the comparative cheapness of the ass would be no compensation. The probability, therefore, is, that in England the ass must be left to its present owners, and remain subjected to its present treatment. It is not indeed an animal adapted to very high states of improvement, how valuable soever it may be in those earlier stages of the progress, when the value of time is much less, and a little additional expense is matter of more serious consideration.

The ass is naturally an inhabitant of the wilderness, and therefore a wild and half-cultivated country is the most natural to it. On bleak commons, and among the thistles and other rough and tall plants, which remain asses' food in the greatest intensity of the summer's drought, the ass is at home; but among rich meadows and highly-cultivated fields, it is out of congruity and keeping—a thing of wild nature, while all around it is art and improvement. It seems that the ass itself is not quite in its element in these rich pastures. It gets fat and sleek, but it at the same time gets indolent and less strong and enduring in proportion to its appearance. If the ground is soft, the hoofs of the ass, which are by nature adapted for hard and dry surfaces, get enlarged by an unnatural growth in length, and the feet become unsightly, and the gait of the animal is awkward—circumstances which do not happen when it is upon the dry commons. In England, surfaces which are good for little else appear to be the most congenial pastures for the ass; and in the present state of the country, the ass seems to be the best animal only to those who can afford to keep no other.

This might be inferred from what has been already stated; for if the ass remains so stubbornly true to its natural external type, it must remain equally so to the nature of its pasture and its food, and the nearer that these approach to what it has in a state of nature, the more will it retain the size and vigour which it has there. Plastic animals, which break into varieties adapted to different climates and modes of treatment.

may be improved by culture, so that the domesticated shall, in the qualities which are desired, be much better than the wild; but those which, like the ass, are not so plastic, cannot be improved, or even kept up to their natural state if domesticated. For this reason the domestic ass is in all countries inferior to the wild ass; and though the differences of those of warm and cold climates be very considerable, they are only indications of different degrees of deterioration.

The wild ass is a native of the arid regions of central Asia, where it is still found in considerable troops. These troops shift northward and southward with the seasons, but they are always more southerly and also nearer the desert than those places which are supposed to be the native regions of the horse. This might be inferred from the more arid pastures and hardier plants upon which the ass can subsist, and indeed from the whole character of the animal. The horse is not adapted for living upon those compositæ, with large roots and tall and hard stems, which form the last vegetation before the saline plants begin; but even at that time when we may suppose that these places were unoccupied by human beings, even in nomadic hordes, and as such free to the range of animals, he must, as a matter of course, have kept further down and more in the temperate latitudes, where vegetation is more luxuriant and grasses more abundant and kindly. There seems indeed to have always been an animal of the same genus, intermediate in its pastures between the horse and the ass; and it shows the perfection of the analogy of nature, that it is intermediate also in its appearance and character: this animal is the *dzeggnetai*, or *dshikketei* (*Equus hermionus* of Pallas). Its form and appearance are very much those of a mule; and the probability is that it is the mule of the ancients;—the mule of which mention is made in the Bible, as being found in the desert. It is not a mule, however, but a distinct species, though, like some others of the genus, it appears to be too wild and untractable for domestication. It is still met with in central Asia, of a sort of cream colour, with black mane and tail, and a black line down the back, but without the cross on the shoulders which designates the ass. Its ears are also short; but in other respects the character of its body is intermediate between the two species whose pastures lie on the opposite sides of its range. For reference to the different species of the genus, which includes all the solid-hoofed animals that are known, see the article Equus.

The pastures of the ass, in a state of nature, being thus on the very margin of the sandy desert, where the temperature is always warm, and seldom any rain falls, and the animal being stubborn to its native habits, as well as to its normal type, it is easy to see that in Syria, in Egypt, in Barbary, in the isles of the Mediterranean, in Spain, in all the south of Europe, and even in those parts of the middle latitudes where there are long tracts of drought in the summer, the ass must be much superior to what it is in England. In all cases, however, the domesticated ones (they cannot be called a domestic *variety*) are inferior to those which are wild. From a saying, which must have been a current one and in accordance with the truth, as it is inserted in the Proverbs of Solomon, the ass must have been a spirited animal in Syria. "A *whip* for the horse, and a *bridle* for the ass," are the words of the proverb in so far as it refers to these animals; and the fair inference is, that the horse being used for warlike purposes, required the application of the whip to urge him on; whereas the ass, used for the ordinary purposes of domestic life, required only the bridle to guide him in the direction required. In the south, though not a very fleet animal, it is still one upon which long journeys can be performed, as it is longer in wearing out, and does not so often require to stop for refreshment as the horse. It is hardy and tenacious of life, even in those countries where it is upon the whole the most deteriorated; for even in those places where they are most abundant in the living state, it is rare to see a dead ass.

The generic characters will be mentioned in the article Equus. The specific ones are few in number, and as all are familiar with the appearance of the animal, they do not require to be mentioned with any minuteness of detail. The long ears, the cross on the shoulders, the tuft at the end of the tail, which is naked or has only short hair for the greater part of its length, and the absence of warts or callous tubercles on the hind legs, are the specific characters which distinguish it from the horse. In a state of nature, the hoof is also narrower in proportion, and better adapted for walking upon hard surfaces: in the teeth and the whole internal structure, there is much uniformity in all the genus.

ASSAFŒTIDA of the druggist, and *Ferula assafœtida* of botanists, a native of Persia. Linnæan class and order *Pentandria Digynia;* natural order *Umbelliferæ.* Generic character: involucrum varied; flowers polygamous, fruit compressed, smooth, margin thickened; costæ very obtuse below. This plant has a large fusiform root, and it is cultivated for the juice which it yields, and manufactured for exportation.

ASSIMILATION, *in Physiology,* is that property, or principle, or whatever else it may be called, by means of which organised beings, whether vegetable or animal, take to themselves, and convert to their own substance, structure, or organisation, those foreign substances which constitute their pabulum or food. The subject is one of great importance, more so perhaps than any other of a merely material nature, which can draw the attention or exercise the industry and sagacity of mankind. Upon it depends the success of every method and instance of culture, and the condition and value of all that can be cultivated. Upon it also depend our bodily strength and health, and all that can render life worthy of being enjoyed.

But the obscurity and difficulty of the subject are as great as its importance; and thus it is one which probably never can be brought within the scope of demonstrative philosophy. The foundations of it lie in the very elemental workings of nature, where the produce of the work is yet too small for our observation; and even in the full-grown subject, where we can trace the process a greater or less way, according to its nature and our opportunities, there is always a point at which we are left in the dark, and our being so left reduces that which we have previously traced to comparatively little value.

The reason of this is very plain, and it is such a reason as to render the success of any attempt at the full elucidation of the subject doubtful, if not hopeless. That reason is this: the important part of the process, that in fact upon which the whole depends, does not come within the province of the philosophy of matter (the only demonstrative philosophy that we have) in any of its forms. It cannot be accounted for mechanically; as little can it be accounted for chemically; nor do we succeed better when we attempt to explain it by a combination of the two. There are mechanical changes no doubt, and there are also chemical changes, but there are others which are neither mechanical nor chemical, and in these we neither know the cause nor the process. It is true that they are invariable concomitants of life, and that we never can find them but in the living subject. Therefore we may say that they are actions of the *principle of life*, or the *living principle.* But either of these expressions is precisely of that nature of which we, on a former occasion, mentioned that the word "instinct" is an example; they enable us to fill up by sound in our words those gaps which the failure of our knowledge leaves in the sense of what we say, and they do nothing more. These necessary ignorances do not, however, lessen the value of that which we really know, only it is important for us to know where they lie, because that prevents us from wasting our time and labour where there is no knowledge to be found; and had we always been aware of and avoided them, all of us might, with the same exertion, have been very much wiser than we are.

Taking these precautions with us, to prevent us from wandering into idle speculations, the subject of assimilation becomes one of the most interesting that can occupy our thoughts. It is indispensable to the growth of all organic beings, whether animal or vegetable; and it is equally essential to their being in a healthy state. It forms, indeed, one of the most unequivocal criteria of organic life, for there is nothing analogous in the inorganic or the dead world. The growth of stones and the formation of crystals, have sometimes been adduced as instances analogous to vegetable, and even to animal growth; but there is no assimilation in these; the substance though changed in form is not changed in nature, either by accretion into a stone, or by arrangement into a crystal.

As we are in a great measure ignorant of the food of vegetables and their mode of feeding, any thing that can be said about assimilation in them, will be much better left to Vegetable Physiology, or to some of the articles subordinate to that. This is further desirable, because perennial vegetables, which continue to increase by growth for more than one season, grow by a sort of accretion, or the mere addition of new parts, while the portion once grown never increases or undergoes any change except what may be impressed upon it by causes external to itself. No doubt, in the animal kingdom, pearl shells grow something in the same manner, as may be seen in the successive additions to the shell of an oyster or a periwinkle, but crusts grow more upon the animal principles; and probably the porcelain shells grow something in the same manner, though that is a subject upon which we have very little information.

We shall render the few remarks which we have to make more clear, and therefore give them a chance of being more generally acceptable and useful, if we narrow the subject still further, and consider assimilation as it takes place in vertebrated animals only.

It is probable, nay certain, that the process of assimilation is coeval with the very first development of the animal germ, nay, with the very commencement of its existence, as an organic being. This part of the subject is exceedingly obscure, and as is the case with all obscure subjects which are at the same time interesting, there are many theories and opinions respecting it. The most rational of these opinions, and the one which accords best with the analogy of nature, and carries us through the other parts with the greatest security from error and absurdity, is that which, we believe, was first advanced by the great Harvey. This is what is usually termed the theory of *Epigenesis*, or that which dates the very first rudimental existence of the animals from "the act of organisation," and denies the existence of all pre-existent germs, except as mere materials to be rendered available by that act. In no other way is it possible to account for the production of mules, or even for that more universal sort of hybridism, by which the progeny generally partakes in some degree of the qualities of both parents. But though assimilation goes on in those early stages, and goes on in a more extraordinary manner than at any future period, inasmuch as it *makes* the whole organic structure of the animal, the process there is so exceedingly nice, and so little is known about it, that it cannot possibly be rendered useful or even intelligible in popular description. We shall, therefore, still further narrow our observations, by confining them to the process of assimilation in the animal, after it is capable of subsisting by itself upon the ordinary food of its species.

We shall suppose that the whole of the matter which is assimilated is taken by the mouth as food; for though there are other circumstances, such as the state of the atmosphere, and the kind and degree of action to which the body of the animal is subjected, which affect assimilation, yet they form no specific part of it, and can be regarded as affecting it only as they affect the other functions, that is, as external circumstances.

The first process which the food undergoes may be said to be purely mechanical, and might be done by other means. This process is mastication, or chewing, on the part of many of the mammalia; trituration or grinding in gizzard birds; and maceration, or softening, and solution in a fluid in some other animals; but in whatever way it is performed, it is a merely preparatory process, not at all connected with assimilation; and when there is a liquid in the case, it is to be considered only as a mechanical solvent, that is, as softening or dissolving the food with which it mixes, much in the same way that water softens and dissolves glue.

This preparatory operation, and indeed the whole process of assimilation, depends a good deal upon the nature of the food. When that is entirely animal, the whole of the processes, and also the apparatus by which they are performed, are much more simple than when it is wholly vegetable; and even in the case of vegetable food, that which is wholly pulpy and farinaceous, requires a simpler apparatus and processes than that which is mixed with fibrous matter. The adaptations of all the parts of this apparatus (which, taken together, are called the *digestive* system, or *nourishing* system, of the animal) to the various kinds of food upon which animals live, exhibit some of the most beautiful instances of means and end that are to be met with in the whole economy of nature; and they are also of great value in that natural classification of animals, by means of which the history of one is made to throw light upon the history of a number, and one part of the history of one is made to throw light upon the other parts. The general law is, that the nearer the food in the state in which it is received by the mouth approaches to the nature of the animal receiving it, the apparatus of assimilation is the more simple, and the operation the more easily performed. But still, so much is each animal an independent being in its substance, that no kind of food goes into the substance or constitution of an animal without undergoing a total change in the process of assimilation. Even if the animal preys upon its own species, as is by no means uncommon among some of the fishes, in which case the food and the feeder may be supposed to make the nearest approximation to each other, the food undergoes as complete a change as if it were the substance most foreign and opposite to the nature of the animal that can be imagined. It is worthy of being borne in mind, too, that in the same animal, or the same species, the product of assimilation is nearly the same, however different the food may be ; or that different kinds of food produce differences in the *quantity* of assimilated product rather than in the *quality*. Consequently, when we say that the food of an animal is of bad quality, we simply mean that it is deficient in nutriment; or if we have any further meaning, it must be, that the food contains some deleterious ingredient which in so far acts as a poison.

The second part of the process is *digestion*, which usually takes place in the true stomach of the animal, although some animals appear to have a digestive power in the gullet, or passage leading from the mouth to the stomach. It is here that the mystery begins ; for though the stomach may be said to exert both mechanical and chemical powers in the process of digestion, yet there are other results produced in it which cannot well be attributed to either. While the process of digestion is going on, the stomach is in continual motion, contracting in one place and expanding in another, as if it were wriggling as a worm does ; and hence this is called its *vermicular*, or worm-like motion.

The most powerful, as well as the most singular agent in the stomach, appears, however, to be the *gastric juice*, a peculiar fluid which is secreted or given out by the inner coat of that organ, and which not only exerts a very powerful action in chemically dissolving the food, but also produces some changes in it which cannot be explained upon any known principles of chemistry. The energy of this fluid has been proved by direct experiment : it has been obtained from the stomach of the living subject (which is neither difficult, nor attended with the slightest danger) ; and by being kept at nearly the natural temperature, it has, to a considerable extent, effected the process of digestion in a separate vessel, in which there could be no vermicular motion to assist its action.

This gastric juice is somewhat singular in its operation. It will dissolve cartilage, bone, and even, in some cases, iron ; but it will not dissolve the skin of a berry, the least bit of cork, or the smallest fibre of cotton wool. It is one of those animal fluids which are so perplexing to the chemist in his investigations, and might alone demonstrate the fact, that life is something which neither mechanics nor chemistry can reach, and in the production of which they can consequently have no concern. Not only while in the stomach of the living subject, but after it is removed, this fluid produces what appear to be very powerful chemical effects ; but when we subject it to chemical analysis, we are unable to detect in it any ingredient to which such effects could, chemically speaking, be attributed : in other words, we discover nothing.

There are two properties of the gastric juice, which seem worthy of separate notice. These are, the prevention of putrefaction, and the coagulation of albumen. The first of these is in opposition to one of the theories of digestion, by which it was maintained that that process is a species of putrefaction. But so far is that theory from being true, that it is well known that if putrid matter of any kind is admitted into the stomach or any part of the digestive organs, in many animals, it is attended with serious and even fatal effects. The gastric juice while it performs that sort of decomposition which is necessary for preparing the food for assimilation, prevents the putrefaction to which the food might otherwise have a tendency, and it seems also to prevent chemical solution by the action of one part of the food upon another. Chemical actions, such as the production of an acid or a gas, do indeed sometimes take place in the stomach ; but these are always disagreeable, and consequently the results of something wrong in the functions of that organ. The coagulative power is, perhaps, more singular ; but coagulation is a subject upon which our knowledge is very obscure and vague. The fact is well known, however, even to those who are equally ignorant of chemistry and physiology. There is not a nurse in the country, but knows that the stomach of an infant is disordered, when it returns the milk of its nurse uncurdled ; and dairymaids have from time immemorial employed the *rennet*, the red or gastric juice from the stomach of animals, for curdling milk in the manufacture of cheese.

The action of the gastric juice, assisted by the vermicular motion of the stomach, converts the food into an uniform pulpy mass, changed in appearance and odour, and which is known by the name of *chyme*. This name means that which is softened and mixed together ; and, therefore, it is expressive of the substance, though not of the process by which it is formed. The solution is, indeed, a peculiar one ; the food is reduced to a pulpy mass, and though there may be a difference in the food, that mass is in the same species of animal in the same state of health always nearly the same. The solution which it has undergone is a peculiar one ; for though it is softened and moistened, it is not dissolved, neither is it soluble in water.

When the food has been properly reduced to chyme, the action of the stomach forces it through the pyloric opening into the duodenum, where it mixes with new secretions from the animal, and undergoes another change. Not far from the commencement of the duodenum, at the pyloric orifice of the stomach, the gall and pancreatic ducts pour their contents into it ; the first the bile, and the second the pancreatic juice. What specific part these perform in the general process of assimilation, is not known ; but it is presumed that their action, especially that of the bile, is very important, both because of the size of the liver by which it is produced, and because of the great derangement which takes place in the whole process of assimilation when that organ is diseased.

At or near that part of the duodenum into which the biliary and pancreatic secretions are discharged, the chyme begins to be separated into two parts, the relative proportions of which vary with the quality of the food. The first is the *chyle* (which means juice or extract), a milky fluid, which is the assimilated matter; and the refuse, or that part which is either indigestible or unfit for being converted into chyle. But the latter still contains a portion of chyle, or matter fit for being changed into chyle, and that is gradually separated in the progress through the remaining parts of the intestinal canal.

It appears that vegetable food is acted upon with more difficulty by the gastric juice, in the first part of the process, than animal food; and it further appears that, after it has been converted into chyme in the stomach, the chyle is with greater difficulty separated from the refuse. For the preparation of vegetable food, by mastication in the mouth, by maceration in preparatory stomachs, or by both, is a much more complicated operation. The intestinal canals of vegetable feeders are also much larger, and the chyme is in consequence subjected to a greater continuance of the action of these viscera. The contents of the intestines are urged onward, from the entrance to the termination, by a sort of vermicular action, which is called the *peristaltic* motion, and which bears some resemblance to the motion of the stomach, only it is more progressive.

The separation of the chyle, which may be considered as the second stage in the process of assimilation, and which continues, though gradually diminishing, through a considerable portion of the intestinal canal, is very obscure in its nature. There are three agencies which may be supposed to be concerned in the production of it:—first, the action of the different parts of the chyme upon each other, the efficacy of which is rendered probable by the fact that certain substances are more nutritious when taken into the stomach together than either of them is when taken singly; secondly, the influence of the bile and pancreatic juice; and thirdly, the action of a peculiar secretion of the inner coat of the intestine itself. Whether one, or another, or all of these produce the effect, or if all, how much is to be attributed to one, and how much to another, is not known. Thus, in this part of the process of assimilation also, we are left in doubt both as to the agent and the specific effect.

From the intestinal canal, and especially from the duodenum, in which it is most copiously produced, the chyle is taken up by the lacteal vessels. These are small tubes which open on the inner coat of the intestine, not by mouths equal even to their small diameters, but each by a number of very minute pores or villi, which radiate from a centre, and whose openings are so small that they admit only the most minute substances. These lacteals with their villous openings continue along the greater part of the intestinal canal, but they become less numerous, as the food advances, and furnishes a smaller quantity of chyle. From the intestine they proceed along the mesentery, uniting into thicker trunks, and also anastomosing with each other, so as, in some instances, to form a sort of network. They also contain numerous valves, and as the seats of these do not expand along with the intermediate parts, the distended lymphatics appear to consist of a succession of little barrels or beads.

All the lacteals discharge their contents into the lower extremity of the thoracic duct, which ascends in the back part of the thorax, and pours its contents into the left subclavian vein near its junction with the heart. Thus the assimilated product of the food is mixed with the mass of the blood. In their course from the intestine to the thoracic duct, the lacteals pass through one or more glands; but whether their contents undergo any change, and if any, what that change is, are obscure points. The chyle differs from blood in many respects, one of the most obvious of which is a considerable admixture of sugar and water.

The chyle does not go to the blood alone, but mingled with the contents of the lymphatic vessels, which appear to fetch their colourless contents from all parts of the body, and united enter the thoracic duct; but as the fluid which they contain comes from the living parts of the animal, it must be considered as a previously assimilated substance; but whether it again enters into the circulation, and if so, what office it performs, are points upon which we have no information, and they form no part of the process of assimilating.

The blood with which the chyle, or new matter, is mixed, does not immediately go over the body in the course of the systematic circulation. It passes immediately into the right auricle of the heart, thence it passes into the right ventricle, where the valves between the two prevent its return. The contraction of the ventricle sends it along the pulmonary artery to the lungs; and after undergoing the action of the air inspired in breathing there, it returns by the pulmonary vein to the left auricle, thence to the left ventricle, and by the action of that and the systematic arteries, it is sent all over the body. The quantity of chyle which mixes with the blood at each pulsation of the heart must be very small, as there is no trace of its colour in the blood which is sent to the lungs, which has the dark colour of venous blood. But the minute division of the blood in its passage through the lungs must tend to the intimate union of the chyle with it, and it may be possible also that the action of the lungs is necessary to perfect the assimilation, and finally convert the chyle into blood, but the agent and the process in this final step of the process are just as obscure as in the two preceding ones.

We have now followed the progress of the food from its first entrance by the mouth of the animal to its union with the mass of the blood, which is understood to be the fluid which supports the growth and repairs the waste of all the parts of the body. In this we have done nothing more than give a simple outline of the process of digestion; but this is, in truth, all that can be given. We have seen that, besides the merely mechanical preparation of the food, there are three distinct operations:—the formation of chyme in the stomach, the separation of chyle in the intestines, and the turning of that chyle into blood after it has passed into the subclavian vein. There may be others, by the glands through which the lacteals pass, and the union of the lymph with the chyle in the thoracic duct; but instead of knowing how these take place, we have no evidence of the fact that they take place at all; and therefore it would be unwise to darken further with them a subject which in its own nature is abundantly obscure. Our inquiry reduces the assimilation to three distinct processes or acts, and we can tell plainly enough *what* takes place at each of them; but in none of them can we tell *how*, or *by what agency*. We can indeed bring all three home to the living animal, by showing that they are neither chemical nor mechanical, from which it follows that they could not be performed by the properties of mere matter, or originate in any new case, except in the ordinary way in which the animal is produced. This is but a small matter in respect of positive knowledge, but it is an important one in the prevention of error.

But when we have followed the progress of assimilation through all the steps that have been traced, from the mouth to the discharge of the arterialised blood from the left ventricle into the aorta, for the purpose of being sent all over the body, we have traced the process only to what may be considered as the beginning of its most curious work. Out of that general circulating fluid there have still to be elaborated all the parts of which an animal consists, and all the products of those parts, whether they be turned to use in the system, or discharged out of it. Of the same fluid are formed bones, ligaments, tendons, muscles, membranes, skin, hair, feathers, nails, horns, teeth, and all the parts of which an animal with such a circulation as has been described can consist. The blood has even to maintain the vessels, and furnish the fluids, by means of which it obtains its supply. Those local assimilations constitute the wonder of the matter, in comparison with which all the external actions, habits, and economy of animals, curious as some of them are, sink into comparative insignificance.

When we contemplate the external actions of animals, we are apt to speak about their reason, and wisdom, and intelligence; but where is the intelligence here? Even in ourselves, all these operations take place, not only without what we vainly, but by no means correctly, call our *will*, but without our ing in the least aware of their occurrence. When they are suspended, or in any way go wrong, we are indeed admonished of the fact by the uneasy sensations of pain and disease. But when the derangement is in those internal and constitutional functions, how little can we tell of what is the matter with us beyond the mere uneasy sensation? And how often are those who have made the structure and functions of the body the subject of most careful and scientific study nearly as much in the dark as we? When we find that all these operations are constantly going on, in manners as varied as the species of animated beings, without design, purpose, or knowledge of the creatures, but merely in virtue of that law of the species which has been given to it by its Creator, descending without change through countless generations, what small reason have we to perplex ourselves about the causes of those far more simple external operations which individuals or races perform? If, in the mightier matter, we must admit the operation of Divine wisdom and power, through the fulfilment of the law which Divine goodness has seen meet to institute, with what consistency of philosophy, with what pretensions to even the humblest shade of reason can we deny, doubt, or question it in the less? Such conduct cannot be called impious, because impiety involves the abuse of at least a certain portion of knowledge; but it is the most gross and utter ignorance; and as it is but too often ignorance which is vain in its own conceit, it is in these cases as hopeless as it is humiliating.

And yet, wonderful as all these organisations are, working unseen and unknown to the owners, and working with the utmost perfection, the special marvel of the whole, that which should humble man in his own eyes, and send him to adore, where adoration is the path of sound wisdom and genuine happiness, remains behind. Whence come all those varied organisations, whose functions are so very curious, and performed in so admirable a manner? They, too, are of the same law—the same simple but sure mandate, which once given forth at the moment of creation, shall remain and operate immutably till time be no more. "Γενεσθε—και 'Εγενετο."—Let the world arise!—And the world arose in all its beauty, and all its inhabitants, in all their forms, functions, and habits, perfect and self-sustained, until He shall command it back into its primæval nothing.

And this, too, is effected in the most silent, and apparently the most simple manner. An egg, for instance, which is perhaps the best form in which to contemplate the beginning of life, is found, upon analysis, to consist of very simple materials; and the egg is walled in by its shell, so that, save the air, through its pores, and the all-pervading influence of heat, it can receive nothing from without—no material substance—nothing that has weight in the scale can be added to its contents; and in the progress of its vivification it no doubt gives out matter, a portion of carbon in the state of carbonic acid gas, for it becomes specifically lighter.

The egg thus contains within its shell both the workman and the materials; and though, in the usual course of nature, it is hatched by the heat of the parent bird, yet there is no specific virtue in that heat which renders it indispensable for the purpose; any heat will do, so that it is in the proper degree and maintained with the proper uniformity. If we take in the whole range of oviparous animals, there are far more eggs cast upon the common bounty of nature than there are tended by the animals which produce them; and those which are so cast fail not a jot more than the others. Countless multitudes of reptiles, fishes, insects, and molluscous animals, commit their eggs to the earth or the waters, or fix them upon, or insert them in the bodies of plants or animals; and these succeed as well as the eggs which are hatched under the most careful bird, or the young of the mammalia, which are brought to maturity in an internal matrix. All these facts, and many analogous ones, which will readily suggest themselves to the reader, tend to show that, from the very instant that the act of organisation passes upon it, the life which is in the egg is that of a distinct and separate being, endowed with all the powers of assimilation, by means of which it can evolve itself to maturity, and maintain its existence for the average of that period of life which is the portion of its species. Once begun, the animal organisation does not require, and indeed cannot receive, the aid of any helping hand from without; but, placed in the proper circumstances, and when not interfered with, the law of nature arranges and adapts these; it works on for its appointed period, and in its appointed way, free and independent.

The vital part is, in the recent egg, a very simple matter—a little of a jelly-looking substance, barely distinguishable; yet, by the action of heat, this simple thing elaborates out of the matter contained in its storehouse, those membranes, with their blood-vessels and blood, which are necessary for its own development. It forms this apparatus gradually as is required, and germ and apparatus then work together, in all the curious operations which take place ere the chick comes out of the egg. Out of the apparently simple contents of that, there are elicited viscera, and bones, and muscles, and nerves, and membranous tissues, and skin, and feathers, and scales, and horny beak and claws;—all the organs which we afterwards admire so much in that beautiful creature, which sings from the spray, wheels swiftly through the air, or rides gracefully upon the water.

And all is effected by the power of assimilation, and that too apparently without a point from which to commence. Assimilation is thus totally different from accretion or crystallisation. In these, new portions of the same matter are merely added, without any change; but assimilation prepares a new material, and either places it where there was no such material before, or replaces with it other matter which has ceased to be fit for the economy of the animal. See GROWTH.

ASTACIDÆ (Leach). A family of annulose animals belonging to the class *Crustacea*, order *Decapoda*, and section *Macrura*, and containing the lobster tribes. In this family the abdominal portion of the body is much longer than the thorax. The eggs are retained in a large pouch beneath the breast, the first pair of legs are generally very large, and terminated by hooks, claws, or a machine for swimming, and the antennæ, of which there are two pairs, are inserted in the same horizontal line, the interior ones with moderate or long footstalks, and terminated by two filaments, and the outer ones naked or furnished with a scale, which never entirely conceals the base.

These characters will at once distinguish the lobsters from the hermit crabs (*Paguridæ*), and prawns and shrimps (*Palæmonidæ*).

This family includes several distinct groups of species, and we have also introduced into it the spiny lobsters or cray fishes (*Palinurus*), which Dr. Leach considered as forming a distinct family (*Palinuridæ*), chiefly from the small size of the fore-legs. These animals, however, which are constantly sold by the London fishmongers, are too closely allied to the lobsters, as may be seen even upon a casual inspection, to warrant their establishment as a distinct family, especially since we see, in the adjoining families, amongst the shrimps, for instance, that the size of the anterior locomotive organs becomes a character scarcely of generic rank.

The extremity of the abdomen is constantly furnished with a fan-like apparatus for swimming, composed of five plates, and the tegumentary envelope of the body is always of a hard and calcareous nature.

The 1st sub-family, *Scyllarides*, is distinguished by the remarkable construction of the lateral antennæ, which are much shorter than the thorax (which is broad and flat), and instead of being slender, are dilated into very broad and flattened plates, having the appearance of a cock's comb; the fore-legs are monodactyle and small, resembling the others, the extremity of the caudal apparatus for swimming is membranous. These crustacea appear in warm climates, some of the species being found in the Indian and other tropical seas, whilst others are taken in the Mediterranean; the latter are known by the name of Cigales de mer, which they probably owe to the noise which they make in swimming: they burrow in clayey soils close to the shore. To this subfamily belong the genera *Scyllarus* (Fabricius), of which the *Cancer arctus* of Linnæus may be considered the type; *Thenus* (Leach), *Scyllarus orientalis* (Fabricius), and *Ibacus* (Leach—*Ibacus Peronii*), from New Holland.

The second sub-family, *Palinurides*, resembles the former in the simple fore-legs and the membranaceous termination of the swimming plates, but the thorax is convex, and not widened in front, and the lateral antennæ are very large, spinose, and much longer than the whole body. One genus only, *Palinurus*, (Fabricius), belongs to this division; it includes some of the largest of the macrurous (long-tailed) crustacea, and the species are in general of elegant colours. They are termed langoustes by the French, a name probably vulgarised from locusta, under which term they were known to the Romans; by the Greeks they were denominated carabos, and Aristotle has given various important observations upon their natural history. It is singular that the common species, in the west of Europe, although noticed by all the old naturalists, should have been overlooked by Linnæus. This is the species of shell-fish sold in our fish shops as the spiny lobster, and is highly prized as an article of food. It is the *Palinurus quadricornis* of Fabricius, the *Cancer elephas* of Fabricius, the *Palinurus locusta* of Olivier, and the *Palinurus vulgaris* of Latreille and Leach. During the winter it seeks the deeper parts of the ocean, but at the return of spring it approaches the shores, preferring rocky situations where it deposits its spawn, which is of a beautiful red colour.

The third sub-family, *Thalassinides*, consists of several interesting genera, of which the majority are natives of our own coasts; they are of small size, and have much of the appearance of small lobsters, the abdomen being long, and terminated by a swimming apparatus of an entirely crustaceous substance; the first pair of legs is terminated by large claws, and the third pair is never furnished with a two-fingered claw; the exterior lamellæ of the tail are composed of one part only. This sub-family comprises the Indian genus *Thalassina* (Latreille), and the British genera, *Gebia* (Leach), *Callianassa*, (Leach), and *Axius* (Leach). The latter are found on the southern coasts of Great Britain, where they burrow in the sand to a very considerable depth.

The fourth sub-family, *Astacides*, have the abdomen long, and terminated by scaly lamellæ for swimming, of which the exterior ones are bipartite. The fore-legs are very large, each with a powerful claw, and the four following legs are terminated by two-fingered claws. This sub-family comprises the lobsters and cray-fish; of the former, the *Cancer gammarus* of Linnæus, which inhabits the rocky shores of our coast, is the type of the genus *Astacus* of Fabricius, and the latter, which Dr. Leach has formed into a distinct genus, *Potamobius*, is found in all our fresh water streams. Their food consists of decayed animal matter, and it is with this, as a bait, that the majority of the vast numbers which are annually consumed are caught.

The LOBSTER, whose economy we shall detail under that word, is distinguished generally from the cray-fish by the middle lamella of the tail being composed of a single piece, and by the sides of the abdominal segments being obtuse.

The *Cancer Norvegicus* of Linnæus, found on the coast of Norway, is the type of the genus *Nephrops* of Leach.

ASTARTE (Sowerby). CRASSINA (Lamarck). VENUS (Montague). This shell resembles a small crassatella in appearance, being thick and solid, and the valves perfectly closing together in every part; but the position of the ligament distinguishes it: nor should it be confounded with the genus *Venus*, since it has not more than two teeth on each valve; and even appears to have but a very large one on the left valve, the other projecting but slightly. The shell is orbicular, transverse, equivalve, inequilateral, and closed; ligament external, and placed on the longest side. Several species of this mollusk having been described by authors previous to Lamarck, under the name of Astarte, Sowerby very properly objects to that of Crassina; De Blainville has, however, included it in that of Venus, and it stands in the second section of the eighth family, *Conchacea*; third order, *Lamellibranchiata*; third class, *Acephalophora* of his system.

ASTATA (Latreille), Dimorpha (Jurine). An elegant genus of hymenopterous insects, belonging to the section *Fossores*, or burrowing sand wasps, and family *Larridæ*. The eyes are very large, uniting behind in the males, whence the name given to these insects by Jurine; the wings have one marginal appendiculated cell, and three submarginal ones. These insects are extremely active, to which the name astata has allusion, and they usually provision their nests with the pupæ of some of the field bugs (*Pentatomæ*), the females in general taking their stand upon small lumps of dry cow dung, in hot situations. Mr. Curtis has figured a species, under the name of *Astata victor*, but from an examination of authentic continental specimens of the *Ast. abdominalis*, it appears that his insect is evidently that species.

ASTELMA (R. Brown). A family of beautiful undershrubs, natives of the Cape of Good Hope. Linnæan class and order, *Syngenesia superflua*; natural order, *Compositæ*. Generic character: anthodium imbricated, the inner scales channelled, and a little coloured; receptacle furrowed, downy; florets of the ray female, imperfectly attenuated; pappus hairy, rough, pencilled at the top, somewhat feathery. There are ten species of this fine family, all of which have formerly been known by other names, as gnaphalium, elechrysum, &c. The genus is now arranged in two sections, namely, *Conniventia*, involucres connivent; and *Radiata*, involucres radiate.

ASTEPHANUS (R. Brown). A genus of two species of climbing plants from the Cape of Good Hope. Linnæan class and order, *Pentandria Digynia*; natural order, *Asclepiadeæ*. Generic character: corolla somewhat bell-shaped, the throat of the tube naked; gynostegium like a bee.

ASTER (Linnæus) Starwort.—An extensive family of perennial plants, sixteen of which are shrubby, and the rest herbaceous. Linnæan class and order, *Syngenesia superflua*; natural order, *Compositæ*. Generic character: anthodium imbricated; receptacle naked; radius of two colours. Of this genus there are one hundred and fifty-four described. They are found in many parts of the world, but chiefly in North America. Almost all are ornamental, and decorate our gardens in the autumnal months. Some are splendid: one of them, *A. amellus*, was celebrated by the Mantuan bard. The family is divided into eight sections, founded on the character of the stem, number of flowers, and form of the leaves.

ASTERIAS (Linnæus). A genus of shells belonging to the division *Radiata* (Cuvier), and to the class *Echinodermata*; section, *Stellerides*.

This animal has a suborbicular depressed body; its circumference divided into angles, lobes, or rays, each of which has a longitudinal furrow in its centre, fringed on each side with moveable spines, and orifices for the tubular or retractile feet; mouth central, and placed beneath, at the union of the grooves, as in the

Asterias rubens (Red Star-fish), with five lanceolate, papillous, and spinous rays; papillæ of the back scattered, and set nearly in rows.

These animals inhabit the sea, and are usually found on the sand, or among the rocks on the sea-shore, below high-water-mark. Their covering is a fleshy, sometimes coriaceous crust, defending them from the attacks of smaller animals; and they possess five or more rays proceeding from a centre, in which their mouth is situated. Each ray is furnished with a prodigious number of tentaculæ, in some amounting to fifteen hundred; and when the animal is thrown on its back, these may be observed projected and withdrawn, like the tentaculæ of snails; by the undulatory motion of these rays the star-fish is enabled to swim, but its progression is extremely slow. Their powers of reproduction are considerable; for if by any violence a ray be broken off, a new one will shortly be produced. The mouth is armed with bony teeth, which are used in seizing and breaking the shells of fishes on which the animal feeds; from this a canal extends to each of the rays, running through their whole length, and becoming narrower as it approaches the extremity.

Persons wishing to preserve specimens of these animals should kill them in brandy or other spirits, keeping the rays expanded in their proper positions, extracting afterwards the stomach and its contents through the mouth by means of forceps.

One species, the *Asterias caput Medusa* of Linnæus (Medusa's head star-fish), mentioned by Shaw in his Naturalist's Miscellany, is occasionally found in most seas, but particularly at the Cape of Good Hope. It has five equidistant thickly-jointed processes proceeding from its centre, each of which is divided into two other small ones, and each of these into two other still smaller; and this mode of regular subdivision is continued to a vast extent, and in the most beautiful order of minute gradation, till at length the number of ramifications amounts to several thousands. One specimen, measuring three feet diameter, had five hundred and twelve extremities to each ray, so that the whole number amounted to two thousand five hundred and sixty. By this most curious structure the animal becomes as it were a living net, and is capable of catching such prey as is destined by nature for its support, the object being secured from all possibility of escape by the sudden contraction of these innumerable ramifications.

Marvellous stories are told of the size of these animals; one traveller having asserted that they are capable of entangling and drawing down a ship's boat. This circumstance needs the confirmation of other persons, though doubtless they sometimes attain a very great size; and it would appear that the minute ramifications of the extremities of the radii multiply in proportion to their distance from the centre of the animal. The great difficulty of expanding these animals in a dried state without injuring their delicate parts prevents their being frequently measured. The state in which they are preserved in cabinets presents the appearance of a turban, the rolled edge of which is composed of countless tentaculæ, intertwined in inextricable confusion, yet with considerable symmetry of arrangement.

ASTERODERMUS—starry-skin. A genus of spinous-finned fishes, belonging to the natural family of the *Coryphenes*, which are surface fishes in the warmer seas, but strictly pelagic, driving about with great rapidity, and most dexterous in the capture of smaller fishes. The *coryphene*, properly so called, is understood to have been the dolphin of the ancients; and it is still called the dolphin by the Dutch, though the true dolphin of modern times is not a fish, but a warm-blooded animal which suckles its young.

The asterodermus has the long dorsal fin of the coryphene, extending nearly from the occiput to the tail; the head also is ridged, but the gape is not proportionally so deep; the ventral fins are shorter, and placed under the throat, and there are only four rays in the gill-flaps, while those of the coryphene have seven. The scales are scattered thinly over the body, and are of a rayed form, like little stars, whence the name.

There is only one known species, an inhabitant of the Mediterranean. It grows to a considerable size, and is of a silvery colour, with black spots, and red fins, the dorsal fin being very high. It is the *Asterodermus guttatus* ("dropped" in allusion to the black spots) of Bonnelli, and the *Diana semilunata* of Risso.

ASTRANTHUS (Loudon). A single shrubby plant, found in Cochin China. Linnæan class and order, *Heptandria Tetragynia;* natural order, *Homalineæ.* Generic character: calyx with a short tube, limb from ten to fourteen cleft, segments alternately less; stamens, ten or more; anthers round; style like a hair; caryopsis included in the tube of the calyx.

ASTRAPÆUS (Gravenhorst). An interesting genus of coleopterous insects, belonging to the section *Brachelytra* (*Staphylinus*, Linnæus), and subfamily *Staphylinides*, and distinguished from every other genus in that large group by the four palpi, which are terminated by a hatchet-shaped joint; the tarsi are very much dilated. The species reside beneath the bark of trees. The only British species, *Astrapœus rufipennis* of Leach, is extremely rare in England, one specimen only having occurred at Coombe Wood, in Surrey, and one in Devonshire.

ASTRAPÆA (Lindley). A genus of three species of lofty trees, introduced from Madagascar. Linnæan class and order, *Monodelphia Dodecandria;* natural order, *Byttnericeæ.* Generic character: flowers umbelled, involucred; involucres imbricated, many leaved, the interior leaflet rather less; calyx bracteated, lance-like, sustained, membranaceous, five-sepaled, erect; corolla five-petaled, convolute; stamens united to the tube; anthers oblong, erect, bifid at the base, five of them sterile; style like a thread; stigmas five; capsule five-celled, each with two seeds. This family of plants are said to be the most beautiful in the world.

ASTREA (Lamarck). A genus belonging to the class *Polypii;* fixed, stony, and incrusting submarine bodies, forming hemispherical or globular masses, which are rarely lobed; the upper surface crowded with orbicular or subangular lamellæ, or sessile stars.

1st subdivision, with the stars separated from the base, *Astrea radiata*, rayed astrea. 2nd. With contiguous stars, *Astrea denticulata*, toothed astrea. The first inhabit the American seas, West Indies, &c.; the second inhabits the Indian seas. See MADREPORE.

ASTROCARYUM (Meyer). A genus of five species of Brazilian palms. Linnæan class and order, *Monœcia Polyandria;* natural order, *Palmæ.* Generic character: flowers monœcious, in a simple spatha; male flowers on a rachis; calyx three-cleft; corolla bell-shaped, three parted; female flowers within male spikes, solitary; calyx urn-shaped, edge three-toothed; corolla bell-shaped, edge three-toothed, double within; style conical; stigma simple; drupe fibrous, one-seeded; three pores at the top like a star; albumen hollow, equally thick; embryo within the pores.

Dr. Von Martius, who has described the palms of Brazil, mentions this among others, but nothing very particular that is not referable to others of the tribe.

ASTROLOMA (R. Brown). A genus of two species of evergreen shrubs from New Holland. Linnæan class and order, *Pentandria Monogynia;* natural order, *Epacrideæ.* Generic character: calyx five-cleft, bracteate; corolla, tube swollen, at the base of the tube a tuft of five hairs; limb short, spreading, bearded; stamens included; disk surrounds the germen, concave, entire; drupe pulpy, shell bony, five-seeded.

ATALANTIA (Correa de Serra). A hothouse evergreen shrub, allied to the lemon tribe. Linnæan class and order, *Decandria Monogynia;* natural order, *Aurantiaceæ.* Generic character: calyx four-toothed, cut at the base; corolla four-petaled, oval, sitting equal; stamens inserted on stipiti, in one brotherhood at the base, equal; anthers oblong, recurved; pods stipitate, oblong, two-valved; style persisting on the apex. This plant is called *Peritoma* by Sprengel.

ATALANTHUS (D. Don). A greenhouse undershrub from Teneriffe; it was previously known as *Prenanthes pinnata.*

ATELES (unfinished or incomplete, sometimes called "four-fingered monkeys"), a genus of four-handed mammalia, which have received that name on account of the thumbs of the fore feet being in general concealed under the skin, though there are two species which have very small rudimental ones, consisting generally of a single phalanx, and without any nail. They are all natives of America, and form a division of the American monkeys, or, as they are often called, *Sapajous.*

The animals of this genus form a tolerably well-marked group, peculiar in their haunts, their appearance, and their habits. They inhabit the wooded parts of South America, the interior of Guiana, Brazil, and generally the forests of all the tropical parts of that continent. One need hardly say the unfrequented forests, for, except a few Indians in the more open places, near the banks of the streams, those forests are all unfrequented by man, and many of them, by their depth and entanglement, to say nothing of the pestilent vapours which arise from them, are impervious to Europeans. It is not, however, in the very luxuriance of the swampy forests, where the exuberance of nature appears absolutely to run wild, and where, what with the ample foliage of the trees, what with the multitude of curling, climbing, creeping, and other parasitical plants, the vegetable canopy is so dense, that a twilight gloom rests upon the surface of the earth, even with a vertical sun at mid-day, that the animals of this genus are chiefly to be found. Forests of the character just noticed are the proper pastures of the sloths, which remain among the small twigs, feed on the leaves, and range but little from tree to tree, or even from branch to branch. The Ateles, as is the case with almost all the quadrumana, live chiefly upon fruits; and that being the case, they must have forests of such a description, as that, while they are below among the branches, they may have openings and light to enable them to see and examine the fruit-bearing part of the tree. Hence they are found chiefly on what may be called the middle grounds of the forest, the rich slopes, which lie between the highly fertile but rank flats by the waters, and the dry uplands, where the forest begins to straggle into the waste which bears no timber, or brushwood only.

These places are not only the best for the peculiar action of the quadrumana ; they also are their richest pastures, as fruit-bearing trees grow more readily and abundantly on those slopes than either in the rank hollow or on the dry height. In these parts of the forests there are many openings, and the trees generally stand more apart from each other, are lower in stature, more spreading and branchy, and less loaded with parasitical plants than farther down. Hence the animals which live in them require to be more active in their motions than the sloths.

In the trees, the Ateles are peculiarly active, especially in getting from branch to branch, and from tree to tree, sometimes to considerable distances. For these purposes the animals are admirably formed, as admirably as the long-armed apes of the Oriental isles are for their upward climbings in the spicy forests of those delightful regions. The four fingers, seizing and holding as a hook, are better adapted for motion generally oblique or lateral than hands with thumbs. But the Ateles have a fifth prehensile organ, and one which is perhaps more efficient in their march among the trees than any of the others. That organ is the tail, which in this genus is perhaps more prehensile than in any other. It is long in all the species, and in some it is twice the length of the body. The under side of it, towards the tip, is naked of hair, and covered with the same species of skin which covers the insides of the fingers, and generally all those parts of animals which are fitted for grasping. This tail can take hold very quickly, and it retains its hold more firmly than any hand ; so that, suspended by it, the animal can swing itself fairly round a branch, vibrate like a pendulum, and by putting the branch into a vibratory motion along with it, command a space of considerable extent.

The tail of these animals has sometimes been compared to the proboscis of the elephant ; and they who have made that comparison have inferred, not from the facts as observed, or from the structure of the organ, but from their own hypothesis, that it is used for similar purposes ; that the animal uses it like a hand in lifting little detached substances, in conveying fruits to its mouth, and in all purposes which it requires, analogous to those performed by the trunk of the elephant. But there is in truth no proper analogy between the two organs, either in structure or in use. The proboscis of the elephant is an organ wholly without bones, capable of flexure in all directions, and also, within certain limits, of lengthening and shortening. It is hollow, and at the extremity it has a grasping apparatus, answering some of the purposes of a hand, which can act with nearly equal facility in all positions of the rest of the trunk. Thus the proboscis not only acts as a hand, but in some instances it can be made to act as two hands. But it acts as a hand only; and though the elephant often makes use of it for pulling down those branches of trees which it cannot otherwise reach, it never suspends its body by it, or uses it in climbing. The tail of the ateles, on the other hand, is an organ having a bony vertebra for its basis, incapable of lengthening and shortening, having its powerful grasping action in one direction only, and having no substitute for a hand at the extremity. It is an instrument for laying hold, and in that way both a powerful and a ready one ; but it is not fitted for lifting loose substances, and there is no evidence that the animal ever uses it for such a purpose, either in carrying food to the mouth, or in any other way. The animal climbs by means of the tail, suspends and swings itself by means of the tail, and uses the tail to steady it in its most ungainly attempts at walking ; but it does not use the tail in feeding, or in any way in lifting or moving about loose or detached substances. It seizes with the prehensile portion of that only such objects as are firm, and it does so in order to maintain its stability.

None of the genus are handsome animals. They have a facial angle of about 60°, a large round head, a large and prominent abdomen, long and slender limbs, and a very long tail. The joints of their limbs appear as if they were more loosely put together than those of almost any other animals, and hence they are very awkward when upon the ground. Their limbs are, in fact, organs of suspension rather than of support, and therefore, when they attempt to use them in supporting the body, they are awkward, because applied to a purpose for which they are not formed. The motion of the sloths along the ground is very slow, and effected with no small difficulty and labour ; but the legs of the sloths are short, their bodies being near the ground in walking, and therefore their march does not appear so painful and unnatural as that of the ateles.

The legs of the latter are abundantly long, but they will not come into any thing like even tolerable marching order. The joints will not be firm, and the palms, the points of the fingers, or any part that would afford a base, will not apply to the ground. The only parts that will apply to the ground are the inner edges of the fore feet and the outer edges of the hind ones ; so that the animal shambles away, with a constant tendency in the fore legs to get too wide apart, and in the hind legs to plait over each other. The looseness of the joints makes the walk appear more awkward than it is, and the reality is awkward enough ; and the awkwardness is farther increased, by the animal attempting to seize with its prehensile tail all objects that seem capable of helping it on, or steadying its course. Walking upon the ground is not, however, the element of the genus ; and though they often descend from the trees to loiter and repose, their marches along the surface are always as short as possible.

But when in the trees, they are just as much in their element, and at home, as they are out of their element upon the ground. That flexibility which unfits them for the one situation, is a positive advantage in the other. The plaiting legs, the wide spreading arms, the flexible joints, and the long prehensile tail, enable them to seize and maintain their hold in situations where animals of more compact and better knit frame could not. The distances to which they can reach, and the certainty with which they take hold, even when they have to appearance been flung some distance through the air, and are falling, are truly admirable ; and when seen in a state of activity in the branches, they seem among the most energetic and the most sure-footed of animals.

Most of the species, if not all of them, are social, attached to each other, and apparently mild and inoffensive in their dispositions. They have none of the gambolling and friskiness, and none of the mischievous habits of common monkeys. It does not appear, indeed, that even in their most abundant pastures, they lavish much of their energy in sporting. Their excursions in the trees are chiefly in quest of food; they make them in the early part of the day, and by the time that the sun is high, and beats strong on the ground, they descend and bask themselves in his heat.

In the more distant and secluded parts of the forests, these animals associate in considerable numbers, and they are said not only to live in perfect harmony, but to make common cause against an enemy, and even against man himself,—if the attacks of the Indians, whose food, in some places, consists in considerable part of the flesh of monkeys, has not taught them, that when man appears it is safer to fly. The allegation is, that they combine to pelt the intruders with sticks and other missiles; but there have been so many stories told of the pelting propensities of quadrumana in other places, without any foundation, that this account of the ateles must be received with caution. When tamed, they are timid animals, and though the tamed ones will bite, it appears to be rather through fear of being injured than from any direct purpose of injuring.

If when they are hunted, or otherwise attacked, one happens to be wounded, all the rest scramble off for the trees, gain the tops as fast as they can, and then set up the most dolorous howling. The wounded one, if able, follows, at least as fast and as far as it can; and having gained a high branch, it coils its prehensile tail two or three times firmly round that, and then putting its fore paws to the wound, it examines, and appears to mourn over the flowing blood. All the quadrumana, however, have a similar habit when wounded; and though the expression is no doubt piteous, as all the order howl and lament, even when there is very little the matter with them, the affecting character of the spectacle has probably been exaggerated.

There are eight species in the genus or group, six of which are wholly without apparent thumbs on the forepaws, and the other two have them merely rudimental. They vary in size, colour, and locality, and the same species is described as sometimes differing considerably in different places, but their habits are all nearly the same.

The six species entirely without thumbs on the fore-paws are: 1. The Coaita (*Ateles paniscus*); 2. The black Coaita (*Ateles niger*); 3. The Marimonda (*Ateles Belzebuth*); 4. The Chuva (*Ateles marginatus*); 5. The Spider Monkey (*Ateles Arachnoides*); and 6. The black handed Coaita (*Ateles melanochir*). The two which have rudimental thumbs on the fore-paws are: 7. The Miriki (*Ateles hypoxanthus*); and 8. The Chameek (*Ateles subpentadactylus*). From what has been said of their haunts and manners, and the comparative uniformity of these, the notice of the species may be brief.

The *Coaita* is pretty widely distributed, being found both in Guiana and in Brazil. This is perhaps the best known of all the species, and is the one usually referred to by the name of four-fingered monkey. Coaita is its name by at least some of the Indian tribes by whom it is hunted, and that under which it is described by Buffon. It is probably, as the most of such names are, a sort of imitation of its cry. The length of the body is not above fourteen inches, while that of the tail is fully two feet; the limbs are long in proportion to the body, slender, and jointed in the loose manner that has been described. The face is nearly naked, and of a flesh or copper colour; but all the rest, with the exception of the under part of the tail toward the point, is covered with black hair. In the woods of Guiana these animals are found in numerous parties, generally hanging suspended from the branches of the trees, and rarely upon the ground, where they have very little command of themselves. They are quiet and inoffensive, and not difficult to tame; but like all the rest of the quadrumana, they are perfectly useless. It cannot well, indeed, be otherwise; because their native haunts are so unlike places which man generally inhabits, and their natural actions so unlike anything which man requires to have done, that their nature would have to undergo a total change before they could be in any way useful.

The Spider Monkey and Black Coaita.

The *Black Coaita*. This species has hitherto been seen only or chiefly in Guiana. In many respects it has a considerable resemblance to the former, and has been sometimes considered as a variety; but the face, instead of being copper coloured and naked, is uniformly black and covered with hair.

The *Marimonda* is also found in Guiana, and appears to be rather a local species. It is about the same size as the two former; but it has some peculiar markings. The hair on the head turns backward from the front, and forward from the occiput; and the two meeting together form a sort of prominent ridge or crest across the middle part of the head. The hair on the back is black; but that upon the belly and under part is dull yellow in the old males, and white in the females and the young. There is a flesh-coloured circle round the eyes, which, with the crested ridge of hair on the top of the head, gives it a peculiar expression. These animals are found associated in considerable numbers, and when they descend from their labours on the trees to bask themselves in the sun, they are said to express their regard for each other with somewhat ludicrous affection, embracing, shaking hands, and paying such other compliments as monkeys can pay. After salutation is over, they are said to lie down upon their backs, with their open eyes to the sun, and fling their long and ill-jointed limbs as carelessly beside them as if they were to be of no more use. In this way they spend the heat of the day, unless an enemy appears, in which case they gather to them their lumbering legs with all possible expedition, and make for the trees as fast as ever they can, swinging and bounding from branch to branch with an alacrity which forms a striking contrast with their indolence and relaxation while basking in the sun.

The *Chuva*. The most remarkable character of this species is a border of white hair round the face, from which it gets the name of *marginatus*, or "bordered." The hair on the rest of the body is black. This species inhabits further into the interior of the continent than those already mentioned; but still it is found only in the woods.

The *Spider Monkey* appears to have obtained its name from the length, slenderness, and pliancy of its limbs, though in these respects it does not appear to differ much from the rest of the genus. Indeed, all the species are so similar in their habits, that the only differences are those of colour. The covering of this species is yellowish grey, much softer and approaching nearer to the texture of fur than that of the others; but it has long black hair above the eyes.

The *Black-handed Coaita* has the back part of the head, a patch on the outside of each knee, and the extremities of all the limbs, black or dark brown. The rest of the body is of a uniform grey colour.

The *Miriki* has a mere rudiment of a thumb on the fore-paws, generally without any nail, though sometimes with a rudimental one; but both nail and thumb are so exceedingly small that they can answer no very efficient purpose, and they do not in any way act against the fingers. The colours of this species are rather more diversified than those of any of the others. The face is flesh colour, but spotted over with grey; the buttocks and basal part of the tail are rusty yellow, and the rest of the body is yellowish grey. This species has been found only in Brazil.

The *Chamuk* has projecting thumbs on the fore-paws, but they are very small and short, consisting only of one little paw, and without any nail. The colour is nearly uniformly black. This is also described as being a Brazilian species, and not found in the countries much further to the west.

It has sometimes been proposed to form the two species last mentioned into a separate genus, on account of their having rudimental thumbs; and, certainly, small and inefficient as these members are, these species are not strictly four-fingered; but still the foundation is a very narrow one on which to institute a genus.

The females of all the species have two pectoral mammæ and the young support themselves by clinging with their long and spider-like limbs, thus leaving the mother the free use of hers; and they cling with security while she bounds and swings. It is rather curious that this genus, which are among the worst walkers of all the footed mammalia, not only on two legs but on all fours, are the only ones that have the biceps muscle of the thigh the same as in man.

ATEUCHUS (Weber). A genus of coleopterous insects belonging to the family *Scarabæidæ*, having for its type the sacred beetle of the Egyptians, and comprising several distinct subgenera. Mr. MacLeay, in his *Horæ Entomologicæ*, has, however, considered that the name of Scarabæus having been originally employed to designate these sacred insects, ought to be retained for the genus, whilst to the subgenus containing the true sacred beetles he has restored the original term of Ἡλιοκανθαρος, Heliocantharus, or beetle of the sun. This system of nomenclature we propose to adopt, and shall therefore detail the economy of the insect under these heads, mentioning it in this place only because continental naturalists employ the nomenclature of Fabricius who adopted that of Weber.

ATHALIA (Leach). A genus of hymenopterous insects belonging to the family of the *Sawflies* (*Tenthredinidæ*). The wings have two marginal and four submarginal cells; the antennæ are described by Dr. Leach to be ten-jointed, but in reality there are eleven articulations, the three terminal ones forming a mass: the third joint is the longest. The perfect insects are of small size, inhabit flowers, and are fond of resting upon the young stems of plants; they are slow in their motions, and instead of flying away when approached, they fold their antennæ beneath the body and drop from the twigs. Their colours are for the most part black and buff, or yellow. There are five British species, the *Tenthredo rosæ* of Linnæus being the type.

ATHAMANTA (Linnæus). A genus of thirteen species, chiefly perennial herbs, natives of Europe. Linnæan class and order, *Pentandria Digynia*; natural order, *Umbelliferæ*. Generic character: involucrum often of many leaves; fruit oval, solid, rough, or woolly, five-ribbed.

ATHANASIA (Linnæus). A family containing seventeen species of evergreen shrubs, introduced from the south of Africa. Linnæan class and order, *Syngenesia superflua*; natural order, *Compositæ*. The genus is arranged in two sections, viz., with entire and with divided leaves. The flowers are yellow, and very lasting.

ATHERICERA (Latreille). One of the primary divisions of the dipterous order of insects, comprising the Linnæan genera *Conops Œstrus*, and the majority of the genus *Musca*, or the modern families *Conopidæ*, *Œstridæ*, *Syrphidæ*, and *Muscidæ*. The insects composing these families have the mouth enclosed in a cavity; the antennæ have only two or three joints, the last of which is furnished with a bristle, and the rostrum, haustellum or proboscis is membranous, long, and elbowed in the middle, with two fleshy lips at the extremity, and bearing two palpi behind the angle. It is furnished with two or four instruments for piercing the food. The larvæ have the body very soft and fleshy, contractile, annulated, and pointed towards the head, which is of a variable figure, and furnished with one or two hooks, accompanied by fleshy mamillæ, and probably in all by a sort of tongue, destined to receive the fluid matter serving for the nutrition of the insect. These larvæ do not cast their skin, nor undergo the usual moultings of larvæ: indeed this is carried so far, that the skin of the grub, at the period of the insect's assuming the pupa state, hardens, becomes shorter, and serves as a covering for the enclosed pupa; the pointed front increases in size until the whole assumes an oval form, whence the pupæ of these insects have been compared by the early French naturalists to "une boule allongée." The families may be thus arranged:—

1. Mouth with four piercers . . Fam 1. *Syrphidæ*.
2. Mouth with two piercers:
   1. rostrum obsolete . . . Fam. 2. *Œstridæ*.
   2. rostrum exserted and long Fam. 3. *Conopidæ*.
   3. rostrum retractile and short Fam. 4 *Muscidæ*.

ATHERINA—Atherine. A genus of spinous-finned fishes, belonging to Cuvier's *Mugiloides*, or mullet family, or rather intermediate between them and the *Gobioides*, but not strictly belonging to either. The species are numerous; and the individuals are also numerous on those places of the shores and estuaries which they frequent. They are of small size, but very delicate flavour, on which account they are in much request for the table; and, as they throng in shoals very close together on their favourite stations, they can be caught in great numbers.

Their general characters are: the body elongated; two dorsal fins considerably apart from each other; the ventral fins placed in advance of the pectorals; their mouth is protrusile, and the teeth very small and standing apart from each other; they have six rays in the gill-flap; and all the species are marked with a silvery band along each side.

There are various species in the European seas, the greater number of which are found in the Mediterranean; and they are inhabitants of the warmer seas rather than the colder. There is at least one species, however, which is found on the Atlantic shores of middle and southern Europe. This species was confounded with some of the others by Linnæus, Bloch, and various other naturalists, who probably had no opportunity of examining the fishes themselves; and the error has been continued by most British writers or compilers on the subject. The name given by Linnæus is *Atherina hepsetus*, which Cuvier is of opinion is a Mediterranean species; and he gives the name of *Atherina presbyter* to the species found on the shores of the Atlantic, from the bright silvery bands having something the appearance of a stole. This species is found on some parts of the south coast of England, especially near Southampton, where it is the Atherine (*A. hepsetus*) of most describers, while the local name is the smelt. Both are wrong; for the true smelt is a soft-finned fish, nearly allied to the sea trouts, and growing sometimes to three times the length of the atherine. The smelt is also found much farther to the north than the atherine. It resorts to the estuaries of rivers for the purpose of spawning; and, like the white bait and some other species, keeps the middle of the brackish water. The white bait has been described by many as the young of the smelt, which is singular enough, as smelts resort in shoals to spawn in estuaries where a single white bait is never found, and white bait are found where there are few or no smelts.

The atherine which is found in the English Channel is not more than four or five inches in length. It is yellowish brown on the upper part, with small dark spots on some of the scales. The under part is silvery; and the silvery bands on the sides are very conspicuous. The head is depressed, and has a mesial ridge: the greater part of the body is semi-transparent. These fishes are understood to spawn about midsummer; but they are caught at almost all seasons, except when the weather is very cold and frosty.

On the shores of the Mediterranean they are still more numerous, and sought after with greater avidity; but the species are different. All the European species are readily distinguished by the number of rays in the fins and of vertebræ in the skeleton.

Atherina hepsetus of Cuvier, the *sauclet* of Languedoc, and the *cubassou* of Provence, has nine spinous rays in the first dorsal fin, and eleven soft ones in the second; the anal fin has twelve rays; and there are fifty-five vertebræ in the spine. The muzzle is rather more produced and pointed than in the other species.

Atherina Boyer of Resso, the *joël* of Languedoc, has the head shorter and thicker than the last species, and the eyes larger in proportion. It has seven spines in the first dorsal, and eleven soft rays in the second; the anal has thirteen soft rays, and there are forty-five vertebræ in the skeleton

Atherina mochon (the *mochon*) is like the sauclet in general appearance. It has seven spines in the first dorsal, fifteen soft rays in the anal, and forty-six vertebræ in the spine.

In size, in general appearance, and in the quality of their flesh, the European species differ but little from each other. Nor does it appear that there are any very great differences among those of other seas, which are numerous, and found in various parts of the world.

ATHERIX (Meigen). A rare British genus of dipterous insects, belonging to the family *Rhagionidæ* of Leach: the antennæ have the basal joint larger than the second, and thickened, at least in one of the sexes; the third joint is transverse; the proboscis is not so long as the head, and porrected. These insects, which have much the appearance of the common flies, may be at once distinguished by the much greater number of nerves and cells in the wings. They are generally found in the neighbourhood of woods, and the sexes are very dissimilar. Mr. Stephens records four British species, of which the *Ath. marginata* has been figured by Donovan, pl. 549, under the name of *Musca Atherix*.

ATHEROSPERMEÆ. A natural order of plants, containing two genera, *Atherosperma* and *Pavonia*, and about twenty species. It has only lately been recognised by botanists as a separate order. By some the genus *Atherosperma* is still referred to the *Urticeæ*, or nettle tribe; and the genus *Pavonia*, to the *Malvaceæ*, or mallow family. The essential botanical characters of the order, as separated from all others, are: flowers hermaphrodite or unisexual; calyx tubular, divided at top into several segments, which are usually placed in two rows; stamens, in the male or barren flowers, numerous, inserted in the bottom of the calyx, in the hermaphrodite or perfect flowers arising from the orifice of the calyx; anthers two-celled; ovaries more than one; styles and stigmas simple; nuts terminated with the style, which remains in a feathery state after the flower withers; seeds solitary.

This order consists of trees or shrubs which are found in South America and New Holland. They have generally aromatic and somewhat stimulating properties, but their qualities are not much known, and only a few of them are applied to any use.

The *Pavonia odorata* has a sweet pleasant-smelling root, an infusion of which is used as a diet-drink in fevers by the Hindoos. The root of the *Pavonia Zeylanica*, a native of Ceylon, is also used for a similar purpose.

ATLAS. Lesueur was the first to constitute this genus from the *Atlas Peronii*. It does not appear entirely known; but, nevertheless, ought properly to belong to the same family as that of *Gasteroptera*, The body of this marine animal is divided into two portions, united by a kind of peduncle, somewhat similar to the gasteroptera, the posterior is oval, the anterior circularly dilated, and ciliated at its edges, but provided with a very small distinct foot beneath, with a pair of very small ear-shaped tentacula above; the vent is in the middle of the right side of the posterior mass. The organs of respiration are unknown. De Blainville places this genus in the family *Akera*, of the order *Monopleurobranchiata*, class *Paracephalophora*. The only species described is Peron's *Atlas*.

ATMOSPHERE. The mass of invisible, transparent, and dry fluid, which surrounds the whole globe, and forms not only the grand natural medium of communication between the land and the waters, but the medium by which the remotest points on the whole surface are enabled to communicate with and be of use to each other.

It has been already stated in the article AIR, which see, that the mechanical and chemical properties of this fluid form no part of natural history; and some of its local uses to plants and animals have been pointed out in that article. The fact is, that the atmosphere is so very important, and the uses of it, both in nature and in art, are so many, that the entire knowledge of it forms many sciences, and some of the applications of those sciences are of vast importance in the arts of life. We may remark, in passing, that it is to the atmosphere that man owes his first and grand triumph over all the other animals. He kindles a fire, and all the savage tyrants of the world avoid its radiance, as if it were the contrivance of powers superior to theirs. This fire once obtained, the uses of it are innumerable, and yet the half of them may not have hitherto been discovered. Without it, we could dress no food, we could have no metals, no glass, no porcelain, no bricks for building, no steam, no gunpowder, nothing, in short, worth the living for; and we could have no fire without the atmosphere. Yet this is but one of its numerous uses, and what we are sometimes disposed to consider a trifling one; at least it is of so very common and familiar a nature that we are apt to pass it over unheeded. Our acquaintance with the weather, too, on which our comfort, our health, and well-being rests, so far as we are cultivators or dependent upon cultivation, (and who is not either the one, the other, or both?) are so much involved, is wholly a matter of the knowledge of the atmosphere. The uses of the atmospheric fluid as a power, whether in the turning of mills and other machinery, the wafting of ships across the seas and oceans or quite round the globe, or any other purpose, to which as a power it can be applied, are well worthy of our study and our admiration. In these respects, it is both a wonderful and a wayward thing; and judging of it according to our plans and wishes, we may say in the language of Holy Writ, "the wind bloweth where it listeth." But when we take all nature into consideration it is not so; for the blowing of the wind is an effect, a natural effect, and is as dependent upon its cause and as proportional to it as any of those effects, over which and their causes, we suppose that we have the most perfect control.

The blowing of the wind, though not in itself simply, or in the notions that we have of it as a mechanical power, one of the natural history properties of the atmosphere, is yet one which tends very naturally to produce these, because it is the mobility of the atmosphere, or the ease with which it is put in motion, which is the foundation of many of the most important functions which it performs in the economy of nature.

In the economy of the earth's surface, and as far below that surface, whether it be land or water, as life and growth are concerned, the atmosphere may be considered pre-eminently above every other agent, as the *messenger* by whose kindly offices the system of nature is preserved, and but for which every living thing must, as a necessary result of those common laws of matter which are still as necessary to the perfection of the whole, as the agency of the atmosphere is, speedily and inevitably perish. Whether, if there were no atmosphere, water could exist upon the surface of our earth, is a question which we are not, in a merely natural history view of the matter, called upon to decide; but analogy points rather to the negative; and some persons believe that we have, in the body which is situated the nearest to our earth, the *moon*, an example of an atmosphereless and waterless globe. We cannot examine the surface of the moon, close at hand, and with our naked eyes, as we can do that of the earth along which our path lies; but science, by furnishing us with the telescope, gives us some advantages in examining the moon, which we cannot have in examining the earth. The portion of the earth's surface which our vision can in ordinary cases command, is a mere speck as compared with the whole; and when we ascend to the utmost elevation to which a balloon has floated, or the foot of man trod the mountain, and take with us there the very best instruments which human ingenuity has constructed, our horizon is still very limited, and though (of which we can have no security) the clouds favour our observation, all that we can by possibility see, gives us no adequate idea of what the globe which we inhabit is like, in all its lands and seas, and all its zones and climates, with their varied productions.

But when we examine the moon through an instrument of sufficient power, we can judge of it as a whole, that is we can command, wholly or nearly, an entire hemisphere, or half of its surface. It is true that we do not see the entire hemisphere in the same position: we see the centre of it in plane, and the rest more and more obliquely, till the parts at the circumference are seen in profile. But this is a very great advantage; because we have planes, elevations, and also views in all degrees of obliquity, the information which we get from each of which, corrects and perfects that which we get from the others. Not only this; but in the course of the waxing and waning of the moon, from the first streak of illuminated surface that appears a little after sunset in the west, to the last vanishing one which appears a little before sunrise in the east, we have the light falling upon the same portions of the surface at a great variety of angles, and thus revealing them by all the advantages of light and shade, which are most essential elements in the judgments which we form of objects on the earth from sight.

The 240,000 miles which the moon is, on the average, distant from the earth, is, no doubt, a long distance, although not more in absolute length than that passed over by a sailor, who makes ten or twelve voyages to India. But to the eye it is really nothing, for the eye can see a star so far off, that 200,000,000 of miles is not a measurable fraction of the distance. The distance of common vision, and the distance of the moon, is therefore a question of the relative magnitude of surfaces equally visible; and it is not overstraining the fact to say that, with the very best instruments, a portion of the moon's surface ten miles square, nay, *one mile square*, may be seen as minutely in proportion to its magnitude, as a surface *one inch square* can, by the naked eye, at the distance of one foot.

We have stated somewhat at length the command which observation has of the surface of the moon, for two reasons: first, because the subject is not, so far as we are aware, mentioned by any writer on natural history; and secondly, because the consideration of it is most essential to the accurate formation of those enlarged views of nature, which are equally essential to the full perfection of the science, and of the lesson of moral and intellectual wisdom, which it is so admirably calculated to afford. No one who observes merely species, if there is in him any speculation at all, can fail to notice how much the habits, and even the forms and structures, are dependent upon the localities of which they are natives, and especially upon the degree and distribution of humidity and heat in these localities.

Now, the object of this article is to show that the atmosphere is the grand agent in regulating both the degree and the distribution of these, especially of the humidity; and therefore we cannot start so as to bring out the full force of its advantages, unless we start with the consideration of a surface which has no moisture to be distributed, and no atmosphere to act in its distribution. On the earth we have no such surface. The atmosphere is every where, and no where altogether without heat and moisture. The genial influence of the sun, borne upon the wings of the ever-stirring atmosphere, acts upon the mountain snows and the polar ice; and, even upon the most dry and thirsty deserts, the dew of heaven descends, and in the season, the rains invade their margins and refresh their oases with fertility. The one and the other are parts of the system of nature, brought into action by the agency of the atmosphere; and though in themselves they are at variance with our common notions of productiveness, we know not the advantages which they may confer upon our own fields and their productions. It may be (and there is more than an idle supposition in the idea), that, but for the dry surface of great part of Africa, the north wind would not blow in winter, and consolidate our vegetable tribes into their hybernal repose, but that through that period of the year they might have their strength exhausted by a sickly action during the day, which should be destroyed by the cold of each succeeding night; and it may be, too, but for the seasonal action upon the " regions of the thick-ribbed ice" in the summer, the soft south would not waft us its heating breezes and its fertilising showers. Such questions are beyond the present state of our knowledge; but as we can take no part of the surface of our globe out of the general system of nature's working, so we are unable to say what part each does or does not perform in that grand system. In the common accounts we find such a proneness to exaggerate, that we ought to pause before we give credence. According to these, the thirsty desert is the region of death; and the " simoom" not only kills, but instantly disjoints and dismembers the slain. But, according to the evidence of those who have been exposed to it, in those places where it is usually represented as being the most fatal, the simoom is misrepresented—calumniated. There is no pestilence in it; and though it scorches with drought, and is mechanically annoying from the clouds of sand which it raises, there is nothing deathly in it; and it *may* be the means of diffusing the elements of health over those very places where it rages in the utmost of its fury. Nowhere on the earth's surface do we find the abandoned spot—the place where the goodness of the Creator is not manifested; and if we imagine that there are any where the elements of ruin, we find that He hath " fenced them in with gates and bars " which they cannot pass. We find the barrier set—the confine traced, by

> " The golden compasses, prepared
> In heaven's eternal store, to *circumscribe*
> The universe, and *all created things*;"

so that all may " work together for good."

Therefore, we must look elsewhere for the total absence of the elements of life, growth, and enjoyment; and we find that dreary state of things in the moon. What may be the use of that luminary in the economy of general nature, besides the light which it reflects upon our earth, and the oceanic and atmospheric tides which its attraction produces, we have no means of ascertaining, because we are unable to cross-examine by any evidence of sense or judgment of reason, the appearance which it presents to the eye, aided by the telescope. But that sight is not simply melancholy, it is awfully appalling, and outrivals all that fancy has delineated of the regions of woe. Seen through a glass of even moderate power, the nearest comparison to the places of it upon which the light falls obliquely, is a piece of half-melted snow, which is honey-combed by the action of the weather, but from which the water is clean gone, and there is no earth in the interstices upon which fertility can in any way display itself. But when we apply the requisite power, the sight is truly appalling; large blisters, of which the margins stand up rugged for a mile, are many miles in circumference, and the depths of the pits fearful; plains of solid matter furrowed, as if chaos had been fixed in death in the wildest of its turmoil; single angular rocks, rising to the altitude of our mountains, with crystals, hundreds of fathoms in length, projecting horizontally from their rugged and perpendicular sides; and angular fragments flung together at their bases, each rivalling a hill in magnitude: —these, these are the visible features of the surface of a globe which contains no water, and is surrounded by no atmosphere. Of course, upon such a globe, there can be no plant and no animal at all resembling those which are found upon the earth; and indeed we must entirely alter our notions of life and growth, before we can imagine that there is either the one or the other there. Compared to such a globe, the most dreary parts of the earth have all the charms of a paradise; and they, in no small degree, owe those charms to the agency of the atmosphere.

But when we consider the state of the surface of our own planet, and the various species of action of which it is the theatre, we cannot fail in being convinced that, but for the agency of the atmosphere, it would speedily become desolate, even leaving out of view its essential necessity for the lives of plants and animals, as shortly explained in the article Air. Much of the surface is covered by water, but from the saline ingredients with which that water is mixed, it is, even if we were to suppose that it could, by some mechanical means, return *en masse* to the land, wholly unfit for land plants and land animals. Those salts are ultimate chemical products—sulphates, chlorides, and hydro-chlorides, beyond the ordinary powers of living action to decompose, or even to separate the water from them in its wholesome and limpid state.

And even if the ocean were as pure as a fountain, or as soft as the rain-drops from a cloud, without the atmosphere, there are no means of bringing it on the land. The law of gravitation which, working in concert, works so powerfully for life, would, working alone, work just as powerfully for death. The spring empties itself into the brook, the brook into the river, and the river into the sea ; and if the sources were not supplied, the whole would run dry in a single season. If it were not for the atmosphere, the tops of the mountain ridges, which now collect the rains, and store up the snows, the melting of which refresh and preserve the valleys in the season of drought, would be the hottest, and for that reason the driest, portions of the whole surface ; and were it not for the atmosphere, the sun, wherever it shone, would be hotter than it now is when its beams fall perpendicularly upon the plantless *karroo*, in the sapless sand, while every night would have the darkness of Erebus, and a degree of cold more intense than that of winter in the extreme north of the American continent; so that the change every twenty-four hours would be that from a cinder to an icicle, or even greater. Nothing could, in such a state, live or grow; nay, the very rocks themselves would yield, and the strength of granite would be mouldered to dust. All would speedily sink to one sad level, and from that level there *could* be no return. These would be necessary results, proceeding from the very nature and constitution of matter, and it is in consequence of the atmosphere preventing them, that the study of it becomes so important to the philosophic naturalist.

And though at times it kindles the lightning, awakens the thunder, and lets loose the tempest and the hurricane, these are but local as well as temporary; and its grand and general action is as gentle and silent as it is beneficent. Its simplicity is its strength, and its power of being so very beneficial arises from the readiness with which it yields to even the simplest impressions.

The constituent parts of the atmosphere, by being in the state of gas, have all their powers, or attractions, of cohesion, completely subdued and neutralised; and they are simply mixed together, so that, as already stated in the article Air, the portion which it requires can be separated by the weakest creature without any effort. This simplicity of constitution renders the atmosphere all obedience to every cause that acts upon it, and enables action begun at one point to be propagated throughout the whole; as, for instance, the intense heat which is produced by the sun beating strongly on one place, is speedily diffused to other places; and the clouds which are drank up by evaporation from humid places, steal their way silently through the obedient atmosphere, till they ultimately descend in refreshing showers upon the thirsty land.

The cohesion of the atmosphere being perfectly subdued or suspended by the heat which maintains it in the gaseous state, it has a tendency to distribute or diffuse itself equally in all directions, unless it be restrained or prevented by pressure. When in a tranquil state, or equally at rest over the whole surface of the globe, it is subjected to only one pressure, the pressure of gravitation towards the centre of the earth, which is at once the proof of its existence and the measure of its quantity as matter. At any point on the surface this pressure acts perpendicularly; and at the mean level of the sea it is on the average balanced by, and therefore equal to about 29 inches of mercury, or 33½ feet of water, which is nearly 15 pounds on the square inch. But as the atmosphere is a perfect fluid, it yields equally in all directions to pressure, and thus it presses every way, laterally and upwards, with the same force as it gravitates downwards. By this means, it enters and fills the smallest pores and openings in all bodies; and while its perfect fluidity admits of the most perfect freedom to all their motions, it bears them up with a very effective support, as if they were equally propped at all points. Upon the surface of a human body of the average dimensions, the pressure of the atmosphere is about fourteen tons and a half, but so perfect is the balance on all sides, that this weight, while it renders the whole body stable, instead of rendering progressive motion more laborious, does not impede the pulse of the minutest artery. All animals and plants are supported in a very wonderful manner by this atmospheric pressure, which gives them solidity, and yet hinders none of those actions which are necessary in their economy.

Its insinuation into the minutest pores and openings also prevents the surfaces of bodies from adhering or sticking together, and the thinnest pellicle answers this purpose. Were it not for this property of the atmosphere, the consequences would be serious : the taking off of a man's clothes would be a much more laborious matter than the flaying of a bullock ; and if we suppose that the sole of the bare foot, when planted on the ground, and bearing the weight of the body, touches with only 12 inches of surface, then the foot would be held to the ground with a force of 180 pounds, or it would lift along with it a stone of about a cubic foot. The stone, however, would, as presenting a larger base, adhere to the ground with much more force, and the foot would remain fixed to it. Thus we see that, without one of the most simple properties of the atmosphere—a property which, in our common observation, we overlook,—there would literally be no motion in the world.

The pressure of the atmosphere can be estimated in height of air, as well as in height of mercury or of water. At the ordinary temperature and pressure water is about 820 times heavier than air; and therefore 27,470 feet in height of air will balance or be equal in weight to 33½ feet of water. This, allowing for the inequalities of the earth's surface, would give to the atmosphere, supposing it equally dense at all elevations, a height of about 1500 or 2000 feet above the top of the very highest mountain on the globe.

But the atmosphere cannot have the same density at all elevations, because its density is owing to its own weight only, or rather to the excess of its weight above its expansive tendency or force. And as we ascend above the mean level, the pressure becomes less, not only because the height to the top of the atmosphere diminishes, but because the pressure thereby taken off allows the expansive force to act. It is evident that the expansive force, or the tendency to spread or diffuse, must be greater when the density is greater, and that it must diminish as the density diminishes. It by no means follows, however, that the two should diminish at the same rate. Indeed, it is obvious that the tendency to expand must diminish faster than the density produced by the pressure or weight; for if such were not the case, no part of the still atmosphere could be more dense than another, for the superior density of the lower strata can be produced only by the pressure overcoming, to a certain extent, the tendency to expand; and farther, if the pressure arising from the weight were not the greater, the expansive force would soon dissipate the whole atmosphere through the regions of space.

But though the pressure or gravitation of the atmosphere is as much greater than its tendency to expand as to prevent any part of it from being thus dissipated, yet the expansive force acts as the pressure diminishes, which it does as the height above the mean level increases, because the quantity of air over head becomes less the higher that we ascend, and the pressure or gravitation, being the measure of that quantity, must be equal to it in all its variations. Farther, as the density is the result of the pressure or weight, it must always be in proportion to that, or the rarity must be inversely as the pressure. The densities at different heights will, therefore, express the quantities of air in the superincumbent portions of the atmosphere above those heights, but not the heights upward to which they extend, or the total range of the atmosphere. That range is not, however, difficult to determine; for as the expansion must be as the diminution of pressure, and the increased action of the expansive force *jointly;* and as these are equal to each other, and each of them proportional to the height, it follows that the expansions or decreases of density will be as the squares of the heights, or conversely, that the heights will be as the square roots of the expansions.

In consequence of this increasing expansion with the height, the atmosphere occupies far more space, with the same quantity of matter, than if it every where maintained the density which it has at the mean level of the sea: we have shown that with that density it would have a height of only between five and six miles. But with the decreasing density it has, at the height of about 44½ miles, body enough so to act upon the light of the sun as to produce twilight. Beyond that, its range must be considerable; but in the extreme of its altitude, our knowledge of it is obscure, or altogether wanting, and the twilight may be taken as the most elevated natural proof we have of its existence; but, as that is an elevation which commands a horizon of about 2500 miles in diameter, or one at which a meteor over the centre of Europe could be seen from every point of that continent and its islands, we may suppose that it includes all appearances that can, with any thing like knowledge, come within the range of natural history.

The short view which has been taken of the mechanical structure of the atmosphere, in its simple state, and without reference to the action of any external agent or cause upon it, is necessary to be borne in mind, in order that we may have a proper understanding of the part which it performs in the operations of nature upon the grand scale. It must be understood to be, in itself, wholly passive; the ready and efficient medium of action, but not the cause. At all altitudes, the two forces which determine its density,—the pressure of gravitation and the reaction of expansion,—so exactly balance each other, that the smallest possible action of any other cause, will turn the scale either way; the smallest condensing agency will produce condensation, or the smallest expansive agency will produce expansion. Thus it is, to all the agents in nature, a medium always at hand, and always ready for action.

In estimating those two opposing actions by which the atmosphere is balanced, we have taken no notice of the centrifugal force arising from the rotation of the atmosphere along with the earth. We omitted that in order not to confuse the statement by the introduction of too many principles. The centrifugal force, as far as it goes, is an auxiliary of the expansive force; but in the case of the atmosphere, it diminishes with the height; for though it increases with the distance from the earth's axis, it is also in proportion to the quantity of matter in a given space, and therefore it diminishes in the same ratio as the density, so that in the higher regions of the atmosphere it must be very small.

But, upon the general principle that, under the same or similar circumstances, the resistance which the inertia of matter offers to any force acting upon it, is always in proportion to the quantity of matter contained in an equal space, it follows that the lower strata of the atmosphere must offer more resistance to the active energies of nature, than the strata which are more elevated, and for that reason less dense;—that, for instance, if we suppose the base of a mountain to be on the mean level of the sea, and the top to rise to a considerable height, the resistance of the atmosphere to any natural action, as, for example, to that of plants and animals, will be greatest at the base, becoming gradually less and less as the mountain is ascended, and be least of all on the summit. Water will boil sooner, a bud will expand sooner, and, generally, any operation will be performed in a less time, or with less effort, on the summit of the mountain than at the base; and, if the height be considerable, the difference will be palpable to common observation. At the Nitee Ghaut, in the Himalaya mountains, the barometer stands at about sixteen inches and a quarter, while, at the level of the sea, it is about twenty-nine and a half; and if the pressure upon the surface of a man's body, at the level of the sea, be fourteen tons and a half, that at the Nitee Ghaut will be barely eight tons, and the pressure on all other surfaces will be diminished in the same proportion. In the elevated situation, there will, in consequence, be a distension of the smaller vessels of the body. Upon the same principle, all expansive forces, in the growth of vegetables, the freezing of water, or whatever else acts by expansion, will act under less restraint of pressure, and, therefore, other circumstances being equal, the same effect will be produced with less exertion.

It must not thence be inferred, however, that the action of plants, or of animals, is rendered more energetic by the removal of atmospheric pressure, for the fact is directly the reverse. The power of action is determined by the resistance which it overcomes, and by that only; and if there be no resistance, the action of the power produces nothing, and amounts practically to nothing. Considering its mass and the rapidity with which it travels in its orbit, the power of the revolving earth is tremendous: so great that all the powers which we see or hear of upon the earth,—the descent of waters, the blowing of winds, the action of men and animals, steam, gunpowder, hurricanes, earthquakes, all combined, do not amount to a measurable fraction of it; and these occurrences affect it no more than a single dew-drop affects the ocean. Yet this tremendous power is silent and ineffective. The earth rolls on; but its motion never hurts the most delicate flower, or the most tiny insect, or interferes with the operations which are going on in the remoter and rarer portions of the atmosphere, where, probably, the millionth part of a grain in weight would affect the whole operations. But if, as it careers along, the earth were to meet with an adequate resistance, say with another globe of the same size and weight as itself, then though that globe were at rest, and thus merely passive, the collision would be even fearful to think on. What it would positively be we are unable to say, because we know nothing at all analogous with which we can compare it; but this much is certain, from what we know of the action of comparatively trifling powers when properly resisted, that it *could*, in an instant, dissipate both globes through the regions of space in viewless air, too thin for being recognised by any sense, or tested by any instrument. Many other instances might be given, but this one may suffice, the more so that any one who reflects, must be convinced that we have no knowledge of power but from the effects which it produces, that is, the resistances which it overcomes. The motion of the earth, the circulation of the blood in our own bodies, and countless other results of power that could be named, never would or could have been found out by any observation of simple facts; and the pressure of the atmosphere comes so much under the same denomination, that the discovery of it is considered as one of the most brilliant, as well as the most useful, in the whole wide field of modern science.

Thus we have, in what may be considered as the merely passive resistance of the atmosphere, a very general and very important power, or, to speak more correctly, an evolver of power, in all the actions of living and growing nature,—a power to which not a few of the differences which we find between the productions at different heights in the same latitude are owing. At the base of the mountain we find, for instance, the vine and the olive; on the middle slopes there are luxuriant forests; to these succeed heaths and other lowly shrubs of slow and creeping growth, then lichens, hardly more vegetable in texture or in taste than the rocks which they incrust; and, lastly, the never-thawing snow, even where the fire of a volcano blazes in the midst, and at times raises its pillar of flame, and volleys its red-hot rocks many hundreds of feet into the air. The variety of animals is as great, from the ox to the buffalo, which grazes in the rich meadow at the base, through all the succession of tribes to the marmot by the margin of the snow, which dozes out half its life in a state of hybernating stupor. The differences of pressure in the atmosphere are not the sole causes of these differences of the productions of the earth at different altitudes; but it is one of the causes, and one upon which some of the others depend; and it is a cause not arising from any action of the atmosphere, either mechanical or chemical, but from its perfectly neuter and quiescent state.

When the resistance of force, or, which is the same thing, of motion (for we have no notion of physical force unless in so far as it produces, or tends to produce motion), attains to a certain degree, it is always accompanied by the evolution of sensible heat; and this result is so constant, that we have no knowledge of the evolution of sensible heat but by the resistance of motion of some kind or other; and conversely there is probably no resistance of motion without an evolution of heat, whether that heat be cognisable by our senses or instruments or not. Of course it is impossible for us to have direct evidence in those cases which are too minute for our observation; but the fact of heat accompanying resistance, and being, unless in cases where we can easily explain the deviation, so exactly in proportion to the resistance, and in truth the measure of it is so general, so free from a single exception, that to suppose it does not extend to every case, whether that case come within the limits of our observation or not, would be a violation of the fundamental principle of all philosophic reasoning.

Here, then, we have another important result of the varying pressure of the atmosphere, as affecting the living and growing productions of nature at different heights above the mean level of the sea. The additional resistance which, in places that are situated low, it offers to the action of plants and animals, produces heat as well as more intense action; and from all that we know of the economy of plants and animals, both of these are essential to their development, and that development must increase with the increase of both, and diminish with their diminution. Thus we see that, in the quiescent atmosphere itself, as a mere resistance, there are varying causes of fertility, which may be considered as having their maximum at the mean level of the sea, and diminishing in the proportion of the density, that is, as the squares of the heights above that level.

But it is by the action of heat that the cohesion of those substances which form the atmosphere is subdued, so that that fluid exists in the state of air; and therefore, the more rare or attenuated it is, the greater degree of action must be required for maintaining it in that state. But the heat which is necessary for maintaining the state of any substance is not *sensible*, not felt, or communicated to other substances; and therefore, the more rare or attenuated the atmosphere is, the greater must be its tendency to take the heat out of other substances. Consequently, as we ascend above the mean level of the sea, the atmosphere must become gradually colder, till at all places there be a point of elevation, higher than which the temperature shall never be warmer than that at which water freezes. This is called the point of perpetual congelation, or frost, and above it there can be no general action either of animal or of vegetable life. From partial data, it is not very difficult to calculate the average elevation of this point above the level of the sea for all latitudes; but when we come to practice, the calculations thus formed will not apply, because local circumstances have very considerable influence. Thus, on the mountains which rise out of the dry and warm table land of Mexico in America, the summer, or lower elevation of this point, is more than a quarter of a mile; and on the northern side of the Himalaya mountains, which have the extensive and dry table land of central Asia on the north, it is more than a whole mile higher than theory would lead us to suppose. Thus, though the law, that the atmosphere is colder as we ascend above the mean level, be a general law, which holds true in all parts of the world, yet the law is so much modified by other circumstances, that the precise determination of the decrease of temperature for any one place must always be matter of local observation. Here, however, we have another general effect of the diminished pressure and density of the atmosphere upon life and growth, which, though subject to local variations in amount, is uniform in principle; there is a diminished temperature as we ascend, and as temperature is one of the elements of living action, whether animal or vegetable, there must be a corresponding diminution of that action as we ascend above the mean level.

When, in addition to these, which may be considered as some of the effects of the atmosphere, considered merely as passive or neuter, upon the action of plants and animals, we add the operation of external causes, we find results of much greater importance. The heat of the sun is unquestionably one of the most powerful agents in the production of life and growth, and the grand medium through which that agent acts is the atmosphere. Clear notions of the mode of the action of heat through that medium are therefore absolutely necessary to anything like a rational understanding of the active parts of nature, and without that, natural history is a mere detail of dead specimens, unworthy the name of science, of small value in the arts, and affording neither occupation nor pleasure to a rational mind.

From the very nature of the atmosphere, or indeed of an organ of any kind, we might infer the general action of heat upon it, without any observation or experiment. The gaseous, or aërial state, is owing to the action of heat, which subdues the cohesion of the substance, and in proportion as it is rarefied, or has its cohesion farther subdued, the action of heat, which goes to the support of it in that state, and which is consequently rendered insensible, or incapable of being given out to other substances without a corresponding condensation of the air, must be increased.

Hence, generally, when air (atmospheric or any other) is heated, it expands, and when cooled it contracts or condenses; and if the expansion or contraction ever take place freely in the exact proportion of the action of heat, which is communicated in the one case or abstracted in the other, the air may pass through a considerable range of density without having its sensible heat altered. But, in consequence of the differences of pressure and density, air at different heights of the atmosphere can neither expand nor contract to the same extent with the same addition or abstraction of the action of heat. The pressure and density of the lower strata both tend to resist expansion, and the pressure at least tends to favour contraction; while, in the upper strata, the diminished pressure and the rarity tend to favour expansion, and the diminished pressure at least tends to hinder or diminish condensation. Wherefore, there is in the lower stratum of the atmosphere a tendency to give out to other substances any heat that may be communicated to that stratum, and this tendency diminishes as the height above the mean level of the sea increases. The effect of this must depend upon the degree of the action of heat which is communicated; but still, if we suppose that the whole of the atmosphere is equally exposed to any heating cause, the heat which is resisted by the atmosphere, and becomes sensible, and is given out to plants and animals, must be greatest at the level of the sea, and diminish as the height rises above that level. But, as heat is one of the most essential agents in the economy of all the living and growing productions of the earth, this tendency in that part of the atmosphere which is at the level of the sea to give out heat most readily, and the diminution of this tendency as the height increases, must again render the lowest places the most fertile, and productive of life of all kinds, and the more elevated ones less so, in the proportion of their elevation—that is, on the supposition that the soil and geographical position are the same, or similar.

But further: the grand heating cause to which the atmosphere is exposed is the rays of the sun, acting either directly, by refraction, by reflection, or by radiation; and in all these ways the solar light may be considered as acting upon the particles, or ultimate component parts of the atmosphere, although these parts are, individually, by far too small for being perceptible by our senses. This being the case, the action of the solar heat, or indeed of any other heat, come from whatever cause, and act in whatever manner it may, must be in proportion to the density of that portion of the atmosphere upon which it acts. Air twice as dense contains of course twice as many particles in the same space; and as these must all be equally acted upon by an equal heating cause, the heat communicated to one of double density must be double, and so on for other proportions. If the surface of the ground, or the objects upon that surface, have a lower temperature than that which the stratum of air next the ground receives from the heating cause, the heat will be, in great part, given out to them, and increase their temperature, and consequently their action in so far as that can be promoted by heat; but if the ground, or what is upon the ground, has a higher temperature, the effect of the heat communicated to the atmosphere will be to expand the portion next the ground, and cause it to ascend in consequence of the diminution of weight which the same volume of it sustains by the expansion.

Much, therefore, depends upon the kind of surface. If that be of a nature capable of receiving the heat which is imparted to the atmosphere, that heat will be communicated to it; and it will, according to circumstances, produce growth, or drying, or parching, and burning up. But if the surface is not in a condition to receive the action of heat, that action will be carried upward in the expanding air, and produce its effects in the atmosphere.

It was mentioned that, in the mountains which rise over the dry and warm table land of Mexico, the line of congelation is a quarter of a mile higher than the theory would lead us to suppose; and that on the *north* side of the Himalaya it is fully a mile higher. The latter would, to common observation, appear the more singular, not only on account of the greater difference, but because the Himalaya are in a more northern latitude than the Mexican mountains, and the situation where the line of congelation is highest is on their northern slope, or that which is turned away from the sun, while on the southern, or sunny slope, it is lower, though still considerably above what the theory from partial data would give. Now the plain of Mexico, though warm and dry, and of a character to have its temperature raised, by the direct action of the sun, so high as to receive no heat from the air, is yet not a barren plain, but in many places under natural plants of considerable growth, and in others under culture. Mexico is also at no very great distance either from the eastern or the western sea, and it is, in consequence, subject to occasional rains. The country to the north of the Himalaya is not so well known; but there is reason to believe that considerable portions of it are barren desert, and, parts of it, at least, are very rarely visited by rain. Accordingly, the country to the northward of the Himalaya, though probably more elevated than the plains of Mexico, high as that is, and having certainly an increase of latitude which with surfaces similar and similarly surrounded, would make it the colder country of the two, has yet its surface so much more susceptible to the direct action of the sun, that the heat which it resists receiving from the atmosphere, and that which it gives out to that fluid, together suffice to raise the line of congelation in the neighbouring mountains three quarters of a mile higher than in Mexico.

These two cases are worthy of being borne in mind, not only as they are in themselves singular and striking, but as showing to what an extent the action of the atmosphere, in the general economy of nature, may be modified by differences in the surface of the earth. This is the more necessary, because the actions of all the different surfaces that are met with on the earth, being matter of very ample and minute detail, some of which are yet but imperfectly known, cannot be developed in a general article.

Still the subject is one, without a notion of the general principles of which no man can either merit the name or enjoy the pleasure of being a naturalist, because it is the one which is pre-eminently concerned in "putting the wheels of life in motion," and causing them to work differently in different places, so as to produce that rich variety of contrasts which forms the grand bond of union and incentive to intercourse between nation and nation, and makes the inhabitants of different zones or hemispheres act as whetstones in polishing and sharpening each other.

The general law is, that the heat communicated to the atmosphere acts most upon those surfaces where its action is the most beneficial; and, where its action cannot be beneficially exerted, it mounts up into the higher strata, and is wafted to, and confers its genial influence upon, other regions. Thus the heat which cannot find fit employment on the thirsty heights of Central Asia, speeds southward to the slopes of the Himalaya; and in consequence the rustics tend their flocks, reap their simple harvests, and live in comparative plenty, where, according to the theory, the surface *should* be shrouded under fathoms of perpetual snow.

This, it must be admitted, is saying very little; and yet, in a general way, it is almost all that can be said, only it may be said in different words. Generally then, the heat communicated to the atmosphere by the sun acts more powerfully on humid surfaces than on dry ones. Not that it heats them more, but the reverse, for the heat is rendered not so sensible on the humid surface, in consequence of the increased action which it performs there. Dry surfaces which are pale in their colour return heat by reflection, and do not get so speedily heated as those of a darker tint, which after they are heated give out heat by radiation. Of humid surfaces, it is not the surface of pure water that most completely absorbs or occupies the action of heat. When still, the surface of pure water reflects back to the air much of the heat which falls upon it; and the more in proportion as it falls the more obliquely. Hence, sheltered places that have a clear lake or tranquil river on the south, or inclining to the south-west, are very warm, especially upon sunny days in winter; but places which are situated the reverse way to the river or the lake are proportionally cold. The contrast of such places, even when at no great distance from each other, is often very striking. Strand-on-the-green and Mortlake, both on the Thames, and not above a mile apart afford an instance. On a clear winter day, with the wind a little sharp at north, the contrast between the river side at Strand and that at Mortlake is almost as great as that between Dorset and Caithness. These are local actions, however, and have little or no effect beyond their limited locality.

When the surface of water is in a state of agitation, it retains much less of the heat which falls on it than when it is tranquil; and water which is shallow, and partially covered with reeds or other tall aquatic plants, returns less heat to the atmosphere than perhaps any other description of surface. All surfaces indeed which are covered with luxuriant vegetation, in a state of vigorous growth, consume much of the heat that falls on them, though there is no doubt that some portion of heat is set free, or become sensible in the process of growth, because in that process there is an expansion of the substance of the plant acting against the resistance of the air, and there is also the change of substances from a more fluid to a more solid state.

The general cause of the absorption of heat, or the apparent cold of humid surfaces, whether of the water, the moist earth, or of growing vegetables, is understood to be *evaporation*, or the conversion of water into invisible vapour, which rises and spreads in the atmosphere. This vapour may be considered as consisting of pure water, whether it is raised from pure water, water impregnated with other substances, the humid surfaces of growing vegetables, or any other source. At all events, if there are other substances accompanying it at the first, they are not raised to any great height, or carried to any great distance. Fogs and drizzling rains from the sea, especially if they come from low sandy beaches where the water is apt to get heated, sometimes tinge the hedges and trees with salt to the distance of a mile or two inland, but they do not reach far; and though the miasmata of marshes are said to produce ague, fever, and other diseases, in those who dwell in their immediate vicinity, the rains which result from vapour raised out of them are perfectly pure and limpid. It seems, therefore, that water is purified as well as raised and distributed invisibly through the air, in the process of evaporation.

This process of evaporation is perhaps the most important, in a natural history point of view, of all those in which the atmosphere is an agent, because it is the one in which the grand circulation of water originates, and without water there could be no life or growth upon land.

The process of evaporation is as general and common as it is important, and yet it belongs to that class of natural actions of which no very satisfactory account can be given. Its importance in a natural history point of view is so great that we shall hazard a few remarks expressly upon it in an article EVAPORATION; but we may remark in the meantime that there are two theories, each of which has some plausible arguments in its favour, and both of which are liable to objections of so much cogency as to render the truth of both very questionable. One of these theories is that evaporation is produced solely by the action of heat upon the water, and that the air has no concern in it, the vapour being buoyed up by its own elasticity. In proof of the theory, there is adduced the well-known fact that evaporation takes place very copiously in a receiver exhausted of air, in which case the air can have nothing to do in its production; and also another fact that a number of gases, of very different natures, are capable of holding exactly the same quantity of water in vapour. In opposition to the first and apparently most conclusive of these proofs, it is stated, that vapour is produced in the exhausted receiver, only because the pressure of the air on the surface of the water is taken off at the same time the air itself is removed; but that when the air is removed, and a pressure equal to its weight continued, which would be exactly the state of things in nature if the air had no agency in evaporation, the evaporation does not go on. In attempting to turn the edge of this objection, Dalton, notwithstanding all his abilities, failed. There are other objections, more in the way of common observation: evaporation is not always rapid in proportion to the heat, for on some intensely cold days, when there is a strong wind, it goes on with great activity; and those east winds which, in the early part of the season, not only dry the surface of the earth, but parch and wither the vegetation, are cold. Still, it is true that evaporation always produces cold; and therefore, though the action of heat is not the sole cause of it, it is certainly one of the causes, or one of the elements of the compound cause.

The other and more popular theory of evaporation attributes it to the chemical solution of water in the air, by means of an attraction or affinity existing between the two fluids; and though it has been urged against this theory that evaporation does not go on most rapidly when the air is densest, which, according to the theory, it ought to do, yet the effect of pressure in preventing, in the exhausted receiver, that evaporation which goes on freely and readily when there is no pressure, shows that, beyond a certain point of density, the ascertaining of which is of course matter of experiment, the pressure of the air checks and diminishes the process.

That some kind of attraction subsisting between air and water is, like heat, though not the sole cause of evaporation, yet, like that, one of the causes, or one of the elements of the compound cause, seems unquestionable. But it is doubtful whether this attraction should be called a *chemical* attraction, or the diffusion of vapour through the air a *chemical* solution. It is true that, in the formation of vapour, there is cold produced, or a certain degree of the action of heat is absorbed, and absorbed, no doubt, in the formation of the vapour; it is also true, that when the vapour is again condensed and falls in rain, there appears to be heat produced, or a certain degree of the action of heat which was previously imperceptible or *latent*, is rendered sensible; and it is also true that similar changes, with regard to heat, take place in many chemical solutions and their reversals. But a chemical solution of one substance in another, or which is the very same, a chemical combination, is never formed without some effort: the two substances so united to a certain extent become one, that one has new properties which did not belong to any of the two singly, and the combination cannot be dissolved without some action.

It would be contrary to the observed facts, as well as to the analogy of nature (the only guide which we have where our mechanics and chemistry fail us), to suppose that the water which the atmosphere holds in the state of vapour, is combined with the atmosphere by any chemical process. One chemical attraction cannot be overcome but by another and more powerful attraction of the same kind, and no chemical compound can be dissolved without more powerful chemical action than that by which it was formed and is held together. But we find the atmosphere parting with its humidity to the smallest animal, or the most tender leaf, with no more effort than when it parts with its oxygen in the process of respiration. Analogy, indeed, points out to us, with a force of reason not easily to be resisted, that no other substance can combine more intimately with the atmosphere, than its two grand component elements, oxygen and nitrogen, combine with each other; and it has been shown, in the article Air, that these can always be separated without any thing approaching to the nature of a chemical process. The atmosphere is the grand messenger of nature, and whatever is carried free to all the productions of nature, without labour or exertion on their part. Chemical compounds are never formed in nature, unless the compound body has some functions to perform as a whole. Such at least is the case with all compounds formed according to our chemistry. But our chemistry, extensive and important as it is as a science, and valuable as its applications are in the arts, is a very partial, and therefore doubtful and deceptive agent, when we bring it to the philosophy of nature. It applies to dead matter only, and therefore when we attempt to use it either in the explanation of any one function of life, or of that upon which life depends, it fails, or leads us into error. Now the atmosphere is preeminently the element of life; and therefore we can hope for little aid from chemistry in our investigation of the natural properties and agencies of the atmosphere.

That there does exist some sort of attraction between the atmosphere and the water which it takes up in the process of evaporation, cannot be doubted; as little can it be doubted, from the short distance to which foreign substances accompany the union, that this attraction is for water in its pure and simple state,—for water, not as it holds only one or two substances in solution, and is fit only for the particular operations in which those substances are agents, but in its simple state, equally fit for all purposes to which water can be applied. Of what particular nature this attraction is, we are ignorant, and it belongs to that class of natural actions, respecting which we have little chance of gaining any information, further than observing the results. Perhaps we shall not err very much, if, to distinguish it from every thing chemical, and from all those attractions in which the action of heat, under any of its modifications, is the agent, we call it a *corpuscular* attraction,—an attraction belonging to the same class with that by which one liquid mixes with another without change of temperature or action of any kind; that by which fluids wet the surfaces of solids, and many others which are not chemical, neither are they mechanical, as they do not depend upon gravitation. It appears, from the fact that there is always air between substances which prevents them sticking together, unless in the case of what appears to be a stronger corpuscular attraction of the substances, that the air has a corpuscular attraction for every known substance; and that all substances whatever might rise in vapour in the atmosphere, provided their cohesion were sufficiently overcome by the action of heat, or by any other means. This property, which is verified by the facts as far as these go, points at a most extensive, almost a universal use of the atmosphere in the operations of nature. This view of the atmosphere opens a very wide field, and one in which the judicious inquirer has still much wisdom to win; but it is one upon which we cannot in the meantime enter. Our more immediate business is with the atmosphere as the recipient of the vapour of water, and the distributer of that water to the general surface of the earth in rain, or to particular substances for silent absorption.

This is the simple and general view of the matter which is most essential to the proper understanding of natural history; and it is of the utmost consequence that our views of it should be clear and accurate, because it is a subject which, if we study nature at all in its connexion, we are constantly meeting. We are, then, to understand that the air takes up, from all humid surfaces, moisture in the state of invisible vapour; that this is taken up by the corpuscular attraction of air and water, and the action of heat, jointly, though the heat may act sometimes as electricity as well as generally as ordinary heat; that the moisture so taken up is distributed through the air, and sustained there by the same agencies which raise it in vapour; but that, though dispersed and invisible, it is not combined, but always ready to be given out without chemical effort.

The heat which the atmosphere receives, whether from the direct rays of the sun, from reflection, or radiation from the earth, or any other cause, in like manner enters into no chemical combination with that fluid, so as to produce what may be its final action there, If the surface of the earth is not of a nature to receive it, and profit by it, then it acts in expanding the atmosphere; and the part so expanded ascends, carrying with it the water which it may hold in a state of vapour. The action of heat, therefore, puts the atmosphere in motion, and enables it to waft from place to place the water which it holds as vapour.

The capacity of retaining water in the state of vapour increases with the increase of heat, and diminishes with its decrease, but the two do not vary at the same rate. In theory, the power of retaining moisture should increase and decrease faster than the heat, because it is promoted by two causes, the action of the heat, and the diminished density or pressure of the expanded air. In practice, the facts agree with this theory; and if they did not, it is not easy to see how the atmosphere could part with the moisture which it has once held as vapour. Those east winds which frequently injure vegetation on the low-lying grounds upon the east side of England, often arrive on the coast in a state of complete saturation, and ready to deposit their humidity in rain; and, where bleak and elevated districts abut upon the shore, they produce rain. But the low and warm grounds, in Essex, Suffolk, and Norfolk, for instance, radiate, or otherwise give out as much heat as converts what upon the bleak and elevated land would be a moist and raining wind into a drying one; and this will go on for weeks, till the fields are as dry as a summer path, and the vegetation is perished and shrivelled; nor is there in the places which those east winds scourge any means by which to stop their progress, or even mitigate their action. But when these winds reach the high grounds in the midland counties, where they have a colder surface, and also a greater elevation, they are no longer able to retain the whole of the humidity with which they are charged, but deposit part of it in rain. The evaporation of that rain cools the surface and the air over it; the east wind is, in consequence, checked in an earlier part of its course; the rain falls more easterly, and may conduct the east wind to the coast, while the south-west wind follows in the rear; or the opposition of the westerly wind may produce a similar result, in a manner to be afterwards explained.

The kinds of surface which the globe, at different places, presents to the sun, are various beyond any enumeration shorter than separate descriptions of the whole, and the action of the sun upon them is just as varied. This holds not only with regard to the land, but in some instances also with regard to the sea, the cold produced by evaporation from which, and the action of its currents, are not jointly able to maintain a uniformity of temperature, either in the water itself or in the atmosphere over it. Unlike the atmosphere, indeed, the sea has very little tendency to be thrown into currents by the different action of heat upon it several parts. The cause is evident: the expansion of water by heat and its contraction by cold are very limited; and the evaporation where the action of the sun is greatest, is not sufficient to produce a sensible motion even of the mere surface. Where the water is comparatively shallow and clear, and the bottom of a light colour, the heat of the perpendicular sun returned from the sea, is indeed not much less than that returned from the surface of dry land. This is severely felt by navigators in Torres' Strait, in a considerable portion of the sea on the north coast of New Holland, and in other places, where one can hardly bear to look down on the water, and the air over it has a temperature of from 110° to 120° of the common thermometer. There, from the heat of the air and that of the water, the quantity of evaporation must be supposed to be very great; but the cold which it produces is not increased in the same proportion. In the polar seas, on the other hand, the effect of evaporation adds so much to the natural cold of the air, that while by the action of the direct and reflected rays of the sun, the pitch on the sunny side of a ship melts and runs down like water, the frost under the shade is more intense than when the sun is obscured. We have approximations to that in some of the colder parts of Britain, where, though the direct sun feels warm, the cold in the shade is more intense than on a cloudy day.

The heat from reflected light over the sea, if none is returned from the bottom, is least where the sun is perpendicular, and increases as the direction becomes more oblique. It is also greatest when the surface is smooth and glassy, and the cold produced by evaporation is then also the least, so that a curl upon the water is always a means of cold. When the water is deep, the heat never has so much influence upon it, so that, even under the vertical sun, there is a cooling effect in the sea.

The surfaces of the land are much more varied, and all that can be said of them is, that with an equal action of the sun, or of any other heating cause, the surface which is the most humid, and parts with its humidity with the least action, is always the coolest.

The leaves of plants which are growing vigorously and cover the ground with their shade, and which have at the same time an abundant supply of water at the roots, present, perhaps, the most cooling of all surfaces. They not only multiply the actual surface upon which they grow many times over, but they aid the evaporation by the tendency they have to give out moisture. Whether they give out moisture by the same pores, or other parts of their surface, by means of which they at other times absorb it, is, though probable, not proved, and perhaps not capable of proof; but it is certain, that when they have an abundant supply, they absorb more than is necessary for the ultimate purposes of vegetation. This, in particular situations, and at particular seasons, they give out in greater quantity than the evaporative power of the atmosphere can receive; and thus they are found humid and dripping, in cases where there can be little or no condensation of atmospheric moisture upon them. Besides giving out to the atmosphere a portion of that moisture which they receive from the soil by their roots, they, under other circumstances, appear to give out to the soil by their roots a portion of that which they receive from the atmosphere by means of their other surfaces; and when the roots have penetrated into strata not capable of retaining any moisture, the plant may be parched while there is humidity in the air, just as by hot and dry air it may be parched while there is humidity in the soil. All these circumstances tend to show that plants excite a more powerful action in the atmosphere, or engage it in more powerful action than bare surfaces of any description, and that, therefore, surfaces thickly covered with them preserve a more uniform temperature amid atmospheric changes, whether diurnal or seasonal, than any other surfaces of the land.

These are but a very few out of a vast multitude of circumstances, but they may afford some assistance in forming a notion of the general principle; so that, bearing them in mind, and bearing in mind also that the atmosphere is always taking up moisture by evaporation, and that heating expands it and gives it a tendency to ascend, and cooling produces the opposite effects, we are in a condition for forming some notion of its general action in the economy of nature.

The sun is the grand agent which puts the whole in motion; and the peculiar motions of the earth so vary the sun's action with days and seasons, that the details of this part of the subject, even without reference to the variety of surfaces upon which the sun acts, render this single part of the subject extensive as well as complicated.

It may hardly be necessary to state, that the rotation of the earth from west to east causes the apparent revolution of the sun from east to west in twenty-four hours; and the path of the point where the sun is vertical shifts northward from our midwinter to our mid-summer, and southward the other half of the year. His daily change is smaller at the beginning and end of each half-year, and greater at the middle of each, which are the times of the equinoxes.

The point where the sun is vertical, or at least that point in the apparent path of the vertical sun where the heat is greatest, is the centre of the solar action; and in the course of each year it travels in the manner which has been stated. At that point the atmosphere has a tendency to expand and ascend, greatest at the surface, and greater in proportion as that surface is susceptible of being heated. The air from the adjacent places presses in to supply the room of that which is heated and ascends; and as the centre of heat is apparently in rapid motion westward, the motion of the air towards it is turned in that direction. The chief motion of the air is of course from the north and south, because the heating cause has passed over the parts to the east. but is approaching those to the west, and the westward motion causes that from the north to come as from the north-east, and that from the south as from the south-east. These do not meet by a considerable space, because, as they approach the centre of heat they begin to feel its influence and ascend. But if the globe had a surface uniformly susceptible to heat, they would play round it constantly, shifting northward and southward with the apparent place of the sun. The surfaces of the great oceans clear of the land are nearly uniform; and these currents play over them, and are well known as the trade-winds. Of course these winds, which are nowhere very violent, diminish as the distance of that which is their cause increases; so that they are not felt to any very great distance either northward or southward. They however produce, in the upper strata of the air, winds in the opposite directions, because the air cools as it ascends, and it is urged onward by the ascent of a fresh supply from the surface. As that returning portion recedes from the central cause of heat, it descends and gives out heat; and thus the atmosphere distributes the heat of the sun northward and southward.

The land interferes with the regular motion of these winds, by intercepting them by its elevation and also by affecting the heat of the air by its surface Thus the wind which is a surface-wind over the desert in northern Africa, is too rare for being a surface-wind over the Atlantic. Therefore it ascends instead of moving westwards; and a considerable portion of the sea is calm or without wind. But the air which was so much heated carries with it much more moisture than it can keep suspended in the more elevated part of the atmosphere to which it ascends; and the result is, that those tranquil portions of the sea are visited by frequent and heavy falls of rain—so much so, that they are popularly called "the rains." These calms and torrents of rain do not take place immediately upon the African shore, but so far out at sea as to allow the stagnant portion of the atmosphere to be compressed laterally by the currents from the north and south east.

On the western coast of America, at some distance from land, there are similar calms and rains; but as the portion of the American continent off which they are found is higher and not so dry as the northern part of Africa, they are neither so marked nor so constant in their appearance. In both oceans these calms and rains are to the north of the equator. There are two reasons for this · first, the parallel of maximum heat is a little north of the equator, as our summer half-year, being the one which occupies the *aphelion* portion of the earth's orbit, is longer in absolute time than the other; and secondly, the land immediately under the equator, and even for a considerable distance to the northward of it, is not favourable for their production. Guinea is a fertile country, with luxuriant vegetation near the shores, and rising into mountains in the interior; and Peru, the greater part of the narrow isthmus in America, and also Mexico till considerably northward, are mountainous.

The places which meet the current of the trade-wind, or receive it from the oceans, are, as may be supposed, the very reverse of those at which it commences. They are the oriental seas and the Malay peninsula on the west of the Pacific, and Brazil, the whole north coast of South America, the West India islands, and the narrow part of the isthmus on the west of the Atlantic. In both situations some places are land-locked, or covered seaward by others, so that the action of the current upon all is not alike: the general direction of the coast, too, throws the current over the Pacific southward, and that over the Atlantic northward. The last is very remarkable; and notwithstanding the intense cold of the north of America, there are traces of a tropical character, both in the plants and the animals, to some distance up the valley of the Mississippi. There is at least one species of palm; there are both land and water reptiles of tropical character; and there are marsupial animals as far to the north as Virginia.

All those places which receive the trade winds, or currents of the atmosphere, which have swept for long distances over the tropical seas, are remarkable for the richness, the variety, and the peculiarity of their productions, both vegetable and animal. The trees of the Oriental isles are equally remarkable for the richness of their foliage, the fragrance of their flowers, the flavour of their fruits, the aromatic pungency of their spices, and the beauty of their timber. They are the chosen habitations of the true-apes, of monkeys innumerable, of climbing birds of the richest plumage, and of that singular race, the birds of Paradise. There, also, the crushing serpents attain their largest size, and the poisonous ones their most deadly venom. Islands with broken surfaces, and romantic alternations of forest and rock, are not the proper haunts for the larger beasts of prey; but those of intermediate size in the Eastern isles are as peculiar as the other productions.

Nor is the exuberance of nature confined to the land; for in all places where the bottom can be seen, the sea is equally fertile and varied in plants and in animals. The mollusca, the crustacea, the annelidæ, and even the common finny tribes of the deep, are abundant, curious, and glowing in their tints, in those places of the intensity of nature's action. Colour of the utmost brilliance, both in plants and in animals, is one of the characteristics of those all-prolific climes; and that colour not only beautifies all upon land, but plunges down into the waters and elicits radiant tints there. Where the solar rays come nearly perpendicular, they act upon the earth and enter the waters nearly in equal parts of the whole spectrum, whereas, when the rays come sloping, the blue and violet, and those tintless rays beyond, which appear to have, with *iodine*, and with the production of both pungency and colour, some mysterious connexion which the present extent of science is unable to explain, are dissipated by refraction; and hence, as we approach the poles, colours, properly so called, become few and faint, and, both in plant and in animal, they tend gradually to the ultimate contrast of black, the absence of light, with white, the presence of light unbroken by action. But, in the regions under consideration, we have every glory which the bow of heaven can display, heightened and varied by all the assistance of deep velvety surface, metallic lustre, and the playful iridescence of changing hues.

In the west, the corresponding lands are different, but they are hardly less striking. We have the rosewoods, the mahogany, the dyewoods, the allspice, and countless species of medicinal trees; we have the sloths in place of the apes, and monkeys as abundant in number though different in form; we have also macaws and humming-birds, and toucans, and many other winged creatures, gay in their colours and curious in their shapes and habits almost beyond description; nor must we forget the fang of the bushmaster, the most formidable perhaps with which any reptile is armed. It is to be borne in mind, too, that here the influence extends over a far wider range. The isles of the east are only, as it were, a few gardens, while America is a wide field; and the influence of the current sweeps round from Cape St. Roque to the Mississippi, and plays along the mighty valley of the Amazon, as far as the base of the Andes.

There is one curious point, though philosophy has not yet brought it into any connexion. The terminations of these two currents are *antipodal*, or at the opposite ends of a diameter of the globe, a coincidence which happens with very few places, as almost all the rest of the land has its antipodes in the sea. They are also both volcanic, and the centres of the great volcanic actions in the east and the west. In the present state of our knowledge, it is impossible to say that the atmospheric currents have any connexion with the last-mentioned circumstances; but the fact is worth bearing in mind, and *may* lead to some important result. The atmosphere is the grand messenger of the whole globe, bearing heat and moisture, regulating the action of these, and therefore highly influential in all that the different regions present or produce. But the philosophy of it is as yet in mere embryo; and the facts to be observed are so many, and the generalisation of them requires so much care and judgment, that the man who shall stand upon the basis of inductive truth, and tell the world all the wonders of its working, is not yet born.

We should now proceed to show how the same properties of the atmosphere work on the local and the minute: how the lake and the dry common, the stream and the meadow, the copse and the field, and even the field which is under crop and that which is bare, work together; but the subject has already beguiled us to the full extent that we can spare; wherefore we must refer for some of the details to the general remarks introductory to the accounts of those vertebrated animals, which are characteristic of peculiar localities, and close this desultory article by recommending every one who wishes to know nature on the grand scale, carefully to study the atmosphere.

ATOMARIA (Marsham). A minute genus of coleopterous insects, belonging to the family *Xylophaga* of Latreille, *Engidæ* of MacLeay, or *Corticaridæ* of Curtis. In this genus are included some of the most minute species of beetles, scarcely any of them exceeding the twenty-fourth part of an inch in length; and yet in these atom forms, which would be almost destroyed by the fall of a pin's head, we find the same beautiful organisation, the same number of parts and joints, and are consequently warranted in supposing a perfectly similar disposition in the internal organisation which is found in the giant stag beetles, or the still more gigantic hercules or elephant beetles. It has been much the fashion to regard every thing coming from the French as at least tinctured with infidelity; we have, therefore, the greater pleasure in quoting the words of that distinguished French entomologist, who had fairly won for himself the title of "Entomologorum princeps"—the late Latreille:—

"The wisdom of the Creator never appears with more effect than in the structure of those minute beings which seem to conceal themselves from observation, and Almighty power is never more strikingly exhibited than in the concentration of organs in such an atom. In giving life to such an atom, and constructing in dimensions so minute so many organs susceptible of different sensations, my admiration of the Supreme Intelligence is much more heightened than by the contemplation of the structure of the most gigantic animals."

These insects have the antennæ clubbed, and as long as the thorax, with the second joint longer than the third; the elytra convex and entire; the thorax with entire margins; and the body ovate-linear. There are more than twenty British species, of which the *Silpha evanescens* (a most appropriate name) of Marsham may be considered as the type. They reside in damp and obscure situations, but are fond of flying in the hot sunshine.

ATOPA (Paykul, Stephens; Dascillus, Latreille, Curtis). A genus of coleopterous insects, belonging to the section *Malacodermata*, or soft-cased beetles of Latreille, and referred to the family *Cebrionidæ* by Latreille and Stephens, and to the *Telephoridæ* by Curtis. The body is elongate and convex; the antennæ are long and filiform; and the lower jaws and lip are furnished with several slender pencilled lobes. There is only one British species, the *Chrysomela cervina* of Linnæus, which is very local, preferring chalky districts, and found upon alders and brambles: it is of a buff or dark brown colour, and not quite half an inch long.

ATRACTOCERUS (Palisot de Bauvais). A very extraordinary genus of exotic coleopterous insects, belonging to the division *Pentamera* and family *Lymexylonidæ*. The body is very long, narrow, and depressed, and the elytra are so minute that a late German author speaks of one of these insects as "Animal valde singulare et memorabile; prope tu credideris naturam quasi hæsisse an coleopteron an dipteron crearet."—From the singular formation of this animal, you might almost fancy that nature was in doubt whether she should create a beetle or a fly. The antennæ are short and fusiform, and the wings extend nearly to the extremity of the body: the palpi of the males are furnished with a remarkable branched appendage. There are three or four species, inhabitants of South America and Africa: they are found amongst woods, probably residing under the bark of trees.

ATRAGENE (Linnæus). An ornamental genus of climbing shrubs, natives of Europe. Linnæan class and order, *Polyandria Polygynia;* natural order, *Ranunculaceæ*. Generic character: calyx of four sepals, deciduous; corolla ten or twelve, linear; stamens inserted on the receptacle, filaments very short; anthers oblong, pointed; style, hairy, with persisting stigmas; caryopses many, with tail-like styles. This genus is nearly allied to virgin's-bower; and when trained to a trellis or wall having a northern aspect, are elegant plants.

ATROPA (Linnæus). A genus of two species, one a British herb, the other a West India shrub. Linnæan class and order, *Pentandria Monogynia;* natural order, *Solaneæ*. Generic character: calyx five-parted; corolla funnel or bell-shaped, limb five, occasionally ten-lobed; stamens somewhat protruded; berry two-celled; placenta loose. The *Atropa belladonna* is one of the most dangerous vegetable productions of Britain. The berries resemble cherries, and are liable to be mistaken for wholesome fruit; but eating them is death, as has often happened to children. This plant grows in waste corners of fields, or under the shade of ruined buildings or old trees. It should be rooted out wherever found.

ATROPOS (Leach). A genus of Neuropterous insects, belonging to the family *Psocidæ*, and separated from *Psocus* by Dr. Leach, from the circumstance of the tarsi being three-jointed, and the wings wanting. The type of the genus is the *Termes pulsatorium* of Linnæus, a minute insect, commonly met with amongst old books, and upon the paper on walls. It is of a dirty white colour, with the eyes and a row of spots long the abdomen reddish. Its specific name alludes to the noise which it makes, similar to the ticking of a watch, and which has often been confounded with the ticking of the death-watch.

Atropus pulsatorium.

ATTA (Fabricius). A genus of hymenopterous insects, belonging to the family of the ants, *Formicidæ*, differing from *Myrmica* by their very minute palpi, and by the large size of the heads of the neuters. In this genus is included some of the largest species of ants, some of them exceeding an inch in the length of the body. The *Formica cephalotes* of Linnæus and Fabricius is the type of this genus: it inhabits various parts of South America, where from its habits it has received the name of the visiting ant, "la fourmi de visite," since it occasionally finds its way in troops into the houses of the residents, who open their doors and receive it gladly, as it consumes or drives away not only the cockroaches and spiders, but even mice and rats.

Atta cephalotes—neuter (magnified).

ATTACUS (Germar). Saturnia (Schrank). A genus of nocturnal lepidopterous insects, separated from the great Linnæan genus *Phalæna*, of which it formed a section, and comprising some of the largest and most beautiful moths; the wings when the insects are at rest are extended and horizontal, and often adorned with a transparent patch in the centre; amongst these, the atlas moth of China is one of the finest species. The cocoons of some of these species are employed in the East Indies for the manufacture of silk, namely the *Bombyx mylitta* of Fabricius, and the *Phalæna Cynthia* of Drury (see the seventh volume of the Linnæan Transactions, also a paper by Colonel Sykes, recently read before the Royal Asiatic Society); the emperor moth, *Phalæna attacus pavonia minor* of Linnæus, is the only British species belonging to this genus, and which is placed by recent entomologists in *Saturnia* as a distinct sub-genus. The *Tau* emperor, *Phalæna attacus tau* of Linnæus, forming the sub-genus *Aglia* of Ochsenheimer, is reputed to be British.

ATTAGENUS (Latreille.) A genus of coleopterous insects belonging to the division *Pentamera* and family *Dermestidæ;* the type of the genus being the *Dermestes pellio* of Linnæus, a small British insect about one-sixth of an inch long, of a black colour and oblong form, with a white spot in the centre of each wing-case ; the antennæ have the last joint long, especially in the males, in which it equals the entire length of the remainder of these organs. The maxillary palpi are filiform, the second and fourth joints being the longest. These insects are sufficiently common in old houses, larders, &c., attacking the skins of preserved animals, old books, paper and wood. The larvæ is particularly destructive to neglected zoological collections. It is furnished with brushes of hair, which it possesses the power of expanding, thus resembling the *Anthreni*, to which it is otherwise nearly allied.

ATTALIA (Humboldt). A genus containing seven species of Brazilian palms. Linnæan class and order, *Monœcia Monadelphia;* natural order, *Palmæ*. Generic character: flowers male and female separate, sitting, on one side; spadix branched, rising from the root; spatha one-leaved; calyx of three small sepals; corolla of three fleshy petals; stamens inserted on the base of the pistils; styles three; drupe fibrous, three-celled, each one seeded, shell woody, furrowed, three holes at the base, kernel solid. These palms are described as most magnificent in form and height.

ATTELABIDES (Schoenherr.) A sub-family of insects belonging to the *Coleoptera tetramera* and family *Curculionidæ*, having for its type the genus *Attelabus* of Linnæus. This genus, it is to be observed, was one of the most heterogeneous of all the Linnæan groups, being a receptacle for all beetles with the head narrowed behind into a neck, and antennæ thickened. As now restricted, and raised to the rank of a sub-family, it comprises those species of weevils which have their antennæ not elbowed in the middle, the head narrowed and lengthened behind the eyes, and the elytra oblong-ovate. The chief genera included in it are *Apoderus, Attelabus* and *Rhynchitis.* The genus *Apoderus* (Olivier) is a pretty group of *coleopterous* insects, having the rostrum short and thick, and the head lengthened behind the eyes into a long neck. In some of the exotic species, especially those brought from Nepaul by General Hardwicke, this neck is nearly half the length of the body. The only ascertained British species, is the *Attelabus avellanæ* of Linnæus,

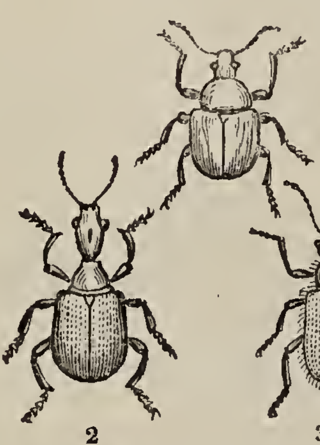


Fig. 1, Attelabus curculionides. Fig. 2, Apoderus avellanæ. Fig. 3, Rhynchites cavifrons.

which is red with a black head; it is about a quarter of an inch long, and is found upon the hazel and oak abundantly. The genus *Attelabus* comprises only one British species, the *A. curculionidæ* of Linnæus. It is distinguished from *Apoderus* by its antennæ being eleven instead of twelve jointed, and by its head not inserted into the thorax by means of a distinct neck. It is of a black colour, with the thorax and elytra bright-red; is about one-sixth or one-fourth of an inch long, and is very common on the nut and oak. The genus *Rhynchites* of Herbst, comprises some of the most beautiful species of weevils found in this country. Amongst these the *Curculio auratus* of Scopoli (hitherto confounded by all British entomologists with the *Curculio Bacchus* of Linnæus) is the most splendid as well as the rarest. The genus is distinguished by its dilated rostrum, eleven jointed antennæ, and head not produced into a neck. There are nearly twenty British species. Schoenherr enumerates forty-seven species. They are found upon various vegetables and trees. Our figure 3 represents the *Rhynchites cavifrons* of Chevrolat (Schon. Curcul. i. p. 226.), a species allied to *Rh. pubescens*, which we here introduce for the first time as a native species.

ATYPIDÆ. A family of *Arachnida Demerosomata* or spiders, having four pulmonary sacs, and four spiracles; the palpi are inserted upon a lateral and basal dilatation of the maxillæ, and are five-jointed, the last joint being long, and pointed at the tip in both sexes : the males have no strong spur at the extremity of the anterior shanks. This family comprises two genera only, *Atypus* (Latreille, *Oletera* Walckenaer), and *Eriodon* (Latreille, *Missulena* Walckenaer). In the former the jaws are very large, the eyes on each side of the head are united together, whilst in the latter they are placed widely apart. The *Atypus sulzeri* has been taken by Dr. Leach, near Exeter and London. It burrows in shelving turfy ground, forming a cylindric cell about seven or eight inches deep, at the bottom of which it spins a lining of white silk, and to which the eggs, enclosed in a similar silken case, are attached. The *Eriodon occatorius* is an inhabitant of New Holland.

Atypus sulzeri.

AUCUBA (Linnæus). A Japanese shrub of great beauty. Linnæan class and order, *Monœcia Tetrandria;* natural order, *Rhamneæ*. Generic character: flowers monœcious; calyx truncated, persisting, imperfectly four-toothed; corolla of four oval spreading petals; disk, round the germen (in the male flowers encircling the base of the style), flat, the middle marked with a hole; stamens inserted in the receptacle, alternately with the petals; filaments thick, very short; anthers oval, double, with four furrows; style short, persisting; stigma headed; berry many-seeded. This fine shrub was introduced from Japan in 1783, and was treated first as a stove, and afterwards as a conservatory plant, for many years. It has now become one of our hardiest and commonest shrubs in gardens, and withstands the rigour of our winters, even better than the common laurel. The flowers are inconspicuous; but its yellow spotted leaves make up for this deficiency, and have gained for it the name of "golden laurel."

AUCHENIA (Marsham). A genus of coleopterous insects, belonging to the division *Tetramera*, and family *Galerucidæ*. It has been much restricted by recent authors; and Mr. Stephens places in it only one species, the *Chrysomela*, 4-*maculata*, a pretty insect, which we have met with in marshy places near London. It is of an ochreous colour, with four black spots on the elytra, and is distinguished from the *Adimoniæ*, with which Mr. Curtis unites it, by the antennæ, having the third joint twice as long as the second; whereas in the *Adimoniæ* they are nearly equal. In the latter genus are comprised two beautiful British species, the *Chrysomela Alni* of Linnæus, which is very rare, and the *Chrysomela halensis*, a very common species on various plants: it is about a quarter of an inch long, of a golden green colour, with the thorax yellow, and the legs brown.

AUGITE. A mineral which derives its name from a Greek word, indicative of its lustrous character. There are four distinct species of augite, viz. the oblique-edged, the straight-edged, the prismatoidal, and the prismatic augite.

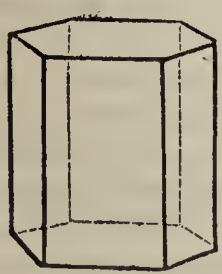

Fig. 1.

Fig. 2.

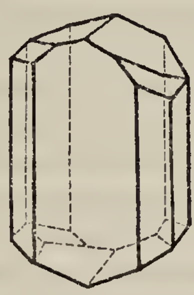

Fig. 3.

The foliated augite, which occupies a prominent place in the first species, is of a dark green colour. The form of its primary crystal is a four-sided prism. One of its secondary crystals is shown at fig. 1, consisting of a six-sided prism. Another form is exhibited at fig. 2, in which it assumes the character of an eight-sided prism, bevelled on the extremities. Fig. 3 is also an eight-sided prism, in which the obtuse terminal edges of two opposite planes meeting under acute angles are truncated. This form of augite occurs in secondary trap-rocks, and in lava as well as in basalts. This mineral is principally distinguished by its strong internal lustre, and peculiarly marked crystallisation.

As augite is sometimes mistaken for basaltic hornblende, it may be advisable to state their respective characteristic distinctions. Augite is, as we have already stated, of a greenish black colour, while basaltic hornblende is invariably of a much deeper black; it is also softer than augite. Another very peculiar characteristic of hornblende is that it can readily be fused by the agency of the blow-pipe: augite, on the contrary, is very difficultly fusible.

The varieties of this mineral, which are very numerous, and possess great interest in a scientific point of view, will be fully described in their alphabetical order.

AULOPUS—"pipe-fin," in allusion to the large external rays of the abdominals. A genus of soft-finned fishes, with abdominal fins, belonging to the salmon family, and combining in rather a singular manner some of the characters of the salmon and some of those of the cod. There is but one known species, the *Salmo filamentosus* of Bloch, so called from the filaments or beard resembling those of the cod. The gape is wide, and extends far backwards. The intermaxillary bones, the palate, the edge of the vomer, and the lower jaw, are furnished with one even row of recurved teeth; but the tongue is smooth, and the flat part of the palate is without any. The maxillary bones are large, but without any teeth. The abdominal fins are placed immediately under the pectorals, having their external rays very large, so that they seem forked. The first dorsal fin occupies a portion of the back, answering to the anterior half of the distance between the abdominal fin and the anal. They have twelve rays in the gill-flaps. Their bodies, cheeks, and gill-lids are covered with large scales, something similar to those of the salmon. In the spawning time they frequent the banks and shallows, but it does not appear that they ascend the rivers.

AULOSTOMA—"pipe-mouth." A genus of spinous-finned fishes belonging to Cuvier's fifteenth and last natural family of the order *Bouches en flute*, which of course has the same meaning as the name of this genus. The fishes of this curiously formed family, which are known to English sailors by the common name of "pipe-fish," without regard to the generic distinctions, form only four genera, and the species are not numerous. They are all natives of the warmer seas, but one species at least is found in the Mediterranean. The distinguishing character of the family is the mouth lengthened into a sort of tube or pipe. There are two divisions,—*Fistularia*, in which the body is long and slender; and *Centriscus*, in which it is oval and compressed. Aulostoma belongs to the first division; but neither the tube nor the body is so long in proportion, as in the other genus of that division, *Fistularia*.

Aulostoma has several free spines in front of the dorsal; the body very scaly but slender, though it is enlarged and compressed in the portion between the dorsal and the anal fins. This enlarged portion is followed by a short and slender tail, which terminates in a caudal fin of the ordinary shape. The air-vessel is uncommonly large for the size of the fish. There is but one species, a native of the Indian seas.

AURANTIACEÆ—the orange tribe. A natural order of plants, the thirty-seventh of the Jussieuan system, containing about a dozen genera, and between thirty and forty species. The name *Hesperideæ* is also applied to this order. The essential botanical characters of the family are,—calyx pitcher or bell-shaped, short, from three to five-toothed, withering; petals varying in number from three to five, broad at the base, sometimes distinct, sometimes united; stamens equal in number with the petals, double or triple; filaments compressed below; ovary many-celled, ovate; one rounded style; fruit many-celled, the cells filled with pulp, enclosed in little bags, and surrounded by a thick rind, which abounds in glands containing volatile oil. The plants belonging to this order are beautiful evergreen trees or shrubs almost exclusively natives of the East Indies, whence they have been introduced into different parts of the world. Their thick leaves articulated with the petiole, and furnished with pellucid dots containing an essential odoriferous oil, are their obvious peculiarities. Their flowers are generally white and fragrant, their wood hard and remarkably compact, and they produce a fleshy edible fruit containing an acid pulp. Many of them are prized both on account of their medicinal qualities and the esculent fruits which they yield. In general, their properties are aromatic, stimulating, and refrigerant.

The orange, lemon, lime, and citron, may be mentioned as examples of this order. Of the *Citrus aurantium*, or orange, there are several varieties, the chief of which are the sweet or China orange, and the bitter or Seville orange. The latter is the variety used in medicine, and ordered in the pharmacopœias. The orange originally came from Asia, but is now cultivated in Italy, Spain, Portugal, and the warm regions of Europe, as well as in the West Indies. It requires a mean annual temperature of 62°. It produces fruit in great abundance. A single orange-tree at St. Michael's has been known to produce 20,000 perfect oranges fit for packing. On the same tree we meet with flowers, unripe and ripe fruit. The juice of the orange has an acid taste, and consists of citric acid, mucilage, and syrup. It is used as a refrigerant in fever and inflammatory complaints, and as a cure for scurvy. The outer rind of the fruit is aromatic and bitter, and contains much essential volatile oil. It is used as a tonic to strengthen the stomach and promote digestion. The oil was formerly employed in epilepsy and convulsive diseases. The rind of the bitter orange is prepared by confectioners in various ways. When boiled with sugar and dried, it is sold under the name of candied orange peel, and when made into a sort of jelly, it forms the well-known preserve called marmalade. The unripe fruit when dried receives the name of Curaçoa oranges, and is used in the manufacture of the rich liquor known by that name. The flowers of the orange are of a beautiful white colour, and diffuse a most fragrant odour. They are used as a perfume and condiment. Orange-flower water is given in large doses to procure sleep. A fragrant red-coloured oil is distilled in Italy from the flowers, and is called *oleum* or *essentia neroli.*

AURANTIACEÆ. Citrus aurantium. *a*, Flower; *b*, stamens, to show the union of the base of the filaments *c*, pistil and germ; *d*, transverse section of the ovary, *e*, ditto of the fruit; *f*, seed.

The *Citrus limonum*, lemon-tree, is also originally from Asia, but is now widely distributed over different parts of the globe. The fruit of this tree is more acid than the orange. The juice is used as a refrigerant and antiseptic in febrile diseases and in scurvy; and along with carbonate of potass or soda forms cooling effervescing draughts, very useful in allaying vomiting and thirst. Citric acid is prepared from the juice. The yellow peel or rind is aromatic, and furnishes an essential oil, known by the name of oil or essence of lemons, which is used for perfumery as well as for flavouring lemonade, barley-sugar, &c.

The *lime* resembles the lemon, but is smaller in all its parts, and contains more acid in its unripe state. Many other plants of this order supply edible fruits. The shaddock, a well-known Indian fruit, larger than the orange, is the produce of the *Citrus decumana.* The fruit of the *Glycosmis citrifolia* and *Triphasia trifoliata* are delicious articles of food. The *Cookia punctata* yields a fruit called wampee, which is highly valued in China and India. The fruit of the *Feronia elephantum,* called wood-apple, is eaten by the Indians. From this plant also is procured a gum similar to gum arabic. Its leaves are aromatic and carminative. The fruit of the *Ægele marmelos* is said to be excellent, and to possess nutritive as well as laxative qualities. The leaves of this plant have been used in asthma, and its root and bark are recommended in Malabar in hypochondriacal complaints and in palpitation of the heart. The rind of its fruit yields a perfume. The leaves of the *Bergera Koenigii,* another plant of this order, are stomachic and tonic, and are used in a raw state in dysentery. Its bark and root have stimulant virtues.

AURELIA. A term employed by the older entomologists to designate the pupæ of lepidopterous insects, i. e. butterflies and moths. The word is synonymous with chrysalis, and both were adopted, the first by the Romans, and the second by the Greeks, in allusion to the golden colours with which the pupæ of many butterflies are adorned, whence, in process of time, these terms were employed generally, although the pupæ of the majority of lepidopterous insects have no appearance of gilding. This appearance was eagerly seized upon by the alchemists, as an argument in favour of the transmutation of metals; but the insufficiency of such reasoning was fully proved, both in France and England, by the application of those principles of investigation by which alone the real cause of natural effects can be ascertained; Reaumur, in France, having discovered that it is owing simply to the shining white membrane immediately below the outer skin, which being of a transparent yellow, gives a golden tinge to the former; whilst Lister, in England, imitated the gilding of chrysalises, by putting a small piece of a black gall in a strong decoction of nettles; this produced a scum, which when left on cap paper will exquisitely gild it, without the application of the real metal. Reaumur also mentions, that for producing this appearance it is essential that the inner membrane be moist, whence may be explained the disappearance of the gilding, so soon as the fluids within the pupa have been absorbed by the formation of the limbs of the butterfly. As the term aurelia is, however, nearly obsolete amongst naturalists, we shall defer our general observations upon the nature of pupæ or chrysalides to a future article.

AURICULA (Linnæus). The *Primula auricula* of botanists. This beautiful species of primrose has been, from its native mountains of Switzerland, advanced to one of the first stations in European flower gardens. In these latter, it is now a stage flower; and as no plant has had more pains bestowed upon it than the auricula, so no other presents the effects of skilful management more decidedly.

Originally the auricula was diminutive in bulk, with small trusses of flowers of nearly unvaried colour; but under the treatment of the florist, the whole plant becomes amplified; both leaves and flowers are enlarged; and the latter are not only improved in regularity of form, but diversified with the richest colours in endless variety.

The florist's auricula is a child of art. On the stage it loses almost all its original hardihood; for neither can it bear the winter's frost nor summer's sun. Kept in pots, and pampered on the richest soil, it is preserved from the extremes of the seasons by having roofed stages erected for its welfare. Here it is defended from every unfavourable vicissitude of the weather, and completely under the control of the owner, who gives or withholds water, admits or shuts out air or sunshine, according as his fastidious charge requires.

That dry air is necessary to the auricula is obvious from its natural habitat being lofty mountains; from experience in its cultivation, and particularly from that curious peculiarity of constitution by which it covers itself with dust. This is certainly a defence against rain; and is a silent hint to the manager to be guarded against keeping his plants too moist, more especially when they are in a dormant state.

The auricula is propagated by seed to procure new varieties, and by slips, to multiply and continue old favourite sorts. In raising them from seed, the most important part of the business is saving seed from the best kinds. The usual precaution is moving the breeders away from among inferior kinds, and placing them where they may be in close contact with superior sorts, in order that they may receive sexual impressions either by accident or by the intentional manipulation of the manager. The breeders are assisted in every practicable way to ripen the seed. Decayed or supernumerary florets (or pips, as they are technically called) should be cut off, leaving only the more promising capsules to mature their seed. When these become dry and brown, they should be gathered and kept in a cold and moderately damp, rather than in an over-dry place, till the month of January, when the seeds, freed from the capsules, should be sown.

Boxes, large sized pots, or seedling pans, are used for seed-beds. These should be carefully drained by a layer of gravel or cinders in the bottom, filled with proper compost, shaken and pressed smoothly down full half an inch below the rim, leaving the middle rather higher than round the sides. On the surface the seeds are dropped regularly, and covered with finely sifted compost to the thickness of a crown-piece. Water is given immediately, but so lightly that the surface or seeds be not disturbed. The seed pans are next placed within a frame or hand-glass, where they will be safe from the mid-day sun, from earth-worms and insects. Air should be given occasionally to prevent mouldiness, and gentle watering if necessary. Some florists raise their seedlings on a mild hot-bed. This not only expedites the germination and growth of the seedlings, but brings up many of the weaker seeds, which would not rise at all without such excitement.

As soon as the plants are fit to handle, they are thinly pricked out into larger sized pots, in which they are nursed till the month of August, when they are again transplanted singly into sixty sized pots, or three together at equal distances round the outside of forty-eights. Here they remain to flower; and then comes the most interesting period of their culture. The sower may have raised many that are worthless; and also many that are only third and fourth rates; perhaps a few second rates; but if he gains only *one* first rate he feels all his labour well bestowed!

Successful management of the auricula depends very much on the suitableness of the soil or compost prepared for it. The different substances employed are maiden, or fresh loam; the droppings of sheep, horses, or oxen; desiccated or very old night soil; dung of pigeons, poultry, and geese; blood from slaughter-houses; sugar-bakers' scum; bone dust; leaf mould; and sea or river sand. Portions of all these substances have been used, but without advantage; many eminent florists using only one-third loam, and two-thirds sheep-house dung, and a little coarse sand, all well incorporated together.

Choice auriculas are kept in thirty-two sized pots, and should be shifted about the first of August in every year. Some individual plants may need shifting sooner, especially those which require to be divested of their slips. The slips are taken off at shifting, and potted by themselves; and then also the condition of each plant should be considered and treated accordingly. Such as have been previously shifted, and have improved in growth during summer, will only require larger pots, with an addition of fresh compost. Such as look sickly, should receive a more severe examination, by shaking off the soil entirely from the root, to see whether canker has seized the tuber: and if so, the knife must be applied to cut away all decayed parts before repotting. In potting the lower leaves should be about half an inch above the surface, and this nearly one inch below the edge of the pot. This depth is necessary, in order to allow as large a top-dressing as possible in the month of February.

After being thus shifted and watered, the collection must be placed where there is full air and light, but shaded from ardent or long-continued sunshine, and also from heavy rains. The morning and evening sun is salutary, but not that of the middle of the day. It has already been observed that the stage auricula is wholly an artificial being; so much so, that it cannot bear extreme changes. An equable degree of moisture is necessary for the roots, and a regular degree of dry air is likewise necessary to the leaves. For these purposes, each plant, when it arrives at a proper age, must not only have its own pot, but the collection must have a suitable platform or shelved stage fitted for its reception, raised high enough from the damp of the ground, and with a covering to exclude the sun and rain whenever necessary.

To combine with convenience all the advantages of shade and shelter required by auriculas, a double stage protected by a double roof is certainly best. On one side of the roof may be glazed lights or pannels, and the other boarded shutters of the same dimensions, so that they may take each other's places as the season or state of the plants require. It would be superfluous to give directions for such an erection; so as the principle of its use connected with convenience is adhered to, local circumstances and the views of the proprietor will direct all the particulars of place, form, and dimension. We may notice, however, a very simple contrivance, constructed for keeping auriculas both in summer and winter. It is built in the form of an alcove, placed against a north or south wall, according to the season. Four substantial corner posts are fixed in the ground; those behind are united by a plate five feet from the ground; the front posts have also a plate six feet high; the ends and back are boarded. The roof is covered with pannels, sloping from the front and attached to the back plate by hinges, to admit of their being thrown off. The width of this frame need not be more than about four feet. This will give room for a stage of four shelves, rising one above the other, on which to place the pots. By throwing back the roof pannels a warm shower may be admitted. The front being open allows the entrance of the mildest air and strongest light in winter, and a curtain of mats defends from frost, or from the sun's heat in summer. If such a frame as this, intended for a small collection, were formed on truck-wheels, so that it might be turned to any aspect, it would serve as well for a summer as a winter repository, and answer all the purposes of a double roofed frame.

On such a stage as this auriculas are kept during spring, summer, and autumn ; and if they can be sufficiently protected during winter also. Constant care is required to supply them with water, light, and air, as best suits them, in such quantity and at such times as the experienced cultivator only knows how to afford. In their progress towards blooming, if more than one truss of flowers appear, the weakest must be displaced. And when the preferred truss begins to open its florets, these, if too numerous, must be thinned, leaving no more than will form a well-balanced head of flowers. Small pointed scissors are used to cut out the supernumerary pips ; from seven to thirteen of the strongest being considered enough. Shading the plants while in bloom—supporting the weak stems by hooked wires—giving water in moderate quantities to the roots only—preventing the visits of slugs, woodlice, earwigs, &c., require the daily attention of the florist ; and when the flowering is over his attentions do not cease. The plants must next be removed to the summer station, and there receive over again the necessary treatment, as before detailed.

A fine auricula should have a strong elastic stem, bearing the truss at some height above the leaves. The parts of each floret, are the tube, the eye, and the exterior circle containing the ground colour with its margin ; these three should be proportional ; that is, supposing the diameter of the floret to be divided into six parts, the eye should occupy three (the tube being one), and the ground-colour the remainder. The face of the floret should be round, not starry ; the anthers should be bold, filling the tube well, and surrounded by the raised edge of the tube, called the cup. The eye round this cup should be a regular circle, purely white, and smooth ; encircling this is the ground colour, which should be intense and rich ; either in an unbroken band, or in very distinct patches, somewhat suffused into the margin. The ground colour should be black, purple, blue, or bright pink ; but glowing scarlet, or deep crimson, edged with green, are highly prized.

AURICULA (Lamarck). VOLUTA (Linnæus). The animal of this genus has its foot entire. The shell is thick, solid, more or less smooth, oval, oblong ; the spire short and obtuse ; the aperture entire, oblong, enlarged, rounded in front, becoming much narrower backward ; the edges disunited, the right constantly thickened and turned outwards ; the left, or columellar side, almost always presenting one or several teeth, or thick decurrent plaits, on the columella.

These shells were blended promiscuously with the *Volutes* of Linnæus, from which Bruguière removed all those not possessing a notch at the base into his genus *Bulinus*, not considering that the plaited, or callous columella, distinctly indicated the dwelling of a differently organised animal. Lamarck has consequently constituted the present genus. He had imagined that the *Mollusks*, with a plaited column, the aperture without a notch at the base, and the margin smooth and sharp, were river shells, and therefore formed them into a separate genus, under the name of *Conovulus ;* but, from the subsequent observations of De Valenciennes, it was discovered that they are terrestrial, and Lamarck has included them in the present genus, which he divided into two ; first, the species having the right lip reflected ; and secondly, those having the right lip plain and sharp. De Blainville has divided this genus into five species ; the first having the columella redge, with three thick plaits or folds, and the internal part of the right lip denticulated its whole length, as in the *A. scarabæus* here figured ;

A. scarabæus.

the second species having the columella with two thick decurrent plaits, and one tooth behind (constituting the genus *Carychium* of Muller, and *Phoetia* of Gray), as *A. myosotis ;* the third species, which have only two decurrent folds in the columella, as in *A. Judæ ;* the fourth species, in which only one plait in the columella exists, as in *A. Sileni ;* and lastly, such species as have their lips without either teeth or plaits, as in *A. lineata.*

The number of recent species thus circumscribed amounts to eleven or twelve, of which three very small ones are European ; the others are from the banks, particularly, of the Indian and American Archipelago. Lamarck enumerates seven fossil species, and De France nine, but some of them are true *pedipes,* and the turriculated species certainly are not of this genus.

The name is derived from a fancied resemblance to the ears of some animals.

These shells seldom present any vivid colouring or elegant pencilling ; they are for the most part covered with a thick epidermis ; but they are frequently delicately sculptured, and form a pleasing and interesting genus, easily distinguished from the *Volutes* by the characters pointed out. Their rank in modern malacology will be seen by referring to the article *Auriculacea*, of which they form the second genus.

AURICULA JUDÆ, a fungus so called, belonging to the genus *Exidea*, found on decayed trunks of elder.

AURICULACEA (De Blainville), a portion of which were blended with the widely-diffused Linnæan genus *Voluta.* The bodies of these molluscous animals are spiral, with subcylindrical tentacula, inflated at the summit, clumsily contractile, having the two eyes placed at their internal base ; one upper tooth is opposed to a tongue provided with little hooks. The shell is thick and solid, the opening more or less oval-shaped, always much larger, rounded in front, and somewhat narrowed by one or more teeth, or thick columellar plaits.

The animals of this family are phytophagous, and constantly inhabit the sea-shores, being even sometimes momentarily covered by the water.

This is the second family of the order *Pulmobranchiata*, class *Paracephalophora*, in De Blainville's Malacology.

AUTOMOLITE. A species of the mineral termed corundum stone. It occurs at Fahlun, in Sweden, and is usually imbedded in talc-slate, along with galena. Automolite resembles both ceylonite and spinel, but it is distinguished from the former by its more distinct green colour, foliated fracture, inferior hardness, and superior specific gravity ; and from the latter by its colour, inferior lustre, perfect cleavage, low degree of transparency, inferior hardness, and greater specific gravity.

AUTUMN. The third in order of the four seasons into which, in the temperate regions of the world, the natural year is divided; and in the kalendar, including the months of August, September, and October, or nearly equal times on each side of the autumnal equinox, or the time when, about the 22nd of September, the day and night are equal to each other. But nature is not regulated by the kalendar, either as to the time or the duration of autumn, or of any other season. Much depends upon the latitude,—not a little upon the surface and the proximate surfaces, and on the currents of the atmosphere and the sea—something depends upon the character of the previous season—and even the culture which man bestows upon the soil has no inconsiderable influence upon this season. Where, by skill and industry, he subdues the wildness of nature, clears the wild, drains the marsh, enriches the sterile field by manure, shelters the exposed one by trees, and, generally speaking, obtains a rich and abundant crop, the elements work in concert with him, and send him a delightful autumn in which to gather it in, and also to take his sport in the cleared fields after it is under the thatch, or to prepare for another year that portion of the crop which is to abide the winter in the fields. And it is not for his crop and his immediate comfort alone that the season co-operates with his skill and industry. The tree consolidates that portion of wood which the year has produced; brings forward its buds, whether for fruit or for an increase of twigs, full and round; and wraps them up in their safe hybernacula, until a new year shall call them into action. The flocking birds are upon the cleared fields betimes, consuming the seeds of the annual weeds before they have begun to germinate. The air is free, dry, and repellent of the premature inroads of winter; and all nature is gradually prepared for that healthy repose which is the surest pledge of vigorous and useful action in the year which is to come.

On the other hand, if man neglects his duty, the neglect is felt by all nature, though the punishment, as in justice it ought, falls most heavily upon the wrong-doer. If the water is allowed to stagnate, the banks of the stream to become marshes or quagmires, and the surface of the earth to run wild, there will not only be poor crops on the few cultivated patches, from the constant warfare they must maintain with the invading weeds, but the very seasons will appear to rebel. Autumn, deprived of its proper accompaniment, will deluge with rains and blight with hoarfrosts; for it seems to be a law of nature, that, if man will not improve the bounty which she sets before him—the talent which she offers for his use, she withdraws what he is too indolent for improving, and strikes in vengeance against that which he abuses by want of industry and skill.

Thus, in thickly inhabited countries, autumn is in some respects a season of "man's making," at least in so far that, if he would have it good and pleasant, he must conduct himself so as to deserve it.

But besides thus being a season, in some sort, of an artificial nature, or at least, in peculiar places, having its characters modified by artificial causes, autumn is altogether a local season, known only in particular latitudes. Summer or winter, or an alternation of the two, is found over the whole earth, from the one pole to the other; but spring and autumn belong to particular latitudes only, and in these they must be, to a certain extent, deserved and won before they can be obtained; and it is worthy of remark, that where these seasons exist, or can be obtained in their best characters, they are always the most favourable for the development of the human powers, physical and intellectual, and the best suited for human enjoyment.

At the equator, within the tropics generally, and often without them, varying in range with surface and situation, there is no autumn—no season analogous to that which we of temperate climates call by the name, and in the abundance of which we all with so much reason rejoice. It is true that, in those regions, fruits ripen and leaves fall in the same manner as they do with us, but not at the same times, or for the same reasons. The fruit does not ripen in order to secure a germ during that rigorous time when the plant may perish. When one crop of the tropical fruit tree ripens, there is generally another half grown, and a third in the blossom. The pause in the growth of the tree, too, is a pause from drought and heat, not from cold; and the leaf does not fall then. Its polished epidermis only concentrates to resist the evaporative action, something in the same manner as the leaves of our evergreens, which have a similar kind of epidermis, consolidate in the winter; and, as in these, the old leaf does not fall till the season of growth has returned, and the young leaf of that season is so far advanced as to take its place, or supply its function. The shrub often loses its leaf, and the herbaceous stem, although in the course of one humid season it grows as much as with us would be considered no mean tree, withers, or is parched up; and sometimes the drought is so intense, that such stems take fire by the collision of their hard and silicious bark against each other, and the conflagration spreads wide, invading the forest, and raging till the whole district is a ruin. But in whatever manner and to whatever extent the power, the change, or the destruction of vegetation takes place, it is not an autumnal change in our sense of the word. It cannot be said to be a preparation for any season, so much as the direct and marked effect of that change from humid to dry which has already taken place.

Then, in the time of its occurrence, it abides less by the kalendar than the autumn of temperate regions, and the action of the earth's surface has more influence in bringing it about than the mere periodic time by the sun. If solar heat regulated the seasons, without the action of the different surfaces upon each other, the two equinoxes would be midsummer days under the equator, because there the sun on them passes directly over head at noon; and, within the tropics, two midsummer days would be carried into each hemisphere every half year alternately, gradually coming nearer to each other, till they met in our longest day, when the sun was over the northern tropic, and in our shortest day, when he was over the southern. But the solar action is so powerful, that it revives the energies of the earth to the utmost, and a new action between surface and surface is produced, regulating the time, the duration, and the intensity of the seasons of vegetable action and repose.

The direction varies, as well as the intensity and duration. At times it is an action between hemisphere and hemisphere, nearly in the direction of the meridian, as in the case of the Indian monsoons; at other times it is between the parched district and the fertile, as between the African desert and the valley of the

Niger; sometimes it is between the mountains and the plain; at other times between the land and the sea; and the periods vary so much, that in some instances, while the one side of an island, or narrow piece of land, has rain in abundance, the other side is parched up with drought. In one place, the alternation takes place only once in the year, while at others it takes place twice, and there is a double season of fertility; and in some favoured spots, where the currents meet laterally, there are showers all the year round, and perpetual growth and fertility. No general theory of the tropical seasons can thus be established, either as to time of occurrence or duration, and so they must be made the subject of local observation for every place. But still, even in the wild and uncultivated places, there is an autumnal pause when the season of growth is over. Very many of the herbaceous plants which die down have tuberous or farinaceous roots, into which the substance of the plant is there concentrated, and the rude people dig these up, and roast them as substitutes for bread; while those which are more advanced and thickly peopled, and most cultivated, are, at a distance from river courses, obliged to do it at vast labour from tanks of water collected in the wet season, or from wells, which have sometimes to be dug to the depth of 300 or 400 feet; so that, if they are exempted from the labour of building close houses, preparing warm clothing, and keeping constant fires, they have not their sunny skies for nothing, but must toil as hard as they of temperate climes.

In these places, many of the smaller animals disappear in the seasons of drought; some by perishing and leaving only the eggs to produce a new race, as is the case of many tribes with us during the winter; others get into the ground or otherwise hide themselves, and *hybernate*—or perhaps *æstivate;* for, in our sense of the words, the dry season may be called either winter or summer, as it has the sterility of the one and the heat of the other. The larger animals also prepare for the season, but it is by casting part of their covering, and not getting an addition to it as exposed animals do with us against the winter. Many of the birds too, migrate, and they do so because the parched countries cease to yield them food. But though in those tropical regions, there is plenty of change, there is no autumnal action and no autumn. As little is there any spring; for by the time that the violence of the opening storm is so far over that men can come out of their houses and hiding places and survey the fields, the world is absolutely new. The fields which when last seen were dry and barren as a rock, are green with leaves and gay with flowers, as if Eden had been charmed forth from the wilderness, instantaneously and by magic. Sometimes they appear new to a greater extent, for the first floods are often so violent that they uproot trees, tear up the earth, and scatter fragments of rocks and banks of rubbish, till the general features of the country are entirely changed; yet these rocks and that rubbish remain but brief space before they too are vested and shrouded in the luxuriance of the new vegetation.

Such is the one extreme of season, that in which summer, varied only by drought and humidity, may be said to hold unbroken sway all the year round.

Let us now take a hasty glance at the other extreme, that in which winter and summer may be said to divide the year; and where that which might be called autumn or spring, has no fixed character as a separate season, but is a sort of conflict between these two. The knowledge of this extreme is as necessary as that of the other, before we can have correct notions of the character and value of autumn in the temperate climates; and, indeed, we can understand nothing in nature rightly, if we do not take it in connexion with its class.

The common notion is, that the cold increases with the latitude, till we reach the pole of the earth's rotation, and that there it is a maximum, the capital and throne of winter as it were; and that this would be the case upon mechanical principles is unquestionably true, because it accords with the ratios in which the sun's light falls upon the earth, supposing the surface uniform. And up to a certain point we can trace a near approximation, if not a perfect accordance to the mechanical law; or if there are local deviations, we can trace them to local causes. But a mechanical theory, though the splendour of Newton's discovery long made it be regarded as a universal instrument of science, and many still look upon it as such, is not a complete, or altogether a safe guide, in matters of natural history; and there is thus much in it of rather a provoking character, that it applies best in those parts of the inquiry where we could do best without it, and fails where we need it as our only guide. In a great measure, at least, it is so with the increase of cold toward the poles, or the seat of its greatest intensity. The accounts of the recent voyagers by sea and travellers by land in quest of a north-west passage (or any thing else they could find) on the north of the American continent, cannot be received as demonstration, though they must be admitted as truths so far as they go. Now the inference from them is, that on the north of America, the maximum of cold is about the latitude of the magnetic pole, or about 71°. The trend of the ice in the North Sea, and observations that have been made at many points of the circumference, shows that, in these high latitudes, the *isothermal* lines, or lines of the same temperature, do not lie on parallels of latitude, or nearly so, even supposing that allowance is made for differences of surface and elevation. Thus we can no more find, in the regions of the poles, a definite parallel of latitude at which to fix the maximum of average cold for the year, than we can find one in the regions of the equator from which to date the maximum of average heat: we find the same temperature more southerly in one latitude, and more northerly in another; and whenever we find the cold far to the south, spring and autumn are always less marked; and they are always more so, and even a greater range in latitude, as the cold is further to the north. Thus if we take the latitude in North America, which corresponds to that of the coast of the Channel in England, we find that in America there is hardly any spring or autumn, and that on the coast of the Channel, except in bleak situations, there is little, if any thing, which an inhabitant of Canada, even considerably to the south of the parallel of the Channel, would call winter.

In the very extreme of the cold, whether situated more or less to the north, there is very little in which autumnal appearances can display themselves. The presence of snow and ice covering the land and concealing the sea, and their partial or total absence, are the first markings of the arctic seasons; and it is not a settled point whether the absence of any thing that we would call vegetation there be more owing to the sunless winter, or the perpetual beating of the sun during the nightless portion of the summer. For a considerable distance, there are few flowers, and what may be considered as the trees, are not taller than the smallest of our under shrubs; while the few trees that do raise their stunted forms to the height of two or three feet, are chiefly evergreens, which make shoots a tenth of an inch long in the course of the season of growth, that does not begin till June is partly elapsed, and is over by the end of August, or early in September. There are some berries; but there are no fruits, and not any large farinaceous seeds to ripen. The first grasses that appear are often viviparous, that is, the seeds germinate on the stems, and the little plants take root in the ground, before the snow descends to protect them from the keen atmosphere of the winter. But there is no autumn; no fall of the leaf; no preparation of vegetable nature for abiding the blast. There is, in fact, no leaf to fall; and in the other vegetables, preparation for the season is not required; for, during the winter, there are no vicissitudes to try their strength, no rains, winds, frosts, and sunny blinks alternating with each other, which require a certain degree of stubbornness in the plant, so that its action may not be excited by the one and killed by the other. Hence, plants from these regions, or from great heights on the mountains where the climate is in some particulars similar, can but ill abide the changeable nature of our winters, even in the most sheltered situations.

The arctic plant, not having to ripen and prepare for the winter, can continue its action during the whole of the short summer; and as the plant requires little or no preparation, the atmosphere gives but slight announcement of winter coming. After the sun has got from a fourth to a third of its low and sloping circle, below the northern horizon during the night, and there is yet a bright twilight in that part of the sky, some day is more than usually tranquil, and the clouds "castle" about sunset, and show tints more rich than usual, or the sky remains cloudless, but there is a greenish yellow tint on the twilight portion, across which the auroras play their feathery beams toward the zenith, now concentrating into one radiant pillar or curtain, and anon breaking and starting into a thousand forms. The rude people know the sign (for the less that there is to study on the earth men contemplate the heavens the more, and hence in part the peculiar superstitions and mythologies of those arctic tribes)—they know the sign, and if they be not "snow-dwellers," they betake themselves to the winter hut. The night turns, the north-wind is up, and the moisture in the atmosphere, which appears to have been increased on purpose by the heat of the halcyon day, is congealed into small crystals of ice. Down it pours, ere the ground has had time to be frozen to any measurable depth; and as the north has gotten the victory, it rages away for days or for weeks. The wind roars and the snow drives, not in flakes, but in fine powder as sharp as that of glass; and the grouse and other field birds, which winter there, are driven from those places into a closer shelter; but are often caught by the storm, and compelled to drive as it lists. Then the fur-clad owl comes abroad to the slaughter, and the arctic bear howls on the beach for another meal ere he takes to his repose. This storm usually comes again and again, with tranquil pauses between, or rather it pauses in one place by shifting to another; but generally it is so violent, and confined within so limited a range, that its duration is not very long. When it is over, the atmosphere is so completely cleared of moisture, the surface of the earth so mantled in snow, the sky so clear, and the moon so bright, that the people almost forget the absence of the sun; and though the cold is piercingly severe to a stranger, those who are inured to it feel it bearable enough, even in their habitations of snow, till the season comes round, and the temperature rises till the snow begins to melt, when they become unhealthy and uncomfortable Nature prepares the wild animals for this season, by an increase of covering, whether of feathers or of fur; and their colour changes wholly or partially to white, which renders it still a worse radiator of heat.

Such is the transition from summer to winter, the only semblance that there is of autumn in the regions of extreme cold. There are, no doubt, some other preparations. The water birds which abound on the shores and banks, and in the open places, as far as they can for the ice, as well as multitudes of those birds not habitual swimmers, that resort to those places to rear their broods on the abundance of insect and other small life, which the uninterrupted action of the sun calls forth during the summer, migrate southward before the storm breaks; and it is said that the whales set out on their migrations. That the northern seas are not then adapted for those unwieldy animals, which do not appear to keep breathing holes in the ice like the seals, and whom such a means of respiration would not suit, as they must range far, and also near the surface, before they can make a meal of the small substances on which they feed, is certain; and it is also certain that they do not resort to the European shores further to the south. Hence there is at least a probability that they range the ocean far and wide; and it may be, as is said, that they double Cape Horn, and find their way to the northern parts of the Pacific. The voyage is a long one, but the whale, notwithstanding its bulk, is a fast sailer, estimated to make way at the rate of more than twenty miles an hour, and feed at the same time; so that, from Davis's to Behring's Straits would not be a voyage of many weeks. The mother whales are said to take their cubs round in that manner, so that in their youth they are tempered to all seas. That whales do sometimes pass from the one side of America to the other is certain: but whether they pass by Cape Horn, or find a shorter passage in the north, which our navigators have sought for but not found, is a point not absolutely settled; though, as they remain on the east side till the ice begins to close in northerly, it is most likely that they make their autumnal trip by the south, but how they return is not so well ascertained, as they are found early in the season as far to the north as there are openings in the ice. That they pass in some way is proved by the fact that spears and harpoons of a form used only in the one sea, have been found in the bodies of whales captured in the other.

Having now adverted to the two extremes between which the countries having a distinct and characteristic autumn lie, we shall notice some of the phenomena of that season in their intermediate places. But here it is by no means easy to speak in general terms, inasmuch as no two countries have their autumn exactly alike. Therefore, as our observations must be either local or vague, we shall make them as few and brief as possible.

The general appearances which, in our own latitude, mark this season, and distinguish it from other seasons, must be familiar to every one who has eyes. The shortening of the day much faster than the apparent diminution of heat, the general transparency of the air, the distance to which the view extends, and the bracing effect which one feels more than at any other season: these peculiarities arise from the diminished evaporation, and that again is owing to the dry and drying state of vegetables, the leaves and barks of which are gradually ceasing to have any action, and of course do not give out so much humidity, or so act upon and alter the state of the air, as when they are in growth. The cleared fields and the dry stubble contribute to the same result, as they do not "steam upwards," either as when they are drying in spring, or when they are supporting growth in summer. The transparency of the air does not depend so much upon the absence of moisture, as on the absence of evaporation; and the latter is, in many cases, not so much owing to the want of evaporative power in the air, as to the want of humidity to be evaporated. As there is less living action going on upon the earth, than while vegetation is in progress, the beams of the sun heat it more while they fall upon it, and it cools faster after they cease to fall. Thus, it approaches in a certain degree to those tropical scenes which are intermediate between growth and parching; the days, too, are nearly of the tropical length. Thus, dew forms more readily upon the surface than at any other season; and in those places which are shielded from the direct action of the sun, it continues longer ere it is dissolved.

In districts which are a little upland, or otherwise colder, fogs creep along the surfaces of the lakes and the courses of the streams, and generally over moist surfaces. These are more owing to the condensation of moisture in the air which is cooled by these surfaces, than to evaporation from the surfaces themselves; for autumnal fogs do not drain the moisture like the fogs of the early season. But in cold districts they continue during the night; and the late corn, the leaves of potatoes, the after-math of red clover, and other plants which are rather delicate, get cold just before dawn, and dew forms on them, and often congeals into a sort of hoar frost, which, though gone before it can be seen in white spiculæ, prematurely whitens the oats and other late grain, and blackens and shrivels up the leaves of green plants.

If the autumn advances dry and kindly, and without frosts and falls of rain (for if the first of these come it is almost sure to be followed by the second), as the atmosphere becomes too cold for retaining its moisture, the changing leaves, as the wood ripens, produce an endless variety of tints. Yellows, browns, and russets, in various shades, with here and there a patch of dull red, are the usual colours of our European trees; and if the tints do not come out free and clear before the leaves begin to fall, it is a sign that all is not well with the groves, copses, and hedges; and if the season be very unfavourable, or the place bleak and backward, the leaves hang dull in a sort of unhealthy green, spotted with mould under the epidermis, without the pleasant smell of leaves that have performed their office well, and are fading in a kindly manner; and these often refuse to cicatrize and come off, but cling in withered patches killed by the frost, till the storms of winter drive them off by force. There are some, however, which retain their leaves after they have ripened, and faded in an apparently healthy manner into the brown of inaction. The common beech, in cold and elevated situations, is one of these, and it often retains the old leaves till the young buds, which in the beech are always rather advanced in the autumn, have half expanded their leaves. On rich and warm soils, where the trees attain a large size, it is not exactly so, though a few tufts often cling; and if suckers are allowed to grow at the roots, the leaves adhere on them after they are cut from the parent tree. In this habit there is a sort of partial approach to the evergreens, only they retain their leaves green, though inactive, during the winter, and do not revive into action in the spring, though shed at a more advanced period of the season than the discoloured leaves of the beech. It is worthy of notice, that when the beech retains the whole of its old leaves during winter, it also gets the slow growth of the hardy evergreens, and forms harder timber than when the growth is more vigorous; but though harder, it is brittle, of inferior quality, and rots equally soon.

There may be exceptions, but it is a very general law in the autumnal fading of the foliage of trees, that those species, which, in their native habitats, are exposed to the greatest vicissitudes, fade through the most numerous and varied tints. American deciduous trees and shrubs, till a latitude as far southward be gained as that in which the deciduous cypress (*taxodium disticha*) is prevalent, are subject to severe alternations of heat and cold in the spring—far more so than the trees of any of those districts of Europe, where deciduous ones form the chief part of the forests. American trees accordingly fade through a great variety and brilliancy of tints; and as they continue their varying hues for a considerable time before the leaves begin to fall, or even to show symptoms of shrivelling and decay, they add greatly to the beauty of grove and coppice scenery during the autumnal months. The shrubs of our more bleak and northern districts, and those of Lapland, in both of which there are contests between summer and winter, in the brief time which may be called spring, have partially the same habit. Trees of more southerly places, which have no frost to contend with, after the buds begin to unfold, have no such rich variety of autumnal colours. When they do fade ere they fall, they fade into a dull and pale straw-colour, or they are spotted with the depredations of small fungi. But many of them come late, and fall with the first frost, or rather with the sun after it, covering the ground with leaves still green and apparently unchanged. The common mulberry is a remarkable instance. It is further worthy of remark, that the leaves which thus fall at once, or yield to the ravages of the fungi, have their epidermis, thin, tender, and without gloss, while those which pass through the richer tints have it compact, and generally to a considerable extent glossy.

But the autumnal woodland, independently of its scenic beauty, offers a wide field for study—a field far too wide for coming within the scope of a general article of moderate length, even though devoted exclusively to the subject. Some notices respecting it *may* be found in the particular descriptions of the groups and genera of forest trees, and to them we must refer the reader.

But though the autumn is the time when the regular vegetation, which buds in the spring and prepares its flowers and seeds during the summer, begins to suspend its action, so that it may, in repose, pass the winter uninjured; yet the autumn has a vegetation which may be considered as more peculiarly its own, a comparatively short-lived vegetation, which begins and ends with the season, and of which even the vestiges are in general gone before the winter. Allusion is not here made to the artificial productions of the garden, many of which are finer, both in their forms and their colours, in autumn than in the strength of the summer's heat, but to the productions of wild nature, which have no human hand to tend, and in many instances no human eye to heed them. The proper wild crop of the autumn, which appear in forest, field, and wild, coming one sees not whence, springing up with vast rapidity, generally melting in the rain, and leaving hardly a trace behind, are leafless and flowerless plants—the *fungi,* in all their varieties of size, form, and habit. No doubt some of them make their appearance at other times, and they subsist upon animal matters as well as upon vegetable, but never upon matter of any kind till it has ceased to live, and corruption, in some of its forms, has begun to work upon it. It seems, indeed, that corruption is the only *nidus* in which the *sporæ* of this singular race can come to life; and as many of the species are microscopic when developed to the extent of their growth, we need not wonder that the germs exist in places to which we can discover no visible entrance.

It is in the autumn that they appear in their myriads—on fields, on the bark of trees, on stems, on leaves, on heaps of rubbish, in humid places, and in places which are comparatively dry, but never wholly immersed in the water, as water dissolves their flimsy organisation. The whole race are feeders upon the refuse which the rest of nature has cast off in the course of the season of action. Many of them are offensive to look on, a very considerable number are poisonous to man, and still more are suspicious; yet there are insects and other small animals to whom even the most offensive of them appear to be welcome. What general purpose they answer is not accurately known, and it would be foreign to the object of this article to inquire. But their numbers are sufficient to show that it must be one of general importance; and as the time of their life is that of the decay and death of the seasonal part of living nature, it may perhaps be conjectured that they in some way work up and prepare the waste, so that it may serve better for running the course of life anew. We have to do with them only, however, as forming a character of the autumnal season; but more minute accounts will be found under the names of the principal groups and the more remarkable genera.

As the autumn advances, thousands of little creatures are busy in storing an endless variety of substances with the germs of life, all so placed and provided as that they shall pass the average winter uninjured, and find the proper nidus for their development and the proper food for their growth and support, when the returning energies of the young year shall call them to activity. Others which could not bear the weather or find the proper food, hide themselves beyond the reach of danger, and seal up their dwellings till the time of revival comes. There are also some which appear to get a new economy for making the autumnal preparation; some races which have been all females for many successive generations during the summer, and have been, race after race, produced alive, or at least so near it, that they attained the size of maturity in a portion of a day, appear as male and females for the production of those eggs which are to subsist during the winter, and continue the race of their own organic energy, for ten or twelve generations, as before. This, which is well authenticated, is one of the most singular facts in the whole animal economy, and puts one in mind of what is alleged of some fruit trees, that they can be continued for a certain time by the graft in the bud, but ultimately die out, if they are not renewed by a return to the seedling. The whole of the preparation which is made for the surviving of the winter by the progeny of those creatures which are unable to bear its rigours themselves, are among the most curious points in the whole curious field of zoology.

The spiders are a race whose habits are peculiarly worthy of study in the autumn, which is with them the grand season of bustle and activity, in house, garden and field; and taken on the whole, they are highly useful to man. There is no species which commits depredations on any thing useful; for though we often hear of the injury done to fruit trees by "the red spider," the red spider is not a spider of any sort, but a species of coccus. The whole of the spiders, without one known exception, feed upon animal substances; they almost universally kill their own prey; and the whole of that prey is in some respects either injurious or annoying to man. In its feeding, the common house fly is, indeed, perhaps more useful than injurious, because it is a sort of scavenger in its way, and consumes matters, the accumulation of which would be offensive. But its familiarity and its numbers render it troublesome; and, in autumn, it often becomes a nuisance. Many insects get active at the time of preparing for the winter; but the house-fly gets languid, and in houses which are surrounded by rank vegetation, and where matters are conducted in a slovenly manner, it so throngs them as to be a pest. Now this insect is a favourite food both with the house and the garden spiders, and they set snares for it, in all places where it has a chance of passing; and the eggs of the fly are so numerous, and deposited in places where they are so safe from injury, that if the spiders were not to cut off tens of thousands, the flies would multiply till they became an absolute plague. In the gardens they snare many other races; and they do so when these are ranging about and depositing their eggs in places where the caterpillars, or larvæ, would generally, in some shape or other, be hurtful to vegetation. The beauty of the web, especially that of the large garden spider, the skill with which it is placed, always in what may be considered as an insect thoroughfare, presenting its meshes in the very line of the insect passage, and being proof against a considerable degree of wind and rain, the industry with which it is repaired when torn, or replaced when any part becomes too dry in its consistency, are all perfectly admirable. This is not the place for entering upon the details, as these will be found under the names of the creatures themselves; but it is impossible to avoid remarking that if there were no creatures preparing for the winter but the garden spider, there would still be an ample field for observation. Suspended in its central spot, with the head downwards, which gives the animal the advantage of the impetus of its weight, both in darting along the lines, and in holding on with its claws, this spider feels, without the trouble of watching, the vibration of every part of the web to the most distant line, and also the general character of that which throws it into a state of vibration. But, even then, there is always a thread in readiness, by means of which the creature can drop down and seek safety on the ground in case of danger. We are ignorant as to the precise nature of the senses, or substitutes for senses, by means of which these small animals act; but it is not on that account the less curious to observe the tact with which this species of spider appears to ascertain what sort of substance is on the web. It is not by *sight* certainly, as little is it by what we call *touch*, for the portion of the foot with which the state of things is tried is covered with delicate hairs; but still there is an instinctive discrimination. A bit of leaf, or any other inanimate substance, is not advanced upon directly, the spider and web are thrown into a vibratory motion for a little while (the equal bearing upon all the main braces of the web, and the perfect vibration which the occupant at the centre can produce, notwithstanding the unequal lengths of the braces, are no bad mechanical study); and if it cannot be cleared by that means, the spider advances to it and cuts it adrift, using a *gy* to steady it, if there is a chance of a second entanglement in its fall. If the prey alights, not very strong, or with too hard a covering, it is instantly pierced by the fangs; but if strong, and not easily pierced, it is shrouded in web; and the dexterity with which it is suspended by a stout thread, and twirled round for this purpose, is worthy of notice. If another spider (for the disposition to kill extends as fully to their own tribe and species as to any other), it is a matter of exertion. As the warfare is one of enmeshing and not of biting, weight appears to be admitted as a certain means of victory, and accordingly the stranger tries the vibration of the web before he advances, and if he finds the tenant too heavy for him he escapes as fast as he can. If he finds the weight suit him he advances, and the instant that his full weight is on the web, the owner is off; he drops down, but still with a thread, escapes to a plant, or posts himself at the end of one of the main braces, but without resting all his weight upon it. From that position he tries the weight of the assailant; and if he has taken an over estimate before, he darts along with so much impetus, that the invader generally pays for his temerity with his life. If the motive which put him to flight is confirmed, or remains doubtful, he retains his post, but without bearing his weight on the brace. The claws of one foot are, however, ready to cut it adrift if the case require. The assailant gains the centre, and tries all the radiating threads for the owner; and, though that is not so clear, as neither of them is very powerful without the assistance of the web, he *may* sometimes try if there is a descending thread of escape. If he finds the place of the lurker, he makes straight for that; but if the lurker is a good tactician, and he is seldom deficient, just as the enemy comes to the single thread, that thread is cut, and down drop both web and invader, often with so much velocity that, with the injury of only a small portion of the web, the invader is flung sprawling on the ground, and the owner of the meshy tenement returns in safety to the remains of it, and repairs the injury at his leisure. These rencounters do not very frequently take place naturally, as each individual in general keeps quiet and constant possession of his own web, but any one who chooses to make the necessary experiments may see them as often as he pleases. The autumnal labours of all the spiders, though differing considerably from each other, are curious. The particulars will be found under their names; those of the species of which these slight notices have been given, under the title Epeira.

The habits of those more minute members of the animal kingdom, the labours which they perform, the organisations by means of which they perform those labours, and their uses in the economy of nature, are all very curious, as well as highly instructive; and the instruction which we may derive from the right study of them, is superior in kind to that which we derive from studying even the noblest examples of human art. In the study of human art there always mingles more or less of human vanity, the effect of which is to narrow the mind; and when the model is of high merit, it destroys our confidence in ourselves, so that we become mere admirers, or at best imitators, in many cases, when the exercise of our own free spirit and undaunted hope would have led us to excel, or at least to equal. In spite of all his roughness, want of obedience to the canons of learned taste, and occasional infractions of the laws of learned accuracy and propriety, there is a freshness — a something which one can hardly define, and dare not refrain from liking, about the man who has run his own course, which one does not feel in the more polished, and as far as the mere matter of instruction goes, the more instructive imitator who constantly feels the superiority of his masters. This indescribable something always gives us much pleasure, and not a little of that pleasure arises from the conviction that it is pleasure communicated to us by one who must have felt it strongly himself.

This is more the case with natural history than with any other subject; and those portions of natural history which come before us every season, and every day of the season, like that of the garden spider in the autumn, are the points at which even every child may take hold on natural history, so that it may be made the vehicle of much useful knowledge—of knowledge really useful, as, while it informs the head, it keeps alive the feelings of the heart, and makes goodness not to lag behind information—not only with pleasure, but without hindering the most active employment in the common business of life. One, therefore, beholds with pain the neglect or abuse of any means by which this great fountain of information, pleasure, and the love of virtue (for it combines all the three pretty equally), might be more freely opened to all the people, so that they might enjoy it more abundantly, more pleasantly, and healthfully.

But from the manner in which the subject is treated, especially in those parts of it which, like the labours of the garden spider, are calculated for exciting thought, and producing a reflective habit most readily in the young, the thought is suppressed, and the wisdom turned to error, by the injudicious comments which accompany the recital of the facts. The grand source of error which mingles so copiously with these is the imputing of forethought, plan, purpose to the animals, differing in degree or mode, but the same in kind, as that which regulates the conduct of reflective man. In principle, this places man in the very same relation to his Maker as the spider is, which breaks down all moral obligation, and disposes man to follow the other habit of the spider, and, by the withdrawal of the tie of moral affection, to eat up his brother whenever strength suffers and opportunity favours. This subject is one of a very serious nature, as it destroys the respect and confidence which should be reciprocal between man and man, makes merchandise of the affections, undermines the foundation of individual happiness, and predisposes to crime by the removal of every restraint but the penal statute, which men, in the hour of secret temptation, always trust to their good fortune that they shall avoid.

This subject is so often alluded to in those parts of the present work which are intended to impress upon the reader the nobler use of the application of natural history in promoting human happiness, that, though there are many to whom no explanation of this departure from the common practice will be necessary, yet, for the sake of others, a sentence or two may be given. There are in this country plenty of naturalists, but the fashion of the times confines their labours in the way of writing to reports and monographs on single points, which, though of great value to the professed student, are not adapted for general readers. The books for these, and especially those which profess to instruct the young in the study of natural history, are not the productions of naturalists, but of compilers, who cull from all quarters those anecdotes and descriptions which appear to be the most striking and effective; and who, by way of giving the whole an air of originality, interlard their works with descants which have the pernicious tendency above alluded to. We have no such objectionable matter in the old books, which *were the productions of authors*—Ray's "Wisdom," for instance, or Derham's "Physico-theology"—which makes us regret that the Rays and Derhams of our time will not condescend to school the public by means of books as wholesome in substance as they are popular in form. Of course we do not mean to affirm that all the popular literature of the present day has this tendency. On the contrary, the desire to illustrate the greatness and goodness of the Creator, by a reference to his works, appears a peculiar characteristic of modern cheap literature.

AUXIS. A genus of spinous-finned fishes, belonging to the mackerel family, and partaking partly of the characters of the mackerel, and partly of those of the tunny, though it does not, at least in the European species, attain the size of the latter. It has the corslet of large and rough scales on the thorax, and the pectoral fins of moderate size, as in the tunny; but the two dorsal fins do not run into each other as in that fish, they are separated as in the mackerel. There is one European species, found in the Mediterranean, which is the *Scomber Laroche* of Risso. It is both a handsome and a valuable fish. The colour on the upper part is bright blue, marked with waving bands of a blackish colour. The flesh is of a deep-red colour, but boils a little paler; when fresh, it has something of the flavour of salmon, and is much esteemed. In the West Indian seas there is another species, which is much sought after for the table; it is there called the tunny, and sometimes attains the size of that fish, or from 400 to 500 pounds in weight; but those which are of smaller dimensions are more palatable. Like all the rest of the family, they are surface fishes, keeping in shoals, and frequenting particular stations only, but, like most surface fishes, they are easily caught.

AVENS, the English name of what botanists call Geum. Linnæan class and order, *Icosandria Polygynia*; natural order, *Rosaceæ*. Generic character: calyx ten-cleft; segments alternately smaller; corolla five-petaled; stamens inserted in the base of the calyx; styles persisting, jointed or kneed, hooked or bearded at top, sideling; receptacle dry; caryopsis many, with the styles attached. There are twenty-one species, two of them British weeds. Some of them are showy, and have a place in every flower garden.

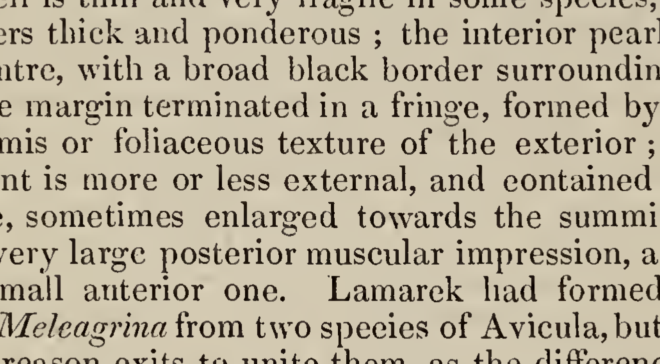
AVERRHOA (Linnæus). A genus of two species, of beautiful trees, natives of India, China, &c. Linnæan class and order, *Decandria Pentagynia;* natural order, *Oxalideæ*. Generic character: calyx five-cleft, or of five sepals; corolla petals spreading, longer than the calyx; stamens alternately longer, joined in a ring at the base (in *A. Carambola* the stamens are alternately abortive); anthers somewhat round; style simple; stigma headed; berry large, with five furrows and five cells; seeds attached to the centre of the angles. These trees, particularly the *Carambola*, are met with in every garden in India, where the green fruit are used for tarts, and taste very much like those made of gooseberries. Indeed, the British settlers call the fruit Coromandel gooseberries, but the fruit are called Carambolas by the Portuguese. The following is a reduced figure of the foliage, flowers, and fruit.

A. Carambola.

AVICENNIA (Linnæus). An East-Indian downy-leafed ornamental tree, introduced into this country in 1793. Linnæan class and order, *Didynamia Angiospermia;* natural order, *Myoporinæ*. Generic charaeter: calyx of five equal parts; corolla tube bell-shaped, limb of four spreading parts, segments leaning a little back; stamens protruded; style short; stigmas two, pointed; fruit leathery, two-valved, one-seeded, seeds sprouting.

AVICULA (Lamarck). *Mytilus hirundo* (Linnæus). This genus of shells has very properly been separated by Lamarck from the Linnæan *Mytili*. The form of the shell is scarcely less remarkable than that of the genus *Malleus*, although of a distinct character. The principal part of the shell, containing the body of the animal, is obliquely attached to a long straight transverse base, and somewhat resembles the wings of a bird; the two extremities of the base (which are frequently elongated and of unequal length) may be compared to the tail, so that the shell, when partially expanded, presents the appearance of a bird flying, from which fanciful resemblance the name of the genus, *Avicula*, a little bird, doubtless is derived.

The body of the animal is generally much compressed; the mantle divided through the whole of its circumference, except along the back, and furnished on its unattached edge with a double row of very short tentacular cirrhi; the foot is rather small and channelled, and has a byssus. The mouth is surrounded with fringed lips, in addition to two pair of labial appendages; it possesses a large strong adductor muscle, and two pair of small retractile muscles of the foot. The shell is inequivalve, with a sinus, or singular notch in the left valve, through which the byssus passes; the hinge is linear, with one primary tooth on each valve, beneath the apices, which are oblique, small, and not projecting. The substance of the shell is thin and very fragile in some species, and in others thick and ponderous; the interior pearly in the centre, with a broad black border surrounding it, and the margin terminated in a fringe, formed by the epidermis or foliaceous texture of the exterior; the ligament is more or less external, and contained in a groove, sometimes enlarged towards the summit; it has a very large posterior muscular impression, and a very small anterior one. Lamarck had formed his genus *Meleagrina* from two species of Avicula, but sufficient reason exits to unite them, as the difference of their specific characters is not so strongly defined as to constitute a well-grounded distinction. De Blainville forms two subdivisions, embracing these differences; the first includes the species but slightly oblique, nearly round, nacreous, *very thick*, with the auricles nearly equal, but little salient, and without teeth at the hinge, forming Lamarck's genus *Pintadina*, which he also sometimes calls *Meleagrina*, and Leach's genus *Margarita;* the second contains such species as are of a *thin* texture, oval, oblique, with auricles strongly developed, particularly the superior one, and one tooth on the hinge, as in the *A. macroptera*, here figured in its young state.



A. Macroptera.

Of the two species of the first division, one, the *Avicula margaritifera* (*Mytilus margaritiferus* of Linnæus) produces that costly but modest gem, the highly coveted *pearl.* Some others of this genus produce these isolated deposits of nacreous matter, but none of such beauty and high price; they are only found in the Oriental seas, while most of the others inhabit the South American seas, and one of the number is found in the Mediterranean.

There are fifteen species known in a recent state, and De France enumerates twelve fossil *Avicula*, and three *Pintadinæ*, or a genus nearly allied to them.

This genus is arranged in De Blainville's Malacology, in the third family, *Margaritacea;* order, *Lamellibranchiata;* class, *Acephalophora.*

The *Avicula margaritifera*, or *Mother of Pearl Oyster*, as it is generally called, is so familiar to every one, as affording that beautifully iridescent substance, of which numberless elegant trinkets and other ornaments are formed, that it needs no particular description to most of our readers. It may, however, be proper to state, that its iridescent character depends on the striated surface of the shell; and even when a new surface is given by grinding the shell, the same effect is still produced. We are indebted to Sir D. Brewster for a knowledge of this curious fact, and our artizans, availing themselves of the discovery, have produced the iridescent character of mother of pearl, by simply ruling the surface of polished metal.

AVOCET—*Recurvirostra.* A genus of birds belonging to the order *Grallidæ*, or waders, and much more strictly deserving the name than very many others to which it is applied. Their form, their habits, and their principal haunts, are all so peculiar, that they are a very distinctly marked as well as a very singular and curious genus.

They are birds of considerable size; their bodies are handsomely formed; and their plumage, which is remarkably close and glossy, is generally pure white and black, which increase the apparent intensity of each other by their contrast, and give the birds a very clean appearance. The legs are very long, but they are proportionably strong and well-jointed, and they are so well adjusted to the centre of gravity, that the birds walk in a firm and stately manner, and have great command of themselves. The hind toes are little more than rudimental, but the three front ones are well formed, firm and elastic, so that the bird can rise upon them as springs, when such a movement is necessary. They are half-webbed; but the webs are of a peculiar form; and they are fitted for walking upon soft and oozy surfaces, and not for swimming. In the middle of the interval between every two toes, the web extends barely to half the length of the toes, but it extends from thence in a straight line to each toe as far as the insertion of the claws; so that half the foot has an entire web, joining all the toes, and the other half has a triangular lobe pointed in front, upon both sides of the middle toe, and upon the inner sides of the others. This, as already hinted, is not a swimming structure, because the lobes are most deficient at those places where their effect in swimming would be greatest; and we find that swimming birds which have lobed feet, as, for instance, the grebes, always have the largest lobes toward the points of the toes. But the feet of the avocet answer well for walking upon soft surfaces, and equally well upon surfaces having different degrees of softness. If the place on which it walks is very sludgy, the bird plants the breadth of the foot, which by affording a base of considerable extent, prevents it from sinking; and if the place is hard and firm, or covered with gravel, which last is an unpleasant surface on which to place a foot which must bear on the web, the bird can spring on the comparatively free fulcra of the toes, or there even find points of rest between the nodules of the gravel. Among all the curiously varied structures of the feet of birds, there is not one better adapted to the place in which the creature finds its food than the foot of the avocet. Upon an emergency, too, it can wade to a considerable depth without wetting a feather; for the tarsi are long; and the tibiæ are bare of feathers to nearly half their length. The muscles which move the legs, though not clumsily bulky, are very strong and compact, so that the bird can wade a long time in water or in sludge without being fatigued.

The neck of the avocet is long and flexible, but at the same time strong and well supplied with muscles, so that it can act powerfully in those directions which the habits of the bird require. The head is of moderate size, and compact; and the head, neck, and under parts of the body are feathered in the same manner as water birds, so that they sustain no injury, and indeed are hardly wetted when immersed in water.

The bill is the most singular part. It is very long, flexible, and apparently sentient, at least it is covered with membrane and supplied with vessels, like the bills of snipes, woodcocks, and other birds which are understood to find their food by the touch of that instrument. But the greatest peculiarity of the bill is its form. Most sentient bills are straight or nearly so, and some have a slight inclination upwards; but the bill of the avocet turns upwards with a bold curve, especially toward the tip, the point of the under mandible projecting a little beyond that of the upper. It is in fact such a bill as, judging from the ordinary ones which we are in the habit of seeing upon land birds, or even from the diving bills of swans or the dabbling bills of ducks, we would be very apt to call awkward, and suppose unfit for any useful purpose. But there is no awkwardness or unfitness in nature; and when we meet with an organ of nature's making, we may always be assured that, however awkward it appears to us, it is the very best adapted to that particular purpose or use for which it is intended. We have already had instances of that in the case of the feet of some of the mammalia, especially in those of the sloths [see AI], over which sentimental naturalists have mourned as if nature had botched them in the making; and yet, notwithstanding the wonder of ordinary observers, and the sentimental bemoanings of those half-informed persons, the sloth is a perfect master-piece of mechanical science and skill,—a creature to be wondered at certainly; but to be wondered at for the perfection of its structure and the beauty of its adaptation, and not for its uncommon, and as we on that account think, its ungainly form. The sloth is a singular animal certainly; and it has a singular office to perform in the economy of nature: it must move about, and find its food, and take its repose, in a position the very reverse of that of most of the mammalia. One instance might suffice to teach us that when we meet with what appears to us to be an unwonted or a curious organ, we may look for an unwonted or a curious office which that organ performs; and therefore instead of stopping to wonder at the peculiarity, we should endeavour to make ourselves masters of the lesson to which it points.

The bill of the avocet is so singular, so different from those bills with which we are familiar, that we may be sure that the avocet has some singular habits; and that the sight of the bill in action, or even the knowledge of how it acts, must be far more curious—far more worthy of our rational attention than the mere form itself, peculiar as that certainly is. But the avocet is a shy and retiring bird, as well as a bird of very local and peculiar haunts, so that few can see it at work, and therefore the description of its working becomes the more necessary.

The avocet may be considered as the last bird upon land,—the one which requires but a few very slight alterations in order to launch it upon the waters and make its "home upon the deep." Indeed it cannot be said to be strictly a bird of the land at all, though it sleeps upon the land, and also nestles and rears its young there. But many of the most seaward birds resort to the rocks and banks for repose, and there is no bird which permanently rests upon the waters, nor in fact that builds a floating nest, though some have been alleged to do so from the circumstance of their nests being sometimes floated by casualties. The avocet is not a bird of the water either, it is a bird of the margin, the line where land and water meet: it is one of the few birds, if not the only one, which is exclusively so; and therefore we might look for some peculiarities in it, distinct from both land birds and water birds.

Avocets are fen birds; but, in feeding, they frequent only those parts of the fens which are alternately flooded and left dry by tidal waters, or the small water-courses which discharge their contents immediately into them. Their bills are not adapted for catching any kind of food upon land; neither are they fitted for fishing in the waters. Both land and water are therefore cut off from them, and retained as the preserves of other races. Even the common soft sludgy ground of the marsh, into which the snipes and woodcocks bore for food, is a forbidden pasture to the avocet, as its bill is not adapted for boring. Thus its proper pasture is very much narrowed; and in no country can it be a bird generally distributed over the surface, or even one very abundant in numbers.

But though the pastures of the avocet are thus local and limited, they are very rich, and the food upon which it generally subsists is so situated that it has few rivals. The regular shore-birds, and even the wagtails and some of the other birds which haunt the margin of the waters, pick up the same kind of food when they see it; and many of the swimming-birds dabble for it when the waters are in. But the time that the avocet feeds is when the general surface of the mud is clear of water, and there are only little runs trickling or creeping along in the hollows. The number of living creatures, or of creatures ripening into life, which is contained in the mud, ooze, or light gravel of these, is immense. Worms, and larvæ, and small molluscous and crustaceous animals, are in great plenty; and the myriads of the spawn of fishes in their seasons (and as these vary they extend over a considerable portion of the year), together with the young fry of the same, are beyond all the powers of arithmetic. The greater number of these are imbedded to a small depth, and those that are not get rolled along by the moving sludge, and partially covered by it.

These accumulated matters, which are not seen by birds which feed by the sight, and are not stationary enough for being either bored or dabbled for, are the harvest of the avocet; and the way in which it avails itself of that harvest has some resemblance to reaping, or rather perhaps to mowing. It moves along the run with slow but rather lengthy steps, and scoops the ooze or mud in curves, right and left, as it proceeds. The traces of its scoopings may be seen by any one who happens to come to the place where it has been feeding before the tide rises to efface them; but the bird itself is so shy and wary, that it can be seen by those only who, themselves concealed, have patience to watch for it. In scooping it does not use the bill only, but the whole body; and as the fixed point from which the action is delivered is the foot, it has a wide swing; while, as the exertion is divided among so many acting parts, it can continue it for a long time without fatigue.

The middle line of its operations is the centre of the run or small water course, or hollow in the ooze of the flat beach, as it may be; and it plays or swings upon that as it moves along. In order to have a more perfect understanding of its operations, we shall suppose that it arrives on the wing, from its nest or other resting place, and alights at the lower part of the run. It, of course, prefers proceeding against the stream where there is running water, because the current is always bringing food to it, and also assists it in the capture. It alights in the middle with its head to the stream, and the one foot a little in advance of the other. This position of the feet throws the axis of the body obliquely across the stream, with the head inclined to that side on which the foot is furthest in the rear. It then stretches and depresses the neck, and gives it a twist, so that the extremity of the bill, which is on a level with the ooze, is turned to the other side. The foot furthest in advance is the pivot upon which it is to turn in making the stroke which scoops one curve. Then it slowly advances the rearmost foot, which elevates the hinder part of the body, depresses the fore part, and throws the support on the advanced foot; while, supported upon that, and moved by the lever power of the other as it is brought forward, the axis of the body is brought to cross the run obliquely in the opposite direction to the position at commencement: by this motion the bill is made to scoop a curve from that side of the run where the foot was in the rear at starting to the opposite side; and by the time that that foot has moved the length of its half stretch in front of the other and been planted, the fore part of the body is elevated and the hind part depressed, so that the bill is raised to the surface of the ooze by the action of the body alone. The head and bill are then elevated a little for the purpose of conveying to the gullet the food which the bill may have taken during the scoop. The food is always taken with the part of the bill near the point, or that part which is flat while scooping; and as the curvature of the bill favours the progress of the food towards the gullet, the swallowing is an easy matter, and does not require much elevation of the bill or head. The advanced foot is not brought forward beyond that position at which it is perpendicular, so that the body can swing forward, and be depressed anteriorly by it during the scoop.

In this way the feet are advanced alternately, and the bill at each movement scoops its curve in advance of the moving foot; that is to say, from the side on which the foot is moved to that on which the planted foot is the centre of motion. Of course the scoops are alternately in opposite directions—from left to right when the left foot is moved, and from right to left when the right is moved.

The motion of the bird in feeding is thus quite as unique as the form of its bill. Perhaps there is no bird which feeds so much by the action of its whole body; and there are certainly few, if any, whose motions in feeding are so graceful, or display so much readily seen and easily comprehended science.

And when we consider the bill, and at the same time the manner in which it is used, all our preconceived notions of its awkwardness vanish; and we find that it is not only the best form, but the only form that could answer the purpose. A bird with a bill crooked the other way, as the beaks of rapacious birds are crooked, or a straight one, or even one with a slight curvature upwards, could take up nothing in scooping, and consequently would be of no use to the avocet; so that if the bird had not its specific form, it could not have its present habit. So ready is the recurved bill to take up substances, that, small pebbles are often found in the stomach upon dissection, which the bird takes up along with its food. From the nature of both the food and the stomach these should not be so much required as they are by the gallinæ and other gizzard birds, which live much upon vegetable seeds; but still they *may*, to a certain extent, aid the progress of digestion, in grinding the crusts of shrimps and the shells of mollusca, the smaller species of which must form part of the food of the bird, as they abound in those places where it feeds.

So well is the bill of the avocet formed for being a scoop, that when a mechanic would make an effective one, he in so far imitates the same curve, even though he never heard of the avocet, and knows nothing of its structure or mode of action. At bleaching grounds, and other places where it is required to throw water to a great distance, and with a certain aim, by means of scoops, those scoops always have their trough or containing part, long, narrow, and recurved; and if a straight one of the same dimensions were tried against the recurved one, it would not be found half so effective. The more, too, that the curvature of the scoop resembles that of the avocet's bill, a scoop of the same dimensions and weight lifts the more, and throws it the farther. That is easily explained: the use of the curvature is to resist the centrifugal force of the water, and that force does not act at all against the upper part of the scoop, but it acts powerfully against the part near the point. The curve resists that force till the whole has got the impetus necessary for sending the water to a distance, while the straight scoop begins to spill the instant that the water acquires a momentum. Thus we have a proof of the efficiency of the avocet's bill, in the fact of its being imitated by mechanics without their knowing it.

Avocets are birds of retirement, birds which have their haunts far from the ordinary dwellings of man, and as they are birds which are wholly unprovided with weapons even of defence, they must find their safety in seclusion and concealment. Hence they flit before the progress of improvement. When drainage, and planting, and culture invade the fen, they are the signal for these birds to be gone; and when once they depart, they do not return to the cultivated country. They are birds which, even in proportion to their limited numbers, are probably more rarely seen than most other species.. Marsh birds which do not swim, or run fleetly, or are powerful and much on the wing are, indeed, in general hiders; but perhaps there are few of them so much so as the avocet.

One species, the common avocet (*Recurvirostra avocetta*), is still found in some parts of the fenny shores of England; but it is rare, and appears, of late years, to be rapidly passing away; so that at present it is merely a remnant, and in the course of a short time it may be only a memory. In the season when they are captured, Leadenhall market is perhaps a better place to seek for the fen birds of England than the fens themselves, especially to those who have not much leisure or knowledge of fens, and wish merely for the birds and not for their manners. Now, up to about the year 1820, the avocet was not at all a rare bird in Leadenhall market; that is to say, there might be as many as a dozen of them there in the course of a week, or sometimes a dozen at one time; but now there are not above one or two seen in the course of a year, though the interest which is taken in rare native birds has increased, which has of course augmented the price and increased the inducement to the capture of them. Thus the avocet claims particular attention as one of the family of our native and resident animals which appears to be fast leaving us, and of which the people of the next generation may never see a live British specimen. The details of it are thus more worthy of record than those of other birds which we have in plenty and without apparent decay of numbers. The following figure will give a general notion of its shape and the markings of its colours; and we shall add some of the details in words.

The Avocet.

The length of the avocet is about eighteen inches; but when the legs are stretched backwards, they reach four inches beyond the point of the tail, and of course make the total length four inches more. The tail is short and the closed wings reach rather beyond it; and when they are expanded, their extent from tip to tip is about two feet and a half. The bird cannot thus be said to be one of very powerful wing; but still its capacity for flight is considerable, and from the length, strength, and mode in articulation of the legs, the bird can take the wing with great ease, there being always plenty of air under it. The same strength of the legs assists it in alighting easily. The length of the bill, measured along the curve, is about three inches and a half.

The irides of the eyes are hazel, the naked parts of the feet and legs blue, and all the feathered part of the body either white or black. White is the prevailing colour, and it is beautifully clear, showing very handsome, both on account of the closeness and smoothness of the plumage, and of the black markings, of which the colour is as deep as the white is pure.

The bill, the head as far as to under the eyes, and the nape of the neck are black; but the upper part of the head is less or more relieved with white. There is sometimes a white streak over each eye, and a white spot on the forehead; but in other specimens the spot on the forehead is wanting, and the streaks over the eyes are broken into spots, which are sometimes inconspicuous. All the black markings are liable to vary, not only in different individuals, but probably in the same individuals at different ages. They are always sufficient, however, independently of the form, the bill and the habit (which of themselves are also enough), to distinguish the avocet from every other British bird. Besides those that have been mentioned, the usual black markings are, the bastard wing, the turn of the wing, some of the scapulars and middle coverts, and the quills; all the rest of the upper part generally, and the whole of the under part invariably are white.

From the brightness of its colours, the bold contrast of its markings, the height which it stands on the legs, and its feeding on the dull brownish surface left by the tide, the avocet is a very conspicuous bird, and may be seen at a very considerable distance; but it sees as readily as it is seen, and the distant view is the only one that can be obtained if the observer goes openly upon it. It makes off one knows not very well where, so that one may search long enough without getting another sight.

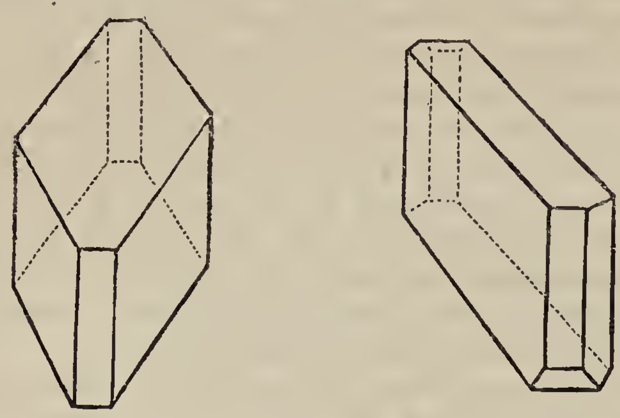
Some of the grallidæ have a shrill and clear whistle, and pipe as loud as a boatswain; but none of them deserve much praise for their "sweet voices." The avocet forms no exception to this, as its cry is harsh and screaming. This is not owing to the bill, uncouth as it seems for a musical instrument; for the bill of birds has very little to do in the sounds which they utter. Their organ of voice is at the lower or pulmonary end of the trachea, and not at the upper or larynx end.

Avocets breed on the borders of the marshes: the eggs are understood to be four, and placed quatrefoil, or in the form of a cross. They are large for the size of the bird, and of an olive brown colour marked with spots. In the breeding season, the birds have much of the shyness which they are said to have in the winter and autumn. They become familiar, and to appearance sportive; but the sport is, like that of the lapwing, a ruse to entice visiters away from the nest. The female especially flies round the head of the visiter, playing in circles, and uttering an incessant but not apparently angry cry of "quheet, quheet," and she receives him, and also takes leave of him, at a considerable distance from that place which she seems anxious he should not visit. The nests are now become, of course, as rare as the birds, and it is as difficult to procure an avocet's egg as to procure an avocet. They and some others of the resident marsh birds appear to be passing away faster than there is any apparent reason for; for in the years that have been mentioned there has really been no alteration, at least no artificial alteration in the fens, that appears at all calculated to reduce their numbers to one in the hundred, which, from their appearance in the market, seems to be about the ratio. The circumstances which influence the numbers of wild animals are, however, but imperfectly known.

Avocets are more numerous in some other countries than they are in England; and there are several foreign species differing from the common one in their colours, though their habits appear to be so much the same as to render details unnecessary. An American species is described as having a reddish or purplish mantle on the lower part of the neck, and there is one mentioned in India which is all white except the wings. The variations which are found in the markings of even the few that are to be found in this country, are sufficient to make us cautious in founding species upon mere differences of colour.

AWLWORT. Called by Linnæus *Subularia*, a tetrandrious plant, found in most of our lakes.

AXINITE. This mineral derives its title from the peculiar shape of its crystals, which somewhat resemble an axe. When any marked peculiarity of this kind occurs, an accurate delineation of the crystal is preferable to an engraving of the mineral in mass. In the present case two of the crystals are represented in the accompanying figures.



The most common colour of this mineral is clove-brown, of various degrees of intensity; from which it passes on the one side into blue, on the other into pearl-grey, ash-grey, and greyish-black. In some few instances it is found of a green colour.

Axinite occurs in rocks of gneiss, mica-slate, clay-slate, and hornblende. The massive varieties are met with in beds, and crystallised in veins. In the Saxon metalliferous mountains, where it occurs in beds, it is associated with massive calcareous-spar, common chlorite, magnetic-pyrites, iron-pyrites, arsenical pyrites, copper-pyrites, blende, and probably also with actinolite and hornblende. At Kongsberg, in Norway, it is grouped along with native silver, galena, slaty glance-coal, and calcareous-spar. In the Felberthal, in Salzburg, it occurs in mica slate; and in the Hartz, along with quartz and asbestos; at Arendal, in Norway, along with calcareous-spar, common actinolite, common iron-pyrites, felspar, epidote, and sphene. The axinite from Dauphiny, Savoy, and several other places, occurs in small veins that traverse gneiss, in which it is generally the uppermost mineral.

The peculiar crystalline character of axinite was originally described by Romé de Lisle, but he arranged it with schorl; and it was Werner who first established it as a distinct species.

AXINURUS. A genus of spinous-finned fishes, belonging to the lancet-fish family, or those which have spines on the sides of the tail, by means of which they can inflict wounds. Only one species is mentioned, *Axinurus thyneroides*, and very little is known respecting it. It is a native of the eastern seas, and has been found only on the coast of New Guinea, where, like the rest of the family, it frequents those places which abound in sea-weeds. But the structure of its teeth, which are small, and stand apart from each other, points out that it does not, like some of the other genera of the family, feed either upon sea-weed or upon animals that have hard crusts or shells. Its form, too, indicates more of a swimmer, and of discursiveness or activity in the capture of its food. Its body is considerably elongated, and its mouth is small, without any projecting snout, and the teeth, as has been said, are slender and wide apart. It has four rays on the gill-flap, and three soft ones on each of the ventral fins. Each side of the tail is armed with a powerful four-cornered spine, very strong, hard and sharp in the edges, and capable of inflicting very severe wounds. These spines, as in all the family, are, however, weapons of defence, not of offence. It has the long intestines of the rest of the family, and therefore, though its teeth are not well adapted for cutting, it may live upon the more succulent species of sea-weed.

AXOLOTL—*Proteus Mexicanus.* A singular species (if not distinct genus) of Batrachian reptile, found in some of the shallow lakes and pools in the interior of Mexico, and especially on the borders of the great lake near the city. It is about eight or ten inches long, of a grey colour, spotted with black, the hinder part having considerable resemblance to a fish, and being furnished with a fin. It has four legs, however, the anterior ones furnished with four toes each, and the posterior with five. Its breathing apparatus consists of three gills in the form of tufts; and the mouth is abundantly supplied with small teeth, very similar to the teeth of fishes in their form and arrangement.

Too little is known of its progressive history, the mode of its production, and the changes which it undergoes, for enabling a positive decision to be made whether it should belong to the genus *Proteus* or not; and therefore Cuvier very properly places it by itself, and marks it as doubtful. It is very plain, however, that Shaw was decidedly wrong in classing it with the sirens, as *Siren pisciformis:* the sirens have only two feet, while it has four, and there are other structural differences. If the young are really without feet, and blind, it may perhaps be admitted as a species of proteus; but the European proteus is very differently furnished with toes, having three on the fore feet, and two on the hind.

AYE-AYE — *Cheiromys Madagascariensis* —the handed rat of Madagascar. A very singular animal, classed by Cuvier among the *Rodentia,* or gnawing animals, as intermediate between the squirrels and rats. From the structure of its teeth, it certainly requires to be so classed; but in the form of its body and the structure of its extremities, it resembles more the quadrumana, or handed animals. But the form of the body of an animal, or the structure of the limbs and their terminations, are much less important characters than the teeth, as the latter determine the food of the animal, while the former point out only the general means by which the food is arrived at.

The above figure of this singular animal will, in part, save the necessity of verbal description.

The size of the aye-aye is about the same as that of a hare; the covering of the body is a mixture of brown and yellow; the ears, which are large, are nearly naked; and the long tail is covered with coarse black hair: the tail is not prehensile. The outline of the head has not the arched or rounded form which is common to all, or nearly all, the true *rodentia*, which are ascertained to gnaw vegetable substances, but more resembles that of some of the quadrumana; the teeth are, however, truly rodent in their structure: the incisors are very large, and curve outwards in both jaws; and on their front edges they are much more deeply furrowed than those of the squirrels. They are two in each jaw, which is the normal, and indeed the constant number in the rodentia. Four cutting teeth in each jaw is the normal number in the quadrumana, though some have as many as six in the under jaw, and some are described as having only two in the one, but a greater number in the other. The subjects from which those accounts are taken are, however, in some instances, only mutilated fragments, so that descriptions founded on them are not very satisfactory. All the quadrumana, too, have canine teeth, which are wholly wanting in the aye-aye, and their grinders are more numerous. Of these, the aye-aye has four in each side of the upper jaw, and three in the under, small in size, and separated from the cutting teeth by wide intervals. The quadrumana also have pectoral mammæ; but the mammæ of the aye-aye, which, like these, are, only two in number, are in the groin. Indeed, all the characters which are usually considered as being most important in the formation of a natural or structural classification, are similar to those of the rodentia.

Still there are some doubts as to the habits of the animal. Like the *galagos* and *tarsius*, which perhaps deviate more from what may be considered the type of the order, and which in structure they resemble the most, the animals of the genus under consideration are nocturnal; and they are said to live upon insects and larvæ, which they pick out of the crevices of the bark with their long and slender fingers. However that *may* be, the form of their fingers is certainly not the best adapted for such a purpose, inasmuch as an insect cannot easily be taken by means of a single finger terminated by a claw, however long and slender it may be. The teeth, too, are very unlike those of any animals which are known to feed exclusively or chiefly upon insects; and the nocturnal habits of the animals, if not adverse to the fact of picking insects and larvæ out of the crevices of the bark, are, at all events, not very favourable to the observation of it. No doubt many of the rodentia are insectivorous, and contrive to capture insect prey in the dark (the common mouse is a great devourer of cock-roaches), but they do not pick them out of small crevices. In confinement, the aye-aye has been fed wholly upon vegetable matter, which it ate very readily, using its hands like a squirrel; or rather its long fingers, as the Chinese do their "chop-sticks."

The aye-aye is described as spending the day in holes of the ground; one would suppose natural ones, because the paws are very unlike those of ordinary burrowing animals; but the same or similar purposes are, in the animal kingdom, so often accomplished by organs apparently very different from each other, that this animal may dig its own burrows.

The general character is, however, that of a climber, though a less expert climber than many other animals because of the shortness of the fore-legs; these are considerably shorter and also more feeble than the hind ones, and the length and slenderness of the fingers makes them look more feeble than they are in reality. All the fingers on these paws (or hands) are very long and slender, especially the second ones; and the claws upon them are long, considerably crooked, and at their bases nearly as thick as the fingers. The thumb on these is articulated near the wrist, and the point of it does not reach beyond the first joint of the fore-finger; but it acts very slightly, if at all, in opposition to the fingers; the fact is, that the hands, like the animal itself, are rather puzzles, as there is not any similar organs with which they can be very fairly compared. From the shortness and feebleness of the arms, and the spider-like structure of the hands, they are neither efficient for walking nor for reaching long distances from branch to branch in climbing; and the lengths of the fingers are so unequal, and the nails so long, that the fingers do not appear very capable of being used in any way but singly.

The hind feet are much more robust, and formed as if they were the principal organs of locomotion; the soles are long, and they plant them fairly upon the ground, and do not turn on the side, like the feet of many animals that live chiefly in trees. The toes on them are long and slender, but not nearly so much so as those on the anterior extremities, and the nails, though sharp and considerably crooked, are much smaller. The thumbs on the hind feet are articulated far back; they are rather short, reaching only as far as the division of the fingers; but they act in opposition to these, so that the foot is both a walking and a prehensile instrument; the hind leg and thigh are as stout and muscular as the fore ones are slender.

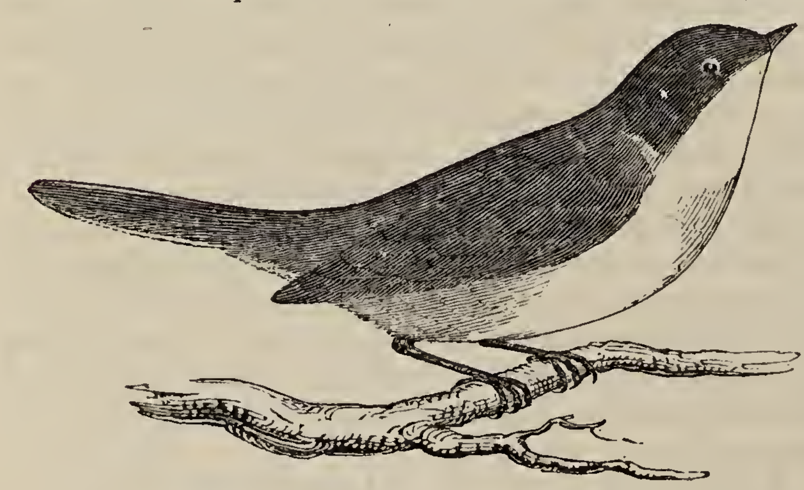
The whole animal indeed is peculiar, almost to the extent of being an anomaly. It is certainly made a separate genus with much propriety; and it can hardly be said to come into any of the natural families, and not very satisfactorily into any of the orders, as at present constituted. If the teeth are to be taken as the basis, and that they are the most certain basis there is no question, the animal clearly and decidedly belongs to the rodentia; because the coincidence with those species which may be regarded as typical of the order are perfect. Upon this point Cuvier appears not to have the slightest doubt or hesitation, and his knowledge of the structure of animals, and discrimination in the use of it for the purposes of arrangement, were of so very superior a description that, except upon some minor points where he was not well informed as to the facts, opposition to what he has deliberately laid down, betrays as much of rashness as of any thing else. If, on the other hand, we depart from the principle of the teeth, and go to the general structure of the animal, we are left in doubt and perplexity. It has analogy to several others; but it has well-established affinity to none; and even the analogies are imperfect, and far from close, even as far as they go. There is not, in any respect, identity between it and any other handed animal. It stands alone, and it wants to be more intimately studied.

AYENIA (Linnæus). A genus of plants containing two species, natives of Jamaica; one is an under shrub, the other a biennial herb. Linnæan class and order, *Pentandria Monogynia;* natural order, *Malvaceæ*. Generic character: calyx five-cleft; corolla petals clawed, the tops bearing brown, star-like glands; urceolus, five-toothed, and bearing the stamens; anthers starry, like the petals; stigma five-lobed; capsules five-united, five-berried; berry one-seeded.

AZALEA (Linnæus). An extensive genus of beautiful flowering shrubs, natives of China, Turkey, and North America. Linnæan class and order, *Pentandria Monogynia;* natural order, *Rhodoraceæ*. Generic character: calyx of five teeth; corolla funnel-shaped, limb in five divisions; stamens inserted in the receptacle, unequal; capsule from three to five-celled, valves of the dissepiments formal. Of this fine family of shrubs there are twelve species, and from these have been obtained no less than eighty-three varieties! to which daily additions are making. The new ones introduced from China within these last forty years are amongst the most splendid plants in our collections: which, together with the old American species, are, in our borders, the chief of the high coloured ornaments.

AZAROLE. A large fruited species of hawthorn, viz., the *Cratægus azarolus* of botanists. Every part of the plant, especially the leaves, are of a more ample form than the common whitethorn, and the fruit being nearly an inch in diameter, are cultivated in Italy for the use of the dessert. The fruit arrive at a fair size in England, but are too insipid for English palates.

BABILLARD, white breasted, and babbling fauvette, or lesser whitethroat (*Curruca garrula*, Brisson). Provincial, *Nettle-creeper*. A small frugivorous warbler, common in the southern parts of Britain, and in many of the more temperate of Europe and Asia. It is a migratory species, arriving in the neighbourhood of London about the end of April, and departing, for the most part, towards the latter end of September, though a few stragglers are sometimes observed till late in the following month. The bill is of a dusky hue, much resembling in form that of the blackcap, but rather smaller and more slender. The irides, in the younger individuals, are dark hazel, with a tinge of reddish; but in the course of three or four years become gradually pure white. The upper part of the head is of a fine ash colour, darkest about the ear-coverts, where it contrasts with the snowy whiteness of the throat: all the other parts above cinereous brown: quills and tail dusky, edged with ash colour; the exterior feather of the latter whitish almost to the base; the outer web quite white. The whole under parts



Babillard.

are white, purest on the throat and belly, and inclining to silvery on the breast and flanks; which last, in the older males, are often tinged with a blush colour. Legs and feet dusky lead colour.

This active little bird is found chiefly about orchards and gardens, and tall hedges, especially of elm and hawthorn, where it may readily be distinguished in the spring and summer by its continual reiteration of a monotonous and loud shrill note, resembling the sound *jee*, or *ghui*, repeated several times in quick succession. It has also a soft and pleasing continuous warble, not very much unlike that of the blackcap (*C. atricapilla*), only more faint and weak, and easily distinguishable by the frequent recurrence of a note like *sip-sip-sip*. As it proceeds, it gradually raises its voice, and mostly ends with the tiresome and monotonous note first mentioned, which is analogous to the clear and lively whistle with which its congener, the blackcap, most frequently concludes. This species is never observed to mount warbling into the air, as is the habit of another near congener, the whitethroat.

The Babillard has usually been represented to pass the whole of its time among low underwood, whence specimens of it could only be obtained with difficulty, and by patient watching. This is, however, quite at variance with our observation, for we have always noticed it chiefly to inhabit trees, and have heard it repeatedly, and shot it, from the tops of the very highest elms. Moreover, from its perpetual activity, when searching the leafy branches for food, it is more frequently visible, and is consequently, perhaps, even easier to procure than any of its British congeners. Unlike the whitethroat (*C. cinerea*), this species is nowhere to be found but where there are trees.

The nest is usually built in low bushes, though sometimes as much as nine or ten feet from the ground, and not unfrequently among nettles, or other coarse herbage (whence the term *nettle-creeper**, its common provincial appellation in the south of England). It is a tolerably compact structure, though in appearance flimsy and frail, being composed of the dry fragile stems of catch-weed, or cleavers (*Galium aparine*), neatly put together, though so scantily that the light may everywhere be seen through it, and invariably lined with small fibrous roots, sometimes with the addition of a little horse-hair. The eggs are four or five in number, of a dull white, speckled with brown and ash colour, chiefly at the larger end, where the spots often form a zone. They are rather smaller than those of the whitethroat, and the spots are larger, having more the appearance of blotches.

The food of this species consists of small insects and caterpillars, together with the various garden fruits, being particularly fond of cherries, raspberries, and currants. It is rarely heard to sing from the time these are about, and soon after commences its autumnal change of plumage; both old and young, however, being still easily recognisable, at this period of their garden depredations, by their constant repetition of a note sounding like the tapping together of two pebbles. This note is also uttered, but more loudly, by the blackcap, and with slight modifications by all the other members of the genus.

---

* In most works on the birds of Britain, this name is applied to the common whitethroat, but erroneously. The two species are often confounded by common observers, as they have been by naturalists; but whenever a distinction is made, we have always found one to be designated *whitethroat*, and the other *nettle-creeper*.

In confinement, the Babillard is a very quarrelsome and domineering little bird, being in general, on this account, quite unfit for the aviary, as it will attack, and completely persecute, birds even double or treble its own size and apparent force. It is a more active species, and quicker in its movements, than any of its British congeners; and it often climbs along the wires, a habit not observed in the rest. It also frequently throws itself over backwards when in a large cage, performing somersets in the air, often for seven or eight times in succession. It is a lively and healthy creature in captivity, and soon becomes extremely familiar and tame.

The female resembles the male in plumage, and the young only differ in the crown of the head being of the same colour with the back.

BABOON. The popular name of a subdivision of the quadrumana, or four-handed animals, extending to more than one genus, and including animals of which both the characters and the habits vary considerably, and some to which the name does not very well apply. The names, ape, baboon, and monkey, have been sometimes all applied to the same species, different species have been called by the same name, and the same species have been called by different names, so that it seems almost impossible to get rid of the confusion in any other way than by a general muster of all the species, and naming them anew. It is doubtful if even that would be sufficient, and it is certain that, with only a single specimen of each, it would not. There appear to be considerable varieties arising from age, haunt, and other circumstances; and these are not confined to mere differences of colour, to which most species of animals are more or less subject; but they extend to size; and, in so far as difference of haunt is accompanied by a difference of food, they extend also to disposition.

Taking the general character from those species which may be regarded as the most typical of the creature, that is from those which least resemble any of the other groups of quadrumana, for that is all which is in general meant by being typical, we might infer that there would be more variety and more disposition to variety in the baboons than in the apes, or perhaps even in the monkeys, if restricted either to those of the eastern continent, or those of the western. The apes, properly so called, are so very local, that there is no scope for breaking them into climatal varieties, and though, as might be expected, there appears to be differences between the chimpansee of Asia and of Africa, yet in each country, that, the most erratic of all the true apes, appears to be constant to its type.

The true apes are, in general, such bad walkers, that their range is confined to the forest, and their food to what they find upon the trees, they are thus as much like each other in habits as human beings which inhabit the same city and live in the same manner, or rather like deer in the same park, or sheep on the same down; and it is well known that, under these circumstances, instead of there being any disposition to run into varieties, there is a disposition the other way.

It is not so with the baboons properly so called. They no doubt are climbers, as all four-handed animals are, climbing being the sole, or at least the chief use of that form of organisation. But they are not exclusively made for climbing; their anterior and posterior extremities have no very marked disparity in length; the soles of their hind feet apply to the ground; their limbs, though clumsy as organs of progressive motion compared with those of running animals, have not the wriggling flexibility of those of the climbers; and they can accordingly walk and run with considerable velocity. Thus, though the baboons are, to a certain extent, forest animals, they are not exclusively so. They are so formed that they could live habitually in the forest if there were no other pastures, or in other pastures, if there were no forest.

Now, it agrees with analogy, and also with the facts, that when any production of nature, whether animal or vegetable, has this compound nature, it can, either by art or by natural circumstances, be so *worked* upon one part of the compound, as to take its leading character from that, and in part lose the other; and this holds whether the circumstance by means of which it is worked be food, climate, or any other. We find proofs of this in man himself, and in all that man cultivates, and we see so many additional instances of its operation in wild nature, that we can have no doubt of its being a very general and invariable law of nature, the operation of which must, in all cases where we have difficulty about species, except where the difficulty is of our own making, be one of the chief causes of that difficulty. That this is at least one of the chief causes of that uncertainty which obscures part of the history of the baboons, there can be no doubt.

Indeed, the characters upon which we proceed in the formation of groups and genera, are not unfrequently the causes of more difficulty to us than if we had left classification altogether alone. They are often mere differences of form in parts of the uses of which we know nothing; and as such, it is impossible to connect them with any thing useful—any thing which can lead to a knowledge of the disposition or habits of that of which they are taken as the characters. That this has been the case with the quadrumana of the old continent, there is little doubt: the foundations of the grouping have been the presence or the absence of cheek pouches or tails; and as we know not very well the uses either of the one or the other (none of the species on the old continent having prehensile tails), the conclusions which we draw cannot contain more information than the premises from which we draw them. If the question were between having no tail and having a very large one, which we might suppose effective in balancing the body, as between the apes proper and the monkeys, there might be at least a show of reasoning set up; but when it is between having no tail and having next to none, as is the case with some of the animals classed as baboons, there is but little scope for philosophy in it.

But there are other circumstances in the structure of the baboons which tend to show that they have a greater range or diversity of habit than the apes: their mouths are more of prehensile instruments; and the nostrils are carried forward near to the muzzle, as if for the purpose of guiding the mouth in the selection of that which it seizes. They have more of both the structure and the expression of animals which are, in part at least, carnivorous; and when both structure and expression point to any habit, that habit is never wanting if there be opportunity for its exercise.

These observations will, in part at least, explain why there is not that clearness of general definition about the baboons, which we find in some of the allied sections, and also why we have not been able to give some account of them as indicating the general natural character of some locality or district. The section contains (part of) several genera differing considerably in their localities and habits; these demand some new arrangement; but as that arrangement falls not within the province of a popular work, we purpose to follow the arrangement of Cuvier, noticing the general characters of each sub-division and giving a slight enumeration of at least the more remarkable and better known species.

In their form and expression, the baboons, in all their varieties, are the least handsome, or perhaps it is more accurate to say, the most positively ugly of all the mammalia. Though the form of the head approaches that of the beasts of prey, there still remains as much of resemblance to man as forms a very ugly caricature; and though the expression is ferocious, it is not the kind of ferocity which we find in carnivorous animals. The most savage expression which we find among those animals whose habit it is to kill prey, sits, as one would say, naturally upon them, is in keeping and congruity with the whole of their character and habits; and when we admit the habit, which is but another name for the use or purpose of the animal in the economy of nature, we must also admit that the expression is natural, and that, were it more mild, we should regard it as an expression of deceit, as which it would be more offensive than that which is in accordance with nature. But the general structure of the baboons does not impress us with the notion of a carnivorous animal, or one which habitually kills for its food. It is ferocity without a purpose, analogous to that of a man who is always offended and snarling without cause; and who, though far from the most dangerous, is certainly the most disagreeable of the whole race. We admire power, even destructive power, when the object of it is consistent with the expression; and if the lion and the eagle had the expression of the lamb and the pigeon, they would be in truth ugly animals. The same is the feeling that we have of the converse, as instanced in the baboons. Their expression is mischievous; but it indicates mischief in which there is no meaning, because there appears to be no necessity for it in the economy of the animals. They have it; yet it is not "their vocation," not in any way essential to the finding of their food, or the performance of any office which appears to be necessary in their economy. Offensive as this expression is, it is perhaps the one which, more than any thing else, led to the ancient comparison of the quadrumana with man. The species which must have been best known to the Greeks and Romans, perhaps the only one with which they were familiar, and certainly the one which was dissected by Galen, and from which he inferred, by comparison, many points in human anatomy, was the magot or Barbary ape; which Cuvier classes with the baboons, and which, though it has not all the characters of the more typical species, has yet much of the ferociously snarling expression.

Those who seek for something correspondent in man and the quadrumana, certainly find it more in this expression of malignant and unmeaning ill-nature than in any thing else; and thus the most repulsive of the baboons has really more of man in him than the chimpansee or the orang-utan; for, except in the baboons and in bad men, we may seek nature in vain for the expression of purposeless malignity. And the parallel may be extended somewhat further. The manners of the baboon are as offensive as his expression is ferocious; and, as is the case with the man of ferocious expression, the offensive manners appear to have as little necessary foundation in nature as the disagreeable expression. The baboon is thus one of the most anomalous of animals. He does not appear fitted for any particular region or place; and he has an expression and habit which we find nothing in his circumstances or mode of life, which, according to the experience which we have of other animals, should call forth or justify that expression or those actions.

But we are not to suppose that this correspondence between certain parts of the expression and conduct of the baboons and those of human beings of a peculiar temperament have any analogy in nature, any more than there is an analogy of nature between the forms of apes and the form of man. That which we find in the baboon is not depravity or corruption arising from bad conduct, bad company, or any of the demoralising causes which act upon man. It is part of the nature of the animal, and must be in some way necessary to the existence and comfort of that animal; and, offensive as from our ignorance it appears to us, there is not the least doubt that, if we could discover its cause, we should find that it is as necessary and perfect as any thing else we meet with in nature. In their native localities the baboons must be exposed to the attacks of the medium-sized cats, which are powerful animals, much swifter on the ground than the baboons, and not much less expert in climbing; for though the baboons can get along very nimbly among the stiff branches, they cannot leap from tree to tree, or swing themselves on the smaller twigs to which their feline foes dare not pursue them. That their fierceness is meant as a protection against their foes has not been fully established, because the attacks of these larger cats upon their prey are not events of every-day observation; but the probability is that it answers some such purpose. We shall now notice the subdivisions of the baboons.

The first subdivision, and the one which has the baboon character and ferocity the least marked, is that to which the name of Macaco (*Macacus*) is applied, though different systematists have divided it differently into genera, but all the species do not get the popular name of baboons, or indeed when the common principles of nomenclature deserve it.

The animals of this subdivision, though very much circumscribed in latitude, have a very remarkable range of longitude, extending from the western parts of northern Africa, or even from Europe (for one of the species is found in the south of Spain, at least on the top of the rock of Gibraltar, and is the only quadrumanous animal found in a wild state in Europe) to China, and the extreme eastern isles of Asia. They are not continuous, however, in all that range, because if a line is laid across the map it will be found that much of what it falls upon is desert, or at least destitute of trees, and as such not adapted for these animals, and that the parts so adapted are but a few points. The species too, at least those which can with any propriety be considered baboons, are not many; and lying far apart in their localities, they differ much in their appearance. They are not so equatorial in their locality as the apes, or the more formidable and ferocious baboons; and it does not appear that they are found in the southern hemisphere, or even within several degrees of the equator.

In their general characters they are intermediate between the apes and the baboons: the muzzle is much more produced than in the apes, but the cranial part of the head is greater in proportion to the bones of the face than in the baboons. The nostrils, too, are not so terminal on the snout, but leave a sort of projecting upper lip; the canine teeth are not quite so formidable, and the whole mouth has a less snarling and cur-like expression. The muzzle is elongated and blunt, the facial angle from forty-five to forty degrees, the eyebrows prominent, the lower part of the forehead arched, the upper part sloping very much backwards, the tail in all the species rather short, and in some a mere tubercle. We shall now, very briefly, notice the leading species in this subdivision.

1. The Magot, or Barbary Ape (*Macacus Sylvanus*). This species, as having been in all ages the most accessible to Europeans, has been the largest and the most familiarly known of all the four-handed race. The second of its popular names indicates its principal locality—northern Africa, the forests on the slopes of the mountains of Atlas, and their lateral spurs, though it is also found in considerable numbers on the rock of Gibraltar, the most elevated point of which rises to the height of 1439 feet above the level of the sea, and has the slopes in many places covered with a profusion of plants both of the south of Europe and of northern Africa. The magot appears to thrive as well and attain as large a size there as on the south side of the Strait. Besides this European colony, it does not appear that the species is found any where out of Africa, or in Africa to the south or east of the desert.

A general idea of the appearance of the animal when in a state of indolent and apparently sulky repose may be formed from Landseer's characteristic sketch, at the bottom of the plate "Baboons." The colour of the upper part, including that of the outsides of the limbs, is clear yellowish brown, rather deeper on the upper part of the head and on the borders of the cheeks. The colour on the under part is dull yellowish-white; and the naked skin, the face, ears, paws, and callosities on the hinder extremities are dull flesh-colour. The fingers are of moderate length, and strongly made; the muzzle, which is broad and flat, elongates as the animal gets old. The tail is a mere tubercular rudiment, altogether unconnected with the bones.

It is not a very large animal, the male not exceeding two feet and a half in length, and the female being smaller. The adult male has the canine teeth large, and is a vicious and rather dangerous animal. But the formidable canine teeth are no indication of a carnivorous habit, as they are very little larger than the other teeth in the female; and in the male, as in the wild boar and some other feeders upon vegetables, they appear to be for mere defence, rather than for predatory purposes.

This species has, from time immemorial, been the showman's "ape" in Europe, and while young it may be *educated* (by blows) into some obedience, and the performance of a few tricks. But as it gets towards maturity, it becomes morose and sullen, and (the male especially) mischievous and refractory, till his strength and spirit both fail under the hateful restraint of confinement, which is obviously very repugnant to the nature of the animal. So contrary, indeed, is confinement to their nature, that their health soon gives way under it, and they perish, not of the effects of climate, as is the case with the species which naturally inhabit more toward the equator, but from the constant irritation of constraint and confinement.

In the freedom of their native wilds and forests they are represented as being very different. Social, active, and energetic; bold and courageous in the defence of each other and of their young; and so strong is the latter propensity, that confined ones, if in tolerable health, whether males or females, are said to adopt, and fondle with paternal attention, any small animals that may be put into the same cages with them. Several fables of the ancients are founded upon the attachment of this species to their young; and, among the rest, the very instructive one of the favourite which was carried in the arms being killed by the fall of the mother, while the neglected one, which rode on the back, escaped without injury.

When in their native forests, they carry on their defensive operations, in part at least, as all the race do, by the noise of their war cry; and it is a curious fact in the history of predatory animals, that many, even of the formidable ones, are sooner driven off by noise than by any other means.

The magot is not a very handsome or a very interesting animal; but it acquires a sort of interest from the length of time that it has been known, and the consequent mention of it which is made in history, both authentic and fabulous. Its general association, in the systems, has been with the apes; its proper natural association seems to be with the Asiatic monkeys (for where tails are not prehensile, the presence or absence of a tail is a secondary consideration); and its being included among the baboons by Cuvier, entitles it to a place in this article.

2. The Wanderoo (*Macacus Silenus*). This species, which has not been so long or so familiarly known in the western world as the former, has been allowed to retain its proper vulgar appellation of a monkey, though it is just as much entitled to be called a baboon as the magot. It is a native of India, of Ceylon, and probably of some others of the eastern islands; and in some of its localities it has, by the gravity of its deportment, procured for itself a name for wisdom far above that of the smaller and more useless and noisy monkeys.

Wanderoo.

The external characters of this species are so marked and peculiar, that they cannot easily be mistaken. The face has not much in the way of beauty to recommend it, being flesh coloured below the eyes and black toward the muzzle, which is prolonged as in the former species: but the way in which the visage is decked out with hair gives it a singular, if not a sage appearance. The hair on the upper part of the head, from a little above the eyes, is of a deep black colour, which contrasts well with the flesh tint of the naked part of the face there, while the lower and black part of the face is surrounded by a produced ruff varying in colour from ash-grey to nearly white. The callosities on the hinder extremities are, as in the former species, of a flesh colour, and they, as well as the cheek pouches, are large for the size of the animal. The hair on the upper part is black, and that on the under part ash-grey or white. The body is about the same length as that of the magot, the female being, as in that species, of smaller size and less irritable disposition than the male. The tail is a regular continuation of the vertebræ, about half the length of the body, and, when perfect, ending in a brush or tuft of long hair, from which the animal has been called the "lion-tailed monkey." The character of this species, especially that of the adult male, is, like all others of the subdivision, a little suspicious; but it is said to be rather more playful than the magot, and not quite so much given to mischief.

3. The Pig-tailed Baboon, or Maimon (*Macacus nemistrina*). There is some confusion about this species, arising from another of the same genus having been called by the same popular name, which shows the inconvenience of naming an animal from the form of its tail, when that tail happens to be a useless organ. The other (*Rhesus*) is generally styled the pig-tailed monkey, this the pig-tailed baboon. Both species are inhabitants of the south-east of Asia. A figure of the present species in an erect posture, is given at the top of the plate "Baboons." Animals of this species are apt to get apparently deformed, by accumulations of pendulous fat on the throat, the abdomen, and other parts of their bodies. They are not very interesting animals, as they are rather untractable, but that seems to arise more from dulness than from vice.

4. The Black Baboon, or Black Ape (*Macacus niger*). This is a species of considerably more interest than the former, on account of its being more rare, more recent as an authenticated addition to zoology, and a more interesting animal in its manners, although by no means a handsome one in its appearance. A figure of it as "the black baboon," is given at the top of the plate "Baboons;" but as there is another "black baboon," belonging to the subdivision, that has more of the baboon character, it is necessary to attend to the circumstance that this one is black all over, while the other is yellowish, or straw-coloured on the under part.

The native locality of this species is not perfectly ascertained. The specimen from which Cuvier mentions it, but which appears to have been too imperfect for enabling him to ascertain its proper place in the system, he describes as having been brought from the Philippine islands; and as such it must inhabit more easterly than any of the species which we have already noticed. Three specimens which have successively been in England in the living state, have led to a more accurate knowledge and appropriate classification of the animal; but as it is not exactly known whence any of those were obtained, the locality remains as undetermined as ever. When there has been any tradition, that has indeed implied that they came from "the South Sea;" but as the South Sea is a common name for the whole Pacific Ocean, the expression is somewhat vague. It is known, however, that no quadrumanous animal inhabits Australia, New Zealand, or any of the remote groups of islands which are scattered over that wide ocean, so that the probability is that the locality may not have been far from that where the mutilated skin from which the French formed their description was obtained; and that they were from some place rather northward, such as the Philippines, is probable, because they appear to bear the climate better than those species which come from near the equator. The first specimen which was known in England was in the Tower menagerie, from which the remains found their way to the British Museum. This specimen was described and figured by Mr. Gray; but the name and place in the system, which Cuvier had founded upon Desmarest's description of the mutilated skin, were retained. Another live specimen was some time ago exhibited at Exeter 'Change, the animals at which, on their removal, formed the basis of the collection at the Surrey zoological gardens; but the native habitat of this one appears to have been no better known than that of the former; and it does not appear that from the inspection of it, any one attempted to correct the natural history of the animal. A third specimen came into the possession of the zoological society, though without any more information as to where it was obtained than the others. In the early days of that society, and while the managers were attempting, most laudably no doubt, to draw toward it such a share of public attention as should ensure sufficient profit as a mercantile speculation, to defray the current expense and pay for additions and improvements, it was of course desirable to get hold of all rare animals. But ignorance of the native locality of an animal, leaves a sad blank in its natural history, and reduces it much to the level of a common museum specimen, which does very well for being wondered at when seen, but comes one knows not where, and is good for one knows not what. So that, now when the zoological society is fully established, and enjoying high patronage, it were much to be desired that no animal should now be admitted into the collection there without an authenticated record of its previous history, or, at all events, a note of "the name of its parish." That would take off every appearance of mere raree-show-ism; and render true to nature in all its parts, a zoological collection which must very soon be by far the foremost in the world. The number of British zoologists spread over the face of the globe, as well as the number of corresponding members which the society now have, must give precision and geographical truth to many of the additions now to be made, and thus there will be less need for having recourse to animals of unknown localities which may be occasionally for sale. The captains of ships, too, if they found that the geography of animals were a *sine qua non* with the best customers in the purchase of them, naturally would, as they in general easily could, fill up that blank in their history. The old showmen spoiled that part of the business; for if they could find an animal which was, or *could be made*, novel enough in its appearance, they soon gave it "a local habitation and a name," with as much poetical licence as the votaries of Parnassus. It is owing to these circumstances that we are still ignorant of the native locality of an animal, whose history it would be desirable to clear up in that point as well as in the others.

As the native region of this species is not known, it is needless to add, that we are in total ignorance of its habits in a state of nature. This is the more to be regretted that, while it has all the essential characters of a true *macaco*, it has also more of the external appearances of the true baboons than any other of the subdivision to which, from its essential characters, it belongs. It would thus be highly desirable to know something of its disposition and habits in a state of nature; for though in confinement it shows more activity, and perhaps a greater love of mischief than the other *macacos*, these displays are not sufficient for forming such an estimate of its character as to show whether that is in any way modified by its baboon-like appearance. The most striking of these is the fleshiness of the cheeks, which nearly obliterate the ridge or prominence of the nose, and also enables it to snarl, or show the teeth laterally, by the furrowing up of the sides of the lip as the baboons do. But the nose does not reach to the end of the muzzle, as in the baboons; and the nostrils are very flat and oblique. The eyebrows are very projecting, and the whole expression of the face is sinister and suspicious. This is rather increased by the tuft of long hair on the top of the head, which curves a little backwards. The hair on the body is all over of a deep black, long and shaggy, or rather woolly; but it becomes slender on the legs. The tail, like that in the Barbary ape, is a mere tubercle. The legs are rather shorter in proportion than those of the baboons, indicating that the animal is more habitually a climber.

Those that have been enumerated are the leading species of *macacos*, to which the name of baboon has, by one or other, been applied. They are not baboons, but rather monkeys, as in a proper natural arrangement, after their characters and habits come to be a little better known, they, with the other allied species which we have not mentioned, as they have never been called baboons, would make a well-marked group, requiring perhaps division into several genera. The most obvious external distinction between them and the baboons, is the termination of the nose before it reaches the point of the muzzle, and the consequent rounding of that part of the profile, and absence of the dog-headed, or *cynocephalous* expression, which not only characterises the baboons, but is made use of as one of their names.

The second, and only remaining subdivision, comprehends the Baboons, properly so called. They are further divided by Cuvier, into *Cynocephalis* (dog-heads) and *Mandrills;* and nearly a similar division is made by Brisson into *Cynocephalus* and *Papio;* but it does not appear that there are any very essential characters upon which to ground this division, almost the only one in which there is a difference being the tail, which, in the cynocephala is as long as the body, or longer; and in the mandrills very short, and projecting nearly at right angles to the spine. But that is not so great a difference even in the single organ, and that not an essential one to any of the known habits of the animals, as is found among the *macacos;* and the other characters of the baboons are certainly more uniform than those of that group.

The true baboons are all inhabitants of Africa, chiefly of the parts of it to the south and east of the Great Desert, or, if they are found in any other part of the world, it is in the south-west of Arabia, or that portion which lies most adjacent to Africa; and it is no great stretch of theory to suppose that the one (for there appears to be only one) which is found there, is a colonist, in the same manner as the magot is on the rock of Gibraltar; and that, in both cases, the animals, finding the place congenial, have remained and multiplied. It has indeed been said that some of the race have been found in India; but the evidence is not very clear or satisfactory; and, if attention is not paid to the terminal situation of the nostrils, which is wanting in all the other quadrumana of the eastern continent, there is danger of confounding the macacos, which also have the muzzle produced, with the true baboons.

Indeed, though when the animals are seen together, the characteristic distinctions between them are very apparent, yet when we come to define them in words, there is hardly one, except this of the terminal position of the nostrils, and the squareness or truncation of the end of the muzzle to which it gives rise, that can be made perfectly clear. Both groups have the produced tubercle upon the last tooth in the under-jaw, which distinguishes them, in their dentition, from all the other quadrumana of the eastern continent; and though in the full grown animals there is a difference in the facial angle—that of the baboons being about one-fourth less than the other, yet this is a character of the adult only, for in both, but especially in the baboons, the young have the muzzle less produced, and the facial angle consequently greater; so that if we were, in this instance at least, to infer the degree of what is, perhaps, not very properly called intelligence, from the size of the facial angle, we should be led to conclude that the immature animal is more intelligent than the adult, which would be contrary to the analogy of the whole animal kingdom.

Taking them altogether, the baboons have a peculiarity of structure. When they stand upon all-fours, which is their usual position on the ground (for they walk erect with more difficulty than the macacos, and seldom attempt it for more than a pace or two), they stand more in the position of common walking quadrupeds than any other of the handed animals. Their anterior and posterior extremities are nearly of the same length, so that the line of the back is about horizontal. The fore-legs stand pretty straight and firm, and though the knees in the hind legs are rather awkward, from their tendency to bend and lower the crupper, that is in part prevented by the turning out of the toes, which throws the line of bending in the knee about half way between the front and the side. This oblique position of the joint gives greater stiffness to the leg, and consequently more firm support to the body, but it produces a shambling gait, from the tendency that the hind legs have to widen at their upper part, and plait over each other at the feet; and thus the walk of the baboon is very slow, and though some of the species are large and powerful animals, it is neither graceful nor stately. Walking is not, indeed, their mode of progressive motion along the ground. They proceed at something between a trot and a gallop, and even that is not swift in proportion to the trouble which it appears to give them; the old ones, especially, soon tire, and if there is no foe in sight which they are afraid to face, they squat down upon their callosities and rest themselves.

When in the trees, where they are more at home, though they spend a considerable portion of their time upon the ground, and even find part of their food there, in the young shoots or various herbaceous plants, and probably also in some of the aboveground tubers which are not uncommon in the warmer parts of Africa, at those seasons when the surface is denuded of green vegetation by the drought. They climb and leap with great ease and agility, so as quickly to reconnoitre the whole of the largest tree ; and though they do not swing to a branch with the same graceful motion as the Oriental apes, they spring into positions in the trees where one would hardly expect to find them.

This structure would lead us naturally enough to consider what must be the nature of their haunts ; and the character of the haunt, when once known, would lead us to the structure of the animal, as the very best adapted for it. The forests over which they range are not masses of contiguous trees, extending for many miles, without breaks, and so thick of underwood as to be nearly impenetrable by the traveller. They consist, for the greater part, of single trees, or of small clumps, with intervals between, which are clothed with rich vegetation in the humid season, but parched and burnt up in the dry. The leaping or running motion is therefore, for at least half the year, better adapted to the nature of the ground than walking would be, and the strength and agility of the animals are required in their frequent ascents and descents, which are of course far more fatiguing than the labours of those apes which inhabit the close and continuous forests of the East.

It is probable, also, that the nature of their haunts, and the severity of the labours which they are called to perform in those haunts, may go far to explain, upon the principles of natural necessity or usefulness, those parts of the character of the baboons which, when the animals are in a state of confinement, appear to be merely wanton caprice and love of mischief, without the least reality, or even traceable indication of any thing that can be called resulting good, either in supplying the wants of the creature, or in any other way contributing to the preservation of its existence.

Baboons have been so universally represented as among the most, if not by far the most capricious of all the mammalia, as passing from the most playful humour to the most violent paroxysms of rage in an instant, and without any apparent cause, as being by far too inconstant for being trusted, and much too able and willing to do mischief for not being feared ; and so well are they said to sustain the same capricious and mischievous character in a state of nature, that it is reported that the wild men of the African forests, who hesitate not to give battle to the lion and the elephant, are afraid of the baboons. It is probable that there is a little exaggeration in the tale, and also some superstition in its foundation. Wild men, however rude they may be according to our standards of civilisation—however ignorant they may be of our arts—and however inferior we may reckon their weapons, always make good their title to their birthright, by subduing the most ferocious animals which are found in their countries. Nothing shows more clearly that the mythologic fables of the ancients are mere foundationless freaks of fancy, than the accounts of the subjugation of hydras and other formidable creatures, imaginary or real, by refined heroes and demi-gods. The bravest hero of modern times, armed according to the very perfection of warlike science, would not be half so much a match for the lion, as the naked African with his rude snare, his bow and his assagai. It is not, therefore, to be supposed that, without some other cause, he would be afraid of the baboon, horrible as some of the accounts of those animals appear to Europeans.

Superstition may, however, assist powerfully, for we have the evidence of mankind in all states, from the greatest rudeness to the highest degree of civilisation, to prove that superstition can not only heighten the terrors of things which are in themselves formidable or dangerous, but that it may clothe with horrors of more than earthly mould subjects which, in themselves, are perfectly innocuous. There is little doubt that the Thoth or Mercury of the ancient Egyptians, which we find so often sculptured upon their monumental remains, was the dog-headed baboon, and not the dog—that it was in fact the very same species which is still to be met with in the east of Africa and Arabia ; and if it had so much superstitious influence upon the people as to get into the mythology of Egypt, and thence into that of Greece and Rome, we can hardly suppose that it has even now lost all effect upon the minds of a people who are known still to be very superstitious, and who have probably inhabited the very same locality from ages before the civilisation of Europe to the present time. These considerations may in so far diminish the tale of the reputed horrors which the negroes have of baboons, and that, once accomplished, may lead to some diminishing of the alleged capricious ferocity of the animals, which, according to the accounts, appears to break out without any natural cause. Some have carried the matter so far as to say, that these animals will sometimes drop down and expire in fits of capricious passion. What they may do when in confinement, and subjected to the rigours of hunger and flogging, which are among the means of education exercised upon animals, it is not easy to say ; and it is known that the native male baboon, as a free tenant of the forest in the wild, will not brook restraint, but will resist it with all his might, and as sturdily and perseveringly to the death, as the best bull dog will battle to his last gasp. But if it were clearly established, that, in a state of nature, and, as one may say, enjoying exactly that which he loves to enjoy, the baboon should show either capricious cruelty or ferocity, which had no reference to his own protection or enjoyment, then there would be an anomaly—a direct contradiction—something in *nature* which was yet quite *unnatural*.

It is a law of animal nature, that no animal offers violence except in quest of its food, or in defence of its own life or that of its species ; and as we do not know all the circumstances which to animals may appear to justify hostilities, we should inform ourselves upon that subject before we venture to accuse them of *caprice*. If we, for a moment, reverse the matter, and suppose a baboon, or any other creature, to look at the apparent causes of human anger and strife, whether on the little scale between individuals, or on the great scale between nations, it is very possible that it might, in the majority of instances of both, conclude that we acted from caprice ; and yet, if the old question, " Dost thou well to be angry ?" were put to us, there is no doubt that, while the fit lasted, we would return the old answer, " Yea, I do well to be angry, even to the death," in full conviction of its truth.

Animals have not the means of communicating to us their codes "*de juri belli et pacis*," in any other way than by showing hostilities when we break the laws; and if even the capricious baboon shall bite, or the multitude of them in the trees shall pelt the stranger with sticks, or even descend and put him to death, it is the man who, in all cases, is in fault, and not the animal. The man has his reason and deliberation, and should see the result before he begins; the animal acts from present circumstances only; and when those which command or controul its action occur, act it must, ignorant and heedless of the consequences as it is of the cause.

These remarks are not to be considered as in any way a special pleading in favour of the baboons. They are ugly animals certainly, and the very ugliest of an ugly nation, both in their appearance and their habits; but it is just as absurd to impute vice, or the perversion of reason, to them, as it is to impute the exercise of reason to the better tempered and more genteel mannered apes. But the baboons have their part to perform in wild nature, are as admirably suited for the performance of it, and perform it as well, as any other race of animals. It may be that their society is not agreeable to man, as there are not very many animals of the wild forest which have that character; but animals which have this character shun man rather than seek him: they fall back when he takes possession; and when he cultivates to a high degree, they vanish. If, therefore, they ever become offensive or dangerous to man, the offence and danger are always of his own seeking.

The baboons, are, as has been said, all rather powerful animals. The average size is about that of a wolf, but some are considerably larger. Of their manners in a state of nature very little is known; and, unless in so far as difference of size gives them different degrees of strength and daring, they appear to be very much the same. There are about six species; but some of them are not very well defined.

1. The Little Baboon (*Cynocephalus babonius*) is a smaller species than any of the others, and has not the nose quite so far produced. It is found in Northern Africa, but keeps in sequestered places, and does not appear to be very numerous. The general colour of the fur of this species is described as being greenish yellow, and the face of a pale flesh colour.

2. The Guinea Baboon (*C. papio*) is found on the coasts of most parts of the country after which it is named. The probability is, that this, and it may be also some of the others have been described as different species, on account both of their size and their colour. Baboons come slowly to maturity, not attaining their full size till they are at least eight or nine years of age; and as the muzzle continues proportionally elongating all the time of their growth, while the young ones are much more nimble in their motions and gentle in their dispositions than the adults, they are readily mistaken for different species, the more so that, if captured and brought to Europe, they rarely live till any very material change takes place in them. When full grown this species attains the height of about four feet. It has the fur yellowish brown, with large flesh-coloured callosities on the hinder extremities, and the face black. The tail is about seven inches long, strong, thick, and crooked; the whole of the anterior part of the body is very strong and muscular; so that, it can take a very powerful grasp, and also strike with the hand, and cut and wound with the nails. There is but one cub at a birth, which the female nurses long and with great care, and carries very pertinaciously in her arms even when exposed to considerable danger. In addition to its vegetable food, this species is said to be very fond of eggs, and to rob the nests of the larger birds which build in trees. They are also said to invade the plantations of the people in considerable troops, and not to be very easily driven off. Some of their achievements in this way, are, however, like many other points of their history, probably a little exaggerated.

3. The Grey or Dog-faced Baboon (*C. Hymadyras*) is a much larger species, growing to the height of five feet or more; and it is said to be very fierce and mischievous. The hair of the general covering is pale ash; but it is freckled over with minute dusky specks on the individual hairs, which give the whole a dull and somewhat changing shade. The hair round the face is very long, and flows over the neck and shoulders like a mantle.

Grey Baboon.

This species is found in the east of Africa, and in the opposite part of Arabia, especially in the finely-wooded hills of Yemen, where it often does considerable damage to the coffee gardens. Wherever there are woods or otherwise pastures to suit it, it extends along the whole south of Arabia to the Persian Gulf. The full-grown males are very formidable in defence; and they are even said to be often the first to attack, though, upon the principle already alluded to, we cannot accurately know the point at which they are prompted to act upon the defensive, and therefore we may consider attack that which is really defence on their part. The nose and muzzle of this species are very much produced; the face, as well as the hands, are black. There appears to be some differences of colour, and also in the degree of production of the hair which composes the mantle at different ages, or different stages of the growth, and these have led to some confusion. The tail, too, is much longer than that of the other baboons, and more resembles the tail of a monkey. The habits of the animal, as well as the general characters, especially those of the head, are, however, strictly those of a baboon, and the manners are such as not to be easily mistaken.

4. The Pig-faced Baboon (*C. porcarius*) is an inhabitant of Southern Africa, and plentiful in some parts of the colony at the Cape. They, however,

keep chiefly to the mountainous parts, and seldom visit the plains except about the time that the crops are ripe, when they often come in troops to plunder the plantations and gardens; and they are so bold and daring on their predatory visits, that it is not easy to drive them away, except by fire arms, at the sound of which they are said to be alarmed. When assailed in their native rocks (for the summits of the rocks rather than the trees are their places of strength), they are said to have recourse to some of the means of defence which the keepers of castles, before the invention of artillery, were in the habit of using against assailants. They throw stones with their hands with very considerable aim and effect, and they also roll down much larger stones than they are able to throw. Along with a considerable share of rather lively mischief, they are said to have more fun in them than many of the other baboons, and to resemble monkeys in their disposition to play tricks. It is said that when they discover a single labourer at his meal in the fields, they steal gently behind him and snatch away part of his provisions; and that they do not make off for their fastnesses with the stolen property, but remain and tantalise the person whom they have robbed. They sit down at a little distance, and begin to eat what they have taken, with the greatest coolness imaginable, holding it up so that the party may see it. It is also said that they are the most imitative of animals; but many of the stories that are told of them must, of course, be received with considerable allowances. It is tolerably well authenticated however, that they have not the sullen disposition of many of the other baboons; that

Pig-faced Baboon.

they are much more given to tricks, and can be rendered more docile in a state of confinement, though when they have attained a considerable age, they cannot, the males especially, be tampered with with impunity. They are said to be very apt to resent injuries, even at a considerable time after these have been inflicted; and as their bite is very sharp and severe, and given without warning, they are thereby doubly dangerous. The bite of the quadrumana, even when they have the canines long, as is the case with the baboons, is not generally given with those teeth but with the incisors: it is therefore not a tearing but a cutting bite; and when they are much irritated and bite hard, they often cut off the piece which they seize as completely and with as even an action as if it were removed by a knife or any other cutting instrument.

Many anecdotes are told of the imitative propensities of the pig-headed baboon. Of these a considerable number are no doubt exaggerated, but still there must be some foundation. We shall mention one as a specimen, without either doubting or vouching for its accuracy:—a Mr. Boodle had one in a state of domestication, which he treated with considerable attention, and that the animal repaid by a close imitation of every thing imitable by him which he saw Mr. B. do. One day the apothecary sent a box of aperient pills, of which two were a dose. Mr. B. took the prescribed number in presence of the baboon, and shutting the box, deposited it on the mantel-piece of the room. The moment that he was gone, the imitative animal seized the box, and set about helping himself to a dose of the pills.

This species is sometimes called the *black baboon*, but the black upon the general covering is marked with greenish and yellowish, and the produced hair upon the sides of the face is grey; the face and hands are black.

5. The Mandrill (*C. maimon*). This is one of the species which Cuvier separates into a different genus from those already mentioned. The chief grounds of separation are, the muzzle very long, the tail very short, and the disposition more savage and ferocious than that of the others, none of which are very clear and satisfactory as generic characters. The mandrill, however, is a very singular animal both in form and in colour. The form is accurately given in the plate "Baboons." The prevailing colours of the adult male are, greyish-brown, inclining to olive on the upper part; there is a small beard of a lemon-yellow tinge on the chin; the cheeks are blue and furrowed; the nose red, brightening into scarlet at the point; some of the other naked parts are red; and the callosities on the buttocks, which are large and conspicuous, are bright violet. This mixture of bright tints, very unusual in the mammalia, give the animal the appearance of being painted for show; and, taken in combination with his grotesque figure and ferocious expression, render him the most singular looking animal in the whole class.

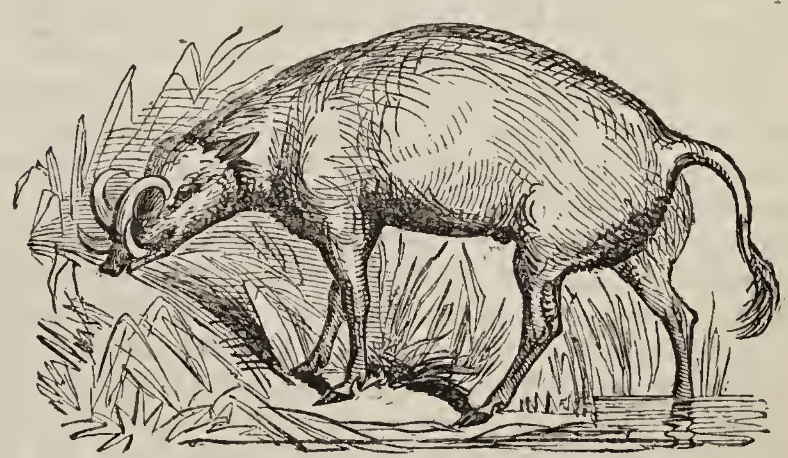
The mandrill is the largest as well as the most singular and hideous in aspect of all the baboons, and he is an animal of great size and strength, his ordinary height when full grown being about the same as that of a man; and he is very strong and muscular, especially in the head, the neck, and all the anterior parts of the body. The history of the species is very imperfect, and it is probable that it is in many particulars confounded with that of the chimpansee; the mandrill getting credit for some of the good, or at all events agreeable qualities of the chimpansee, and the chimpansee being in return saddled with some of the mandrill's disagreeable ones. The fact is not fully ascertained, but it is probable that the mandrill is proportionally as much longer in coming to maturity as he is larger in size than the common baboon of Guinea; and as the colours and the full elongation of the face appear in the mature male only, it is probable that many of the doubtful species enumerated by authors may be the young in different stages of their growth. The mandrill is more a forest animal than the common baboon; and he is not very pleasant to visit, as he is bold and fierce when attacked, and very apt to regard a visit of curiosity in the light of an invasion, and treat it accordingly.

6. The Drill (*C. leucophæa*). This species is described as being rather smaller in stature than the mandrill, and not so ferocious. Its general colour is yellowish-grey, with the face black, and the tail very short and slender. It seems to be subject to very considerable varieties of colour at different ages. In the adult male, the hair over the upper part becomes much deeper in the colour, and the chin bright red.

Head of the Drill.

Such is a list of what appears to be the principal and best authenticated species of this very singular race. The notices which we have given of them are very short and very imperfect, but it cannot be otherwise, inasmuch as no inconsiderable portion of their history rests upon no more satisfactory foundation than that of museum specimens. It would no doubt have been very easy to extend the description by the introduction of many stories of the ferocity and offensive manners of the animals, especially of the mandrill; but these stories are all probably very much exaggerated; and though they were true, the repeating of them would neither promote good taste nor useful information. The baboon has long been what is, in common speech, called "a lion," something to round a tale of the "monsters of nature," which are to be met with in the wilds of foreign parts, where the ardour of the climate may be supposed to make the earth as fertile as the imagination of the describers. But in these cases, imagination always outrages nature, and gets contrary to it, by forming its compounds out of those materials with which it is acquainted in different climates, so that they do not suit the places in which they are put. When we remember the *acephali*, the *monoculi*, and the other strange races with which the ancients peopled the unknown parts of the world, we may expect to find a little of the same attaching to all the obscure points of natural history. Good taste, and the promotion of useful knowledge, both require the repression of these matters, in order that the ground may be clear for the reception of better information, when that shall be obtained. The baboons, especially the true baboons, or the six that are last enumerated in the above list, stand in need both of more extended and accurate information, and of clearing the ground for the reception of it.

BABYROUSSA (*Sus Babyroussa*). A species of pachydermatous animal, belonging to the genus *Sus*, the pig; and sometimes, but without much propriety, called the "pig-deer," or "deer-pig;" for in the length and clean make of its limbs, and also in the covering of its body, it differs from most of the genus; and the latter difference is not confined to the mere clothing, but extends also to the skin, which is much thinner, and more membranous than that of the hog. It is an inhabitant of the Oriental, or Indian Archipelago; and the mildness of the climate there, and the regular succession of food, which an animal that feeds indiscriminately upon young shoots and leaves, fallen fruits, and roots, can procure, may readily account for the difference in covering between it and those species of the genus which inhabit where the climate is less genial, and the seasons less uniform. Its general covering is soft and woolly, more so than the second, or under covering of the common pig. Its colour is paler than that of the wild boar, but it has a trace of the same tint: it is reddish or brownish ash, while that of the other is dark blackish-brown, with a slight gloss or tint of red. It has no bristles, properly so called, but still there is an indication even of this character of the genus. Among the woolly hair, which is rather inclined to curl or mat slightly, there are other hairs, considerably larger than the rest, quite straight, and of a silky or glistening texture. No lard forms under the skin, as in the common pig, at any season, how abundantly soever the animal may be fed; and from the regular supply of food, which its native localities furnish at all seasons, the accumulation of fat would not only be useless, but it would be an incumbrance. Common pigs, though one use of their thick and peculiarly formed skin appears to be to prevent changes of temperature from affecting the consistency of the fat or lard, accumulate very little fat in tropical climates, and comparatively little in the warmer countries of Europe. All animals have a greater aptitude for accumulating fat in cold countries than in warm ones; and naturally the fat so accumulated is always, to a certain extent, a store against that season when food is scarce. The native country of the babyroussa is very near the equator; and we believe that there are few instances of equatorial animals accumulating annual fat: those that feed on vegetables rather migrate if there be seasons when food fails; and the *carnivora*, whose subsistence they form, of course migrate along with them. The genus *Sus* are not much of migrants in any country, their chief marches being from the forest to the fields, and from the fields back again to the forest; and, as already hinted, the species under consideration has little occasion to migrate.



Babyroussa.

From the above figure it will be seen that the general character of the animal is in some respects that of a pig—a handsome pig, as compared with the wild boar, or even the best-shaped varieties of the domesticated pigs, but still, to all intents and purposes, a pig. The snout is produced, cartilaginous, and flexible; and though some of the accounts say that the babyroussa does not *root* up plants after the manner of pigs, the snout is certainly one that *could* be used for that purpose—in fact, one formed expressly for it; and if it has not been observed so using it, the conclusion is, that it had no necessity for doing so. Though rooting-up is a general habit with tame pigs when they are let into pastures where there is nothing but grass, it must be considered as a dernier ressort with them when in a state of nature; for in the forest of deciduous trees, such as oak and beech, which are their favourite haunts, the cartilaginous nose is used chiefly for the purpose of pushing aside the herbage, so that they may get at the fallen acorns and mast; and while these last, they never root up grass or any other plant. When necessity compels them to have recourse to grass and other herbage, the parts which are blanched under ground suit both their taste and digestion better than those which are above the surface and green. Their teeth are not so well adapted for chewing grass as those of grazing animals; and their digestive system is much more simple: thus they require more succulent and nutritious food, and they find that in the roots of plants, especially when the vegetation of the part above ground is not very vigorous. It may be that, from the nature of its pastures, the babyroussa may not generally practise that operation; but it is evident from its structure that it could find its food in that manner if necessary.

The form of the head, the size and position of the eyes, which are small and oblique, and the shape of the ears, are all pig-like; and the thickness of the neck shows that the animal is formed for overcoming resistances by the action of the snout, without giving an impulse to the body by means of the feet. The body, though not quite so thick in proportion to its length as that of the wild boar, is still formed after the same model; and there is the same fulness of muscle on the upper parts, both of the fore and hind legs. The tail is longer than in the wild-boar, or the common hog, and it ends in a brush; but still it is a true "pig-tail"—slender, round, and, though sometimes straight, admitting of being curled. The feet also correspond, though the two middle hoofs on which the animal walks are broader, and not so sharp; and the lateral ones, which are in the rear, are not quite so much produced or pointed, as those in the wild-boar. The feet are less apt to sink in soft ground; and that, with the increased length and lightness of the legs, indicates that, in its ordinary habits, the animal travels more in quest of its food.

The most extraordinary parts of the babyroussa are its tusks. They follow the general character of the genus in sticking out of the mouth; but they are more produced, and different in form. There is an approach to the same character in the Ethiopian boar, in which all the jaw tusks, which are very formidable weapons, are curved upward, and have their points above the line of the muzzle. But the tusks in the upper jaw of the babyroussa form quite a spiral in the adult males; and though they are large and formidable, the animal cannot readily use them for the purpose of inflicting wounds. Those in the lower jaw are not nearly so much recurved; and as they are powerful, and have their points very keen, they are weapons of a very formidable description. The strength of the neck, and the action which it has when the animals "root," assist the whole genus greatly in giving those terrible wounds which they can inflict by the upward stroke; and which, if we except those given by the horn of the rhinoceros, are perhaps the most fatal inflicted by any animal. No mere bite, by the motion of the jaws alone, can make so terrible a laceration as the tusks of this genus, delivered as their stroke is, by the whole muscular action of their very powerful neck.

Still these formidable weapons, and this power of giving them effect, are defensive only on the part of the whole genus; and the same may be said of the horn of the rhinoceros. All weapons of attack which animals use when no danger is apprehended, contribute directly to the killing or capture of that upon which they feed. But the tusks of the genus *Sus* do not in any way assist them in the procuring of their food; they never use them but for the purpose of defence; and though we are apt to suppose that they make wanton and vicious attacks, we should, were we able to analyse all the cases, invariably find that apprehended danger, of some description or other, is the cause. If the defence of the animal is personal only, it seldom, if ever, shows fight, unless directly assailed; but almost all animals have, occasionally at least, other defences besides that of their own persons. The female, the young, and even the pasture, are all at times objects to be fought for; and those animals which are not carnivorous are generally more forward and more valiant in those cases than when the object is simply their own safety. The genus *Sus* probably have more powerful instruments of defence than most other vegetable feeders. Their young are numerous, and quite defenceless; and their flesh, at all ages, is, in a state of nature, sweeter, perhaps, than that of any other race of animals.

In this last respect the babyroussa is not an exception. Hence it is much hunted; and, like all hunted animals, is shy and distant. The shyness of hunted animals is rather a curious matter; and, simple as it may seem, it is one upon which mistakes are committed. The vulgar notion, both in conversation and in books, is, that the hunting is the cause of the timidity. In the case of the individual or the herd, that might have at least some appearance of truth, but it could not extend to the race; and even in the individual it is an assumption rather than a truth. The stag, which has never been hunted before, runs as readily and as fleetly as he that has been kept for the purpose, and hunted every season for years. The converse of the vulgar opinion is, indeed, much nearer the truth; and the dispositions of the animals to run, or otherwise to make their escape, seems rather to be the cause of the hunting. In most chasing animals there is what we may call a dash of cowardice—at least it is slaughter they seek, and not battle—for they all prefer catching their prey unawares, or by stealth if they can; and accordingly, those which will pursue a strong animal if it runs, will be checked, or even retire, from a much weaker one, if it stands and shows fight. Hence running, and especially running in packs or herds, is a great inducement to the animals which give chace: if overtaken, the capture will be without a battle; and the number in view render that capture more probable. There is not much truth in the common saying, that animals get shy in proportion as they are hunted by man: that cannot change the nature of the animals, though it may thin their numbers, and make them shift their localities.

The fact of the babyroussa being a hunted animal makes it less seen in proportion to its numbers; and also makes less be known of its ordinary habits. Accordingly, though it may have been known from remote antiquity, its history is still very imperfect, amounting to little more than where it is to be found, and how it endeavours to escape from its pursuers. Ælian and Pliny mention pigs with four horns, or with two horns on the forehead, and tusks like a wild boar, which comes near to the character of the babyroussa; but they *may* have meant the four-horned antelope, or the musk animal.

When alarmed, the babyroussa grunts and squeaks exactly like a pig; and though it runs more swiftly, it runs pig fashion, by leaps, throwing the whole body into the air at each bound, and *labouring* more than the proper running animals. When near water, it readily takes to that element for safety; and it swims well, so that it often voluntarily crosses rivers and estuaries of considerable breadth, and even passes from island to island when they are not far apart. As is the case with the common pig, its swimming action is the action of running or leaping, not of walking; but its blunter hoofs, and especially the greater length of its legs, prevent it from lacerating its throat with the fore-feet in swimming, as pigs are apt to do. It thus bounces away through the water with considerably more safety and speed than the common pig, though from the absence of fat it is not so buoyant. Its long nose, however, enables it to breathe easily, though it floats rather deep; and it is altogether an animal having much command of itself in the water. Its flesh is wholesome, nutritious, easily digestible, and of agreeable flavour, so that it is much sought after as an article of food.

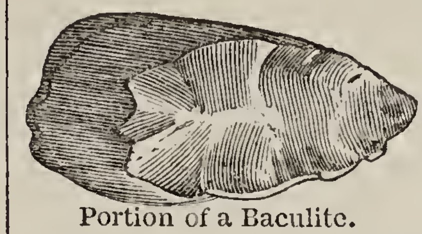
BACCHA (Fabricius). A genus of Dipterous insects, belonging to the family *Syrphidæ*, distinguished from *Syrphus* by having the abdomen very long, slender at the base, and thickened at the extremity. The face has a very slight nasal prominence, the antennæ are very short, with the third joint circular. They are found about the borders of woods, settling upon leaves, and alternately elevating and depressing the abdomen. There are six British species; the type being, *Baccha elongata*, Fabricius.

BACILLUS (Latreille). } Two genera of Orthop-
BACTERIA (Latreille). } terous insects, belonging to the family *Phasmidæ*, and destitute of wings in the perfect state; in the first the antennæ are long and setaceous, in the second they are short and subconical. The species are exotic, residing upon trees, to the twigs of which they bear so great a resemblance that they have been termed "*stick insects*."

BAETIS (Leach). A genus of insects belonging to the order *Neuroptera* and family *Ephemeridæ*, or Mayflies. Wings four, tail with two long thread-like filaments. There are nearly twenty British species, many of which have recently been described by Mr. Curtis in the "Annals of Philosophy." These insects pass the larva and pupa states in the water, from which they then emerge, and undergo a remarkable casting of the skin, after assuming the perfect form, which we shall more minutely describe under another head.

BACTRIS (Jacquin). A genus of five species of South American palms. Linnæan class and order, *Monœcia Hexandria*; natural order, *Palmæ*. Generic character: spatha double, flowers sitting. Males, calyx three-cleft; corolla three-petaled; stamens, from six to twelve. Females, calyx and corolla cylindrical; stigmas three, sitting; drupe one-seeded, three pores, but not starred; embryo within the pores horizontal. The stems of these palms are made into walking sticks.

BACULITES (Linnæus, Lamarck). A genus of shells, as yet only known in a fossil state. Its form is straight, more or less compressed, conical and much lengthened, the opposite sides smooth and depressed, sutures with lobed dentations, the septæ at irregular distances, pierced by a marginal siphon. They sometimes are found of a great size, and are abundant in all parts of Europe. De Blainville places this genus in his 1st class, *Cephalophora*; 3rd order, *Polythalamacea*, 1st family. The name appears to have been derived from baculum, a *staff*.



Portion of a Baculite.

BADGER (*meles*). A genus of plantigrade, carnivorous animals, of which the leading generic characters are: five cheek teeth in each side of the upper jaw, and six in the under; the first tooth very small, the second and third pointed, the fourth trenchant or cutting on the inner side, the fifth in the lower jaw more so, and the last in both jaws large and tuberculated in their crown. The incisive and canine teeth are like those of the generality of carnivorous animals, only the middle incisor on each side of the under jaw is inserted farther inward than the one on each side of it, though it slopes outwards so as to range in a line with the others at the crown.

The animals which the badgers most nearly resemble in the system of their teeth are the gluttons (*gulo*), but their habits are not the same. The structure of the teeth is, indeed, of that mixed kind which renders it no certain index to the food of the animal. The anterior part of the mouth, as far as the canines, is decidedly carnivorous, and could be applied with much effect in the killing of prey. It very much resembles the same portion of the system of teeth in the martens, which, in proportion to their size are among the most bold and deadly of all the carnivora; but the smallness of the teeth which immediately follow the canines, and the structure of the ones in the rear, adapt the mouth fully more for preparing vegetable substances for the stomach than animal ones; at all events, the system of cheek teeth is not adapted for bruising the flesh of large animals in the recent state. It is probable that the canine teeth of badgers, like the tusks of the genus *sus*, are weapons of defence rather than instruments of prey; and the same may, in part at least, be said of some of the other plantigrade mammalia.

The classing of plantigrade animals as carnivorous is not quite natural; and, indeed, there does not appear to be any part of the present system into which they can come with strict propriety. Eating flesh is so far from being their natural propensity, that there are few of them that will kill and eat any warm-blooded animal if they can find other food. This appears to be the case with the bears, which are considered the most fierce and sanguinary of the whole; and much more is it the case with the badgers. But the plantigrade animals are, in general, quiet and retiring, so that they are seldom seen unless when they are forced out, by natural circumstances, or by direct pursuit;

and thus their natural manners are much less known, than from the familiarity of their names and forms would be supposed. The badger, for instance, is, in some parts of Britain, not only blamed but persecuted as near to extirpation as possible, not only for being destructive to game, but for preying upon the young of the flocks. But the badger does not inhabit where game are the most plentiful, and it is seldom, if ever, found on sheep pastures. The strength, the sharp bite, and the persevering resistance of the badger, as observed by man, are all defensive qualities; and though weapons or powers which are efficient for defence, *could* be used offensively, it does not follow as a general analogy in nature that they *must be* so used. The carnivorous furnishing of the anterior part of the mouth, and the classification of the animals as carnivora, both tend to make that the general nature of their character; and thus far the imperfection of the system tends to mislead.

It is certainly desirable that the natural orders of animals should be as few as possible, because that makes the knowledge of the system more easily acquired; but they should, at least, be natural; and if the name of the order be formed upon a character, that character should unquestionably be the leading one. Carnivorous is not so as respects the badgers, or indeed the majority of the plantigrade animals of that order, as at present arranged by even the best writers on systematic natural history. In as far as analogy can hold between mammalia and birds, there is an analogy between the plantigrade animals and those birds which are usually described as *omnivorous*, —the crows, magpies, and analogous tribes; and perhaps it might not be amiss thus to distinguish these plantigrade animals, if not as an order, yet as a suborder or group. When Cuvier places them as the first tribe of the carnivora, properly so called, in his order of *Carnassiers*, one is very apt to conclude that they have the killing and flesh-eating propensities in the very highest degree, which, assuredly, is far from being the case.

The badgers have the body thick, squat, and heavy, and the legs short, but the whole very compact and strong. The head is rather slender, and the muzzle narrow; but it is not cartilaginous and moveable, so that it cannot be used in *rooting*, like the snouts of pigs. The eyes are very small, and the nictitating membrane, or third eye-lid, can cover the whole pupil; the ears are also small and rounded, and the external concha is very simple in its form. There are five toes on all the feet, having the phalanges nearly united by a membrane, and the claws on the fore-feet large and well adapted for digging. Under the tail there is a scent bag, the odour given out by which, especially when the animal is alarmed or irritated, is very rank and offensive.

Badgers, though not timid animals, but rather familiar and even playful when taken young and treated with kindness, are animals of wild nature much more than of the cultivated districts. The entrance to the burrow, which is usually placed in concealment, and so far elevated as to secure it against being flooded by water, is usually under a bush of tangled herbage and shrubs; and when this species of cover is grubbed up the badger soon disappears, being, as it should seem, deprived both of its shelter and its food.

There are only two known species of badger, the common badger (*Meles vulgaris*) and the American badger (*Meles Labradorica*).

The Common Badger is, when fully grown, about two feet and a half in length, and the tail, which is covered with long hair, is about half a foot more, the weight varies much with the individual and the season, some not being more than fifteen pounds, and others exceeding thirty. The hair with which it is covered is long, close, and fine, adhering very closely to the skin, even after that is removed from the animal and prepared by dressing. The coverings of holster pistols, the pendent pouches of those Highland regiments that wear kilts, and some other light articles for which a tough skin with fine and durable hair is preferred, are made of the skin of the badger. The hair is also employed for making a peculiar sort of painters' brushes, called 'sweetening tools,' with which those artists pass lightly over their work before it dries, for the purpose of softening and blending the tints.

Common Badger.

Upon the living animal, the skin is equally remarkable for its toughness, its flexibility, and the ease with which, from the loose nature of the cellular tissue under it, it will rise when pinched, without including any of the flesh in the fold. From these properties of the skin, as well as from the thickness and softness of the hair, and the difficulty of either cutting it or removing it from the skin, the badger is very difficult to bite, at least in such a manner as to wound or injure it. Even the skin is not easily pierced by teeth, and it is very difficult to tear, so that when dogs assail the badger, they, if they are not peculiarly trained, merely take hold of the skin and shake that, without occasioning any serious injury or even much pain, while the badger bites very sharply in return. From these circumstances, as well as from the offensive odour which the scent-bag never fails to emit when the animal is assailed, the badger is very little hunted in a state of nature. It thus dwells as much at peace with and in safety from the other animals, as it dwells quietly in itself.

It is a very quiet and inoffensive animal, more so perhaps than any other quadruped of the same size, for it hurts neither animal nor plant, at least in those species in which man takes an interest, or upon which he sets a value. Its food is understood to be fruits, roots and grass, and also insects and other small animals, though not any thing larger than a lizard or a frog. It is not capable of climbing, and thus it can injure nothing which grows or perches upon trees, bushes, or tall stems; and as it usually keeps its burrow during the day, the live part of its food must consist only of those creatures which come out to feed during the night, many of the mollusca, and other small animals which have that habit. It is thus very probable that badgers are of service as scavengers in those places which lie near their burrows, by destroying animals which, but for them would, in the natural state of those rude places, become noxious from their numbers, and destructive from their havoc upon vegetation. In some parts of the country, the badgers have been most unfairly accused of invading the mansions of the dead for the purpose of gratifying their appetite. Their facility in burrowing, and their offensive odour, may both contribute to strengthen such a prejudice on the part of the ignorant. But it is, nevertheless, totally without foundation. Badgers burrow, not for the purpose of eating, but that they may have warm and safe berths, which they render comfortable by bedding them with soft grass; and they would not eat the contents of graves, even if offered to them without any trouble on their part. The writer of this article remembers, when a boy, being present at the extirpation of a small colony of badgers which stood accused, by current report, of this species of profanation. The surface of an upland, but rather rich district, was finely diversified by swelling knolls along the north bank of a winding rivulet; and as the rivulet had, according to the custom of rivulets, "taken from the height and given to the hollow," there were steep and tangled banks at different places, open to the south-west, which was the descent side of the country; and snug and warm, and as well adapted for both birds and badgers, as thickets of fragrant broom upon sloping banks could be. The name of the badgers operated in some sort as a protection to the birds, as the boys seemed afraid to venture far into the brake in their nesting excursions, lest they should slip a leg into a badger's hole, and be drawn out *minus* a toe or even a foot. So linnets, and black-caps, and white-throats, reared their broods, and sung "round," and in high glee, protected by the mighty name of the badger.

One of these tangled banks was immediately below an ancient place of sepulture, where, previous to the Reformation, there had been a little chapel. This place was still the burial ground for the barony, and it was a place not altogether free from the suspicion of things unearthly. There was a large equisitum tufted pool, between the knoll of which the cemetery occupied the summit and the higher grounds above; and *ignes fatui* sometimes sported on its margins under the suspicious name of "elfin candles." Besides, immediately under the south-west angle of the little enclosure, there flowed a fountain of pure and sparkling water, so abundant that it would have sufficed permanently to turn a mill. This fountain abated not a jot of its quantity, and altered not a degree of its temperature, summer or winter, wet or dry; and while all around was coated with snow to the depth of two or three feet, this fountain not only remained "clear in the eye," but the stream from it flowed smoking along an open channel, which was proof alike against the powdering snow and the curdling frost. The springs of these things, fountain and all, lay deeper than the rustic philosophy, and thus, as the general custom is, they were sent to the limbo of superstition, and all whom immediately thereabout dwelt, along with them. The sod upon some graves, one summer, sunk deeper than had ever been known to proceed from the mere insatiate yawning of that "daughter of the horseleech" for the relatives of the occupant; and the suspicion of foul play—foul play to the brim of horror's deep chalice—fell upon the badgers. The "landwehr" were summoned; and they came, girt with fierceness or with fear, and armed with spades, mattocks, and pitchforks, to take by sap and mine the stronghold of the grey-pates, and let the light of heaven shine upon the den of their secret abominations. One party plied the work with mattock and spade, while another stood with their arms prepared in case the besieged should make a hostile sortie, or attempt escape; and to guard against the latter some dozen of curs had been brought as auxiliaries. At length they came to a little chamber, in which there was a small quantity of withered grass, but not a single vestige of bone or other animal remains. Again they worked away; and soon the male badger made his appearance and his escape, the opening ranks on either side greatly contributing to speed the latter, and one man declaring with "*ecce signum*" display, that the monster had "dinted a steel spade with only a passing snap." Two or three grievous whines from the curs, gave proof that the badger could "dint" something else; and soon a most triumphant flourish of yelping announced that he was fairly in the next cover and the danger over. It was now resolved to change the mode of attack, and proceed by fire and smoke. When these were continued till it was judged that all within must be either roasted or suffocated, they began to dig anew, and after passing another chamber which contained only grass as before, they came to a third containing the bodies of a suffocated female and three cubs, the latter very small in size, and two of them clinging to the teats of their mother. These bodies were not treated with that decorum which became a generous foe in the hour of victory. It was found that the excavation reached no farther than the entrance, and the three chambers, so that the badgers could have had no subterraneous communication with the graves, which rendered the sunken appearance more a matter of alarm than ever. Throughout the whole burrow there was not the smallest vestige of any animal remains; nothing but "beddings" of grass, rather more abundant in the chamber where the family was, than in any of the others. The result of the search did not, however, remove all stigma from the character of the badgers. The story is mentioned as one instance of the means by which the characters of animals come to be misrepresented. They have one or two traits of appearance or habit which do not suit the popular taste, and by means of loose analogies, often drawn from subjects of a totally different character, others are added, till the truth is completely buried under a mass of exaggeration. The cause, a very general one, though not so often mentioned as to put people on their guard against it, is this: A has several qualities in common with B, C takes up some of the qualities of B which are not common to B and A, and drops some of those that are. The series proceeds in the same way, with a marked likeness between every consecutive pair, till all the qualities of A are left out; but still, taking advantage of the whole succession, and giving the last all qualities of the first.

The common badger is pretty generally, though in no place very abundantly, distributed over all the colder parts of the temperate portion of Europe, and some of Asia. Much cold and much heat appear to be equally unsuited to its habits. The first, it seems constitutionally, but ill able to endure; the second when accompanied by severe drought, appears to be contrary to its habits; and may be so by keeping the frogs and mollusca off its pastures during the night. It does not appear to have been known to the Greek naturalists, at least it has no name in the Greek language. But the knowledge which the Greeks had of nature applied to places to the east and south of Greece rather than to the north and west; and thus their knowledge lay in the opposite direction to that in which they would have found the badger. The Romans, on the contrary, whose knowledge did extend to the west, and for some distance at least to the north, not only were acquainted with the animal, but had two names for it, *melis* and *taxus;* and sometimes the one, sometimes the other, and sometimes both of these, have been used as the name by modern systematists, since the animal was, very properly, separated from the bears, of which genus it was made a species in the system of the great Swedish naturalist.

It is probable that, in the days of the Romans, the proper locality of the badger lay in a more southern latitude than it does at present, because it is certain that the climate along the line of the Danube was then as cold, if not colder, than the southern shore of the Baltic is at present. It is doubtful, however, whether it ever extended so far to the south-east, as that the "badgers' skins" which are mentioned in the Bible as forming part of the hangings of the tabernacle prepared in the wilderness could have been the skins of the *melis* of modern times. If it had been so common in the "wilderness," (which has either undergone great physical changes, or else it must have been a very unlikely and even unnatural haunt for badgers,) it is not easy to see how an animal so common, and of which the skins appear to have been in so much request, could be unknown both to the Egyptians and the Greeks. But, at the time the standard translation of the Bible was made, natural history was in a very imperfect state; and the translators, in turning the whole book into English, were of course confined to the use of such English names, both for plants and animals, as were then known; so that, however the nervous vigour of the style then in use by the best writers (now somewhat altered and not for the better) may have been calculated to do justice to the sentiment and the sublimity of the sacred volume, there is no question that the way in which the natural history has been translated is calculated to mislead the ignorant. Therefore, a natural history of the Bible is very much wanted. But it is a work, the proper execution of which would be attended with difficulties of no common magnitude; and when we consider the brevity of human life, the large portion of it which must elapse before the preparation for such a work is begun, and the vast extent, difficulty, and even incongruity of some of the essential elements, it is a work of the appearance of which in a style worthy of the subject we may almost despair. If attempted by the unworthy, and bungled, as has been the case with many other important but difficult subjects, the evil will be made worse, the errors more difficult to be eradicated. Without such a work, the progressive natural history of the central parts of the eastern world cannot be made complete, as it wants the beginning; while the Bible, if we could rightly apply the truths which it contains, would give us facts and fix their date at a period anterior to that of any other authenticated history.

The badger is an animal of very peculiar localities certainly, but it is so fond of concealment, and comes out so much in the dark, that we can hardly describe it as being characteristic of any peculiar climate, or land, or surface, or say what stage of a country, either in its natural or its artificial changes, accords the most with the abundance of its numbers. It is not an animal of the forest, of the dry heath, of the arid waste approaching to the sandy state, or of the humid tracts which border upon inundation. There is no broad locality, no general description of surface, which we can call the badger's country, as we call the green savannah the country of the buffalo, the wild upland the country of the deer, or even the sandy plot by the seashore with its short grass and its stunted furze bushes the natural country of the wild rabbit. The best approximation which we probably can make, though it certainly is a loose and wide one, is that the badger is an inhabitant of the country in what may be called an intermediate state between the close forest and the open champaign; that it indicates that state of things in which man *should* cultivate, because his cultivation would be attended with advantage, but it is not a sign that man *does* cultivate, at least to the extreme breadth of the land. The place which the badger inhabits must be a wild spot, and though our information upon that part of the subject is imperfect, it is probable that the pasture on which the badger finds its food must also be in a great measure wild.

But though the badger does not furnish us with those means of judging from country to animal, and conversely from animal to country, so that if we have half the information either way, we can arrive at the other half by analogy, which we have in many other species, it is still a very interesting animal, and one the study of which may furnish a good deal of information. Badgers have no quarrelsome or pugnacious disposition, either against each other or against animals of any other kind. They are not strictly social, neither are they altogether solitary. Their common habit is to live in pairs, which are attached to each other, as is understood, for life. But in places which are very favourable for them, more than one pair may be found in the same small copse or brake, or even sometimes in the same burrow; though it is also said that the male and the female separate during the last stage of gestation and the early one of the suckling. It is probable, however, that this separation extends no farther than in the occupation of different rooms in the same burrow (for all the completely-formed burrows have separate rooms), and the nursery, which is understood to be more exclusively the work of the female, is more spacious than the rest, and more abundantly and completely bedded with grass. The young are produced in the warm season; and their number, which is generally from three to five, is perhaps never more than that of the teats of the mother, which is six. They arrive at maturity in two years, though they continue afterwards to increase in size; and indeed the size is liable to considerable variations, whether chiefly owing to the supply of food is not known. As the season advances they become very fat; and when the cold sets in they pass into an indolent state, dozing out the time in their burrows, till the heat of the returning season calls them again into action, which is not very energetic at any season, though it can be momentarily roused to powerful efforts.

Badgers are, indeed, very susceptible of changes of temperature, fonder of heat and more impatient of cold than almost any other animals that inhabit such cold latitudes. When in a state of confinement, in which, if taken young, they are easily domesticated, and gentle, and even playful in their manners, they are, notwithstanding the thickness and closeness of their covering, fond of basking near the fire, and often loiter so near it that they burn patches in their fur, as is the case with sickly cats, and with the dogs of temperate climates when carried to the polar regions.

And it would really seem, that, contrary to what is the case with most animals, they have the colouring of their coats so arranged as to render them susceptible to the cold rather than proof against it. Most other animals which live in wild nature in the same latitudes, have the under part of their bodies (the neck and the thorax at least, and the abdomen as far as the region of the principal stomach) white, or light-coloured, especially in the winter. But in the badger those parts are not merely darker than the upper part of the body, they are quite black, and the covering upon them is neither so thick nor so good a preservative from cold, independently of its colour. The upper part consists of two kinds of hairs, woolly ones and silky ones, which have a shining or glistening lustre. These last are, from their structure, and also from the nature of their surface, worse conductors of heat than the others, and they are wanting on the under parts where the colour is black.

It may be as well here to mention the usual distribution of the colours, though it must be borne in mind that these colours are subject to considerable variations in different individuals, from the darkest shade, which is the prevailing appearance, up to almost complete albinoism, in which the parts which are usually grey are white, or nearly so, and those which are usually black are reddish brown. Usually, the upper part is dull grey, appearing as if the animal were in part soiled, either by rolling a white body in soot, or a black one in whiting. The colour of this grey portion is made up of particoloured hairs. The woolly ones are white, with yellowish points; and the silky white have a black portion at the middle. This mixed colour becomes lighter toward the flanks, and passes into a dull reddish white on the posterior part of the abdomen. The remainder of the under part, including the greater portion of the abdomen and the legs, is very brown or black. On each side of the head there is a black streak, beginning on the lip, and proceeding across the eye to the ear, which is black, with a white border on the upper part. The remainder of the head is a dull reddish white, which is met by the black on the under part, about the middle of the lower jaw. In addition to these markings of colour, it may be mentioned, that the feet of the badger are very amply supplied with pads or tubercles, so that it can pass over hard or rough surfaces securely, and without injury. One of these is at the end of each toe; three others, arranged like a trefoil, occupy the sole of the foot, which have an additional one on the rear of the fore foot, and two on the hind. As the badger passes the inclement season in retirement and shelter, its colours do not undergo those seasonal changes which take place in animals that are exposed to the weather.

That the colours of the badger should be the reverse of those of most animals, is not a little singular. The upper part is in the most effectual manner protected from the cold. The hair is close, and the greater part of it is white. But when we come to the under side of the animal, to the portion which covers the vital parts, we find the colour black, which is the tint most susceptible to changes of temperature. Whether, when in its burrow, or when abroad in search of its food, we find the back of the badger almost as well secured against atmospheric influence or changes, as those animals which acquire winter coats; but instead of this defence being extended to the vital parts, they are exposed more so than the corresponding parts of any other wild animal of the same latitudes. The badger must, therefore, have its vital functions more under the control of the atmosphere than any other animal, at least any other of the mammalia. It must be much more affected in this manner than if the whole had been of the same dark tint, as the non-conducting covering of the upper part necessarily throws the atmospheric action upon the under, much in the same manner as if it were well clothed everywhere else and naked there. The organs of respiration, circulation, and the chief ones of digestion, are all under the dark covering, and must be all regulated by the weather, increasing in activity as that is warmer, and diminishing as it is colder. To pass along the dry earth on a hot summer's day would, therefore, throw the badger into a state of fever; and exposure to the frozen earth, and the cold air of winter, would soon reduce it below the temperature of vitality. Thus it is, from its very structure, constrained to keep its burrow in the heat of the day, and also during the night, after the temperature has sunk below a certain degree. But still, as this is the habit of the badger, and as its food is understood to vary with the seasons, to be abundant in the heat of the year, and to fail in the winter, anomalous as it may at first sight appear to be, it is as perfect an instance of adaptation as any other creature. As it is never exposed to a high temperature, and takes no exercise but what is absolutely necessary in the finding of its food, the action of its system must, at all times, be slow, and the quantity of food which it requires moderate. When temporary colds set in, its action must, from its perfect obedience to the temperature, diminish, and so must its desire for food. The badger, in its ready yielding to the weather, is therefore as comfortable, and in as good condition at all times, as those more energetic animals which are fitted for contending with the seasons—braving both the summer's heat and the winter's cold.

The retired habits of the badger cause little to be known of it in a state of nature, as it is seldom seen unless when forced to quit its stronghold. In ordinary confinement its habits are of course altered; but there is one case, reported by M. F. Cuvier, which comes so near to a state of nature, that we shall quote the substance of it:—Two young badgers, a male and a female, were taken out of the burrow of their mother, and placed in a paved yard, which was so fenced in that they could not escape, and yet allowed them considerable range. They unpaved a portion of the yard, and dug a burrow, in which they spent the day, and came out in the night only to eat the food which was placed for them. After continuing a year in the court, they were put into a small enclosure, walled round with stone, and having a mound of earth in the centre. True to their habit of digging on sloping banks where there are stones to support their entrance, they first tried the walls all round, to find a place where they could dig a habitation. They then chose an opening between two stones, which was a little elevated above the ground, and had the upper stone projecting over it. In nature, the entrance to the badger's burrow is often under a projecting stone, which partially conceals it, and protects it from the rain. They had some difficulty in reaching this place, as it required nearly the whole length of their bodies, standing on the hind feet, and the fore feet had, in consequence, little influence upon the plaster and stones. They tried a resource, however: the male lay down close by the bottom of the wall, and the female, standing on him, could reach the desired place with more effect. All would not do; so they abandoned that place, and tried the result at others, always selecting a place under a projecting stone. In these attempts, which, though they all proved unsuccessful, were carried on with great energy and perseverance, the female was the most active, selecting the places, and being the principal operator.

After many fruitless attempts, they abandoned the walls, and betook themselves to the mound of earth, the female, as in other cases, leading the way. Even here they did not at once begin to form the burrow, but ran trial lines or trenches over a considerable part of the surface, till they came to a place which suited them, and there they began their regular operations. In the first loosening of the earth they used the nose; then they dug deeper with the fore paws, flinging the earth backwards between the hind ones, and soon using these to remove it still farther to the rear. When the heap behind them accumulated, they retreated backwards upon it, and, using all the paws, gradually removed it from the hole. Sometimes one of them would lie down to rest by the side of the other at work, and remain, though half buried in the earth, and apparently giving considerable interruption to its fellow. The male was most prone to indulge in these lazy fits, while the female was by far the most industrious in the labour.

Such is probably the best account we have of the cunning operations of the badgers, though not exactly what the animals would do in a state of nature, as they were limited to two kinds of substance, the stone wall and the mound of earth. From the repeated attempts they made to burrow in the wall, at some elevation above the ground, and under stones which projected, we are led to the kind of place which they would naturally prefer. These are stony banks, where the earth is loose and easily excavated, and the water does not stagnate.

The case of the badgers above noticed is a good instance of the working of instinct as different from reason. These young animals could have had no experience in burrowing when they were first placed in the court, and they made their burrow there in the ground. But when they were placed in the enclosure, they did not act upon their experience, and again dig in the ground; they attempted to burrow in the walls. Here, therefore, we have a principle, which can have no connection with reason, choice, volition, or experience—which can in no way arise from, or be directed by, knowledge acquired or acquirable by the animal; and yet this principle leads them to act in direct opposition to their former experience; and the repeated attempts to burrow in the wall, notwithstanding the experience of failures, shows the strength of the principle. But the disposition to burrow, to find or form a subterraneous abode, which is evidently as little connected with reason or volition as the other, is a stronger principle than that which disposes them to burrow in a particular place; so it triumphs, and they burrow in the mound of earth. The greater tendency to burrow shown by the female also points out how, without plan or contrivance of any kind, all the tendencies of an animal are linked together. The male requires the burrow only as a place of shelter during the day and the winter; the female requires the additional accommodation of a nursery for her young. Therefore, she is in part influenced by her natural instinct, and works in accordance with that before she is of age to become a mother; while the male, into whose composition no such instinct enters, takes the work more easily. We can trace something analogous in the young females of many animals, and it is a curious point in the philosophy of that very interesting, but almost inexplicable subject, instinct. See INSTINCT, for some general remarks.

A distinction between "dog-badgers" and "hog-badgers" is sometimes made by the country people; but it appears to be a distinction without any difference. The dog-badger is said to prefer soils which are light and sandy; the hog-badger those which are more rich and loamy; and the latter is said to be the more clumsy animal of the two. With the exception of the *preference* (for animals have no rational or voluntary preference, though it is not easy to speak about their habits without using the term), these allegations may be true; and yet so far from there being any difference of species, or even variety, the dog-badger and hog-badger may both belong to the same litter, or the same individual may be a dog-badger one year and a hog-badger the next.

It has been mentioned how much the badger is under the controul of the atmosphere; and the state of the atmosphere is so much influenced by the character of the soil, that a dry sandy tract and a moist loamy one, which lie within a mile or two of each other, may have as much difference of temperature as if they differed a degree in latitude. Colour, size, condition, and along with that shape, may vary considerably in different countries, or in different parts of the same country; and there is not the least ground for supposing that all the badgers of the eastern continent, from the British islands to China, are of the very same species.

In no country are they found at a great height above the level of the sea, or in places which are subject to much rain or to burning drought, though from the situations in which they live, and the effect of cold upon them, the dry is more congenial to their habits than the over-moist. When in proper season, the flesh of the badger is wholesome and palatable food; as such, it is much used in China, where the animals are encouraged for the table; but, from the fœtid odour, and some other causes, it is not much used in Europe. The odour belongs to its peculiar apparatus only, and that can easily be removed without giving the least taint to the flesh of the animal. Both skin and body could thus be turned to as valuable account as those of any of the animals which are called game. The hind quarters, when properly cured, make excellent hams. In Britain, however, the badger is seldom brought into public notice except in some of those unmeaning and disgusting exhibitions to which the ignorant and the worthless give the prostituted name of "sports;" but which, to the credit of the age, are fast becoming as unfashionable as they are useless and brutalising.

The American Badger. It was long a matter of doubt among the naturalists of Europe whether the badger was to be found in America; and after the fact of its existence there was ascertained, it was by some considered either as identical with the common species, or a mere variety of it. But it is now tolerably well ascertained that the American badger is a distinct species; and indeed it is probable that none of the land mammalia of the two continents are the same species in both, how much soever they may resemble each other in many parts of their characters. The following account, from Dr. Godman's "American Natural History," is the most circumstantial which has appeared:—"Nature has destined this animal to a subterraneous and solitary mode of life, which, together with its timid disposition and nocturnal habits, throw great difficulties in our way while endeavouring to ascertain its peculiarities. It is entirely inoffensive, and apparently feeble, but, if denied the advantages of swiftness of motion or great size, it has not been left entirely destitute of the means of providing for its own safety. The long claws on its fore-feet are admirably adapted for removing the earth, and the celerity with which it can escape from danger by burrowing, is really surprising. It is altogether fruitless to attempt to secure the animal by digging after it, as its progress is too rapid, and the depth to which it descends too great. It is only by artifice that the badger can be brought from its retreat; this is effected by the aid of dogs, smoke, &c., and when driven to the last extremity, the strength of its jaws and the sharpness of its teeth, enables the animal to inflict the severest injury on its persecutors. The body of the badger is thick and heavy, and its movements on the ground slow and creeping; there is little appearance of vivacity or intelligence in its aspect, yet it does not exhibit any appearance of dullness or stupidity. It is, in fact, endowed with exactly the degree of understanding, the proper instruments for securing itself from ordinary enemies, as well as strength and courage enough to defend itself when pressed, but little sagacity is necessary to enable it to obtain the requisite food, or to continue its kind. Neither should we indulge in reflections similar to those which are found in many books of natural history, and believe that the life of this animal is gloomy and wretched. To men it may appear gloomy or dreadful to live under ground, or to steal forth under cover of the night in search of food; but this is the only mode of life the badger is susceptible of enjoying, and the only kind of action he is capable of.

"The burrows of the badger are deep and extensive, and several individuals have been found inhabiting one excavation. Within his subterraneous retreat he passes the day in sleep, and it is not until night veils all objects in shade that he comes forth to seek his subsistence. Then, fruits of different sorts, frogs, insects, and most probably any small animals to be procured, constitute his food.

"The badger has its young in summer, and generally two, three, or four at a litter, which are occasionally brought out to the mouth of the burrow to enjoy the sunshine. The young become capable of procreating when two years old, and the period of their lives is extended to ten, twelve, or fifteen years. If taken when young, the badger is easily tamed, soon becoming quite familiar and obedient.

"The American badger is a pretty little animal, and its aspect is not unlike that of some small dogs. It is found most frequently on the plains adjacent to the Missouri and its tributaries, as well as those near the Columbia river. It is not uniformly found in the open country; Lewis and Clark sometimes observed them in the woods.

American Badger.

"This animal is about two feet five inches long, including the tail, which measures three inches, and its body appears long in proportion to its thickness.

"The fore and hind legs are short, but remarkably muscular, the fore-paws are provided with the long claws peculiar to this genus, which gives them the means of burying themselves with great celerity, even in a hard soil. The neck is short, and the mouth wide; the eyes are black and small; the ears short, wide, and appearing as if a portion had been cut off. The whiskers are arranged in four points on each side of the nose and on the jaws close to the opening of the mouth. The hairs are much shorter on the sides and rump than on other parts of the body, which imparts an appearance of flatness, especially when the badger rests upon its belly. The length of the hair is upwards of three inches, especially upon the rump, whence it extends so far towards the extremity of the tail, as to conceal it entirely, and gives to the whole of the posterior parts of the body 'the appearance of a right-angled triangle, of which the tail forms an acute angle.' Intermixed with the hair we find a small quantity of coarse pale-reddish yellow fur.

"The American badger differs from the European by generally being smaller and more slenderly formed; its head is full as long, but not so pointed toward the nose; neither is the profile at all similar to the badger of Europe. In the European animal the outline drawn from the forehead to the nose is quite straight, while in the American there is a considerable depression on a line with the eyes.

"There is also a very striking difference between the markings of these animals. In the American badger there is a narrow white line running from between the eyes towards the back, the remainder of the head is brown; the under-jaw and whole of the throat are white. A semi-circular brown spot is seen between the ears and the light-coloured part of the cheeks. Above the eyes the white marking extends triangularly for a short distance, and below it runs in a line with the eyes towards the fore part of the mouth; yet the whole eye is within the dark colour of the upper part of the head, and that colour runs at the corner of the eye, with an acute angle, into the white.

"The badger of Europe has three broad white marks, one on each side and one on the top of the head, between which there are two broad black lines, including the eyes and ears; all the parts under the throat and jaw are black. The hairs on the upper part of the body and sides of the American badger are fine, long, and greyish; in the European they are darker. In our animal the legs are of a dark brown; in the European quite black.

"Notwithstanding the European badger is generally the largest, its dark coloured nails are smaller than those of the American, which are of a light horn colour. The tail of the American badger is shorter than that of the European. The American badger weighs from fourteen to eighteen pounds."

The characters given by this accurate describer of American animals, show enough of difference for the establishment of a distinct species, such as could hardly have resulted from the difference of climate. The white on the throat, and the paleness of the colour generally on the under side, would lead to the conclusion that the American species is not affected by the weather in precisely the same manner as the common. From the proportionally larger size of its claws, which almost equal those on some of the armadillos, one would conclude that the American is by much the more expert burrower of the two; and its finer, more produced, and more lightly tinted fur, obviously fit it for existing under greater variations of climate and temperature. Whether its fur undergoes any seasonal change, and what are its habits during the winter months, are not stated.

BADISTER (Clairville). A genus of Coleopterous insects, belonging to the section *Pentamera*, family *Carabidæ*, and sub-family *Harpalides*. They are of small size, but their colours are elegantly varied with red or ochre, and black or blue. They are chiefly found under stones, in moist situations. The chin (mentum) is not toothed, the mandibles obtuse, the labial palpi have the last joint oval, and the maxillary have the third joint longer than the fourth. De Jean gives only five species in his new catalogue; Stephens describes three British (*Carabus bipustulatis* of Fabricius being the type), exclusive of two others which he has described as a distinct genus, under the name of *Trimorphus*.

BÆCKIA (Linnæus). A family of ornamental greenhouse shrubs, chiefly natives of New Holland. Class and order, *Octandria Monogynia;* natural order, *Myrtaceæ*. Generic character: calyx turbinated, limb five-cleft, persisting; corolla imposed on the calyx; stamens numerous, variable (from five to fifteen), inserted in the calyx, like so many gems within the petals; filaments awl-shaped; anthers roundish, two-celled; style short; stigma capitate; capsule three-celled, many-seeded.

BAIKALITE. A mineral found near the lake Baikal in Siberia. It is sometimes considered as a variety of SAHLITE, which see.

BALÆNA and BALÆNOPTERA. Two genera, or perhaps rather, subgenera, of *Cetaceous* mammalia, inhabitants of the sea, and including all the *toothless* or *whalebone whales*. The chief external distinction is, that the *balænæ* have no dorsal fin, and the others have, on which account they are called *balænopteræ*, or "winged balænæ." Of balæna, there is one remarkable species, *B. mysticetus*, the common black or Greenland whale; of balænoptera there are several species, which will be noticed after we have made a few general remarks on the characters, habits, and haunts of these singular and highly-interesting animals. The differences between them and the toothed whales and other warm-blooded tenants of the deep, which have partly the external forms and apparently some of the habits of fishes, but which in their internal structure and all the essential parts of their economy, are yet as truly mammalia as any of that class which inhabit the land, will be pointed out in the general article on the order CETACEA.

In modern times, *Balæna mysticetus*, has been "the whale" by way of eminence, though perhaps now other species, or rather another genus, may be as much in request, and held in fully more estimation. It is not probable that this species was familiarly known to the ancients, as they were familiar only with the animals of the Mediterranean and of the shores of the Atlantic as far northward as Britain; and their whales are represented as being armed with formidable teeth, and capable of swallowing dolphins (*Coryphænæ*, not the dolphins of modern naturalists), and other large and fast swimming fishes, which the balæna neither do nor can do. It is probable, however, that in the time of the Romans, this genus may have been occasionally seen, especially in the Bay of Biscay and on the British shores, in the former of which places the modern whale-fishery is said to have begun. That the Romans were acquainted with the size of whales on the British shores, and that these were larger than those in the Mediterranean, though one of them is described by Pliny as being sufficiently formidable to engage in the port of Ostia the emperor Claudian and his army, is certain; for when Juvenal, who generally gave effect to his satires by selecting illustrations familiar to the people of Rome, ridicules the aping of the great by the small, he takes his contrast from the dolphin and the whale of the British seas.

Quanto delphinis balæna Britannica major.

The point of which was very much increased by the whale being by common repute "the devourer of dolphins."

But though the ancients thus knew the whale, it was to them little else than the monster of the deep, serving, as in the line above quoted from Juvenal, "to point a moral," or, as in the fable of Perseus and Andromeda, to "adorn a tale," it does not, in any species, appear to have been known to them as a subject of science, or as valuable in the arts of life.

Independently of its commercial value, the whale is one of the most interesting of nature's productions. The regions in which it is usually found; its vast size; its singular form; its curious habits; its combining at once the maximum of physical strength and gentleness of disposition; and a variety of other circumstances, all conspire to render the whale the wonder of the deep. And those qualities belong in a pre-eminent manner to balænæ, the apparent simplicity of whose lives, and the smallness of the individual substances on which they feed, give them an interest superior to that of the more ferocious and formidably armed species.

The common whale may be said to inhabit the whole ocean, and its size and power render it worthy of that ample field. It is not quite so discursive over the ocean, or so frequently seen in the middle latitudes, or indeed in any places where the temperature is warm, as the more voracious whales which feed upon large fishes. Those, like the predatory land animals, are furnished with powerful weapons of prehension, so that wherever the sea is inhabited they can find food, and the shark himself cannot escape their all-powerful jaws. The common whale, on the other hand, more resembles some peaceful animal which grazes the savannah, or browses the leaves of the evergreen forests; and therefore it can remain and feed for a season in peculiar localities only.

These localities may be said to be in an eminent degree the margins of the polar ice—the very extremes and confines, as it were, of the ocean. Little is known with certainty of the times or the extent of its migrations, because its march along the mighty waters is too fleet for our observation to follow. It is said that they can move as fast as a mail coach and feed while they are moving; and as, when wounded by a harpoon, they can "take out" the line so fast that, if not watered, it would speedily take fire by the friction of the roller, it is probable that they can make equal despatch on their journeys; that is, they can move twenty-five or thirty miles in the hour, the least of which would send them 600 miles a day, or from 60° north latitude to 60° south, in the short period of fourteen days.

The velocity with which they move, and the periods at which it is probable their migrations take place, may both tend to make them in a great measure unobserved. It is probable that they pass the middle latitudes in the stormy weather about the equinoxes; and thus thousands may pass without one of them being observed from a single ship. They may make their whole course too without feeding, because of the vast accumulation of fat or blubber under the skin, which analogy leads us to conclude can, like the accumulated fat of land animals be, in part at least, absorbed as nourishment when food is scarce, or the habit of the animal prevents it from feeding, At those periods too, the young of many fishes are discursive near the surface, and these may serve for food on the passage,

These whales catch their food with the plates and fringes of the *baleen*, as with a net, and the only sense that can guide them in the selection is taste, residing in the tongue; and the current of water passing over that when the motion is rapid, must be like the stream of a rivulet. It is thus probable that they have little more selection of food than what the throat can swallow. In the balæna that is very limited, the greatest extent of the gullet not being more than would admit a hen's egg. In some of the balænoptera it is considerably wider—as much as between three and four inches in diameter; and thus, though these are much smaller, they can swallow food in larger morsels. The common large whale certainly could not swallow any fish larger than the herring; and from its summer feeding in the arctic seas, the times and places where we are best acquainted with its economy, it probably feeds very little upon fish of any description.

Whales are found near the ice, or in the bays or openings among the different ice-fields, and generally in what is termed the *green water*. This green water derives its colour from the immense multitude of small animals which are dispersed through it; and these animals, many of which are almost or altogether microscopic, appear to be the ordinary and proper food of the common whales. The creatures which colour this water may appear to be but slender cheer for the largest of all animals; but their numbers are such as to make up for their small size; and the prehensile apparatus which the whale displays, is sufficient to filter a mile of the sea in a comparatively short time.

The size of the mouth of course varies with that of the body; but a gape of more than twenty feet in length and fifteen in breadth is not extravagant. The opening of the jaws may be estimated at eight or perhaps ten feet, which is about the length of the longest plates of baleen, which are situated near the middle of the length. The section of the mouth is therefore about 375 feet, and the solid contents 3000. So that making every allowance, the whale, as it feeds along the deep, commands more water than the Thames discharges; and this immense volume of water passing regularly through the mouth of one animal, at the rate of say only five or six miles an hour, enables it to collect an incredible quantity of the small matters upon which it feeds.

The form of the mouth, the way in which the plates of baleen are arranged, and the fringes with which they are furnished both on their edges and at their extremities, enables the animal to detain every small substance which the water may contain, while the whole arrangement is such that these substances are, as they accumulate, carried towards the opening of the gullet.

It may here be mentioned that the lips of the whale have a peculiar double curvature in their lateral outline. The lower one is also larger than the upper, and has a double margin, forming a groove into which the edge of the upper lip fits when the mouth is shut, and the ends of the baleen when the mouth is open. The internal palate is formed of two curved inclined planes, one on each side, and to these the thick ends of the plates of baleen are attached by a ligamentous substance. These plates are parallel to each other, and placed across the mouth. There are sometimes several hundreds of them on each side. They are thinned off toward their inner sides, and it is to these that the fringes are attached. The plates appear to have no proper motion or muscular apparatus for effecting it. When the mouth is opened they fall pendent by their own weight, so that the fringes on their lips touch the tongue, and those on their sides reach from the one plate to the other. When the animal moves forward, the plates are bent back a little at their points by the resistance of the water, and the fringes are also turned to the direction of the throat. At the anterior part they are shorter in proportion to the middle of the gape, so that they give way and admit the water more freely; but become stiffer and offer more resistance as the throat is approached. From the great length of the gape the water escapes easily in the lateral interstices between the plates, while the eatable substances which it contains are kept back by the fringes. The bending backward at the points, sends all the food downwards in the direction of the ample and fleshy tongue, which lies like a great cushion filling the under part of the mouth. It does not appear however, that the tongue acts in directing the food to the gullet, in any other way than by influencing the *set* of the current of water that way. From the smallness of the gullet the quantity of water which reaches it must be small, and as a return by the same way that it arrives would be inconvenient, it is received into cavities in the head; and, from time to time, discharged by the operation of blowing.

The feeding apparatus and the whole operation of feeding are thus, in the baleen, or whalebone whales, very peculiar, and quite different from those of any other species of animal. Feeding, in them, can be attended with no more fatigue than what results from their progressive motion through the water, and the occasional blowing of the water from the cavities in the head. There is no motion of the jaws, or of the baleen, and it does not appear that there is much of the tongue. The food receives no kind of preparation in the mouth, but goes to the gullet in precisely the same state in which it is separated from the water by the filtering action of the baleen. Though interrupted in all parts of its progress by the plates, the current of water toward the gullet may be compared to a wedge, which gets smaller as it proceeds, in consequence of the quantity which escapes laterally. Toward the top of this wedge, the food is collected, and by that it is carried onward to its destination, the small quantity of water which carries it there being disposed of in the manner above stated. If the productiveness of the water be considered as uniform, the rate at which the whale feeds will thus be proportionate to that at which it moves through the water; and rapid motion along a bare pasture will have the same effect as slow motion over a rich one. The only efficient organ of motion in whales is the tail; and therefore, strange as it sounds in words, the tail of the whale is the active instrument in the procuring of its food. Its usual mode of feeding is near the surface, so that a considerable portion of the body is above water. That portion is wholly black in colour, and not very handsome in shape; and as there is no fin on the back, and the eyes, though well formed and even expressive, are very small for the size of the animal (about equal to those of an ox,) there is nothing animated in the appearance of the floating whale when seen from a distance. It looks like a floating log, or the top of a small dark islet; and when the jets of water and steam are thrown up in the operation of blowing, it does not require much stretch of imagination to consider the islet an infant volcano.

An animal which has its feeding apparatus formed, and which must feed, in the manner that has been described, can be, as has been already hinted, an inhabitant only of peculiar parts of the sea; and, large as it is, it appears to be the only animal fitted by nature for reaping the harvest of those places. If we were to suppose the volume of the whale divided into a million of herrings, and each of these to attempt the capture of the food upon which the whale subsists, it is probable that the whole million would not, with the snap of their toothed mouths, which is an operation of some labour in addition to their progressive motion through the water, catch one-tenth or even one-hundredth part of what the whale catches by means of its baleen. Thus, when we consider the subject we find that, large as the whale is in proportion to that on which it feeds, and singular as is the structure of its feeding apparatus, it is yet a very perfect instance of adaptation, and acts a part in nature which could not be acted by a differently-formed animal.

That it is found as a surface feeder in those parts of the sea that have the very extremes of seasonal change, is in itself a proof that its food must be seasonal. But the seasonal history of the whale's food is a subject of which very little is known, and upon which it is not easy to obtain information. The seas where both whales and whales' food are found in summer, are a sealed book in the winter. They are hidden under snow and ice; and at that period of the year when the seal is set, or the mantle spread, the storms are such that we dare not stay to see what goes on. But we have proofs from all the rest of nature, both in the preparation of living creatures for the winter, and in their state while that season lasts, that the setting in of the polar winter cannot be in any way instrumental in the production of contemporary life, whatever influence the prey which it affords may have on the life of other seasons.

The question thus becomes: whence came these countless myriads of little animals, which tinge the "green water" in the arctic seas, and form the chief food of the balænæ? Are they wafted from more genial climates by the action of currents, or are they an annual or permanent production of those seas in which they are found? The former they can hardly be, for if they migrated we should have some notice of them on their march. We should find them, for instance, dyeing the current of the gulf stream on the American shores, as that is the only permanent northern current in the Atlantic; and we should also have the common whale feeding in that current, and in the places whence that current originates,—because animals of all kinds are found in those places where their food is most abundant. There are, however, no such productions in the West Indian seas, or in any other seas within or near the tropics. The water there is usually remarkable for its transparency, so that the bottom can be seen when the depth is considerable.

The action of the tropical sun upon the sea must evidently tend to a different action of life. The solar influence there, by falling more perpendicularly than in the high latitudes, must act upon the waters to a much greater depth. The heat of the sun will have more effect on the bottom of the tropical sea at the depth of forty fathoms than it will upon that of the arctic sea at the depth of twenty feet; because in the first of those localities it penetrates straight downwards; and in the second much is reflected from the surface, and the rest is turned toward the surface by the refraction, so that, beyond a comparatively small depth, there can be neither solar light nor solar heat in the sea near the poles. But the refraction, and also the continual, or more continued presence of the sun in the summer months, will cause a comparatively greater action at or near the surface of the polar sea.

The summer action of the sun upon the polar seas is, therefore, in a great measure a surface action, while that near the equator is more an action extending to a considerable depth, or to the bottom, if the depth is not great. Accordingly, we find that the bottom of the tropical seas, wherever it can be seen, is abundant in life and growth; and that many of the productions are so highly tinted with colour, that it has been described as being "as gay as a garden;" and the more gay, the more hot and barren the adjoining land. But, even in our latitude, the productions of the sea bottom have little beauty of colour; and when we reach nearer the pole they are fewer and less coloured still.

Thus it seems that, though the influence of gravitation, and some other circumstances are removed, there is a curve of solar action below the level of the sea, in the water, just as there is above in the air. On the average this curve descends to the greatest depth at the equator, and its depth becomes less and less as the poles are approached; though, like the curve of congelation in the air, it shifts northward and southward with the seasons. Whether, therefore, we regard the action of life in the atmosphere above the mean level of the sea, or the action of the water below that level, we must understand that its range in altitude diminishes as the latitude increases. Whether they come to the level at the same point, at any period of the year, it would not be easy to ascertain; but that they—that is, the upper limit of the sun's action in the air, and the lower one in the water—do approach near to each other in the high latitudes, is certain.

It must be borne in mind, too, that in proportion as the latitude increases, and the rays of the sun fall more obliquely to the mean level, proportionally more of the action of those rays must be directed to the plane of that level, by the action of both the atmosphere and the water. The oblique rays pass of course through a much greater portion of dense atmosphere than the perpendicular ones, and are in consequence refracted downwards in proportion. By falling more obliquely on the surface of the water, they are reflected upwards by that surface; and when the angle at which they fall is very small, and in high latitudes, its maximum is only twenty-three and a half degrees more than the distance of the place from the pole, they are reflected wholly into the atmosphere, and barely heat the surface, unless by a second reflection from the atmosphere. Thus it may be considered that, in the polar seas, while the sun is constantly above the horizon, the solar light and heat are continually playing between a limited portion of the mere surface of the sea, and a limited height of the atmosphere over it; and that as the pole is approached, the extent of action, downward in the sea, and upward in the air, is continually diminishing, while as it diminishes, it becomes more uniform during the whole twenty-four hours. It is not possible to speak with absolute certainty without direct experiments, and experiments which would not be easily made in such a manner as to be perfectly satisfactory; but, from what has been said, it is highly probable that the maximum of seasonal action during the polar summer, though limited both in height and depth, is much greater at the surface than the solar action at the equator. The great rapidity with which the scanty vegetation of the arctic lands performs its functions is a proof of this: one month it is a budless bush, just escaping from under the snow; next month it is in full bloom; and the third month "the cheering purple berry big with wine" is ripe and racy. The rapid production of summer insects under the influence of the unsetting sun of those distant climes, is another proof of how powerfully the continued duration of solar heat, and the action of the atmosphere and the earth or waters, concentrating the heat toward the mean surface in a manner not altogether dissimilar from the operation of a convex or burning lens, work together in giving increased energy to the powers of life during the brief period when these are in operation. Whether those insects be produced from eggs committed to the land or to the water, they must be, for great part of the winter, at a temperature as low as the freezing point of water; and the transition from that to almost continual solar action, which comes on in brief space, has upon them an effect as great, though happening in a different manner, as that which takes place in tropical climates, where the rains succeed the seasons of parching drought. But the insects, when in their winged state, require at least some height; and therefore, though they are abundant to a high latitude over the arctic lands, their numbers diminish as the upper and lower limits of solar action approach closely towards each other.

No where on the land is the mere surface action, in these high latitudes, so great as it is over the sea. The melting of the ice, which takes place to a considerable extent during the early part of every season, no doubt retards its operation; while, on the other hand, the freezing during the autumnal months retards for a little the cooling of that portion of the surface which is still unfrozen. The operation of these retarding causes must be considered as kindly to the creatures, both in coming into their summer activity, and in subsiding to their winter repose; and the effects must be equally beneficial to the migrant races, whether of the land or of the water, which periodically go to share the bounty of the polar summer, and retire to other climates during the winter.

This great increase of production must be, to preserve that balance which is every where the order of nature, accompanied by an equal increase of consumption. The number of birds which throng to those seas is incredible to those who have not witnessed it; and there is, perhaps, no part of the whole seasonal arrangements in these high latitudes more wonderful than the production of whales' food in the green water. The greenness there is not a vegetable, but an animal greenness; but still it is not a very overstrained comparison to say, that, just as it appears to demand the largest of the ruminant mammalia to crop the green vegetable life of the temperate meadows, so does it require the presence of the largest of all the mammalia to crop, and keep down to the proper measure of permanent preservation, the green animal life of the polar seas.

The analogies which we find in nature, though often curious, and to our casual or superficial view, not unfrequently inconsistent, are yet, when we come to study them with attention, all in wonderful harmony with each other; and the coincidence which we find in point of superior magnitude, especially in the animals that browse the small vegetation of the meadow, and the balæna, which cull as their food the small surface-productions of the sea, is far from the least striking. It is true that the pastures of the ox tribe are more perennial, more independent of season than those of the whales; and that the animals are less fleet in their motions. But these are circumstances which we might expect, as no land animal, without wings, could annually migrate to the extremes of latitude. And we find that taking the ox as the commencement of the race upon land, and the common whale as the commencement in the sea, we have gradations of species or genera becoming more discursive. The balænoptera stand in nearly the same relation to the balæna, as the sheep, deer, and antelopes do to the ox, they are lighter in their forms, more fleet in their motions, rather more varied in their food, and when we come to the most discursive species, they have much less proneness to accumulate fat. As we proceed in the gradation, too, we find that the fat which they do accumulate, contains proportionally more *stearine*, and less oil. Nay, if we continue the parallel a little farther, we find that the larger toothed whales have a tendency to accumulate hard fat as the camels do in their humps; and that both of these range the warmer latitudes.

These circumstances show that the land and the sea, different as they are in their characters and productions, yet form parts of the *one* system of nature, are acted upon by the same general agents, and, as we may express it, subject to the same common laws. Therefore, though the land influences the terrestrial animal and the sea the marine one, we err if we state absolutely that the one is *a production of the land*, and the other *a production of the sea*. There is enough to show that, however the sea or the land may *modify*, or, to express it more accurately, however the animal *may be modified*, so as to fit it for the one or the other, neither land nor sea could of itself produce a single animal. As little can we say that a single animal is *self-produced;* and yet as every organisation is evolved by *itself*, and *not by its parent*, —See the article Assimilation—we find that we search matter in vain for the *cause* of its production, though we readily enough find the means of its being of one form and in one place rather than another. This holds in all the kingdoms of nature, animal, vegetable and mineral; for though the productions of the last are more simple, as having none of the characteristics of life, yet when we come to what may be properly called a natural species of mineral, we can no more find the production of that in the rest of the minerals, than we can find the production of one species of animal or plant in the rest of animals or plants. Alchymists who laboured so long in attempting to obtain gold by the "transmutation" of other metals, were as much in error as those naturalists who supposed that a goose could be produced from a bernacle shell, or an eel from the hair of a horse's tail. Both the distinctions of species and the production of species, are, therefore, without any material cause which we can name or even know, they are both known to us only as continuations of that which has previously existed; and we can trace them to no other source than a Creator. The necessity of this inference meets us so constantly that we must either at once admit it, or be contented with our knowledge of nature as a mere disjointed fragment, originating we know not whence, and continued we know not how. As such it can have no moral value, and little value of any kind, to raise it above the common class of idle occupations. But when we confess our belief in the Creatorship (for whether we confess it or not, nothing but utter and brute ignorance can prevent us from having it), the moral obligation follows by necessary connexion; and, in proportion as we advance in knowledge, it is very difficult, and must require some habit or association in more than an ordinary degree pernicious, to prevent us from in the same degree increasing in the desire of doing that which is right. Plants and animals are thus our instructors in rectitude of conduct, as well as in merely speculative knowledge: and when any of them is preeminently calculated to engage our attention, as is the case with the whales, we may always be sure that the lesson which they have to impart, is fully in proportion to that enticement by which we are drawn to the contemplation of it.

We shall now, very briefly mention the species, bearing in mind that the chief distinction of an external kind is, that the balænoptera have a dorsal fin, and the balæna have none. The presence of the dorsal fin indicates that those species which have it, go deeper in the water in their ordinary habits, than those which have it not; and this is accompanied by other characters, which also indicate differences of habit. Whether these differences are generic or only specific, is a question which must be decided by the systematists. At all events, they are a well defined group, being the only animals which capture their food by means of baleen, or whalebone in the mouth.

Balæna. The general characters of the genus are: the head very large, elevated at the blowholes; the gape wide; the plates of whalebone long; and the two bones which form the under jaw curved something in the form of ribs, and sometimes improperly called by that name. In places where the whale fishery is established, these may often be seen as gate-posts. The body becomes taper and rounded toward the tail, which is the only organ of motion, and has its breadth in a horizontal direction, or the opposite of the tails of fishes. The females have two mammæ, but no nipples; and though the mammary glands are more simple in their structure than those of many land animals, the milk is as rich, and nearly if not altogether as thick as cream. There are usually reckoned four species, of which the most important are, the *common whale* and the *Iceland whale*. They inhabit nearer the poles than any other of the whales, and the common whales more so than the others; though they all meet in the same seas, and sometimes the toothed whales are found there also.

The Common Whale, black whale, or Greenland whale (*Balæna mysticetus*), being the species chiefly alluded to in the introductory part of this article, may be more briefly noticed here. Historically, it is the largest of animals; and though the reports with which we sometimes meet of whales 900 or 1000 feet in length are certainly exaggerations, it is equally certain that whales of much larger size, as well as in much more abundant numbers, were formerly found in the Greenland seas than are found there now. The slow growth of these animals, the limited portion of the sea which appears to be properly adapted for them, and the assiduity with which the whale fishery has been for a long time carried on, may, in great part, account for the diminution. Sixty feet in length and about forty in circumference now form what is considered as a full-sized whale; and one of these will, if properly cut up, furnish upwards of one hundred tons of oil. There are tolerably well authenticated accounts of individuals formerly taken, of double these dimensions, and, consequently, as the volumes of similar animals are the cubes of their lineal dimensions, of eight times the bulk and weight. The general section of the body is cylindrical, largest a little behind the swimming paws, and becoming a little smaller towards the head, the neck also marked by some furrowing in the skin. For some general remarks on the structure of the whale tribe, we must refer to the article Cetacea; but we may mention that the neck has the same number of vertebræ as the land mammalia—as the camel or giraffe, for instance, and that the articulation of the cervical vertebræ resembles that in the armadillos. That portion of the tail which may be considered as the stalk or peduncle of the lobes, is of a conical shape, the lobes are very broad, twenty feet from tip to tip in a large specimen, and furnished with muscles of great and varied power. The terminal outline of the tail is a double curve ;. the one lobe being convex and the other concave. This form no doubt assists in some of the many motions of which the tail is capable. These are of all kinds, direct flexures and oblique twists ; so that, though the one is an instrument of prehension and the other one of propulsion, the proboscis of the elephant is probably not a finer instance of muscular combination than the tail of the whale.

The whale's tail is the most powerful animal organ of which we have any knowledge ; and in the common whale it is more powerful than in any of the other species. Other than the involuntary muscles which carry on the living functions, and the local ones which move the swimming paws, the lower jaw, and the eyes, and act in the operation of blowing, the whole mass of muscle, and the whole power of the spine of the common whale, are concentrated in the tail, which may be said to be its only weapon of defence as well as its chief organ of motion. In its ordinary habits, the common whale offers no violence to any animal, not even to the small ones upon which it feeds. It does not, in any way, bite, or lacerate, or crush : the current of water simply carries the food to the throat, and it is swallowed. An animal of this habit, could not, consistently with its nature, be the aggressor ; but the whale has many enemies, of various sizes and degrees of strength, from the largest of the toothed whales to the dolphins, and some species of fish properly so called ; and as it is not the regular food of any of these, it becomes necessary that it should be able to resist their attacks. Its defence consists in the blow of the tail, which, according to the published accounts, is more powerful than that of the toothed whales of the same size. We have not, on land, any thing but miniatures of it ; because we have neither the same mass nor the same concentration of muscular action. Perhaps the nearest resemblance to it are the kicks of the kangaroo and the giraffe, the first of which, when it takes effect, is said to kill the dingo, or Australian dog, upon the spot, and the second to fracture the skull, or even to cripple the paws of the lion. The stroke of the whale's tail, which is firm and cartilaginous, can cut a stout boat in two, or dash it many fathoms under water, according to the way in which it takes effect ; and as it is probable that it cannot strike a boat with the same force as it can an animal in the water, the well-aimed blow seems enough to stun every creature which inhabits there.

The usual colour of the whale, on the upper part, is shining black ; the under part forwards, and partly the lower lip, are pure white ; and the under part toward the tail, slate or lead colour. The white colour extends as far backwards as the vital parts, and no doubt co-operates with the mass of subcuticular blubber or fat, in preserving the temperature of the animal, immersed as the lower part of it is in the cold water resulting from melted ice. The upper part is no doubt also protected by the blubber; but the black colour forms another ground of argument in favour of its migration, it being doubtful whether a naked black skin could, under any circumstances, bear an exposure for months, or even for weeks, to a temperature of the air as low as that of freezing. The places in the middle latitudes, where the common whales have been said to have been most frequently seen, are those which point at the fact of its migrations by speedy journeys over those parts of its range in latitude which supply no food, or comparatively little. They are usually the offings of large rivers, or the return eddies of large bays, both being situations where we may suppose the return water much charged with the smaller productions of life,—the estuary of the St. Lawrence, the Gulf of Guinea, the offing of the Red Sea, about Socotora, and that of the Bay of Bengal, about Ceylon.

As is very generally the case when the female has either to defend her offspring from powerful enemies, or to find food for a voracious progeny, the female whale is said to be larger than the male. She is also generally accompanied by one young one, to which she is remarkably attentive, and which she carries clasped with her swimming paw when young. Wounding the mother only increases her maternal solicitude, and the death of the young one gives rise to the deepest expressions of maternal sorrow. Indeed, all those expressions in animals, which appear to resemble most the better feelings and more tender natural sympathies of the human heart, appear to be displayed in their fullest perfection in the whales, so that those who throw away their claims of relationship upon apes and turtles, and all those land animals whereof so much has been " said or sung," had much better claim kindred with " the monster of the deep." The poetical pets are, in the plain prose of natural history, a set of " profligate rascals." The eagle is a far more orderly bird than the turtle ; and the tiger himself is a " most moral brute," as compared with the mandrill, or even the orang-utan or the chimpansee In truth, when we come to predicate either wisdom or well-doing, as qualities resulting from any *mere forms of material substance*, be that substance what it may, we have arrived at that plastic pitch of philosophy, according to which any cause may produce any effect ; and the transition from making the animal a man, to making him a god, aye, and immolating human victims on his altar, is not, in the judgment of reason, more than a single hairbreadth removed from each other. What we regard as the kindly affections of animals, are never wanting where the circumstances require their display ; but they are no more the results of *good intentions*, than the predations of wolves are the result of an organised plan for the extirpation of the whole race of sheep.

The domestic manners of whales are, however, but little known, as we have them but in snatches, and these generally from those whose avowed business it is to kill every whale they see. They are rather cumbrous museum subjects, and can be preserved only in skeleton, as their flesh, though sweet, and even wholesome, and far from unpalatable (when young), in the recent state decays sooner in the air than that of land mammalia. From the gentleness of their manners, the mild and intelligent expression of their eyes, and many other circumstances, there is reason to believe that whales would not be difficult to tame ; and it is not among the absolute physical impossibilities, that some future Neptune may yoke them to his car, and so circumnavigate the globe in five or six weeks ; but the process is not yet begun ; neither has it been "brought out" as a scheme by any one of those marvel-manufacturers who are always astonishing the ignorant, and too often cheating the simple, by projects which involve plain and palpable impossibilities.

The period of gestation in the whale is not known; and we can judge of that of suckling only from the accounts which the fishers give of the cubs. When sucking, which is understood to last for at least a year, they are very fat, often yielding fifty barrels of blubber; but the capture of them is hazardous, on account of the boldness of the mother whale; and the mother, when suckling, is not so productive of oil. In that stage of their growth they are called *short-heads*, because the jaws are but little produced, and the plates of baleen almost rudimental.

There is one circumstance here which is worth mentioning, as it shows a coincidence where we would be little apt to look for one—a coincidence between the whale and the ornithorhynchus of the streams and pools of Australia. The mammary glands in the females of both are of the same structure, and both are destitute of nipples. The mouth of the full-grown whale, with its fringes of baleen, and that of the full-grown ornithorhynchus, with its duck-like mandibles, are most ungainly instruments for sucking. The young of both are, accordingly, *short-heads* at their birth, though the one is not as many tenths of inches, perhaps, in length, as the other is feet. The *maxillæ* of both are so short, that though they do not appear capable of drawing a nipple, they contrive to squeeze the milk from pores in the areolæ of the mammary glands. When two years old, at which age they are just weaned, and being still but imperfectly able to find their food, they are very lean, and on that account disregarded by the fishers, they are called *stunts*. When they begin to get fat, and till they have attained their full size, they are called *skull-fish*.

The *whale fishery*, of which, in the north seas, whether nearer the coast of Europe or that of America, the common whale is the chief object, is an employment of no small peril as well as profit. The details of it are inconsistent with both the nature and the extent of this work; but the reader who is fond of such subjects will find ample and correct information in "Scoresby's Account of the Arctic Regions."

When it is stated that whales are discursive, and have been seen in the middle latitudes, it should perhaps be understood rather of the *balænæ* generally, than of the common whale in particular. That species certainly can move with great rapidity, even when it plunges downward in nearly a perpendicular line; and the fat with which it is loaded could be but little impediment to it in making its way through the waters. But the great thickness in proportion to the length, together with the accumulation of fat, would, according to our notions of mammalia upon land, indicate a quiescent and hybernating animal—one which dozes out the winter in a state of inaction; and we find that to be the habit of very many of the mammalia which reside in those latitudes in which the whale is found in the summer. On the other hand, those land mammalia which migrate do not accumulate so much fat, or accumulate so much in a layer immediately under the skin; and they are of more stretched and limber form than the species which remain in the same localities and hybernate. Thus far, therefore, the common whale has both the shape, and at least one of the habits, of a hybernating animal, and it wants those of a migrant one.

But the idea of a warm-blooded animal hybernating in the water is one of which we have no instance in nature, and it is one of which the possibility, upon any known principle, is not easily made out. The old popular error, of the swallow tribe leaving the air to pass the winter under water, is now of course exploded by every one having the least knowledge of natural history; and though it be true that many of the pelagic fishes, which range the surface of the wide seas at some seasons, at other seasons plunge to a depth at which the rays of the sun have but little action, and remain there in what may be called a dormant state, yet these fishes are not only breathers of water, or of the air which is mixed with water, but they are more easily killed by being removed out of the watery element than fishes which naturally dwell at greater depths; consequently they afford no analogy which can be adduced in favour of the aqueous hybernation of whales.

Also, though it is true that the mammalia which hybernate have more disposition to accumulate fat under the skin than those which migrate with the seasons, yet the fact does not hold with those classes of animals which are more generally migrant in their natures. Migrant birds, just before the time of their migration, accumulate more fat than stationary ones; and the same may be said of migrant fishes. On this point, therefore, we must not look so much to the general law of the class, as to what appears to be the general law of migration and hybernating. The migration of land mammalia is a slow and laborious process, and they must feed by the way; and if they are vegetable feeders, they must spend a considerable portion of their time in finding food. An accumulated stock of fat is therefore less necessary for them than for those species which spend the winter in a foodless region, and must supply whatever there is of waste in the foodless season. With migrant birds and migrant fishes the passage is made by long stages, in which they cannot feed; and as, with both, there are times of exertion, we may suppose that there is considerable waste of the system, which can be supplied only by absorption of the accumulated fat.

Thus, from the form or accumulation of fat in the common whale, we can draw no certain conclusion as to the manner in which it passes the winter; and there is little in direct observation to assist us in our difficulty. We know that these whales keep more upon a particular ground than the more light and lengthened species; because, when a whalebone whale happens to be cast upon any shore in the temperate climates, that whale is rarely, if ever, the common whale. But the range is obviously regulated by the food, and the more discursive species are more miscellaneous in their feeding.

In the present state of our knowledge, the migration of the common whale is the more rational hypothesis; but still it is only a hypothesis, and one of which the proofs are not easily found. Whales have not been traced upon their journey from the one pole to the other, nor have they been found in the middle latitudes, either singly or in squadrons, in such a way as that we could positively say that they were upon their march. Indeed, the fact of their being seen in the middle latitudes at all, is one which, though confidently stated, must be received with caution. There they are seen but *en passant* as matters of curiosity, and not captured or examined closely. The passing voyagers see whales; but they do not stop to ascertain whether they are common whales or not, or even whether they are whalebone whales or toothed whales; and when the fact of their being seen is mentioned as part of the story of the voyage, they are very naturally referred to the common species, which is always meant when the whale is simply mentioned by any one belonging to the north of Europe.

The Iceland Whale (*Balæna Nordcaper*) is about the same length as the common whale, or perhaps a little longer; but it is far more slender in the body, and the form and colour are different. The head is much smaller, the lower jaw broader in proportion to the upper one, the outline of the snout a little hollow, the blow-holes near to each other, the whalebone short, the swimming paws long, the back also long, the tail very much tapered, and the lobes large—larger in proportion than in the common whale. The upper part of this species is grey, or grey clouded with black; and its position in the water is much deeper than that of the common whale. It has generally only the blow-holes and a small portion of the head above the surface, which may, in part, arise from its greater specific gravity, as it has much less fat in proportion than the common whale; but it also feeds deeper, and in more southerly latitudes, and is more active and vigorous in its general motions. Hence the probability is, that its food is somewhat different from that of the common whale, consisting more of fry and the smaller fishes which are found near the surface.

The nordcaper is said to be more ferocious, or at least bold, than the common whale, as well as more active. When struck by the harpoon, it does not *run* like the other, but makes for the boat from which the harpoon proceeds; and if it came up with that, it would dash it to splinters. From this habit, and the swiftness of its motion, it cannot be safely attacked but by several boats in company, which contrive to strike it, and draw its attention by turns till it is exhausted by wounds and exertion. The inhabitants of Iceland and of the coast of Norway sometimes capture this species, but it is not sought after by the ships which resort to the North Sea whale fishery.

Balænoptera. These agree with the balænæ in being without teeth in either jaw, in having the mouth furnished with baleen, and the blow-holes double; but they differ in having a dorsal fin, in being more slender in proportion to their length, and in being discursive over a much greater extent of the ocean. They also live more upon fish; and, some of the smaller ones especially, drive about after the manner of porpoises and dolphins, and the fishes may be seen leaping out of the water in their attempts to escape from them. Lacepede divides them into two sections: those that have the skin of the throat flat or smooth, and those which have it formed into folds or wrinkles; but it does not appear that this form is accompanied by any peculiarity of character, other than that some of the plaited throated ones are, perhaps, smaller, and more discursive than the others. There are usually reckoned four species: one belonging to the first section of Lacepede, and three to the second. In an economical point of view they are of small interest or value, compared with the balænæ. But as these are the whales of description, the balænoptera are the whales of observation, being almost the only whalebone whales which, now at least, are found in the seas, or stranded on the shores, of the temperate parts of Europe.

The Finner, or Gibbar (*Balænoptera gibbar*), is distinguished by its dorsal fin, which is often the only part of it which is seen above water, and which may be mistaken for the sail of a small boat. The gibbar is now not much longer than the common whale, that is, ninety or one hundred feet; but it is thin and slender in the body.

The head is conical, and equal to about a third of the whole length. The gape extends far back, and the eyes, which are small, are placed near its termination. The plates of baleen are short, only a few inches, or not more than they are in breadth; but the fringes on them are much produced. The swimming paws are rather long, and placed a little in the rear of the gape. The dorsal fin is far backward, about four feet long in the full-grown animal, and having its apex bent to the rear. The colour of the upper part is a uniform shining brown, that of the under part pure white; and in the young the brown is paler, and has a tinge of grey.

It is not found quite so far to the north as the common whale; and when it appears in numbers, the common whale is said to shift its ground; but for what reason is not explained. It is certainly the more active animal; but it cannot bite, or otherwise offer violence, except by the stroke of the tail; and it is doubtful whether it can deliver that with the same force and effect as the common whale. The weight of the common whale is of considerable advantage to it in the use of that weapon, by affording a more steady point of rest; and the height at which it swims in the water is another advantage, as the tail moves through the air in a large portion of its sweep. Whether these are more than counteracted by the superior activity of the fin-fish is not known, and there is no instances of any hostile rencontre between the two; but the account of the one quitting when the other arrives is as has been stated.

The fin-fish is probably more numerous than the common whale; but it does not appear to be in general so social, being found dispersed over a wider extent of sea, and seldom in those bays and openings of the ice in which common whales are found in packs, though not close to each other, like a flock of sheep, yet appearing to belong to one party.

One of the largest of this species will not furnish above two tons of oil, and the capture of it is much more arduous and dangerous than that of the common whale, so that it is but little annoyed by the fishers. As soon as it finds that it is attacked or pursued, even before it is wounded, it makes a formidable resistance, throwing the water into agitation, and lashing with its tail, so that it is not easy or altogether safe for a boat to approach it so closely as to be able to strike it with the harpoon certainly and with the proper effect.

On this account its numbers have been less thinned, and its natural habits less interfered with, than those of the common whale; so that its numbers and haunts have probably not changed so much. That it is the species which the Romans describe as, in their day, being found on the British shores, there can be little doubt; but there can be as little doubt that it must have been far more plentiful in their days than it is now. For one bark that the Romans had afloat on the British seas, it is no exaggeration to say that there are now a thousand; and yet our modern navigators so rarely see a whale, that instead of describing it as a native animal, characteristic of the country, they look upon it as a very rare stranger. Specimens are, no doubt, still occasionally cast upon the shores of Britain and France; but they are so rare that the skeletons are collected for museums, or exhibited to the public as a curiosity. Of this there was a recent instance, in a large specimen, which had been cast on shore in Flanders, being brought to London, and exhibited for many months in a pavilion erected expressly for the purpose.

The great decrease which has thus unquestionably taken place in the numbers of this species within the last two thousand years, which cannot be attributed to the assiduity with which it has been sought by the fishers, and which, if we are to believe even a reasonable portion of the old accounts, show that during that period there has been a gradual change taking place in the sea. The same facts render it conclusive that the fishing (probably it would be more correct to say the hunting) has not been the sole cause, and probably not the chief cause, of the diminished numbers of the *mysticetus*. That species is more dependent upon locality, and more limited in the nature of its food; and therefore we may naturally suppose that it would be the first to yield to the change.

The sea keeps no record of those races which have become extinct, and of which it becomes the final and total sepulchre. We do, indeed, find the remains of marine animals in deposits; but we are unable to say whether these have been stranded, like the whales which are occasionally cast upon our shores, or have perished in the ordinary course of nature; and if the remains be very different from any thing that we find now existing in the sea, it becomes of course very difficult to say whether the accumulations in which they are found be marine deposits or not. In some places, as in the hill of Bolca in Italy, we find vast multitudes of what were unquestionably former tenants of the deep; but those are always found in places where there has been volcanic action: though the evidences of that action do not explain how the accumulations were formed.

We do not hear of epizooty falling upon any species of whale, and cutting them off by thousands, as it has been known to do in the case of seals; and it is very rarely that we meet with the skeletons of whales, except in alluvial deposits, which show that they are stranded specimens, and have not perished in the course of common death among these animals. That the remains of those huge animals should be so few is a curious matter, and would lead us to conclude that the bones of the giants of the ocean are entombed in its profoundest depths.

The *kreng*, or carcase, of a whale is of such specific gravity, that, after the fat or blubber, and a portion of the flesh, are removed, it sinks; and even before the commencement of the whale fishery, the petrels and other sea-birds, which are exceedingly numerous still, no doubt existed in such numbers as even to perform the operation of removing the blubber, and tearing away much of the flesh. The bones of whales are very porous; but, like the bones of land mammalia, they contain much less gelatine, and much more of the salts of lime, than the bones of fishes. They are, therefore, specifically heavier than sea-water in all their solid parts; and, after they have sunk to the depth of hundreds of fathoms, the pressure of the water will expel the oil from their pores, and send it up to the surface to form part, and it may be no small part, of the store which is always floating there, and upon which the storm-petrels, and it may be many other surface animals, in great part, subsist. What becomes of the salts of lime, whether they are changed into chlorides or sulphates, the one diffusible through the water, and entering into new combinations, and the other forming beds of gypsum or plaster stone, while the phosphoric acid rises, and contributes to the phosphorescence which is so observable in the sea, or in its inhabitants, is matter of conjecture, not of proof; but still it is matter of very rational and probable conjecture. The ocean is a laboratory on the most gigantic scale, and therefore it is quite natural that we should find its giant inhabitants connected with its most extended and powerful operations. It is worthy of bearing in mind, too, that, in the depths of those polar seas into which it is most probable that the bones of whales descend, the powers of the ocean must work nearly alone; because the rays of the sun, slantingly as they fall on the surface there, and much as they are bent upward, both by reflection and refraction, can have but little effect, either as heat or as light, in those profoundly obscure depths.

The exploring of these abodes of darkness is of course beyond the scope of human ingenuity; but yet there is food for more than the mere fancy in accompanying the remains of the whale to this their last home—a home from which nothing can fetch them back, save that action of heat which can rend the solid strata of this earth more easily than the hailstone breaks the most slender filament of gossamer.

There can be in those depths no change of day or night, or of seasons; but, if the weight of water remain on them, the same utter and unbroken darkness while the earth endures, the chains upon all action are heavy beyond what would be readily imagined. There is a pressure of, say, one thousand atmospheres, without estimating the depth at its maximum; that is, in round numbers, a pressure of about twelve tons on the square inch. We mentioned (see the article ATMOSPHERE) that the intensity of action is always in proportion to the resistance which is opposed to it; and thus the action of heat, or any thing else that could act at those vast depths, would be a thousand times more intense than at the mean surface of the sea. If, then, the action of heat, displayed as forky lightning in the thin air, can cleave rocks, and make iron run liquid like water, or burn it as a taper, what shall we think of the energy of the same agent in the depths of the ocean! This may seem a digression from the describing of a species of animal which are found at the surface of the sea; but the continual enticement which it holds out to such digressions, is one of the great beauties of natural history. They let us see what nature is capable of accomplishing; and, by direct inference, we can know how mighty must have been that Voice, which, in one moment, spake the whole into existence.

The natural decay of the whales during the period of authenticated history, involves, as an almost necessary consequence, the ultimate extinction of the race, unless some power, of which we can form no idea, shall pass over the ocean with renovation on its wings. And when we look at the land, we see proofs of similar extinctions having taken place there. Of these the more remarkable ones are in nearly the same latitudes from which the whales are now feeding. The races of land animals that have perished from these latitudes are also, in many instances, of larger dimensions than those which are left. They appear, too, to have perished in the order of their locality commencing with the *ichthiosauri* of the waters, then marsh animals, and so on for a succession of races, till we come to the elephant, the deer, and the bears of northern forests. But the details, though of the greatest interest, belong not to this place, farther than that we can see in the whales the progress of a change in the ocean similar to those of which we find demonstrative evidences on the land.

The Beaked, or Piked Whale (*Balænoptera acuto-rostrata*), is one of the smallest, but the most active of the tribe. It is not much sought after as an oil animal; but the northern people, who also eat the last-mentioned species, set a high value upon its flesh. It gets its trivial name from the form of its snout, which is very much produced and pointed, the lower jaw projecting beyond the upper. The plates of baleen are small, light-coloured, and of a triangular shape; and the long hairs which fringe them are almost white. These small plates are numerous, amounting to at least three hundred upon each side. There is more motion of the tongue than in most of the other species; and it is capable of being elevated or inflated, and also thrust forward as far as the extremity of the upper jaw. This action of the tongue probably assists in swallowing the prey, which consists chiefly of fishes, in the capture of which it is by no means inexpert.

The skin on the under jaw, the throat, and the anterior part of the body, is formed into transverse folds, which however the animal has the power of effacing, by inflating a sort of paunch. The use of that inflation is not well known, any more than that of similar inflations of various reptiles and fishes. It has sometimes been conjectured that the inflation is a means of altering the specific gravity, but that is not very probable. It may assist in swallowing, as it extends to the tongue, and indeed the paunch extends to nearly the whole space between the lower jaw-bones. The colour of the upper part is black, and that of the throat and anterior portion of the under part white, but the furrows of the folds have a reddish tinge. This species is most abundant in the north, but it occasionally ranges southwards, and individuals have been met with in the British seas, though it is not so frequently stranded on our shores as the gibbar.

BALANETE. The name of a stone which frequently occurs in the works of Pliny and the older writers on natural history. They describe two species of it, the one yellow and the other green. It is stated to have been always found in the form of an acorn, and the probability is, that they mistook a fossil for a common mineral body. Fossils were but little known to the ancient naturalists, and when they really were found, they generally had ascribed to them some mystical or supernatural powers. The discoveries of a few distinguished men on the Continent, and in our own island, has, however, given birth to a new science and one that promises to illustrate every other part of natural history.

BALANIDÆ. The second family of the class *Nematopoda* of De Blainville's System of Malacology. The animals inhabiting and constructing these very singular mollusks have a sessile body, enclosed in their operculated shell, with numerous branchiæ in double rows, unequal, articulated, and ciliated, composed each of two cirri, supported by a peduncle and exertile; the mouth with four transverse and dentated jaws, and provided with four hairy palpi-like appendages.

All the animals of this family live constantly and immediately attached to solid submarine substances, in general at a short distance from the shore. They are found in the seas of all countries, closely placed by the side of each other in numerous groups or clusters, and in most instances so crowded that the symmetrical form of the shell is distorted by being compressed against its immediate neighbour.

The establishment of the genera, and the order in which these mollusks are now classed, is according to a consideration of the base or support of the operculum, and of the number of pieces composing the coronary part; also, the position of an internal thin separation, which doubles these shells by descending more or less towards the base; and finally, by the separation or *not* of their external surface into two triangular areas, the one concave, the other convex.

BALANINUS (Germar). The Nut Weevil. A genus of coleopterous insects, belonging to the section *Tetramera*, division *Rhyncophora*, and family *Curculionidæ*. The rostrum is very long, sometimes equalling the entire length of the body, which is of a somewhat triangular form, the thighs are thickened, and sometimes slightly toothed. In the larva state these insects reside in the interior of nuts, acorns, &c., in which eggs are deposited by the female beetle, whilst the fruit is in a young and immature state, a passage being first made by the parent for the introduction of the eggs, by drilling through the rind with its rostrum. A single egg of a brown colour is then introduced into each nut, from which, in about a fortnight, a grub is hatched, which by a wise arrangement of Providence does not attain its full size until it has consumed the whole of the interior of the nut, the kernel forming the last part which it attacks; this indeed is suffered to ripen, since were it to have been consumed at the first the grub would be starved. It has been stated (Insect Transformations, p. 242), that this would occur because the insect has not the power of perforating another nut when the first is consumed: this is, however an erroneous statement, because the powerful jaws which enable the insect to work its way through the hard ripe shell of a nut would surely enable it to find a passage to the interior of a younger one, if by accident it did not find sufficient food in its original habitation. When full grown, that is, when the nut is ripe and falls to the ground in the autumn, the grub bores a hole with its jaws through
